Temperate forests occur across a wide range of local physiographic landforms, from rocky slopes to rolling plains and river floodplains, although generally under non-extreme physiographic conditions. Trees that occupy slopes or well-drained substrates with low organic matter such as sandy outwash plains (e.g., pines and some oaks) are adapted for drier (xeric) sites low in nutrients. Trees adapted for moderate (mesic) sites are found on plains, glacial moraines, or low hills with greater stocks of soil organic matter. Nutrient- and moisture-demanding broad-leaved species, for example, maples and beeches, thrive in mesic landscapes. Trees occupying river floodplains, wetlands, or bogs have environments that can be very moist to wet (wet-mesic to hydric). These soils are relatively rich in organic matter but trees in these landscapes must be adapted to withstand flooding, including long periods with wet, anoxic soils with low nutrient availability.

Climatic and Physiographic Subdivisions

Given the great geographic extent of temperate forests it is not surprising that regional differences are observed. Systematic classifications of ecoregions and climates describe subdivisions within the biome (**Table 1**). The extensive temperate mixed-deciduous forest occurs primarily in Bailey's warm continental division (210), hot continental division (220), and marine division (240); these are Köppen–Trewartha classes *Dcb*, *Dca*, *Do*, and *Cf*. The warm continental division has snowy cold winters, while the

Table 1 Temperate forest biome types and corresponding geographic regions, Bailey ecoregions, and Köppen–Trewartha climate classes

Temperate forest type	*Geographic region*	*Bailey ecoregion*	*Köppen–Trewartha*[a] *climate class*
Temperate mixed-deciduous forest	• Eastern North America • Asia • Europe • South America • Australia/New Zealand	Humid temperate domain (200) • Warm continental division (210) • Hot continental division (220) • Marine division (240)	*Dcb*: Temperate continental, cool summer *Dca*: Temperate continental, warm summer *Do*: Temperate oceanic *Cf*: Humid subtropical
Temperate mixed-evergreen forest	• Southeast North America • Asia • South America • Australia/New Zealand	Humid temperate domain (200) • Subtropical division (230)	*Cf*: Humid subtropical
Temperate rainforest	• Northwestern North America • South America • Southeast Australia/New Zealand	Humid temperate domain (200) • Marine division (240)	*Cf*: Humid subtropical *Do*: Temperate oceanic

[a]*Dc*: Temperate continental: 4–7 months above 10 °C, coldest month below 0 °C; *Cf*: Humid subtropical: 8 months 10 °C, coldest month below 18 °C, no dry season; *Do*: Temperate oceanic: 4–7 months above 10 °C, coldest month above 0 °C.

hot continental division has warmer, wetter summers and milder winters. In the marine division (240) winters are mild, summers relatively cool, and precipitation occurs most of the year.

The temperate mixed-evergreen forests occur primarily in Bailey's temperate and rainy subtropical division (230) which is most analogous to the Köppen–Trewartha mid- and lower-latitude *Cf* (humid subtropical) class (**Table 1**). These climates have no dry season, with even the driest months having at least 30 mm of rain, and have hot summers with the average temperature of warmest month greater than 22 °C.

Temperate rainforest conditions largely occur where ocean moisture is abundant and prevented from moving inland by mountain ranges. These conditions occur in particular continental placements within Bailey's marine division (240) and Köppen–Trewartha *Do* class in higher latitudes and within Bailey's subtropical division (230) and Köppen–Trewartha *Do* and *Cf* classes in lower latitudes (**Table 1**).

Disturbance and Forest Structure

Major disturbances occur naturally in temperate forests, although particular locations vary in the types, frequencies, and severities of disturbance. Major natural disturbances include fires, windthrow during severe storms, ice storms, flooding, disease, and irruptions of defoliating or wood-boring insects. The array of natural disturbances that occur at a particular location constitutes its disturbance regime, a strong force in shaping forest structure and composition. Smaller-scale disturbances also shape forests over long time periods in the absence of a major disturbance. These include the production of forest gaps from the mortality of one to a few large trees. In some cases, idiosyncratic combinations of processes may produce repeated disturbance. An example is `fir waves' that occur only in Japan and the northeastern US. In these waves of mortality that pass through the forest repeatedly, a fungal pathogen weakens the roots in mature trees while wind gusts cause the weakened roots to break as they rub against sharp gravel in the rocky soil. Because of the repetitive nature of natural disturbances and the long lifetimes of temperate forest trees, trees are often adapted (through what is termed `vital attributes') to withstand particular disturbances or to regenerate following disturbance. Some examples are trees that re-sprout from stumps following fire or from branches following windthrow, cones that require fire to open, and seeds that germinate best on exposed soil.

Human activities have substantially altered the disturbance regimes in many temperate forests. The large-scale harvesting of trees for timber, whether cutting selected sizes or species of trees or cutting all of the trees in a stand, are relatively new forms of disturbance that now affect forest structure and community composition throughout much of the temperate biome. Human activities also cause large-scale chronic disturbances, including polluted rainfall (e.g., acid rain) that causes soil acidification and nitrogen enrichment over large regions of the US, Western Europe, and increasingly in eastern Asia. Still another category of human-induced disturbance is in the introduction of invasive species. In the eastern US, the introduction of a fungal pathogen in the early twentieth century caused the chestnut blight, essentially eradicating one of the dominant trees (the American chestnut, *Castanea dentata*) from a large region.

Structural Layers of Vegetation

Disturbances in temperate forests vary not only in their type and frequency but also in their intensity or severity, the latter gauged by the percentage of vegetation mortality. A major disturbance that causes widespread or near total mortality of trees in a forest stand, followed by the development of a new (secondary) forest stand, is known as a stand-initiating event. Following such an

event, but mediated by the occurrence and severities of subsequent disturbances, the vertical structure of a forest stand tends to grow more complex over time. More favorable site conditions such as organic-rich, fertile soils and ample moisture also promote structural complexity. With full development, the vertical structure includes a canopy overstory, understory, a shrub layer, and an herbaceous layer. In achieving such development the forest passes through several stages. These include a stand initiation stage in which seedlings and saplings dominate and new species may continue to arrive; a stem exclusion stage in which the canopy closes, shading out shorter individuals; an understory re-initiation stage in which shade-tolerant species grow as seedlings and saplings; and finally an old-growth or steady-state stage. In the old-growth stage, the overstory typically includes both canopy dominants and subdominants (the latter with crowns only partially in sunlight) together with understory and shrub layers made up of mature, shade-tolerant individuals. Old-growth stands can be identified through a few key characteristics, including a distribution of age and size classes of trees, the absence of saw-cut stumps, and the presence of decaying logs the size of overstory trees.

The understory in a structurally complex temperate forest stand comprises trees and shrubs that spend their entire life cycle there as well as young or suppressed individuals of potential canopy-dominant species. Understory-tolerant species are those that can survive in, or even require, the shade of a forest canopy (e.g., sugar maple, *Acer saccharum*). In old-growth stands or those not recently disturbed it is common to see shade-tolerant species in both the understory and overstory because the overstory trees are those that regenerated in the shade of the canopy. Some temperate forests have a dense layer of understory shrubs, for example *Kalmia* spp., *Rhododendron* spp., and *Vaccinium* spp. (blueberry). The herbaceous layer of a temperate forest commonly contains mosses, lichens, vines, and forbs. Many shrubs and herbs are adapted to low-light environments or grow before canopy leaf extension in the spring or after overstory leaf abscission in fall; in summer only about 10% of full sunlight reaches the herbaceous layer, but this figure can rise to 70% in deciduous stands in winter. Shrubs and herbs that require more light grow in well-lighted gaps or extend their crowns into openings. Vines grow into forest canopies to access light and may be plentiful following a disturbance that kills canopy trees but leaves the dead trees standing.

Soils and Woody Debris

Soils provide a physical rooting medium, the capacity to store and release water, and the capacity to store and release nutrients for growing trees. The soils of the temperate forest regions occur in five orders of the system of soil taxonomy, namely Spodosols, Alfisols, Ultisols, Entisols, and Inceptisols. They range from somewhat infertile (Spodosols) to quite fertile (Alfisols). Spodosols are characterized by a heavily leached surface mineral horizon and a deeper accumulation of Al and Fe-rich organomineral complexes. Spodosols form under coniferous or mixed forests in relatively cool regions with substantial hydrologic leaching, particularly at the northern borders of the biome in the Northern Hemisphere. Further toward the subtropical in cooler areas of eastern North America, Europe, and parts of Asia and Australia, Alfisols form, characterized by organic-rich mineral soil horizons throughout the soil profile, moderate leaching and high fertility. Ultisols, the oldest and most highly weathered soils in temperate zones, are located in the unglaciated and warmer portions of the biome, including southern North America, Asia, Australia, and New Zealand. Because of their advanced age and weathering, these can be deep soils with relatively poor fertility. Inceptisols and Entisols, the youngest soils characterized by less weathering and poor horizon development, are widely distributed in temperate forests. In particular, these form in areas where glaciers left behind new parent material either as till or outwash.

A characteristic that distinguishes temperate from tropical forest soils is the much larger stores of soil organic matter typically present in temperate soils. In temperate regions, litter in various stages of decomposition from fresh litter to humified matter often accumulates atop the mineral soil, forming the forest floor. This organic layer is key in retaining water, retaining and releasing nutrients, and providing animal habitat. It varies in thickness from a few centimeter to tens of centimeters, depending on the age of the stand, the soil pH, the inherent decomposability of the species of litter, the amount of rainfall, and the presence or absence of earthworms.

An additional important category of organic detritus found in many temperate forests is coarse woody debris. This includes standing dead trees and downed, decomposing logs. Rotting woody debris provides a rooting medium, a habitat for soil fauna, a substrate for the saprotrophic flow of energy to the food web, and a means for returning nutrient elements to soils, as well as important structural material for forest streams. Logs undergo a wide range of decay rates, from relatively rapid (a few years) where logs are small and wetting–drying cycles are rapid, to very slow (lasting to a century) where logs are large and the environment is wet and cool. In harvested or managed forests, coarse woody debris may be absent because logs are removed for timber. In unmanaged temperate forests, the long time periods needed for large logs to be produced and decomposed produces a U-shaped curve in the mass of woody debris over time (**Fig. 3**). After a stand-initiating disturbance, woody debris from the previous stand accumulates rapidly and then decays slowly. A lag time of several decades typically exists before woody debris from the new stand begins to accumulate. If the new stand remains even-aged, a second peak may occur as the new stand passes through the stem exclusion stage of development and widespread mortality occurs in smaller trees that compete unsuccessfully for light after the canopy has closed.

Ecological Communities and Succession

Vegetation Communities

Temperate forest vegetation communities span the range from single-species stands to mixed-species stands as well as the range from even-aged to all-aged stands. Which type of community is present at any point in space and time depends on the site

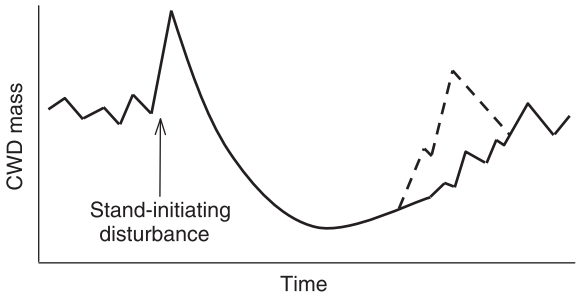

Fig. 3 Dynamics in the mass of coarse woody debris (CWD) before, during, and after a major stand-initiating disturbance in a temperate forest. The solid line represents a U-shaped curve in CWD mass over time. The dashed line represents a secondary peak that may occur if the newly initiated stand remains even-aged and undergoes a self-thinning stage.

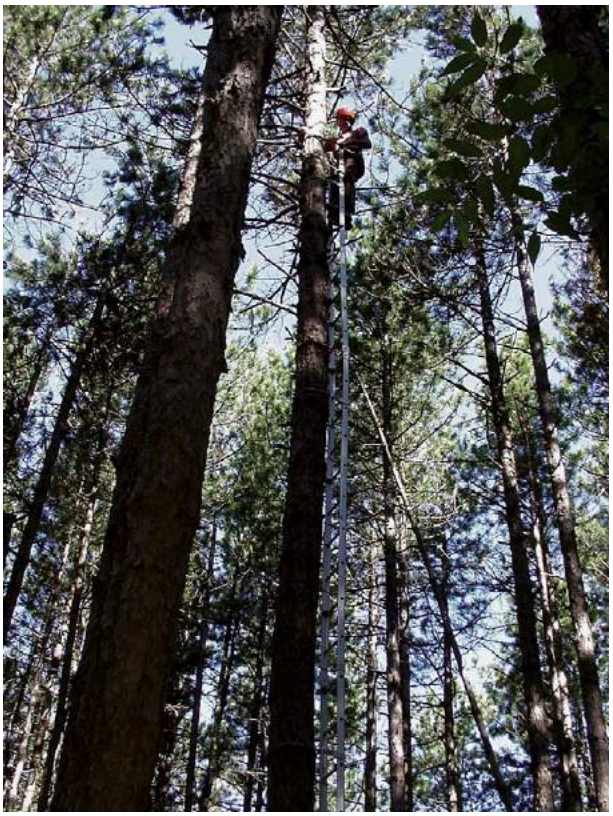

Fig. 4 The canopy of an even-aged red pine plantation, aged about 75 years, in Massachusetts, USA. Photo by W. S. Currie.

physiography, soil, and climate together with its disturbance history. Species such as pines, eucalyptus, cottonwoods (*Populus* spp.), and others may form natural single-species, even-aged stands (Fig. 4). Pioneer species such as aspens (*Populus* spp.) and some pines may initially form even-aged monocultures which eventually diversify in composition and vertical structure as growth, self-thinning, or succession proceeds. Long-lived hardwoods and other conifers also form stands where, increasingly with forest age, great diversity exists in tree ages and sizes. An example of the latter are hemlock-northern hardwood forests of the Great Lakes region of the United States. If horizontal structure and heterogeneity are taken into account, small patch mosaics of even-aged forests of varying ages form larger landscapes of mixed-aged stands, known at the landscape scale as a shifting-mosaic steady state.

It is easy to observe apparent associations of forest trees that occur at certain scales, for example old-growth hemlock–sugar maple (*Tsuga canadensis–Acer saccharum*) stands that form at the scale of square kilometers, or the oak–hickory (*Quercus–Carya*) associations that form more loosely in secondary forests over hundreds of thousands of square kilometers. However, a long-standing debate concerns whether forest communities represent organized associations or simply continuously varying associations as tree species respond individualistically to environmental gradients.

Temperate forest tree species form apparent associations with one another and with the abiotic environment not only across space but also over time at a particular location. A key organizing principle in understanding such temporal associations is the concept of succession, or the replacement of one dominant species or set of dominant species with another, over time, on a particular soil. Primary succession refers to the replacement of species over time occurring in the first forest stand to grow on a newly exposed soil, for example, following the retreat of a glacier. Secondary succession refers to species replacement over time following a major disturbance such as massive windthrow, mortality, or forest harvest. Early-successional species, termed pioneers, are those that are able to fix nitrogen from the atmosphere (see the section titled Nutrient cycling) or those that grow rapidly under high-light conditions but cannot tolerate shade. Late-successional forest species are typically those that can tolerate low-light or low-nutrient conditions as understory trees, while continuing to grow over long time periods, eventually reaching the overstory. Forest ecologists have long sought general principles of succession – for example, the identification of a deterministic sequence leading to a particular stable endpoint or `climax' vegetation community in a particular climate and physiographic landform. Current understanding, however, emphasizes that while certain successional mechanisms exist, the particular sequences and possible endpoints of succession at a particular location are typically numerous, ultimately depending on a complex interplay among competition, species arrival, regeneration, disturbance regimes, and species' modification of the environment.

Temperate Forest Fauna

Faunal biodiversity in temperate forests is not as great as that in tropical forests, but is greater than in boreal forests. Because temperate forests are highly seasonal in their climate and cycles of vegetation physiology and production, faunal life cycles, ecology, and populations are often tied strongly to the seasons. Animal habitats within temperate forests are numerous and heterogeneous, including soils, the forest floor, woody debris, woody stems, and the layers of vegetation canopies. Although some animals depend on particular tree species, many are more dependent on certain aspects of forest structure.

In the temperate forest, the greatest concentration of fauna is on and just below the forest floor, in the litter, humus, and soil. Animals not only inhabit these strata, but through their activities drive soil carbon and nutrient cycling. Also within these strata are gradients of moisture, temperature, gases, and organic matter. Soil microhabitats are pore spaces, water film on soil particles, plant remains, the rhizosphere, and tunnels and burrows. Together, soil fauna and saprophytic flora contribute to the decomposition of organic matter. While most decomposition and nutrient release take place in the warm, humid summers, coinciding with the growing season of the vegetation, microorganisms and invertebrates can remain active below the insulating winter snowpack. Some animals occupy the litter in summer and move to the mineral soil in winter.

Because of the moist soil conditions, many temperate forest floors are home to reptiles (turtles and lizards) and amphibians (toads, frogs, newts, and salamanders). In the mixed-deciduous temperate forests there are over 230 species of reptiles and amphibians. These animals live on the forest floor close to streams, depressions, or lakes where there is available moisture. Lizards are found in moist woods and also in disturbed areas. Turtles live in or near bodies of water and toads and frogs are widespread, needing only shallow water. Temperate forest streams and rivers can support abundant fish populations, particularly under less-disturbed conditions and in coastal temperate rainforests.

Mammal populations in temperate forests tend to be comprised of scattered individuals or groups, and their habitat ranges from the forest floor to the canopy layers. Examples of small mammals are squirrels, rabbits, mice, chipmunks, skunks, and bats. Very large mammals are the exception and in temperate forests may include bear, mountain lions, deer, and other ungulates such as moose and elk. These mammals depend on the herb and shrub layers of the forest in addition to the litter and woody debris for food and habitat. Edge areas form transition zone habitats; for example, deer and other large animals usually live near the edges of forest openings with the trees providing shelter while edible ground vegetation is available in the openings all year.

Trunks are also habitats for spiders, beetles, and slugs. Birds are especially versatile across habitat structures; they are found on the forest floor and in several of the vegetation layers depending on nesting and foraging preferences. Types of birds that breed in mixed-deciduous forests include bark foragers (woodpeckers, flickers), canopy gleaners and pursuers (chickadee, vireo, flycatchers), ground species (thrushes, ovenbirds), and warblers. Deciduous forest are also breeding habitat for larger avian species including turkeys, vultures, owls, and hawks. In addition, moths, butterflies, and other flying insects feed and reproduce in the canopy, the understory, and the forest floor.

Water and Energy Flow, Nutrient Cycling, and Carbon Balance

Water, Evapotranspiration, and Energy

Water enters temperate forests as rainfall, snowfall, fog, and the direct condensation of water vapor onto plant or soil surfaces. Some water, amounting to less than 10% of rainfall under most conditions, is lost immediately to the atmosphere through evaporation. Depending on the season, water drips from the forest canopy to enter soils or accumulates as snow until a mid-winter thaw or spring snowmelt. Entering the soil, water is stored, taken up by plant roots, or moves to groundwater or surface water. Water taken up by plants moves upward through the xylem and exits as water vapor through leaf stomates in the process of

transpiration. Typically, through the combined processes of evaporation and transpiration, less than half of the annual precipitation is passed directly back to the atmosphere as water vapor. Somewhat more than half of the annual precipitation passes through the rooting zone of the soil to enter groundwater or surface water such as streams and lakes.

Evapotranspiration, or evaporation and transpiration taken together, makes a large contribution to the ecosystem energy budget and to the regulation of temperature. In the conversion of liquid water to gas, evapotranspiration carries away large amounts of heat as latent heat. This cooling effect combines with other terms in the energy budget of a forest canopy to regulate the temperature of leaves and of the forest as a whole. Other major terms in the energy budget include the absorption or reflection of short-wave (sunlight) and long-wave radiation (from sunlight and from the atmosphere), the emission of long-wave radiation, and the gain or loss of sensible heat from the atmosphere. On a typical summer day the vegetation canopy absorbs energy in short-wave radiation from the Sun and dissipates the energy as sensible and latent heat to the atmosphere, heating the troposphere from below. On warm days with strong sunlight, the ability of forest tree canopies to dissipate heat allows the trees to maintain leaf temperatures closer to the photosynthetic optimum while also minimizing plant respiration. The opening and closing of stomates, governing transpiration, is under plant physiological control and is an important aspect of plant adaptation to life in a particular environment. During prolonged periods of drought, when trees are less able to use water to cool the canopy and maintain leaf turgor, foliar wilting and tissue damage can occur. Some temperate forest trees can be unexpectedly drought-deciduous, dropping their foliage during a late summer drought.

The photosynthetic conversion of light energy to stored chemical energy is a minor term in the physical energy budget of a forest, amounting to no more than 2% of the energy in sunlight. At the same time, this energy conversion represents the largest term in the ecological energy budget of a forest. The energy stored in photosynthate drives the life processes of all of the plants and animals in the ecosystem. A large portion of this energy is consumed by the vegetation itself through plant respiration, supplying energy for growth, metabolism, and reproduction. Another large flow of energy enters the food web through herbivory; herbivores eat seeds, fruits, and living plant tissues. The consumption of living leaves by insects, while normally minor, can grow during insect irruptions to encompass virtually the entire forest canopy over large areas. Similarly, the consumption of living leaves by forest ungulates including deer and moose are typically small energy fluxes at the ecosystem scale (although the browsing of seedlings and saplings can have a strong impact on forest regeneration and the future composition of the vegetation community). The chief means of energy flow to the faunal food web is through the saprotrophic pathway. Fungi and bacteria (often called soil flora) decompose dead and senesced plant material including leaves, roots, and woody debris. The soil flora is grazed upon by soil microfauna, which are in turn preyed upon by other fauna including arthropods, amphibians, and birds.

Nutrient Cycling and Carbon Balance

To achieve the high levels of productivity typical of temperate forests, trees require ample and reliable supplies of nutrient elements. Those required in the largest supplies include N, P, K, Ca, Mg, S, and Mn. Trees acquire most of their nutrients through root uptake from soils, which store nutrients in soil solution, on the surfaces of mineral grains, on the surfaces of organic matter, and in decomposing organic matter itself. A forest ecosystem receives inputs of nutrients from the atmosphere and from mineral weathering, experiences losses of nutrients via leaching (the water-driven movement of elements out of the rooting zone, ultimately to streams), and cycles nutrients internally (**Fig. 5**). A key internal cycle is the plant–soil cycle in which an element such as calcium (Ca) is taken up by plant roots, used nutritionally by the tree, returned to the soil in foliar litterfall, and returned to the pool of soil-available nutrients during decomposition of the litter. Temperate forests are characterized by the fact that, for most nutrient elements required for plant growth, the internal cycling is greater than the ecosystem inputs and losses of these elements.

While most of the required nutrient elements can be released through mineral weathering, a notable exception is nitrogen (N). Temperate forests rely on inputs of N from the atmosphere. Combined with the fact that trees have a high demand for N, and with the fact that N is strongly retained in unavailable forms in soil organic matter, this makes N the most limiting nutrient for plant growth in most temperate forests. Trees have a high demand for N because photosynthesis and plant metabolism require enzymes, which are made of N-rich amino acids. Amino acids are also one of the primary needs of herbivores that consume plant tissues, including defoliating insects, deer that browse saplings, and beavers that girdle trees by eating the cambium around the tree base. Given the high demand for N by forest trees, it is somewhat ironic that trees in temperate forests are surrounded by two large, potential sources of N that are limited in availability because of the chemical form of the N. The first is N_2 gas, which is the primary constituent of the atmosphere. Most forest trees cannot access gaseous N_2, although a few exceptions include red alder (*Alnus rubra*) and black locust (*Robinia pseudoacacia*) in the USA, which access atmospheric N_2 through the process of N fixation (**Fig. 5**). In this process, symbiotic bacteria living in root nodules fix the N_2 into plant-available forms. The second large pool of poorly available N occurs in humus and soil organic matter, made up of partially decayed and humified plant and microbial detritus. Typically, large accumulations of N are bound in this material in large, polyfunctional macromolecules that form during litter decomposition. Temperate forests are characterized by the combined facts that (1) cold, wet winters impede microbial decomposition and allow these pools of organic matter to accumulate, and (2) warm, humid summers promote decomposition by fungi, causing these soil organic matter pools to turn over and release nutrients at slow but continuing rates. Nutrient release during decomposition is termed mineralization because N is converted from organic to the inorganic forms of nitrate (NO_3) and ammonium (NH_4) which are easily taken up and used by plants (**Fig. 5**).

Carbon is the primary elemental constituent of both forest vegetation and the organic matter in forest soils. Carbon (C) is not considered a nutrient element *per se* because a C atom passes through a forest once, in a single direction, closely linked to the flow of energy; unlike nutrients, carbon does not cycle between plants and soils repeatedly. Forests are highly open systems with respect

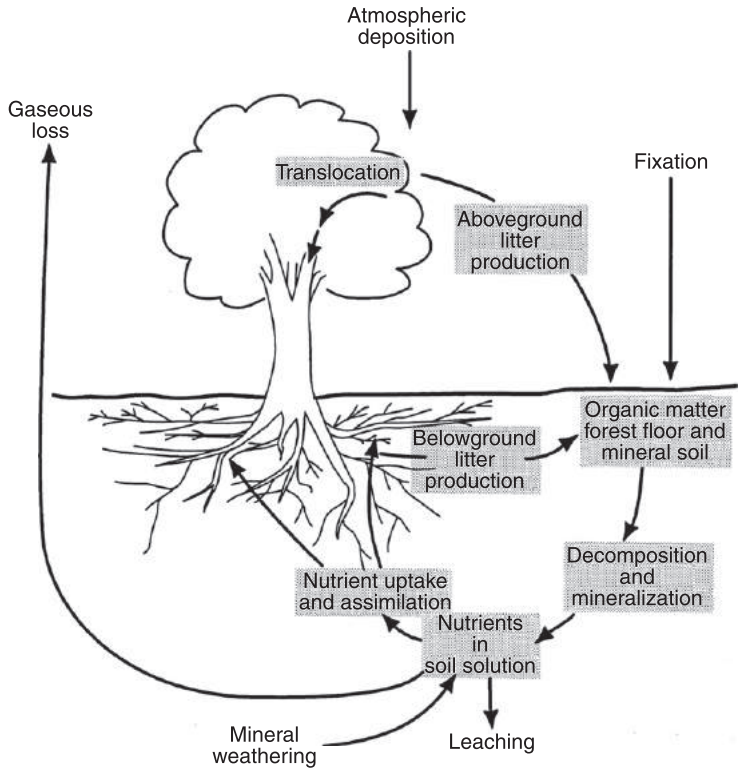

Fig. 5 Schematic diagram of generalized nutrient cycling in temperate forests. Shaded terms represent nutrient cycling fluxes within the system, while unshaded terms represent ecosystem inputs or losses. From Barnes, B.V., Zak, D.R., Denton, S.R., Spurr, S.H., 1998. Forest Ecology. New York: Wiley.

to carbon, exchanging large quantities of CO_2 with the atmosphere. The carbon balance of a temperate forest arises from the interplay among processes controlling forest sources and sinks of atmospheric CO_2. Photosynthesis, or primary production, converts atmospheric CO_2 to reduced organic compounds, storing energy and C in the forest. Autotrophic respiration, the conversion of organic compounds to CO_2 by plants, provides energy for plant metabolism. Heterotrophic respiration, the conversion of organics to CO_2 by herbivores, microorganisms, soil fauna, and other animals in the food web, releases energy for animal life processes. Fire, the rapid oxidation of organics, also releases CO_2 to the atmosphere. Depending on the balance among these processes, temperate forests can either store or release large quantities of carbon. The primary storage pools include growing trees (particularly the woody stems), the forest floor, standing and downed woody debris (Fig. 6), and soil organic matter. The transfer of carbon among these pools is linked to forest disturbance and stand dynamics including aggradation and succession. The flows of carbon into and out of the ecosystem are closely coupled to the availability of water, flows of energy, and the cycling of nutrients.

Temperate Forest Land Cover

Historical Land Cover and Land-Cover Change

Temperate forests in all regions of the globe have been significantly altered by human activities for thousands of years. Their moderate climates, fertile soils, and vegetation productivity have been favorable to human settlement and clearing for agriculture, as well as direct use of trees themselves for lumber and fuels. Agricultural and settlement activities have included development of urban areas, widespread grain and other crop (e.g., corn, vegetables) cultivation, livestock grazing, gathering of mulch, and alteration of natural water drainage. Under these historical pressures, it is estimated that only 1–2% of the original temperate forest remains as never-harvested remnants scattered around the globe. The vast majority of temperate forest land cover is in secondary forest responding to human harvest or other human-induced disturbance.

The longest histories of substantial forest clearing have been in Asia and Europe. In China clearing for agriculture probably began some 5000 years ago, where the Chinese civilization is believed to have begun around the Huang He (Yellow River). The primary sociopolitical factor contributing to deforestation of China over the centuries has probably been the focus on an agriculture-based economy. At present, there is negligible large-scale reforestation in temperate China and significant soil erosion problems hampering reforestation.

Fig. 6 An old-growth sugar maple–birch–hemlock forest showing a large piece of downed woody debris. This forest is located in northern Michigan, USA. Photo by W. S. Currie.

Forest clearing for agriculture in Europe began over 5000 years ago starting in present-day Turkey and Greece and moving northwest through Middle Europe to Northern Europe. Forests of Britain were substantially cleared for agriculture and grazing. Woodlands regained some area in the Middle Ages; however, even remaining European temperate forests were degraded, being used for fuelwood, woodland pasture, and later for charcoal. Coppice practices promoted species that re-sprouted more quickly than beech – including maples and oaks, and this activity altered the natural floristic composition. Tall trees in Britain and Western Europe were removed for shipbuilding. Manorial estates provided some of the few refuges for natural forests. Reforestation in recent centuries in Europe began subsequent to reduction in the use of woodlands for pasture and fuel; reforestation has also occurred through the introduction of planted managed forests and scientific forestry. However, spruce, pine, and larch have been widely planted on areas previously occupied by once deciduous temperate forests.

North American indigenous populations cleared or burned small areas for some agriculture, but land-cover change in North American temperate forests began at large scales in the late sixteenth century with the European settlement. Eastern North American was rapidly cleared as the population moved westward in the nineteenth century. By the start of the twentieth century only a small amount of the original North American temperate forest remained. When the richer soils of the topographically level Midwest and Great Plains were found to be more productive for agriculture than those of eastern North America, eastern farms were abandoned and natural forests began to re-grow. At present, secondary forests are regrowing in the eastern and central United States.

In the Near East the temperate forest occurs in a narrow belt including in Turkey and Iran. This area probably served as a plant refugium during the Ice Ages and the floristic composition is more diverse than that in Europe. Some forests have been exploited for coppice, timber, or grazing and others transformed into agriculture and fruit-tree plantations. Beech forests are the most significant of the present-day broad-leaved forests in the region. In the small area of temperate deciduous forest in South America, forests have been moderately altered since the arrival of the Spaniards in the sixteenth century; the further south one goes the more recently the vegetation has been undisturbed and wooded areas remain. Australia first saw introduction of European agricultural practices only approximately 150 years ago.

Present-Day Land Cover and Rates of Change

The global temperate forest continues to be changed by a combination of long-term effects of historical land-cover change and by present-day change agents. Present-day drivers of land-cover change in temperate forests include accelerated population growth, continued industrialization, and changes in agricultural practices. These are expressed on the landscape as continued clearing for settlement and agriculture in some regions, abandonment of agriculture and reforestation in other regions, and widespread alteration in landscape spatial structure and biodiversity.

While rates of tropical deforestation increased between 50 and 90% in the 1980s, the area of temperate forests has remained constant or increased in the last 50 years in the form of new second-growth forests. In some areas, in eastern North America and parts of Northern Europe, farming is less economically viable than in other parts of the temperate region, leading to reforestation in these areas. Preservation in the form of parks has expanded by active conservation efforts worldwide. Managed forestry has maintained existing temperate forest lands by re-planting after harvest, and sustainable forestry practices are receiving increasing attention.

While the temperate forests may have stabilized or increased in terms of total area, most regions continue to experience other alterations manifested in the landscape spatial patterns and forest biodiversity. Today the temperate forest biome is a mosaic of settlements, patches of forest, and agriculture. Large expanses of unbroken forests from past centuries have been replaced by

considerable landscape-scale heterogeneity and fragmentation. Temperate forest communities have changed compositionally, as disturbance regimes have shifted from natural to a combination of natural and human-caused, producing different patterns of regeneration and succession. While some recently established nature preserves have a natural forest structure, reduced biodiversity characterizes many temperate managed and secondary forests. Considerable present-day challenges lie in understanding and addressing the impacts of land-use change and other aspects of global environmental change in the temperate biome on forest biodiversity and forest ecology.

Temporary Waters

EA Colburn, Harvard University, Petersham, MA, USA

Overview

What Are Temporary Waters, and Why Are They of Interest Ecologically?

Temporary waters are shallow lakes, ponds, pools, rivers, streams, seeps, wetlands, depressions, and microhabitats that contain water for a limited period of time and are otherwise dry. They occur across the globe, on all continents and oceanic islands, at all latitudes, and in all biomes, wherever water can collect long enough for allow aquatic life to develop.

Numerous and widespread, many temporary waters are small and easily studied. Their communities are diverse, with much among-site variation (i.e., high β diversity), and differ from those in permanent waters, contributing to regional (γ) biodiversity. Endemic species are often present. Organisms survive through species-specific behavioral, physiological, and life-history adaptations. Community composition and structure change in response to environmental variations. Temporary waters are highly productive and their food webs are relatively simple. For all of these reasons, temporary waters lend themselves to surveys and experimental manipulations designed to test hypotheses about biological adaptation, population regulation, evolutionary processes, community composition and structure, and ecosystem functioning.

In many parts of the world, most temporary waters have been lost. The conservation and restoration of vulnerable temporary waters is a major thrust of applied ecology. Also important are applications of ecological understanding to the control of disease vectors, especially pathogen-transmitting mosquitoes, from temporary water habitats.

What Is Covered in This Article?

This article is divided into two sections. The first introduces temporary waters – definitions, important variables, types, geographic distributions, and terminology. The second section examines the ecology of temporary waters, with an overview of the biota and their adaptations, and summaries of some key questions in organismal and community ecology, ecosystem ecology, and applied ecology.

Introducing Temporary Waters

Definition

In temporary waters, aquatic habitat is present for noncontinuous lengths of time, in contrast to permanent water bodies, which are always flooded except under unusual conditions such as extreme droughts. This discontinuity in the availability of water is the defining characteristic of temporary waters.

For this article, temporary waters include temporary inland salt waters, whose chemistry and biota are allied to fresh waters and not to marine ones, but they do not include coastal areas flooded by ocean tides. Also excluded from this discussion are subterranean waters.

Important Variables

Apart from periodic drying, there are no hard and fast rules about the characteristics of temporary waters. Classification may be useful, provided it contributes to understanding. The important considerations governing how to classify temporary waters in a given situation should be: what is the purpose of classification, and what are the desired outcomes in terms of distinguishing different types of temporary water bodies? Researchers have developed many approaches to classifying temporary waters using the descriptive variables listed below.

Geography

Regional location (e.g., Ontario, Malay Archipelago), latitude (e.g., tropical, Arctic), or climate (e.g., humid, arid) may contribute to similarities among temporary waters.

Biome

Temporary waters occur in all terrestrial biomes, even the wettest. Regardless of their location globally, habitats within a particular biome, with similar hydrologic characteristics on similar substrates, often are much alike.

Table 1 Major types of temporary waters found throughout the world

Rockpools or rock pools – Accumulations of rainwater or floodwater in depressions on exposed bedrock or boulders
Rainpools or rain pools – Accumulations of rainwater on any substrate
Seasonal woodland pools – Fill annually, usually as a result of winter or spring rains, and from melting snow in northern areas, and dry later in the year
Grassland pools – Temporary ponds in grassland environments
Marsh pools – Temporary ponds that occur within larger grass, sedge, or rush-dominated wetlands and remain flooded after most of the wetland has drawn down
Swamp pools – Depressions within larger wooded wetlands that remain flooded after the surface of the swamp has dried
Floodplains – Land areas that are inundated seasonally by high waters spilling over the banks of rivers and streams
Floodplain pools – Low areas in floodplains that remain flooded after floodwaters have withdrawn and left most of the floodplain dry
Springs, seeps, and spring seeps – Sources of water derived from groundwater or from subsurface flow reaching the land surface after heavy rains. Springs are expressions of the groundwater table and tend to be relatively permanent; seeps may be more transitory. Both vary in output with rainfall over the source area, and both may provide seasonal or continuous sources of water. Flow from springs and seeps may extend from the source as marshes, pools, or streams that may contain water during cool or wet seasons and become dry during periods of high temperature and/or low precipitation
Intermittent headwater streams – The smallest tributaries at the head of stream systems, often seasonal in their flow, containing water during the wet and/or cooler months and becoming dry during the hot/dry months
Arid-land rivers, intermittent rivers, or ephemeral rivers – Flowing waters that occur in regions where the groundwater table is far below the surface and where annual potential evapotranspiration is greater than precipitation. They typically flow only during the rainy season, when runoff travels over the land and is carried downstream; some only carry storm runoff, but others may have extended flow maintained by seasonal groundwater discharges. During the dry season, there may be water below the surface and in isolated pools within the channel, and there may be brief spates of flow following cloudbursts
Dry lakes or playas – Shallow water bodies in arid regions, especially in closed basins, where water collects from large areas. Due to the arid conditions, the water usually evaporates rapidly. A long history of flooding and drying leads to accumulations of salts in these basins, and dry lakes are typicaly saline. Many dry lakes occupy basins that contained large freshwater lakes earlier in geological history. Deposits of salts and sediments left behind when the lakes dried may be tens or hundreds of meters deep beneath the lake beds, and they contribute to saline conditions in the playa
Sinkholes or sink holes – Depressions created in calcareous bedrock by the gradual dissolution of the rock by water. They range in diameter and depth from meters to kilometers. Sinkholes that contain water are fed by groundwater, precipitation, and/or streamflow and include both permanent and temporary waters
Snowmelt pools, icemelt pools, and meltwater pools – Formed by the seasonal melting of ice and snow in the Arctic and Antarctic, along the margins of icefields and mountain glaciers, and in areas that receive snowfall
Meltwater streams – Flowing waters that develop seasonally as glaciers, icefields, and winter snows melt; they often flow during the day and stop flowing at night as low temperatures inhibit melting
Plant-associated microhabitats or natural containers (phytotelmata) – Microhabitats formed where plants produce small depressions in which water can collect (see **Table 2**)
Artificial containers – Any human-made concavity where water can collect, including gutters, birdbaths, tires, empty cans, tractor ruts, canoes, split and discarded coconuts, and other water-holding depressions

Water body type

Temporary waters may be lotic (flowing) or lentic (still). There are several major categories, and many unique regional names (**Tables 1**–**3**). Some categories overlap; for example, pools formed after thunderstorms on exposed rocks on coastal Scandinavian islands are both rainpools and rockpools.

Substrate

Substrate (e.g., rock, organic debris, sand, clay, limestone, mud, basalt, wood) influences hydrology, water chemistry, and temperature and is an important habitat variable in its own right (e.g., for seed germination or shelter for burrowing animals).

Size

Some classifications distinguish microhabitats, mesohabitats, and macrohabitats.

Hydrology

Hydrologic variables are the most important factors influencing aquatic life in temporary waters.

Water sources

Water sources include groundwater, runoff, precipitation, snowmelt, streamflow, and floodwater.

Flood timing

Flood timing encompasses both season and predictability. Vernal, estival, autumnal, and hibernal (or brumal) refer respectively to filling in spring, summer, fall, or winter. Intermittent systems flood predictably at annual (seasonal) to multiyear intervals. Waters that flood unpredictably are ephemeral if they fill several times a year, and episodic if they fill just once or twice a decade.

Table 2 Examples of phytotelmata and other natural containers that provide temporary aquatic habitats for mosquito larvae and other organisms

Ant nests
Insect-bored bamboo, bamboo stumps
Fungal cap concavities
Log holes
Buttress-root slits
Eggshells
Flower bracts
Fruits
Horns
Leaf axils
Fallen leaves
Nuts
Modified leaves of pitcher plants and analogs
Pods
Reeds
Rockholes, potholes
Mollusk shells
Skulls and other skeletal remains
Stumps and trunk cavities
Treeholes

Derived from Index in Laird, M., 1988. The Biology of Larval Mosquito Habitats. Boston: Academic Press.

Seasonality and predictability of flooding influence the biota. Predictable filling of Mediterranean vernal pools by rainfall during the winter growing season facilitates plant growth and has contributed to the development of an endemic flora. When the pools dry, high summer temperatures prevent the establishment of terrestrial vegetation.

Flood duration, or hydroperiod

Across most categories of temporary waters, there is a continuum of flood duration: days, weeks, months, or years. Ephemeral waters are flooded for hours, days, or weeks. Intermittent refers to flood durations of several months. Semipermanent or near-permanent waters dry only occasionally, during major droughts. Within a water body, the hydroperiod varies across filling cycles, depending on weather, with some waters being more stable than others (**Fig. 1**).

Typically, with increasing hydroperiod, the potential aquatic community becomes richer, and the adaptations of the flora and fauna become less extreme. Waters with shorter hydroperiods have fewer total species but more that are unique to temporary habitats.

Chemistry

Important chemical characteristics include salinity (fresh, $<3\ g\ l^{-1}$ salts; brackish, 3–35 $g\ l^{-1}$; saline, $\geq 35\ g\ l^{-1}$), major ions (e.g., sulfate- vs. chloride-dominated desert waters), color (e.g., clear vs. stained dark with organic acids), pH, and dissolved oxygen.

Distribution of Temporary Waters

Most types of temporary waters occur widely across the world's biomes, from the poles to the equator. Their numbers and varieties vary with annual precipitation, temperatures, and local geology and geography. They are most common in arid or cold areas where liquid water is unable to persist for long periods of time.

Tropical rainforests

Tropical rainforests, although well watered, contain many temporary waters. Cavities in bromeliads and other epiphytes retain rainwater (**Fig. 2**) where decaying organic materials support microorganisms, insects, and amphibians. Rainpools on the forest floor fill, dry within days, and support distinct communities. Lowlands of great tropical river systems, including the Amazon and the Paraná–Paraguay, are inundated during the rainy season, and the retreating floodwaters create a mosaic of ponds that retain water for varying time periods.

Boreal and temperate forests

Temporary waters in deciduous and coniferous forests include rainpools, rockpools, and treeholes. Intermittent headwater streams dry in summer when forest trees are transpiring (**Fig. 3**). Floodplain pools fill in spring or after major storms. Seasonal woodland pools, commonly called vernal pools, fill from groundwater, snowmelt, and spring rainfall and dry in summer (**Fig. 4**). Many are

Table 3 Some terms used to describe temporary waters around the world

Avens	France: depressions hollowed out in limestone
Baias	South America: temporary lakes
Billabongs	Australia: pools that are left behind in floodplains as large, seasonal rivers recede after flooding
Bogs	Worldwide: freshwater peatlands with acidic water chemistry; usually with limited connection to other surface waters, often fed exclusively by rainfall
Buffalo wallows	North America: created by buffalo (*Bison bison*) rubbing their bodies on the ground, these shallow excavations on the prairies fill seasonally with water
California vernal pools	Western North America: seasonally flooded pools in Mediterranean scrub of western North America, especially California, and characterized especially by rich plant communities with large numbers of endemic species
Carolina bays	North America: round or oval depressions of uncertain origin in the coastal plain of the Southeastern United States, often supporting endemic plant communities and temporary-pond fauna
Corixos	South America: temporary-water bodies in floodplains, especially in the Pantanal region
Dambos	Southern Africa: shallow, treeless, seasonally inundated wetlands at heads of drainage networks
Dismals	North America: swamps or marshes in the Mid-Atlantic region of Virginia, Delaware, and the Carolinas
Doline	Western Balkan states/Dinaric Alps: depressions and sinkholes in limestone
Fens	Worldwide: freshwater peatlands with alkaline water chemistry
Gator holes	North America: excavations made by alligators (*Alligator mississippiensis*) in the Florida Everglades; they remain flooded when waters recede and serve as refugia for aquatic animals during droughts
Gnammas	Western Australia: temporary waters formed on granitic outcrops
Heaths	Great Britain: freshwater peatlands with acidic water chemistry
Mires	Northern Europe: freshwater peatlands with acidic water chemistry
Kettles, kettle holes	Worldwide, in areas affected by continental glaciation in the past: largely circular depressions formed by the melting of blocks of ice calved off of retreating continental glaciers and buried in morainal debris
Moors	Great Britain: freshwater peatlands with acidic water chemistry located on hilltops
Mosses	Scotland: raised bogs, i.e., freshwater peatlands with acidic water chemistry located on hilltops or above the groundwater table
Muskegs	North America: freshwater peatlands with acidic water chemistry (Algonquin)
Oshanas	Namibia and Angola: linearly linked shallow pans that are filled by floodwater and precipitation
Pakahi	New Zealand: shallow, groundwater-flooded areas with acid soils, inappropriate for cultivation (Maori)
Pans, panes, pannes	Worldwide: shallow temporary waters that flood periodically from rainfall in arid regions; also refers to temporary pools that form in salt marshes from monthly flooding by spring tides
Phytotelmata	Worldwide: a technical term describing temporary waters associated with plants, in axils of leaves or branches, modified pitchers and similar structures, nuts
Plunge pools	Worldwide: deep holes that form in bedrock at the base of waterfalls through the action of water over time, and that retain water for a period of time after the stream has dried up
Pocosins	North America: upland-coastal floodplains or groundwater-flooded seasonal wetlands in the South Atlantic United States
Potholes, pot holes	Worldwide: rockpools in or along streambanks and streambeds, created by the action of water and rock scouring out round depressions into boulders or bedrock. Potholes may be a few centimeters to more than a meter in diameter
Prairie potholes	North America: in the Great Plains, largely circular depressions formed as blocks of ice left by departing continental glaciers were covered by morainal debris and then melted
Ramblas	Spain: temporary streams that usually flow only after rainstorms
Sabkhas, seabkhas	Arabian Gulf: saline lakes
Salinas	South America: saline lakes
Sinkholes	Worldwide: depressions in limestone, formed by the solution of surface rock or by the collapse of underground caverns or caves collapse where the subsurface has been dissolved by gradual solution in water. Sinkholes may be dry on the bottom, intermittently flooded, or contain water continuously
Sinking creeks	North America: flowing streams that disappear from the surface into one of the many cracks or sinkholes in limestone regions, or into the ground in arid areas
Sloughs	Worldwide: the term has a variety of meanings. In Great Britain it refers to muddy and shallow waters. In North America it is used to refer to prairie potholes, temporary ponds, oxbow wetlands, permanent ponds, deepwater areas in the Everglades, brackish marshes on the west coast, seasonally flowing depressions in forests, freshwater wetlands in the Great Plains. Some use the term to refer to areas where water is not stagnant but rather, flowing slowly; others specifically define sloughs as areas with stagnant water
Swallow holes	Great Britain: sinkholes in limestone, especially deep holes through which water funnels underground
Takyrs	Turkmenistan: pans in the desert
Tenajas	North America: rockpools, usually in temporary stream channels, that remain flooded for several months after the stream dries; some develop plant communities similar to those in vernal pools
Turloughs	Ireland: temporary waters formed in limestone, filled primarily by groundwater although may sometimes fill from precipitation; usually fill in fall and dry in spring or early summer
Vasante	South America: temporary streambeds connecting lakes in the Pantanal region during the rainy season
Vernal pools	North America: temporary woodland pools that fill in spring and dry in summer; applied more broadly to all seasonal woodland pools that reach maximum depth and volume in spring. Worldwide, the term applies to any temporary pools that fill in spring. The term `California vernal pools' is used to represent a class of Mediterranean biome temporary ponds characterized primarily by their endemic plant communities

(*Continued*)

Table 3 Continued

Vleis	Southern Africa: seasonally inundated wetlands in southern Africa, typically flooded by rivers at high water
Whale wallows	Eastern North America: seasonal woodland ponds along the Delaware coast in the United States

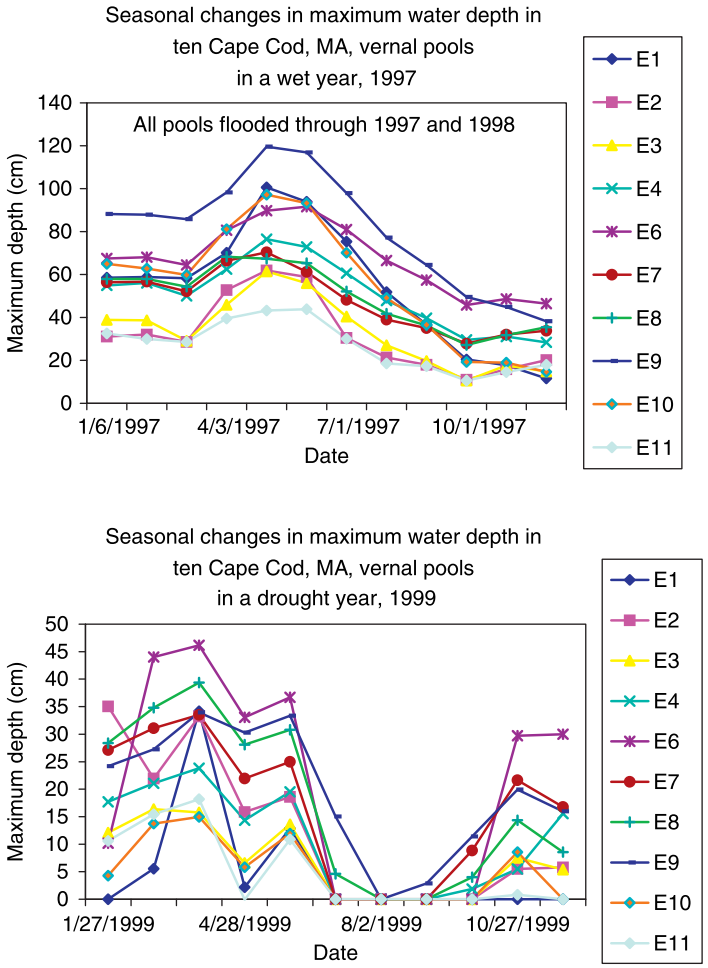

Fig. 1 Water depths differ within and between years in ten temporary ponds clustered together on Cape Cod, MA, USA.

Fig. 2 Bromeliads and other plants serve as natural containers for rainwater and provide microhabitats for microorganisms, mosquito larvae, and some tropical amphibians.

Fig. 3 Intermittent headwater streams drain up to 80% of the landscape in temperate forests and support distinctive communities of aquatic invertebrates and stream salamanders.

Fig. 4 Temporary woodland ponds, or vernal pools, are common in temperate and boreal forests. Water levels vary significantly over time. In this pool, normal high water reaches the base of encircling maples, and in wet years it is more than a meter deep.

important breeding habitats for amphibians, crustaceans, and aquatic insects. Carolina Bays in the Southeastern United States, and other previously unglaciated systems, support endemic plants.

Tundra and icefields

Where temperatures are cold and the growing season is short, temporary waters appear when the summer sun melts glaciers, ice, and snow. For a few months, Antarctic rockpools, high-mountain ponds, and myriad shallow water bodies perched over permafrost in Arctic tundra teem with bacteria, protozoans, planktonic crustaceans, and insect larvae. This broth of aquatic life provides food for nesting birds which flock in hundreds of thousands to high latitudes to raise their young.

Fig. 5 A salt crust left by evaporating water overlies dry lakes, or playas, in many desert basins.

Mediterranean scrub

The Mediterranean scrub biome occurs along the Mediterranean Sea; from Baja California to eastern Washington; and in parts of Chile, southern Africa, and Australia. Rains during the winter–spring growing season collect above impervious substrates, forming water bodies known as vernal pools, vleis, pans, Mediterranean temporary pools, and gnammas. They support endemic floras, including *Isoëtes* spp.; endemic faunas, including fairy shrimp and other crustaceans; and cosmopolitan temporary-pool plants and animals. On other substrates, temporary pools are less predictable and lack endemics. Most rivers in this biome flow only during the wet season, although isolated pools retain water for part of the dry season. Treeholes and other natural containers provide microhabitats after rains.

Deserts

In deserts, extreme aridity, high temperatures, salinity, and isolation of waters are especially stressful for aquatic life. Brief rainstorms create ephemeral pools on rocks and other surfaces. Extended rains collect water from large areas to fill closed basins, forming shallow, usually saline lakes that leave extensive deposits of encrusting salts upon drying (Fig. 5). Many rivers and streams flow seasonally, especially in wet winters, or flash-flood unpredictably after storms, leaving behind pools of varying permanence (Fig. 6). Permanent springs overflow during winter, creating seasonal streams, marshes, and thickets. Salts accumulate in the soil along the edges of desert waters, and temporary water bodies are generally brackish or saline.

Grasslands

Temporary waters in grasslands include pools, marshes, floodplains, and seasonal rivers and streams. Rich assemblages of plants, invertebrates, and amphibians occur in these waters and are critical for bird populations in the prairie pothole region of North America (Fig. 7); the Eurasian steppes; the Indus, Ganges, Assam, Sylhet, and lower Mekong river plains in Asia; the southern African veldt; and the Pampas, Campos, and Pantanal regions of South America.

The Ecology of Temporary Waters

The Biota

All major groups of freshwater organisms occur in temporary waters. Many families and genera are found in similar habitats throughout the world, and there are some cosmopolitan species.

Hundreds of species of prokaryotes, including photobacteria and bacterial decomposers, proctotists, including green algae and diatoms, and protozoans, including ciliates, flagellates, and sarcodines, have been identified from temporary waters. Plants include mosses and liverworts, ferns, grasses, sedges, rushes, spike rushes, and other taxa typical of local wetlands. Microinvertebrates include rotifers, tardigrades, and gastrotrichs. Arthropods, especially water mites, crustaceans, and insects, dominate the macroinvertebrates. Many microcrustacean species, especially ostracodes and copepods, swim in the water, feed in the sediments, or cling to surfaces. Branchiopod crustaceans, particularly Notostraca (tadpole shrimps) (Fig. 8), Anostraca (fairy shrimps), Conchostraca (clam shrimps), and some Anomola (daphnias and other water fleas), are largely restricted to temporary waters. All aquatic insect orders include temporary-water species, with the largest number in the Diptera, or true flies. Water mites selectively feed on insects and crustaceans. Platyhelminthes (flatworms and flukes), Annelida (segmented worms and leeches), Nematoda (roundworms), Nematomorpha (gordian worms), and Mollusca (snails and bivalves) are also represented. Annual tropical killifishes (Cyprinodontiformes) and African and South American lungfishes (Lepidosireniformes) survive periodic drying, and fully aquatic fishes move seasonally into floodplains and intermittent headwater streams to feed and breed. Most anuran amphibian species, including true frogs, treefrogs, and toads, and some salamanders, preferentially breed in temporary habitats. For many of the

Fig. 6 (a) Seasonal rivers in arid regions flow seasonally. (b) When flow ceases, the pools that remain persist for varying lengths of time.

Fig. 7 Prairie potholes dot the landscape of the upper Great Plains in North America, provide habitat for aquatic life, and support breeding waterfowl. Reproduced from Sloan, C.E., 1972. USGS Professional Paper 585-C Ground-Water Hydrology of Prairie Potholes in North Dakota. Reston, VA: US Geological Survey.

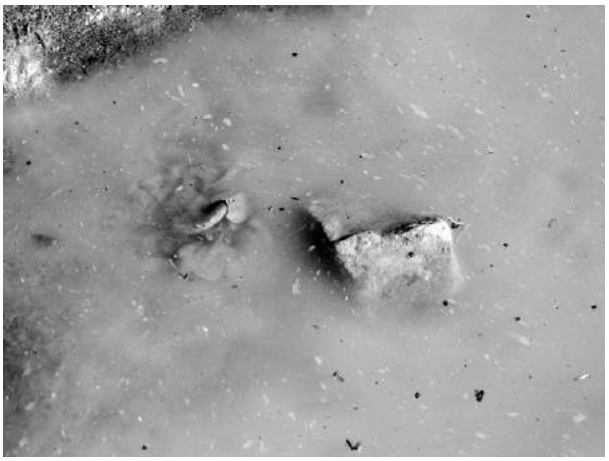

Fig. 8 Notostracan crustaceans, known commonly as tadpole shrimp (left of center), are temporary-water specialists. Diapausing eggs lie for months, years, or decades in sediments of desert playas, rockpools, and woodland ponds. Hatching upon flooding, the animals are voracious predators and scavengers and their presence restricts the distributions of other temporary pool animals.

world's birds, temporary waters are critical food sources during breeding or migration. Reptiles and mammals feed and hydrate in these seasonal waters.

Autecology: Organisms and Populations

Temporary waters lend themselves to thousands of ecological questions about adaptations, population regulation, and evolutionary pathways linking sibling species and cosmopolitan taxa.

Adaptations to drying

Inhabitants of temporary waters are distinguished by their ability to survive periodic drying. Adaptations include diapause, quiescence, and active avoidance. Rapid responses to flooding, fast growth, and flexibility in initiating the drying response maximize organisms' habitat use.

Diapause

Diapause involves suspended development. Hormonally controlled, and initiated and terminated by specific environmental cues, diapause is the most common and most effective drought-survival mechanism. It can allow survival over years – even decades – of continuous drying.

The rapid appearance of living organisms when water fills formerly dry puddles, containers, and floodplains is not, as formerly believed, spontaneous generation, or life miraculously developed from nothing. Instead, much of the life in newly flooded areas emerges from cysts, spores, seeds, or eggs diapausing on the dry substrate.

Found from bacteria to fishes in temporary waters, diapause is common in organisms with limited dispersal. Typically, the organism is replaced by a small, highly desiccation-resistant structure that awaits rehydration in the sediment. The substrate reservoir of diapausing microbes, plants, and animals is termed a seed bank, egg bank, or propagule bank. Diapause also occurs in larval and adult stages. Reproductive diapause is seen in some insects, and certain flatworms and annelids enter diapause after encysting in mucus.

Other dormancy

Other responses to drying involve decreased activity and lowered oxygen consumption. Some bdelloid rotifers, tardigrades, and nematodes survive complete dehydration to revive when flooded. Perennial plants may lose their leaves and die back to subsurface roots, tubers, or rhizomes when water levels recede. African and South American lungfish on drying floodplains encase in mud, breathe air, and more than halve their metabolism. Many mollusks burrow into sediments and estivate. Some insect pupae become dormant, delaying adult emergence. Dormancy is generally less effective than diapause for surviving extended drying or unpredictable flooding.

Avoidance

Anatomical, behavioral, or physiological adaptations can help organisms avoid drying. Some plants extend long roots deep into groundwater (**Fig. 9**). Crayfish excavate burrows that remain flooded after surface drying. Animals in intermittent streams move downward into areas of high moisture or subsurface flow. Some insects and fish migrate between permanent and temporary waters. Amphibians and some insects have aquatic larvae and terrestrial adults.

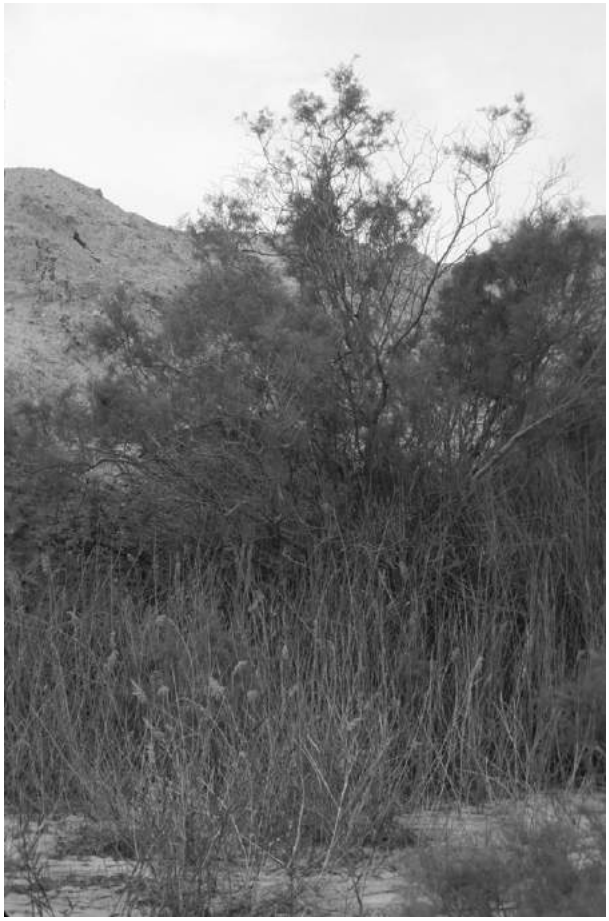

Fig. 9 Along the banks of ephemeral rivers and seasonal waterbodies in arid regions, deep-rooted trees and shrubs such as these tamarisks (*Tamarix* spp.) tap the groundwater and can influence drying of the waters at the surface. A gradient of increasing salinity tolerance is seen in plants radiating outward from the water source.

Physiological ecology

Life in temporary waters may require biochemical modifications and major physiological adaptations. Many endemic plants from temporary waters use C_4 or crassulacean acid metabolism (CAM) photosynthesis, biochemical pathways that use water more efficiently than the C_3 photosynthesis of most plants. Species along salinity gradients show increasing osmoregulatory specializations.

Temporary waters have large local thermal gradients and over time may be subfreezing or above 40 °C. Biological processes vary with temperature, typically doubling with each 10 °C increase. Most species grow within narrow temperature ranges, and thermal cues regulate many life-cycle events. Enzymes need to function over temperature ranges found in temporary water bodies during organisms' life cycles. For example, inhabitants of Antarctic rockpools are active in cold water, and they diapause or secrete antifreeze substances to avoid consequences of subfreezing temperatures; their physiology differs markedly from relatives in temperate or desert pools.

Most freshwater plants and animals cannot regulate internal ionic concentrations in salt water. Inhabitants of many desert waters have impermeable body surfaces, salt-exporting cells, modified life histories, and well-developed drought-resisting adaptations (**Fig. 10**). Many are active in winter, when salinities and temperatures are low. Energetic costs of osmotic and ionic regulation must be compensated for by benefits, such as abundant food or reduced predation. Distributions in desert waters reflect species' physiological tolerances, with no plants and few highly adapted animals in hypersaline pools, greater diversity at low salinities, and low richness in highly unpredictable, ephemeral, freshwater rainpools.

Populations

Bet hedging

Desiccation-resistant seeds of annual plants from temporary waters germinate when chemicals in the seed coat are washed away. Seeds from the same parent have different levels of resistance, ensuring that not all germinate at once, and that some remain in the sediment seed bank. Similarly, crustaceans and some insects form an egg bank comparable to the seed bank of plants; some of the eggs hatch upon flooding, others hatch another time. African and South American annual killifish deposit diapausing eggs into the

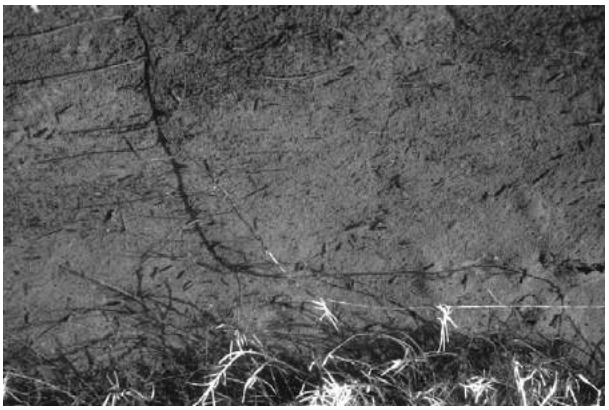

Fig. 10 The stick-like cases of salt-tolerant caddisfly larvae (Insecta: Trichoptera: Limnephilidae: *Limnephilus assimilis*) litter the bottom of Salt Creek in Death Valley, CA, in winter. The ability to regulate hemolymph osmotic and ionic concentrations in brackish waters, rapid growth, adult reproductive diapause during the hot summer months, and the presence of fewer predators than in low-salinity waters contribute to the species' persistence in this temporary desert stream.

egg bank in the sediment of floodplain pools, and these eggs, too, hatch differentially upon flooding. This strategy of spreading risk is predicted from game theory and is termed bet hedging. The new field of resurrection ecology uses egg and seed banks to establish new communities in restoration projects, and obtains insights into evolutionary processes by growing individuals from samples collected a century or more ago and comparing them with modern individuals.

Life-history strategies

Numerous studies address short-term controls on population growth and survival in temporary waters. What are appropriate responses to flooding and drying, when they occur at different times from one year to the next, or to salinity and temperature? Theories of *r*- and *K*-selection predict that some species produce many, small progeny, raising the odds that some will survive. Others produce fewer, but larger progeny with more reserves to support them over adverse conditions. Examples tending toward both extremes can be found in temporary waters. Environmental conditions and evolutionary history shape species' responses, and many cues stimulate the initiation and termination of life cycles (**Tables 4** and **5**).

Short, irregular hydroperiods should favor *r*-selected life histories including rapid hatching/germination upon flooding, fast growth, and timely entry of many propagules into a drought-resistant state. Under longer, predictable hydroperiods, *k*-selection should produce slower growth, larger sizes, and longer life spans. In rockpools worldwide, with hydroperiods from hours to weeks, algae, insects, and crustaceans in the most ephemeral pools complete development in less than 24 h. Life spans are longer in longer-duration pools, and in those with predictable flood regimes. Temperate *Eubranchipus* fairy shrimp and some aedine mosquitoes have one generation per year; they hatch, grow, mature, mate, deposit diapausing eggs, and die. In some fingernail clams, only young individuals resist drying, and they enter obligatory diapause as soon as they are born. Similar patterns are seen in many species.

Life-history tradeoffs, such as the ability to grow while water remains, potentially allow production of more offspring, or development to a larger size, which may enhance survival and reproductive fitness. A longer developmental period may also mean higher intraspecific densities and competition as habitat shrinks, and it increases the risk of being stranded if drying occurs rapidly. *Haematococcus pluvialis*, a photosynthetic flagellate related to *Volvox* from rockpools worldwide, is typical – diapausing spores develop rapidly when flooded, the organisms grow and reproduce, and upon pool drying, the motile cells form aplanospores that withstand drying and high temperatures. The diapausing spores form in less than a day, at any stage in the life cycle, providing *Haematococcus* with flexibility in the face of variable habitat duration. Widely different taxa grow rapidly to a minimum size threshold, after which they can reproduce and grow through multiple generations (e.g., *Daphnia* spp., snails, some bivalves), or become larger (e.g., amphibians, insects), as long as water is present, or until other cues initiate diapause, dormancy, or transformation.

Complex life histories

Many species' life cycles are complex. Post-hatching populations of the cosmopolitan water flea *Daphnia pulex* are all-female and reproduce parthenogenetically while conditions are favorable. When drying threatens, males are produced, and fertilized eggs develop into diapausing, drought-resisting ephippia that lie in the substrate until the next flooding event and temperature cues stimulate hatching. Similar alternating generations occur in some rotifers.

Diving beetles (*Agabus* spp.) have a 2-year life cycle. They hatch from eggs in temporary pools and, when mature, fly to permanent waters to overwinter, returning to pools to breed the following spring. The eggs they leave hatch the following year, before the next wave of adults arrives. Some water-mite larvae that parasitize *Agabus* and other migratory insects are transported by

Table 5 Some cues initiating life stages adapted to drying in temporary waters[a]

Developmental stage (obligate diapause/dormancy/transformation once development reaches a critical threshold, regardless of habitat favorability)
Developmental stage plus other cues (diapause/dormancy/transformation initiated facultatively after development reaches a critical threshold, only after habitat becomes unfavorable)
Water temperature
Photoperiod
Chemical cues (pH, dissolved oxygen, chemical signals from predators or competitors, salinity, nutrients, other)
Drawdown-associated cues (chemical concentrations, crowding, depth)

[a]Note that if drying occurs before necessary developmental thresholds have been reached, cues cannot initiate drought-resistant stages, and organisms may die without completing their life cycles.

their hosts from temporary waters in fall and back in spring; they then pass through two predatory life stages before laying eggs that hatch into new parasitic larvae.

Dispersal, population maintenance, and evolutionary ecology

How nonmotile organisms disperse has long fascinated biologists and has implications for community composition and stability. Mechanisms include transport by wind; bird feet, feathers, and digestive tracts; water; humans; and insects. Many temporary-water populations are units of metapopulations; they undergo periodic local extinctions and are recolonized from other waters or provide colonizers for other sites. Genetic analysis and modeling help determine the extent of genetic mixing needed to maintain populations or allow divergence.

Endemic species, especially in crustaceans and some plant taxa, are widespread in temporary waters. New species of copepods, anostracans, and other crustaceans are still being identified from all over the world and provide exciting opportunities to understand evolutionary processes.

Community Ecology

Community studies include questions about local and regional biodiversity; community composition and structure in relation to environmental and biological variables and disturbances; patterns of colonization and extinction; predator–prey, host–parasite, and competitive interactions between species; and food webs.

Comparable temporary waters differ in their biota. Distributions of species, and thus community composition, shift along gradients of size, hydroperiod, predictability, and salinity, with richness increasing with decreasing stress. Community composition may change between years, and it can also vary seasonally, with a succession of new hatches and migrants entering waters over time. The presence of potential community members as unhatched propagules in the sediment complicates assessments of community composition and structure.

Community theory

The theory of island biogeography postulates that species richness in isolated habitats is regulated by local extinction and colonization and should vary with habitat size and proximity to potential sources of colonizers. The intermediate disturbance hypothesis predicts high richness in communities subject to a moderate degree of disturbance or stress; according to this model, high stress leads to mortality in all but fast-growing individuals, and under low stress, inter- and intraspecific interactions such as competition and predation determine community structure. Other models look at resource and habitat partitioning/niche diversification, temporal offsets in life histories, and other mechanisms controlling community composition and structure. Studies of amphibians, plants, invertebrates, and algae in temperate woodland pools, Mediterranean temporary pools, Negev and Namibian desert pools, Scandinavian rockpools, Arctic snowmelt pools, and other areas show complex relationships between

community composition and habitat variables such as size, hydroperiod, frequency of flooding, hydrologic predictability, distance from other waters, and salinity. The data suggest that community richness is related to both degrees of disturbance and the predictability of disturbance. Isolation is also important, with greater richness in waters that are connected to larger bodies (e.g., in floodplains) but also fewer taxa specifically adapted to temporary habitats. Species pools in individual water bodies are poor in comparison to the regional set of species (**Table 6**), and experimental assemblages comprised of larger subsets of available species function differently than the smaller natural communities.

Interspecific interactions

Food web manipulations allow examination of relationships among species and show interesting relationships. For instance, algae grow better when grazed by tadpoles than alone. Some potential competitors avoid conflict by preferentially choosing waters with different hydrologic or other characteristics when the other species are present. The survival outcomes for some species of amphibians and insects when they co-occur with competitors depend on which species becomes established first.

Certain aquatic insects, crustaceans, and vertebrates can survive in pools with long flood durations, but they are typically found only at the more ephemeral end of the flooding continuum. They are excluded from the longer hydroperiod pools by predators such as amphibian larvae, tadpole shrimp, and water bugs. The ovipositing females of some species explicitly avoid pools with predators. For example, vulnerable species of mosquitoes avoid laying eggs in pools containing predatory backswimmers, whereas predation-resistant midge larvae do not; American toads (*Bufo americanus*) avoid temporary pools with omnivorous wood frog tadpoles (*Rana sylvatica*).

Ecosystem Ecology

There are many questions about temporary waters as ecosystems. How do tiny, intermittently flooded water bodies produce huge numbers of insects, amphibians, and other organisms? How do nutrients, carbon, and energy flow within temporary waters, and between them and adjacent terrestrial landscapes?

Some temporary waters are among the most productive ecosystems known. In some temporary habitats, photosynthesis by microscopic producers is the base of the food web. For many, from microhabitats in plant leaves to large woodland and floodplain pools, decomposing detritus is the primary energy source. Much remains to be learned about the sources and fluxes of energy and nutrients in temporary-water ecosystems.

Applied Ecology

Vector Control

Mosquito-borne diseases including encephalitis, yellow fever, West Nile fever, and, especially, malaria affect millions of people and are a major focus of world health agencies. Most mosquitoes breed in temporary waters. Their populations have expanded following human alterations of natural habitats, the creation of flooded areas by equipment and land-use change, and the dispersal of water-retaining containers. The effective long-term control of disease vectors requires understanding of the ecology of the pest animals and of their habitats.

Table 6 Regional species pools (β diversity) are greater than local species pools (α diversity), as illustrated by numbers of non-dipteran macroinvertebrates found in early spring from nine adjacent temporary pools on Cape Cod, Massachusetts, USA

Water body	Number of taxa
Pool 1	34
Pool 2	22
Pool 3	24
Pool 4	37
Pool 5	12
Pool 6	38
Pool 7	48
Pool 8	28
Pool 9	22
Total species	89

Ecological Engineering and Conservation

Bird and amphibian populations and unique aquatic species depend on temporary waters, and the overall contributions of these systems to biodiversity are still being explored. Losses of these habitats are severe (e.g., loss estimates for California vernal pools exceed 90%), and remaining sites face draining, filling, excavation, pollution, water abstraction, invasive species, and climate change. In many regions, seasonal rivers and pools are important water sources; elsewhere, temporary waters provide the only arable areas. Many have been dammed, or converted for rice culture and other crops. Hydraulics, hydrology, surface–groundwater interactions, and biology affect management of these systems for human use and conservation, habitat restoration, and habitat creation.

Tropical Ecology☆

Harald Beck, Towson University, Towson, MD, United States

Geography of the Tropics

The tropics include all geographic regions of the Earth that extend from the equator towards the northern hemisphere up to the Tropic of Cancer (23°30′ latitude), and in the southern hemisphere down to the Tropic of Capricorn (23°30′ latitude, Fig. 1). Tropical regions cover only about 7% of the Earth's biosphere but harbor more than 50% of the world's species. Different types of forests dominate the plant community within tropical latitudes; around 58% of rainforests occurs in the Neotropics, which encompasses southern Mexico, Central America, and most of South America. Some 32% of the world's rainforests are located in Brazil, the remaining 42% occur in the Paleotropics, a region including Africa, Madagascar, Southeast Asia, New Guinea, and parts of Australia.

Tropical Climates

Most people imagine the tropics as steamy lush evergreen forests with high humidity and hot temperature throughout the year. However, a wide range of climates occur within tropical latitudes, ranging from snow peaked mountains (i.e., Andes in South American, Mount Kilimanjaro in Africa) to deserts (i.e., central Australia, Kalahari Desert in Africa). However, anthropogenic climate changes have been altering tropical climates, foremost perception patterns and temperature, which has negative effects on the terrestrial and aquatic biotas and adverse socio-economic consequences for humans.

Temperature

Tropical regions receive perpendicular solar radiation at noon almost year-round, thus the mean annual temperature is higher and seasonal changes are less pronounced than in areas at higher latitudes. The intensive solar radiation also increases evapotranspiration (see below).

Typically, low-altitude tropical areas have an annual mean temperature of 26°C (range 23–35°C). However, cloud cover, particularly during the rainy season, can reduce sunlight by absorbing photosynthetically active radiation. A fundamental question is the degree to which sunlight is a limiting factor for plants. Graham and colleagues increased light availability by installing high-intensive lamps above the canopy of a common tree species in Central America. They found that branch growth, number of flower buds, and fruits production increased significantly compared to control trees. Because the researchers quantified additional variables, they suggested that light rather than water or temperature was the main limiting factor for that tree species.

Precipitation

The amount and onset of precipitation is primarily determined by the Intertropical Convergence Zone, an equatorial low pressure system that follows the sun's zenith. Because the evaporative power of the equatorial sun is at its maximum, areas within tropical latitudes receive the highest annual rainfall, except in some locations (i.e., within Africa, Australia). Similar to temperature, rainfall is tied to geography and can range from 0 mm (Chilenian Atacama desert) to over 11,900 mm (Hawaii) annually. Apart from some ever-wet regions (i.e., Sundaland in southeastern Asia, New Guinea), most tropical regions have a predictable annual seasonality with one or two rainy seasons (monsoon) alternating with a dry season. During the dry season, which may range from 1 to 6 months, water lost due to evapotranspiration is greater than the amount of rainfall.

To what extent precipitation is a limiting factor for plants is an essential question and a challenging one to answer experimentally. Researchers have carried out a remarkable large-scale rainfall exclusion experiment in the Amazon over several years. Results have shown that most trees had reduced transpiration and photosynthesis rates, resulting in lower leaf production, reduced trunk growth and stunted saplings growth. Large canopy trees that were fully exposed to sunlight had an increase in annual mortality, from 1% (the typically background mortality) to 9%.

Other factors that contribute to the variations in tropical climates include cold ocean currents (i.e. Humboldt Current), warm ocean currents (i.e. El Niño Southern Oscillation), distance from oceans, and prevailing wind conditions (i.e. trade winds).

☆*Change History:* November 2017. H. Beck made updates to the text and the references section.

This is an update of H. Beck, Tropical Ecology, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3616–3624.

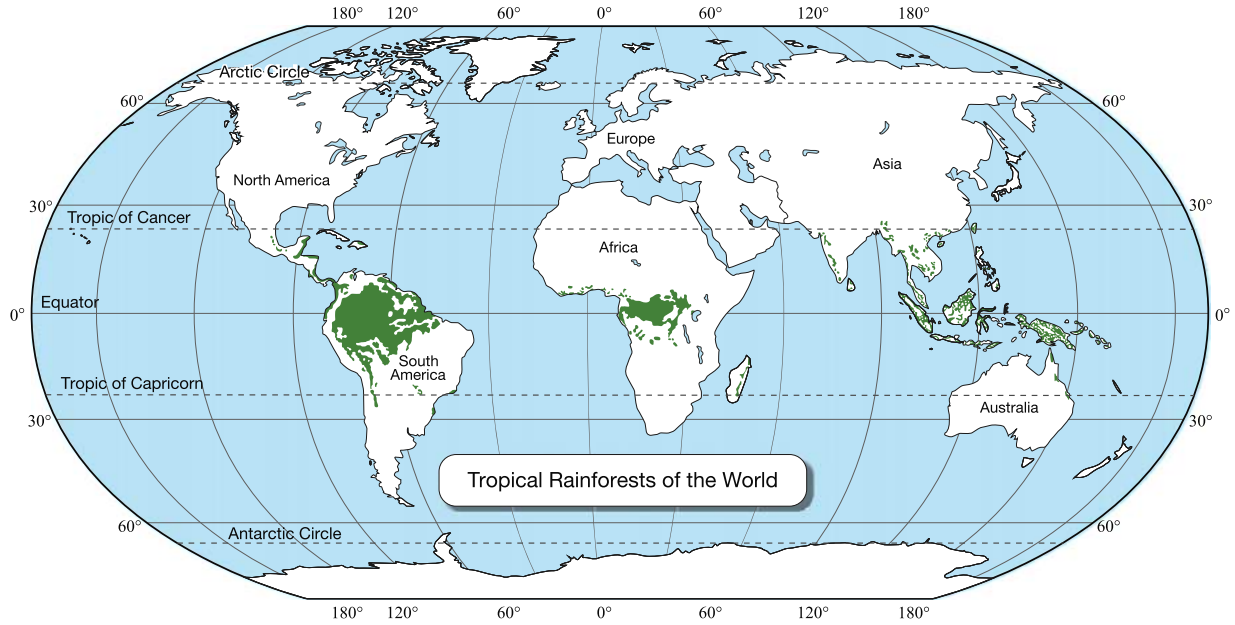

Fig. 1 Approximate distribution of tropical rainforests of the World. The tropical latitudes are centered at the equator and extend northwards up to the Tropic of Cancer (23°30′ latitude) and southwards to the Tropic of Capricorn (23°30′ latitude). Over half of the original rainforests have been destroyed by human activities and currently only around 6% remain; most of these are in different stages of degradation. Map created by Dr. Paporn Thebpanya.

El Niño Southern Oscillation

Only recently, scientists have begun to understand the direct and indirect effects of El Niño events. El Niño events occur every 2–8 years with varying intensity, resulting in interannual climate variation on a global scale. El Niño episodes can lead to below-average rainfall and above average-temperature in some areas (i.e. in Indonesia, New Guinea, West Africa, and Amazonia), whereas in other areas it can lead to abnormally high rainfall, sometimes resulting in floods (i.e. in South America). Studies found that El Niño events can affect plant and animal species across the tropics. Above-average solar radiation during El Niño events in some areas in Central and South America have resulted in drier and sunnier climates, favoring higher fruit production. However, during the subsequent milder dry season the fruit production was unusually low, leading to famine and high mortality of numerous frugivorous and granivorous species. Conversely, in Southeast Asia, after El Niño event, mass flowering and fruiting of many species occurred, triggering migration of numerous animal species, and increased reproduction.

Future studies monitoring the climate, Earth surface temperature, fruit production, and animal densities across numerous geographic locations are needed to better understand the ecological impacts of this phenomenon. Anthropogenic climate changes also affect the frequency, locality, and intensity of El Niño events. Researcher now call those events "extreme El Niños" which disrupted global weather patterns and negatively impact aquatic and terrestrial ecosystems, and socio-economic of humans living in the impacted areas (i.e. drought, flooding, and wildfire).

Seasonality Drives Many Ecological Processes

Scientists found that annual seasonality directly and indirectly affects the ecology of most organisms. For example, many tree species flower during the dry season to optimize cross-pollination by insects. The vast majority of plants that rely on wind for seed dispersal fruit during the dry season. In areas with a prolonged dry season, many tree species are deciduous and produce new leaves at the onset of the subsequent rainy season. Seasonality also can affect recycling pathways of organic matter, nutrient availability and energy flow.

Many studies further demonstrated that plants and animals that experience pronounced seasonality evolved unique adaptation. For instance, most plants that rely on animals as seed dispersers, fruit at the onset or during the rainy season, whereas many mammals (i.e. rodents) cache seeds for later consumption. Another strategy to cope with seasonal food shortage is migration. One of the most spectacular animal migrations can be observed in east Africa, where millions of herbivores including wildebeest, zebras, antelopes, and gazelles migrate to greener pastures. Migration also occurs in other tropical regions such as in Sumatra and Malaysia, where the bearded pigs migrate to track mast fruiting dipterocarp trees.

Long-term satellite climate monitoring, improved satellite animal tracking (GPS) technology, and GIS software will certainly provide new exciting details on the influence of seasonality on migration routes at large and small spatial scale.

Biogeography of Tropical Organisms

In the 19th century, while working in the Malayan Archipelago, the British naturalist Alfred Wallace was one of the first to observe and describe an underlying pattern in the distribution of species. Bird species with Oriental origin occur west of the border line, whereas bird species with Australian origin occur east of it. In recognition for his pioneering work, this line is called the Wallace Line. This fundamental question as to why species are distributed the way they are remains to this day an area of interesting research. To address it, scientists may use a combination of geological (i.e. plate tectonics, volcanism), historical (i.e. glaciation, dispersal), geographical (i.e. altitude, stream routes), molecular techniques (i.e. genetic), and climatic (rainfall, wind direction) factors. For example, taxa with large geographic distributions (i.e. ants, ferns) might have originated before certain continental plates separated. A recent molecular study found that Old World driver ants and New World army ants had a common ancestor before the southern supercontinent Gondwana (over 105 mya.) broke apart. Since then, they evolved into thousands of different species on both continents. One would, however, not expect to find army ants on tropical islands (i.e. Galapagos), unless they were able to disperse over water. In fact, many plant and animal taxa dispersed from mainland to distant islands. For example, with over 3900 km to the nearest mainland, the Hawaii archipelago is the most isolated area in the world. Nevertheless over 23,680 species including 8427 insects (5462 endemic), 294 birds (63 endemic), and 44 mammals (2 endemic) occur on the Hawaiian Islands. Dispersal to isolated islands has been repeatedly possible for numerous volant (flying) and non-volant species. The latter ones required driftwood for their long journey. On the other hand, many typical tropical plant (i.e. Annonaceae) or animal taxa (i.e. Ursidae) are absent, demonstrating that long-distance dispersal is limited to taxa with certain intrinsic characteristics that allow for long journeys.

Successful colonizing species may evolve into new species, a process called adaptive radiation to occupy not-yet-filled ecological niches. For instance, ancestral finch species that arrived on Hawaii evolved different bill shapes to explore new resources, including flowers, resulting in over 40 Hawaiian honeycreepers. Other examples of adaptive radiation include Galapagos finches, marsupials in Australia and the Neotropics, and lemurs in Madagascar. Adaptive radiation can lead to high levels of endemism, and increases topical gamma diversity (the regional diversity of all habitats).

Active volcanoes can form land bridges between separated areas, thereby allowing species exchange. The most dramatic example of faunal exchange occurred (some 3 mya ago) after volcanic activity lifted the Isthmus of Panama out of the sea, connecting North and South America. Many animal species migrated in both directions, a phenomenon known as The Great American Interchange.

Prior to the land bridge formation, South America was isolated for almost 80 million years, since breaking and drifting away from Africa. Therefore, more archaic mammals including anteaters, armadillos, marsupials, sloths, and now extinct species such as the giant ground sloth and the saber-toothed marsupials dominated its fauna. North America, on the other hand, had been repeatedly connected to Eurasia and harbored more modern mammal species including bears, camels, cats, dogs, elephants, horses, peccaries, rodents, and tapirs. Most of the original North American species underwent explosive adaptive radiation and today comprise over 50% of South America's mammal species. The South American species, however, were less successful; only one armadillo, opossum, and porcupine species survived in North America.

New fossil records and a better understanding of phylogenetics, paleoclimatology and paleogenetics, among other disciplines, will further improve our understanding of past and extant species distribution.

Tropical Species Richness: Anyone's Guess

How many species are out there? This is one of the most fundamental questions in biology, yet we do not know the answer. Until the early 1980s, biologists estimated that around 2 million species occur worldwide. In 1982, however, Terry Erwin fumigated the canopies of tropical trees with insecticides. After a downpour of invertebrates, mostly unknown species, he estimated that in the topics alone there might be as many as 30 million species. More recent estimates of global species richness suggest between 1.8 and 8.7 million species ($\pm$1.3 million), of which only 1.7 million are known to science. Every year new species are found either in museum collections or in the field, including the spectacular discoveries in 2005 of three new primate species from India, Africa, and South America. In 2016 three new mouse lemur species have been discovered in Madagascar.

Most groups of organisms exhibit a tendency for increases in species richness or biodiversity from the poles towards the tropical equatorial region. This phenomenon often referred to as the Latitudinal Gradient in Species Diversity, is one of the most widely recognized patterns in biogeography. Scientists have argued for over a century about its underlining mechanism. In 1808, the German naturalist Alexander von Humboldt was the first to suggest that energy (sun radiation) is the mechanism driving this relationship. Since then over 100 hypotheses have been proposed to explain increased biodiversity in the tropics but we still lack a satisfactory answer. Most hypotheses focused on: historical events, energy availability, productivity (or both combined), species-area relationship, stability, disturbance, spatial heterogeneity, patchiness, habitat complexity, evolutionary rate, and direct interactions (i.e. predation, competition, mutualisms).

A synopsis of some of the main hypotheses and empirical evidences are discussed in the following section.

- *Historical events*: Continental glaciation during the late Pleistocene in northern latitudes may have accelerated the extinction of many species, thus preventing species to reach higher diversity. Given sufficient time (i.e. millions of years), species will reach equilibrium and the latitudinal gradient in species diversity might vanish.

- *Energy availability and productivity*: Because the tropics receive more solar energy and rainfall, there should be an increase in net primary productivity compared to the capricious seasonality of higher latitudes.
- *Intermediate disturbances hypothesis*: Species richness should be the highest in communities with intermediate levels (i.e. temporal and spatial) of disturbance (i.e. fires, hurricanes, and treefalls), because no single species can attain dominance no equilibrium is reached. At low disturbance levels, however, competitively dominant species would exclude subordinate species. Whereas at high levels of disturbance, selection would favor only few fast-growing species.
- *Evolutionary rate hypothesis* (or climate-speciation hypothesis): Higher ambient temperature in tropical regions may result in higher mutation rates and shorter generation times, which may result in higher speciation rates compared to higher latitudes. Thus, tropical organisms would evolve at a faster rate than temperate organisms.

Joseph Connell used treefall gaps to support his intermediate disturbance hypothesis. Treefalls are the most frequently occurring disturbance in tropical forests. These light gaps in the canopy allow more sunlight to reach the ground and can trigger the germination of many heliophilic (pioneer) species. Studies have found that gaps increased plant and animal species richness. For instance, researchers found higher species richness of insectivorous birds, and a distinct gap community of lizards, frugivorous birds, insectivorous bats, and small mammals. Other research indicated higher small mammal species richness in gaps than in the undisturbed understory.

To test whether the rate of speciation is faster for tropical organisms than their temperate counterparts, John Wiens and his collaborator combined three previously independent ideas and proposed the Tropical Conservatism Hypothesis. Later, John Wiens et al. used Neotropical treefrogs as model organisms to test this hypothesis. Their results supported all predictions and the authors argued convincingly that the tropical environment was not responsible for an increased speciation rate, but temperate regions were colonized more recently, thus when given sufficient time, more species will evolve in temperate regions.

Contradictory results were found in another recent study. Shane Wright and her colleagues tested the Climate—Speciation Hypothesis (whether warmer tropical climate leads to higher metabolic and mutation rates, resulting in higher speciation rates). This hypothesis is very similar to that one John Wiens et al. tested. To date, the Wright et al. study is one of the most comprehensive ones because they compared the rate of plant evolution across a wide geographic distribution (including Borneo, New Guinea, Australia and South America) with closely related temperate plant species (including North America, Australia, Eurasia and New Zealand). They found that tropical plant species had more than twice the rate of molecular evolution (nucleotide substitution) compared to temperate plants.

The mixed results from these studies demonstrate that understanding tropical diversity remains a complex and challenging endeavor. Considering geologically diverse settings, the evolutionary, and biogeographic history of taxa, it seems more likely that multiple factors rather than a single "holy grail" hypothesis will explain the underlying mechanisms responsible for high species diversity found in the tropics.

Tree Plots: A Wealth of Knowledge for Plant Ecology

Tree plots have been a powerful approach to quantify and compare structural differences between forests across tropical areas. Plots range between 0.1 and 50 ha in which all trees of a given diameter and height are labeled, identified, and various measurements are taken annually. Depending on the specific question, scale is important because the larger a plot, the more likely it will include individuals of rare species. However, because of the high tree density and species richness of tropical forests, it may take years and many dedicated people to establish a single 50 ha plot. For example, the initial census of a 50 ha plot in Malaysia rendered over 335,000 individuals from 814 species. Therefore, few 50 ha tree plots are established (i.e. in Borneo, Ecuador, India, Panama, Malaysia, Sri Lanka, and Thailand). But many smaller plots have been set up, for example, over 450 have been established in the Amazon. Combining data from smaller plots within a region can be a powerful approach. For example, ter Steege et al. pooled data from 275 tree plots (ranging from 0.4 to 4 ha) scattered throughout the entire Amazon Basin. They tested the Rainfall—Density Hypothesis, which predicts a positive relationship between rainfall and species diversity. The authors found that the length of the dry season negatively correlated with tree density and maximum α-diversity (diversity within a particular area). This is one of the few studies that confirmed, over a very large scale, that rainfall is a major factor for local tree diversity.

The 50 ha tree plots have been extremely valuable to test other major ecological hypotheses, i.e. testing the spatial distribution of tree species. Results indicate that the vast majority of tree species are spatially clumped (in the neighborhood of a given species there is a higher than average density of conspecifics), rather than randomly distributed, and rare species are even more clumped than common species.

Other results relate to recruitment pattern of juvenile plants, impact of disturbance (i.e. gaps, drought), density dependent effects, community ecology, management and conservation related question, genetic structure among individuals, and seed rain. Furthermore, thanks to long-term data records, scientists can test the effects of El Niño events, and anthropogenic climate changes (see below).

Tree plot studies have stimulated a wealth for hypotheses and have increased our understanding of spatial dynamics and plant diversity. Despite this, many funding agencies are not keen on supporting long-term projects. More projects like this across different tropical ecosystems are needed to address fundamental ecological questions.

Interactions and Interdependencies of Tropics Species

To illustrate the manifold and complex interactions and interdependencies of tropical species, a synthesis of numerous studies focusing on one plant and one animal genus is provided in the following section.

The Ficus Genus: Master of Many Trades

Ficus, the genus to which fig trees belong, has over 1000 species that occur throughout the pantropics. Figs have a wider variety of growth forms than any other tropical plant genus including shrubs, woody lianas, hemiepiphytes, epiphytes, and trees. Some figs (strangler trees) start their lifecycle as epiphytes on other trees and eventually become majestic free standing trees. Soon after a bird or monkey deposit a sticky fig seed on a large tree, it starts germinating (similar to mistletoes). The young plant grows and sends aerial roots downward. Once the roots reach, the soil, they engage in mutualistic interactions with mycorrhizal fungi. The fig provides carbohydrates while the fungi facilitates the uptake of water, minerals (i.e. phosphorus), and other nutrients. The plant continues to grow, eventually overtaking the host's canopy. Meanwhile, the fig roots expand, forming a tight network that starts to constrict the host trunk. Eventually, the host tree dies and slowly decomposes within the woody network of the now free standing fig tree (Fig. 2).

Compared to the smooth trunk of most trees, the trunk of strangler figs started as network of roots and therefore contains many crevices and holes. The higher structural heterogeneity of strangler trunks provides a variety of microhabitats such as den, nest, and foraging habitats for invertebrates (i.e. ants, bees, spiders) and vertebrates (geckos, lizards, rodents, marsupials, birds). Species that create habitat for other species are called ecosystem engineers (sensu Jones) or niche constructors (sensu Odling, Smee, Laland and Feldman). Thus strangler figs are considered autogenic engineers because they modify the environment by modifying itself.

The pollination of fig flowers is a textbook example of coevolution. In general, each fig species has its own highly specialized wasp species that pollinates its flowers. Hundreds of little flowers are enclosed within a small (0.5–0.6 cm) fruitlike globular structure called synconium. Inside the sealed synconium are also eggs laid by fig wasps before the die. After development, male wasps hatch first and inseminate the unhatched females. Later these pre-born impregnated females hatch, picking up pollen as they chew exit holes through the synconium. The freed wasps visit other flowering figs, chew entrance holes into the synconium, pollinate its flowers, lay their eggs, and die. There are also parasitic fig wasp species that utilize the synconium and consume fig tissues without providing any pollination service.

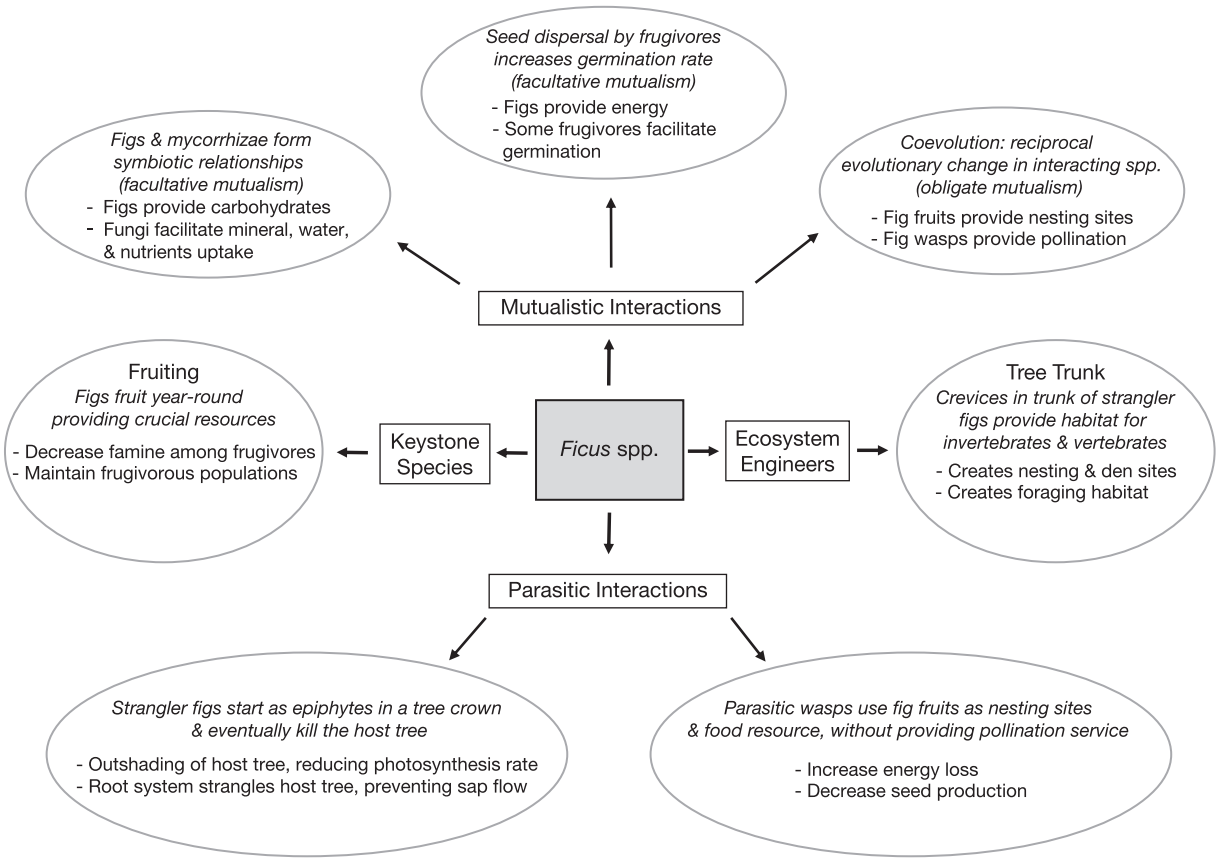

Fig. 2 Summary of some interactions and resulting interdependencies of Pantropical figs with other species and their ecological ramifications.

Fruiting fig trees are magnets for a myriad of species such as pigeons, hornbills, toucans, parrots, macaws, bats, flying foxes, and monkeys. In fact is has been demonstrated that these seed dispersers have evolutionary shaped the fruit trait such as size, color, and odor. This is another great example highlighting how tropical mutualisms can generate and maintain biodiversity. As animals move through the fruit-loaded canopy, they create a fruit rain and terrestrial species like duikers, peccaries, and rodents can thrive on them. Most of the tiny seeds (0.5–3 mm) survive digestion and are dispersed at different scales, depending on retention time and movement pattern of the animal species. Some seeds will end up in crowns of other trees, presenting an opportunity for strangler figs (see above), while others will be deposited on the forest floor.

Because fig species fruit asynchronously year round, including the dry season when the vast majority of other plants do not fruit, figs are critical for many animal species survival; it is for this reason that figs are called Keystone Species for frugivorous vertebrates. Studies showed that fig fruits can constitute over 50% of chimpanzees' diet (Africa), up to 70% for some primate species (Peru), and almost the entire diet of some Neotropical bat species. It is safe to say that without fig fruits during the dry season, the density of many vertebrate species would dramatically decline, if not crash (**Fig. 2**).

Neotropical Peccaries (*Tayassuidae*)

Three (potentially four) peccary species (a pig-like mammal) occur in the Neotropics. All of them are gregarious species, for example, white-lipped peccaries can occur in groups of several hundred individuals and represent the largest terrestrial biomass (230 kg km^{-2}) for mammals in Neotropical forests. Peccaries are omnivores and utilize seeds, roots, fungi, invertebrates, and vertebrates. They consume fruits from over 207 species and destroy the seeds of over 79% of those species. Peccaries are primarily seed predators and only small seeds such as those of figs, escape their mastication and digestive system and are dispersed (endozoochory) over long-distances. Trees that drop their fruits underneath the canopy attract herds of peccaries, which ferociously bulldoze through the soil and leaf litter and trample juvenile plants while searching for fruits. Peccaries prefer seeds infested with nutritional insect larvae such as bruchid beetles, thereby they may also control insect populations in a top-down fashion, and indirectly enhance future seed survival. Some seeds are too hard to be cracked by peccaries; in those cases peccaries chew off the fruit pulp and expectorate (spit out) the seeds in close vicinity of the parent tree. Some of those seeds are accidentally trampled deep into the soil and are thereby protected from insect predation. This shot-distance dispersal can lead to clumped distribution of plants i.e. Mauritia palm swamps (**Fig. 3**).

Numerous plants have hooks on their seed coat that allow them to attach to the hair of animals and fall off later. This dispersal mode is called epizoochory. Some of those seeds have been found in the fur of peccaries, an indication that they may facilitate the dispersal of epizoochorous species.

Studies have shown that because peccaries destroy a large number of seeds and seedlings of many plant species, they play a fundamental role in regulating recruitment, demography, and the spatial distribution of plants; thereby reducing competitive exclusion among plants and promoting plant species diversity.

Considering the high biomass of peccaries particularly of white-lipped and their consumption of such a large diversity of fruits, they can (out)-compete many other frugivorous species (including the collared peccaries), thus affecting their population dynamics.

Peccaries can be considered ecosystem engineers, because their rooting and bulldozing behavior leads to the removal of leaf-litter and soil. Leaf-litter can act as physical or chemical barrier to the establishment of litter-gap dependent species. Thus peccaries create new habitats which may permit the establishment of litter-gap dependent species.

Peccaries also create and maintain wallows. Research indicates that most of these wallows contain water year-round, including the dry season when most other terrestrial water bodies dry up. Studies found that wallows are critical breeding habitats for several amphibian species which go locally extinct shortly after peccaries are extirpated.

Because of habitat fragmentation and hunting, peccary populations, particularly white-lipped and Chacoan peccaries, are continuously declining, and they are one of the most endangered mammal species throughout the Neotropics. Aside from a few isolated white-lipped peccary populations this species is extirpated throughout Central America. Considering their manifold interactions with other species, local extinction of peccaries may result in changes in the distribution, community composition, and species diversity of plant and animal species.

Anthropogenic Impacts on Tropical Ecosystems

Both terrestrial and aquatic tropical ecosystems provide critical ecological services that humans, no matter where they live on this planet, depend upon. For example, tropical forests affect the global carbon cycle and via carbon sequestration (photosynthesis) store up to 50% of all terrestrial carbon. They produce over 40% of the world's oxygen, influence the global weather, and provide fresh water, food, wood, rubber, and other chemicals for billions of people. Currently, over 41% of the World's human population live within the tropics and estimates suggest that by 2050 their population will increase to over 50%. Human overpopulation and their activities have devastating effects on tropical ecosystems. For instance, habitat destruction, deforestation, fragmentation, forest fires, mining, infrastructure constructions, and selective logging have already reduced global rainforests to one half of their

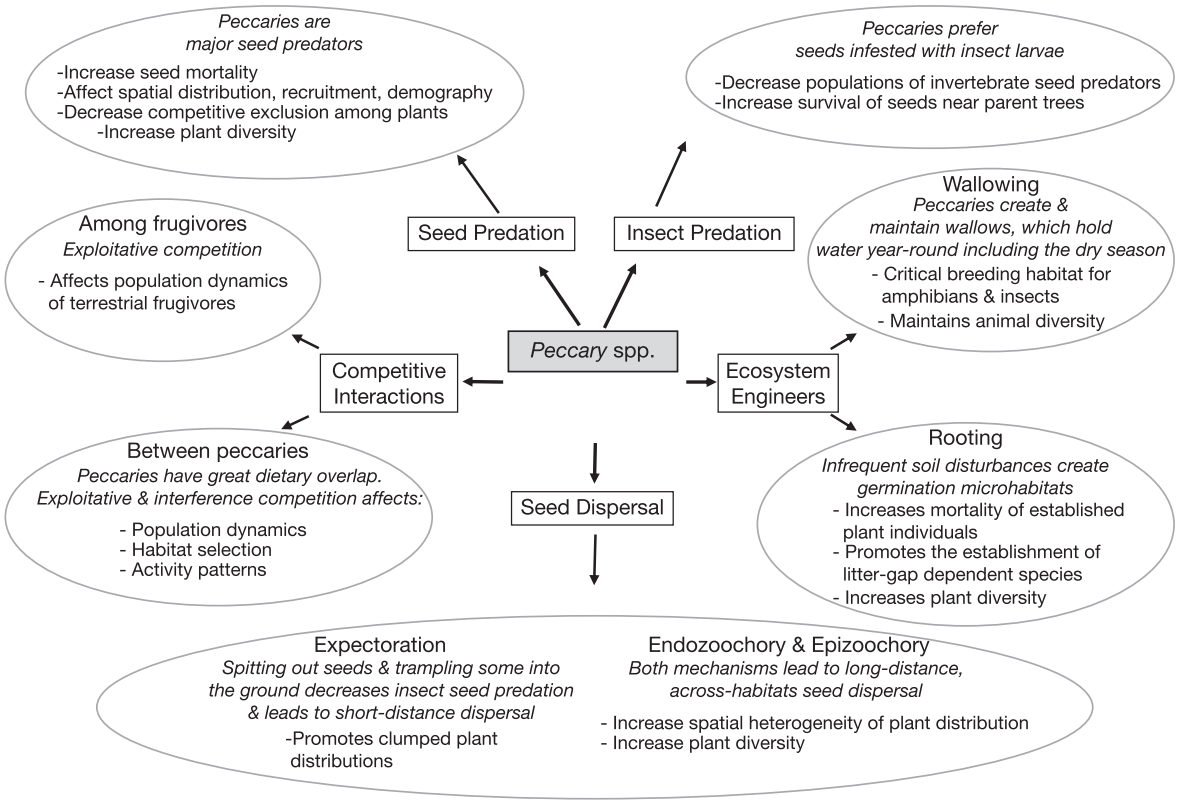

Fig. 3 Summary of some interactions and interdependencies of Neotropical peccaries with other species and their ecological ramifications. Adapted from Beck, H. (2005). Seed predation and dispersal by peccaries throughout the Neotropics and its consequences: A review and synthesis. In Forget, P-M., Lambert, J. E., Hulme, J. E. and Vander Wall, S. B. (eds.) *Seed fate: predation, dispersal and seedling establishment*, pp. 77–115. Wallingfort: CABI Publishing, with permission from CABI Publishing, UK.

original size. If the current rate of deforestation continues, then the world's rainforests and many of their species will vanish within 40–100 years.

Legal and illegal hunting and wildlife trade (problems that also occur in many established national parks), brought many species to the brink of extinction, including gorillas, chimpanzees, rhinoceros, tigers, macaws, parrots, amphibians, mahogany, cacti, and orchids, to name a few. Defaunation driven by unsustainable overhunting has led to a "Bushmeat Crisis" occurring in many tropical regions. The original densities of most large mammals in tropical forests have been reduced to around 10%. Many species are locally extinct, described as The Empty Forest (sensu Redford). Because many of these animal species have evolved non-redundant mutualistic interactions with plants (**Figs. 2** and **3**), or may also affect other animal species (i.e., via competition, predator or prey interactions), almost every extinction event will result in trophic cascading effects and negative consequences for remaining species and their ecosystem.

Anthropogenic induced global climate change might become the biggest threats to tropical ecosystems and its inhabitants. Climate change has and will continue, with increased magnitude, to alter global weather patterns such as the frequency, passage, and intensity of El Niños, Hurricanes, Typhoons, and seasonal rainfall patters. Higher temperatures and several mega-droughts (in 2005 and 2010) across the Amazon caused unprecedented mortality among drought-sensitive tree species. In fact, the biomass loss was so large that the Amazon, rather than being a carbon sink, became a carbon source, by releasing greenhouse gases and contributed to global warming. Other consequences of global climate change include alterations to forest structure, dynamics, species composition, and loss of biodiversity. These effects will further cascade and affect species that had mutualistic interactions with these drought-sensitive plants.

The complex abiotic factors, biotic interactions, and interdependencies of tropical species that are interrupted by human activities will result in an extraordinary ecological meltdown, species extinction, and the destruction of most of the tropical ecosystems.

Meanwhile how about humans, their food security, and economy? Billions of humans may be starving, dying, or become environmental migrants with consequences that will also profoundly affect countries outside of the tropics. As I am writing this chapter, millions of migrants from North Africa and the Middle East shocked the neighboring regions and the European Union to its core. Imagine what will happen if billions have to move! National and international political and social actions are needed to truly address our self-inflicted threats: global climate change, overpopulation, poverty, and our obsession with a constant increase in GDP and economic growth. We must reform our socio-economical thinking towards the development of renewable energy

forms and real sustainability. We need comprehensive science-based agreements, true commitment to an ecologically-balanced world from individual governments and their citizens, and stronger support and efforts by watchdog and conservation organizations may be able to slow down this ecological crisis.

Conclusions

Tropical ecology advanced impressively since the last century. A mosaic of individual studies has slowly revealed the larger picture. New insights into fundamental questions such as the impact of climate, the distribution of species, and the interactions among species have helped improve management and conservation of our natural resources and provided future research directions. The field of tropical biology and, in particular, conservation has recruited more enthusiastic local students from tropical regions than ever before. Their voice can now be heard loud and clear in their own countries but they must become even louder, if we really want to avoid further loss of species and most tropical ecosystems.

Tropical Rainforest

RB Waide, University of New Mexico, Albuquerque, NM, USA

Introduction

Of all of the Earth's ecosystems, tropical rainforests exist on the extremes of temperature, rainfall, biodiversity, and structural complexity. Tropical rainforests exist only where high year-round temperatures are found in conjunction with moderate to high rainfall, which limits both their latitudinal and elevational distribution. Compared to other ecosystems, tropical rainforests have high numbers of plant and animal species and often show great specificity in their biological relationships. This high taxonomic diversity contributes to high functional diversity, which results in a complex forest structure comprising many different life forms and sizes of plants. This diversity and structural complexity makes tropical rainforests one of the most interesting and complex ecosystems on Earth, and, as such, tropical rainforests have captivated the imaginations of scientists and the public alike.

Definitions

The common use of the term `tropical rainforest' varies among regions of the globe depending on the ecological context. There is general agreement that tropical rainforests are tall, dense evergreen forests existing in wet and warm places, but since there is a degree of subjectivity in these terms, the name `tropical rainforest' is applied to forests on different continents that may be quite different structurally. Moreover, since the characteristics that define tropical rainforest grade with latitude and elevation, the boundary between tropical rainforest and other forest types is by necessity arbitrary.

The classical definition of tropical rainforest focuses on features of the vegetation: evergreen, hygrophilus, tall, and rich in lianas and epiphytes. Additional characteristics of tropical rainforest include the dominance of woody plants (**Fig. 1**), principally trees; high species richness; sparse undergrowth; relatively slender trunks compared to trees of temperate forests; straight boles without branches except near the top; buttresses (**Fig. 2**); large, dark green leaves with entire margins; the occurrence of flowers on the trunk or branches; and inconspicuous green or white flowers.

Alternative definitions of tropical rainforest focus on characteristics of the forest community and its environment, including the proportion of deciduous trees in the canopy, the elevation of the forest, and the length and severity of the dry season. Some local classifications of forest type incorporate floristic information, but such classifications require detailed knowledge of the flora as well as trained experts to implement them.

Several schemes attempt to classify vegetation types based on climatic conditions including temperature, rainfall, length of dry periods, and evapotranspiration. Such classification systems avoid the subjectivity inherent in definitions that depend on relative terms, but by necessity are oversimplifications of the factors controlling the distribution of tropical rainforests. The Köppen classification uses the average annual precipitation, average monthly precipitation, and average monthly temperature to divide the globe into six major climate regions and their subregions. Under this system, the tropical rain climate has no month whose mean temperature is less than 18 °C and the mean rainfall of the driest month is >60 mm. In the Holdridge classification, rainforests are defined as areas where the ratio of potential evapotranspiration to rainfall is low, with tropical lowland rainforests occurring where the mean annual temperature exceeds 24 °C. Shifts between forests classes are determined by changes in rainfall and temperature related to elevation and latitude. These classification systems work well in areas where plant formations are strongly controlled by climate, such as Central America and northern South America, but are less useful where edaphic factors or other environmental factors are major controlling factors, as in the lower Amazonian region in Brazil.

The rest of this article focuses on lowland, evergreen tropical forests occurring in hot, wet conditions. Tropical forests at higher elevations or in areas with a pronounced dry season are covered elsewhere.

Distribution

Tropical rainforests exist wherever conditions are appropriate, but are mostly confined to a broad belt around the equator. The latitudinal distribution of tropical rainforests is limited by the distribution of freezing temperatures, which tropical plants are unable to withstand. A circumglobal belt of dry conditions also limits the distribution of tropical rainforest and, except in rare cases, prevents a continuous transition between tropical and temperate forests. Some gaps occur in the equatorial band of tropical rainforests, such as in eastern Africa, where prevailing conditions are too dry for tropical rainforest to develop. Moreover, in some areas on the eastern margins of continents, conditions suitable for tropical rainforest exist outside of the tropics. In all areas suitable for the development of tropical rainforest, human actions limit the present distribution of forests.

Fig. 2 Broad buttresses are found on many rainforest trees, such as this specimen from Providencia, Antioquia, Colombia. Credit: Robert B. Waide.

Large areas of tropical rainforest exist on continents and large islands that straddle the equator. Roughly half of the tropical rainforests on the planet occur in three areas in tropical America. The largest of these forest areas (somewhat over 3 million km^2) occupies the drainage basins of the Amazon and Orinoco Rivers in northern and central Brazil and surrounding countries. A narrow strip of tropical rainforest runs along the Atlantic coast of Brazil from 7° to 28° S (from Recife nearly to São Paulo), but less than 5% of this forest remains in its original condition. A third block of forest occupies southern Mexico, Central America, and the area of northern South America west of the Andes. Many Caribbean islands also have small areas of tropical rainforest.

In Africa, another large block of tropical rainforest occupies the basin of the Congo River in the Democratic Republic of the Congo, the Republic of the Congo, Gabon, and Cameroon. Previously, part of this forest extended into Nigeria. Belts of tropical rainforest also extended along the coast of West Africa and the eastern part of the island of Madagascar, but little remains of these forests but isolated patches.

A third large area of tropical rainforest existed on the Malay Peninsula and the islands of Borneo, Sumatra, and Java. Sulawesi, the Philippines, and many of the smaller islands in Indonesia also have substantial areas of rainforest, but the condition of the remaining forest varies widely from island to island. Rainforests also occupied parts of mainland Southeast Asia where rainfall was sufficiently high. Isolated patches of tropical rainforest occur in the area of the Western Ghats in India and on the island of Sri Lanka. Most of the island of New Guinea supports tropical rainforest, and there is also a small area of rainforest in NE Australia. Patches of tropical rainforest also occur on some of the Pacific Islands (Solomons, New Hebrides, Fiji, Samoa, New Caledonia).

Climate and Soils

Tropical rainforests are found under a surprisingly wide range of climatic conditions. Annual rainfall is generally high in tropical rainforest compared to other ecosystems, but can range from 1700 to 10 000 mm. Many rainforests experience 1–4 dry months a year, when the rainfall is less than the water lost through evaporation and transpiration. These annual dry periods exert a strong effect on the phenology of biotic processes such as flowering and fruiting. In some tropical rainforests, rainfall is uniformly high throughout the year, and no annual dry periods exist. In these forests, dry periods may occur at multiyear intervals and trigger strongly synchronized biotic responses including mass flowering, increased animal reproduction, and migration. In some parts of the world, these multiyear cycles are related to periodic El Niño–Southern Oscillation (ENSO) events. While strong ENSO events result in more severe dry periods in many tropical rainforests, the strongest biological consequences seem to occur in forests that do not normally experience a dry season, especially in areas of Indonesia and Malaysia.

Mean annual temperatures in tropical rainforests generally fall in the range between 24 and 28 °C near the equator, but a consistent characteristic is the absence of a cool season. In general, diurnal temperature differences (6–10 °C) exceed monthly differences. The amount of solar radiation is higher in the topics than in temperate zones, but tropical rainforests generally have lower available solar radiation than drier tropical forests because of the greater amounts of water vapor and increased cloudiness in more humid climates. As a result, plant growth in closed-canopy tropical rainforests is often light limited.

The environments of tropical rainforests are characterized by high relative humidity during the daytime and generally saturated conditions at night. However, because much of the rainfall in tropical rainforests occurs in intense events, even months with high rainfall can have periods of a few days when little or no rain falls, saturation deficits increase, and plants wilt. The dry periods can be exacerbated by winds; evaporation rates are higher in the trade wind zone than in equatorial forests where average wind speeds are less.

Tropical cyclones can have severe effects on tropical rainforests. In general, areas within 10° latitude of the equator are not subject to tropical cyclones, but tropical rainforests in the Caribbean, Madagascar, northeastern Australia, many oceanic islands, and parts of Central America and Southeast Asia are affected by these storms. The strongest tropical cyclones can have severe but, in most cases, temporary effects on forest structure and composition. Tree mortality can be high as a result of one of these storms but the forest recovers quickly through regeneration, new growth, and refoliation of damaged trees. In those areas of tropical rainforest subject to recurrent tropical cyclones, forest structure and the biological traits of forest species may be affected by the frequency and intensity of storms.

The soils underlying tropical rainforests can have important effects on plant distribution and primary productivity. The complex interactions between soil characteristics (e.g., soil texture, age, drainage characteristics, nutrients) and the considerable topographic and geographic variation in these characteristics make it difficult to determine the importance of specific soil properties. Most areas supporting tropical rainforests have very old soils that are highly leached and weathered and as a result acidic and infertile. Such soils have low levels of the nutrients necessary for plant growth and high levels of toxic aluminum and thus are unsuitable for most forms of permanent agriculture. However, these soils can sustain high-diversity, high-biomass tropical rainforests because plants of these forests recycle nutrients efficiently. Some tropical rainforests occur on relatively fertile volcanic or floodplain soils and can sustain permanent agriculture.

In areas of the Amazon with low local relief, soil properties can have a strong effect on plant communities and therefore overall biodiversity. Small changes in topography and the depth of sand overlying the clay subsoil can cause large changes in the plant community.

Forest Structure

Tropical rainforests support a more diverse set of organisms than other kinds of forests. The number of different life forms, or synusiae, is greater in tropical forests that in temperate forests. A synusia is a group of organisms whose members are ecologically equivalent. When applied to plants, the term reflects an aggregation of species with similar life form and function. Autotrophic plants (e.g., those that photosynthesize) include those that do not need mechanical support (i.e., trees, shrubs, and herbs) and those that do (i.e., climber, epiphytes, and hemi-epiphytes; **Fig. 3**). Heterotrophic plants include saprophytes and parasites.

The structure of a tropical rainforest arises from each synusia's methods for obtaining resources for survival and growth: water, nutrients, and sunlight. In some forests, photosynthetic, self-supporting plants seem to form distinct strata depending on their size.

Fig. 3 Bromeliads and other epiphytes cover branches of trees in La Planada Reserve, Colombia. Reproduced by permission of Art Wolfe/Photo Researchers, Inc.

Such stratification is by no means a uniform characteristic of tropical rainforests. Photosynthetic plants that are not self-supporting use other plants as a platform for growth. Climbers (lianes) have roots in the ground but use other plants to support their elongated stems. Epiphytes depend on their host plants for support only, although a specialized group of this synusia (the mistletoes) obtains both support and water and dissolved substances from the support tree. Hemi-epiphytes initially live as epiphytes on supporting plants but eventually send roots down to the ground. Saprophytic and parasitic plants obtain required energy and nutrients from other living or dead plants, and therefore do not require light for growth or reproduction.

Background mortality of individual trees from natural causes is a major cause of spatial heterogeneity in tropical rainforests. Gaps caused by dead or fallen trees change the structure and the environmental characteristics of the forest. However, tropical rainforests are also dynamic ecosystems subject to a large number of natural disturbances including storms, lightning strikes, landslides, and the effects of animals, all of which can produce gaps in the forest canopy.

The canopy is an important structural element of tropical rainforests because the height and degree of closure of the canopy plays an important role in determining conditions in the understory (**Fig. 4**). Moreover, the lack of easy access to forest canopies means that their importance as a source of biodiversity and an influence on ecosystem processes has probably been underestimated. Forest canopies have important roles in the regulation of nutrient cycling and in the storage of carbon. Large pools of nutrients exist in live and dead components of the canopy, and decomposition of organic matter in the canopy influences access to these nutrient pools. The forest canopy serves to filter air- and waterborne nutrients and to provide a site for nitrogen fixation. Canopy-dwelling organisms are efficient at acquiring and storing nutrients, thus providing a buffer for pulsed nutrient releases. Forest canopies are rich in species of plants and animals that are independent of the forest floor. Moreover, canopy trees and their epiphytes provide important sources of food for birds, mammals, and insects that occupy other strata.

Biodiversity

Understanding of the biodiversity of tropical rainforests is still being refined. New species of all taxonomic groups are found every year, and knowledge of the diversity of some taxa, especially insects, is rudimentary. Tropical rainforests are extremely rich in species of all taxa compared to other terrestrial ecosystems. For example, the tropical rainforests of the world have an estimated 175 000 species of plants, which constitutes about two-thirds of the global total. Considerable variation in diversity occurs among tropical rainforests around the world, with the largest number of tree species (>250 species per hectare) occurring in Amazonia and Malaysia, followed by the islands of New Guinea and Madagascar, and then Africa. The largest areas of tropical rainforest (Neotropics, Africa) have the greatest number of primate species. Similar comparisons for other taxa are difficult because of the lack of data.

Conservation Issues

Because of their global significance with regard to carbon storage and the maintenance of biodiversity, conservation of tropical rainforests is an important and hotly debated topic. Solution of conservation issues is made more difficult because most areas of tropical rainforest occur in countries that are trying to increase the standard of living of their people. Partly because of this controversy, adequate data to judge the loss of tropical forests are difficult to come by. However, it is clear that tropical forests, including tropical rainforests, are disappearing at an increasing rate. The percent of the original forest habitat that has been lost exceeds 90% for some countries (Ghana, Bangladesh, Philippines). Estimates suggest that very little tropical rainforest will remain by the year 2050. The ultimate causes of forest loss include increasing populations in countries with tropical rainforest, extreme poverty, and the lack of effective government protection for forests. Proximate causes of forest loss include logging, clearcutting for agriculture, loss of ecosystem integrity because of

Fig. 4 Canopy of lowland tropical rainforest of La Selva Biological Station, Costa Rica. Photographed from a light plane flying 200 feet above the canopy. Reproduced by permission of Gregory G. Dimijian, MD/Photo Researchers, Inc.

Fig. 5 Rainforest has been cleared for timber and agriculture in this subsistence farm in Providencia, Antioquia, Colombia. Credit: Robert B. Waide.

forest fragmentation, and hunting (Fig. 5). Hunting of large animals may have insidious effects on forest structure, as the populations of prey species may explode when released from predation. Increased populations of small mammals, for example, may have severe effects on other organisms, leading to the breakdown of whole ecosystems over time.

Because the issues facing tropical rainforests vary considerably from one place to another, generic conservation solutions are not practical. However, the major elements of a conservation strategy for tropical rainforests will include the creation of reserves to protect biodiversity, the regulation of exploitative use of tropical rainforest products, the engagement of traditional societies, the development of sustainable use strategies that will address the issue of poverty, and an increased effort by developed countries to form partnerships with developing countries.

Tropical Seasonal Forest☆

Egbert G Leigh Jr., Smithsonian Tropical Research Institute, Panama, Republic of Panama

Glossary

Eddy flux towers Towers with three-dimensional anemometers above the forest canopy, adjacent to devices for sampling the air's CO_2 content. Vertical movement of CO_2 (which is downward when the forest is photosynthesizing) is calculated from the covariance between the vertical velocity of the air and its CO_2 content which these instruments measure. These data allow calculation of gross productivity.

Evapotranspiration, actual The water evaporated from a forest or transpired by its leaves (released through the leaves' *stomata* when they are absorbing CO_2 from the atmosphere).

Evapotranspiration, potential The water that would evaporate from a forest or be transpired from its leaves if rainfall kept soil moisture content reasonably high without waterlogging it.

Gross productivity The total rate at which the forest's photosynthesis transforms carbon dioxide and water into carbohydrate, usually measured as the amount of carbon in the carbohydrates thus produced.

Phenology The seasonal timing of events such as leaf flush, leaf fall, flowering and fruiting, either in individual trees or in the forest as a whole.

Savanna Tropical tall grassland, that burns during the dry season, with scattered fire-resistant trees.

Species turnover The change in species composition encountered in passing from one place to another. Zones where species turnover is concentrated are sometimes called "biogeographical knots."

Stomata Pores in leaves which, when opened to let in CO_2, causes transpiration, the release of water vapor from the leaf, which pulls replacement water by capillary traction up from roots through *xylem vessels* into these leaves.

Trade-off A circumstance where selection to enhance one structure or ability necessarily diminishes another, as selection for earlier reproduction necessarily decreases longevity.

Xylem vessels Tubes <0.5 mm in diameter through which transpiration pulls water from the roots up to the leaves.

Definitions and Distinctions

Tropical humid seasonal forest is defined here as lowland tropical forest (mean annual temperature $\geq 20^{\circ}$C, mean temperature of the coolest month $\geq 18^{\circ}$C) which averages ≥ 1700 mm year^{-1} of rainfall and ≥ 100 mm month^{-1} for at least 7 months of the year, with a single severe dry season averaging <200 mm for the year's driest quarter and <100 mm month^{-1} for at least 3 consecutive months (there may be a second, milder dry season). Its wetter counterpart, tropical rainforest (everwet forest), which is almost entirely evergreen, averages ≥ 1700 mm year^{-1} of rainfall and ≥ 100 mm nearly every month (no 2 consecutive months average <100 mm). Its drier counterpart, tropical dry seasonal forest, where many trees lose their leaves in the dry season, averages 650–1700 mm year^{-1} of rain and ≤ 100 mm in the year's driest quarter and ≥ 5 consecutive months averaging <100 mm (**Table 1**). On less fertile, more acid soils, the same climate supports savanna, tall fire-prone grassland with scattered trees (Pennington and Lavin 2016, p. 25). There are also severely seasonal evergreen forests, some averaging ≥ 2500 mm year^{-1} of rainfall, with a single, long dry season of six or more consecutive months averaging <100 mm apiece.

This article's definition of seasonal forest is arbitrary. We will soon discuss a forest, Khao Chong in Thailand, with only one dry month, averaging 50 mm (**Table 1**), which behaves like a seasonal, not an everwet, forest. Second, many forest characteristics vary continuously with the length of the dry season, without "natural divisions". Third, rapidly draining soils that hold little water support tree species typical of drier climates (Pyke *et al.* 2001, p. 563), whereas soils better able to hold water, which release it slowly enough that plants can still extract some water at the height of dry season, support tree species typical of wetter climates (Kursar *et al.*, 2005). Finally, a criterion based on the ratio of a forest's actual to its potential, evapotranspiration must be a better way of predicting a forest's degree of limitation by water shortage than the length of the dry season or the rainfall during the year's driest quarter. Data on potential and actual evapotranspiration, however, are far less readily available.

Distribution and Evolution of Different Forest Types

Most rainforest occurs near the equator, where the midday sun is within 18° of zenith all year round (normally, the nearer the midday sun to zenith, the higher the rainfall 6 weeks later). Rainforest also occurs at higher latitudes near the base of east-coast

[a]BCI stands for Barro Colorado Island.
[b]HKK stands for Huai Kha Khaeng.
Data for Pasoh, BCI and HKK are from Leigh (2004); data for Khao Chong, from Bunjavejchewin S. and Davies S. J. (unpublished, used with permission), and data for Kirindy are from Sorg and Rohner (1996).

slopes facing trade winds, as in Puerto Rico's Luquillo Mountains (18°N), La Selva, Costa Rica (10°N), Las Tuxtlas, Mexico (18°N), and most of the east coasts of Madagascar and the Philippines. Humid seasonal forests flank equatorial forests to north and south. Nearly all of the African forest block, including Makokou (Gabon), Korup (Cameroun), and the Congo's Ituri forest, as well as the forests of Ghana, the Ivory Coast, and Liberia, are humid seasonal forests. Large blocks of southern and southwestern Amazonia are humid seasonal forest, including Cocha Cashu in Peru's Parque Nacional Manú (12°S). Humid seasonal forest also extends northward from roughly 7°N, near the Thai–Malaysian border, into the Isthmus of Kra, where Khao Chong is located, and formerly covered most of lowland Java. The best-studied humid seasonal forest, Panama's Barro Colorado Island (**Fig. 1**), is at 9°N, but in Central America, humid seasonal forest extends to Belize (18°N). The Amazonian humid forest block is separated from dry forest by a large expanse of savanna on its southeast, and a smaller one on its northwest, flank (Simon and Pennington, 2012). Likewise, in Africa, dry seasonal forest (forêt dense sèche) and woodland (forêt claire) are separated from humid seasonal forest by bands of humid savanna whose tall grass supports really hot dry-season fires (Menault *et al.*, 1995). Dry seasonal forest occurs at higher latitudes than humid seasonal forest, as does Thailand's Huai Kha Khaeng (16°N), and in rainshadow, as on Madagascar's west coast (the location of Kirindy Forest, 20°S), and on the west coast of Central and North America from Costa Rica's Parque Nacional Santa Rosa (11°N) to Chamela, Mexico (19°N) and beyond. Severely seasonal evergreen forest occurs at 13–15°N in the Western Ghats of southwest India (Pascal, 1988).

Savanna only evolved $\leq$8 million years ago when productive fire-prone tall grassland became widespread in South America, Africa, and Asia, and many tree clades from both humid and dry forests colonized these new grasslands (Simon and Pennington, 2012; Maurin *et al.*, 2014). On the other hand, flowering rainforest existed all through the Cenozoic, and Neotropical dry forest evolved >30 million years ago (Simon and Pennington, 2012, p. 712). Curiously, Neotropical dry forest is rarely invaded by rainforest or savanna clades, and dry forest clades are far less likely to colonize other biomes than rainforest or savanna clades (Pennington and Hughes, 2014; Pennington and Lavin, 2016).

What Difference Does Even a Short Dry Season Make?

This difference is clearest in Southeast Asia, so we start with evidence from that region, as summarized by Bunyavejchewin et al. (2011) and Ashton (2014).

Southeast Asia

On the Isthmus of Kra between the Malay Peninsula and Thailand, rainfall during the year's driest quarter declines from >300 mm at 5°N to 112 mm at 9°N. On this isthmus, 200 plant genera reach their southern limit where seasonal forest ends, at the Kangar-Pattani line near 7°N, whereas 375 genera reach their northern limit at this line, the northern limit of rainforest. Of the 157 species of the tree family Dipterocarpaceae south of this line, only 27 occur north of it, along with 19 other dipterocarp species which only occur north of this line (Bunyavejchewin et al., 2011).

Fig. 1 View of old-growth seasonal forest on Barro Colorado Island, Panama, facing southward, downslope from the island's central plateau. From left to right, the canopy trees are *Prioria copaifera* (Leguminosae), an epiphyte-laden *Anacardium excelsum* (Anacardiaceae), and *Quararibea asterolepis* (Malvaceae). Drawing by Daniel Glanz, used by permission from the artist.

Baltzer et al. (2009) identified trade-offs driving this "biogeographic knot." In the everwet forest of Pasoh Reserve at 3°N in the Malay Peninsula, trees of species restricted to everwet forest grow faster and survive better than those that also live in the more seasonal Khao Chong forest, north of the Kangar-Pattani line in Thailand. Despite the slight differences in seasonality, species also living at Khao Chong were more drought-tolerant. Their narrower, thicker-walled vessels are less likely to fail under water stress, but they supply their leaves with water more slowly when conditions are favorable, thus reducing photosynthesis. Pasoh trees of species present in Khao Chong also have lower photosynthetic capacity per unit leaf area, and absorb CO_2 from the air less readily (have lower stomatal conductance) than everwet specialists.

Moreover, seasonal forests (even Khao Chong!) differ in phenology from their everwet counterparts (Bunyavejchewin et al., 2011). Everwet forests have little seasonal variation in leaf flush. Many of their tree species fruit simultaneously every few years in episodes of "gregarious fruiting," often associated with El Niño. In seasonal forests, phenology conforms far more nearly to the annual cycle of the seasons, perhaps because it is best for seeds to germinate early in the rainy season, to have time to sink deep roots before the next dry season.

Finally, everwet forests have higher, often far higher, tree diversity than their seasonal counterparts (**Table 2**).

The Neotropics

Although all forest near the Panama Canal is seasonal, there is a gradient of increasing seasonality from the Caribbean to the Pacific side where, over 80 km, annual rainfall declines from 3200 to 1800 mm and rainfall during the year's driest quarter declines from 168 to 75 mm. Condit et al. (2004) showed that species turnover between the two coasts was nearly complete. The 10 most common tree species on a 5 ha plot near the canal's Caribbean end included 1191 of its 2492 trees $\geq$10 cm in trunk diameter, but only one of these species was represented by trees this large (just four such trees) on a 4 ha plot near the Canal's Pacific end. Similarly, the 10 most common species on the Pacific-side plot included 690 of its 1083 trees $\geq$10 cm trunk diameter, but none of these species was represented by a tree this large on the Caribbean-side plot.

Trade-offs driving this "quasi-knot"

The trade-offs driving this "quasi-knot" differ somewhat from those in Southeast Asia because in Panama, as in Ghana (Richards, 1996), soils of wetter forest are less fertile. Engelbrecht et al. (2007) defined the drought sensitivity of a tree species's seedlings as the proportion of seedlings surviving 22 weeks without watering divided by the proportion of comparable but well-watered

Table 2 The relation of tree diversity to dry season severity

Site	*Latitude*	*No. of dry months*	*P*	P_3	P_1	*N*	*S*

Number *N* of trees ≥10 cm dbh, number *S* of species among them, average annual rainfall *P*, average rainfall P_3 for the year's driest quarter and average rainfall P_1 for the year's driest month, at selected sites.

Data for Kirindy, Madagascar are from Abraham et al. (1996); for Mudumalai, from Sukumar et al. (2004); for Huai Kha Khaeng, from Bunyavejchewin et al. (2004); for Khao Chong, Thailand, from S. Bunyavejchewin and S. J. Davies (unpublished, used with permission); for Pasoh, from Manokaran et al. (2004), for Lambir Hills, from Lee et al. (2004); tree data for Santa Rosa, Costa Rica, are from Burnham (1997), climate data are from the Instituto Meteorological Nacional, Costa Rica, Departamiento de Informacion; tree data for Parque Metropolitana, San Lorenzo and Santa Rita Ridge are from Santiago et al. (2004), rainfall data for Parque Metropolitana and San Lorenzo, Panama are unpublished data from Steven Paton, Smithsonian Tropical Research Institute, used with permission; rainfall data for Santa Rita Ridge are from the Autoridad de Canal de Panama, Hydrologic Resources Section; data for BCI from Leigh et al. (2004); data for Bajo Calima, Colombia, from Faber-Langendoen and Gentry (1991); tree data for Manú, Peru are averages from 13.9 ha from Pitman et al. (2002); rainfall data for Manú were read off from the page facing p. 1 of Gentry (1990); data for Yasuní are from Valencia et al. (2004).

seedlings surviving during these 22 weeks. The more sensitive to drought a species's seedlings, the higher its number of trees ≥1 cm dbh on the Caribbean-side 5-ha plot per tree ≥1 cm dbh on the Pacific-side 4-ha plot ($r^2 = 0.44$, $N = 23$ species).

In another study near the Panama Canal, Santiago et al. (2004, 2005) and Santiago and Mulkey (2005) showed that the species turnover reflected a trade-off between tolerating drought and tolerating poor soil. On the poor soils of wetter sites, leaves are tougher, longer-lived and have less nitrogen per gram than their dry forest counterparts. In wetter forest litterfall, richer in lignin, is more resistant to nutrient cycling, which keeps the soil poor. Finally, Spear et al. (2015) showed that a trade-off between drought tolerance and pest resistance contributed to this species turnover. Moreover, plants forced to grow more slowly by some harsh circumstance such as poor soil must invest more in anti-herbivore defense (Coley et al., 1985).

Phenology and seasonality

From Colombia to tropical Mexico, leaf flush, flowering and fruiting are less seasonal in more nearly everwet forests (Hilty, 1980). Although, as Wright and Calderón (2006) showed, Neotropical trees flower and fruit more abundantly during El Niños, at least in seasonal forest, and El Niños favor gregarious fruiting in Malaysia, Neotropical trees of everwet forest do not fruit gregariously.

On Barro Colorado Island, Panama, and Amazonian Peru's Parque Manu, synchronous seasonal shortage in production of fruit and new leaves largely control populations of vertebrate herbivores (none of which weighs over 500 kg), although big cats may be required to stabilize this control over the long term (Terborgh, 1983, 1990; Leigh, 1999). In paleotropical seasonal forests, seasonal shortages of fruit and new leaves do not coincide, which may explain why paleotropical forests support a higher biomass of primates than their neotropical counterparts (van Schaik et al., 1993).

Indeed, on Barro Colorado Island, the onset of rainy season is like the coming of spring (Foster, 1982). Although some seasonal forest plants, including big trees with colorful flowers, depend on dry season rains to trigger synchronous flowering, many more plants, especially those with small flowers pollinated by small, easily desiccated insects, flower after the rains begin, when small insects become abundant. Many trees bear fruit and/or flush leaves at or soon before the rains. Most canopy trees in seasonal forest can reach water even at the height of the dry season. The onset of the rainy season is also a season of abundance for vertebrate herbivores, the most favorable season for bearing and rearing young.

Seasonality, pest pressure, and tree diversity

In the Neotropics, as in the Paleotropics, tree diversity is higher in forests receiving more rain during the year's driest quarter (**Table 2**). Unlike dry season, poor soil does not diminish tree diversity (Duque et al., 2017) unless the poverty is extreme (Leigh, 1999). Work in Neotropical forests has shown that pest pressure is the primary factor maintaining tropical tree diversity. Kursar et al. (2009) showed that, on Barro Colorado Island, coexisting, recently diverged, species of the tree genus *Inga* differ primarily, often only, in anti-pest defenses, as if the best way to coexist with a related species was to avoid its pests.

On a 50-ha plot at Barro Colorado, all woody plants ≥1 cm trunk diameter of free-standing species were mapped, marked, identified and their trunk diameter measured every 5 years, to learn how tropical tree species coexist. Later, Comita et al. (2010)

marked, identified, and measured the height of all tree seedlings on a 1 × 1 m plot at the center of each of the plot's 5 × 5 m quadrats every year for several years. These data showed that a seedling grew more slowly, and was more likely to die, the more plants of its species were nearby. Moreover, the more a seedling's prospects suffered from an additional nearby plant of its species, the rarer that species, as if the sensitivity of a species's seedlings to near neighbors of its species governed that species's relative abundance. Mangan et al. (2010) found evidence that soil-borne pathogens were what kept each tree species too rare to crowd out the others. In six tree species, a seedling grew more slowly, and died faster, when grown in soil from under trees of its species than when grown in soil from under trees of other species. Moreover, seedlings of rarer species suffered more from being grown in soil from under trees of their own species. Soil pathogens may play the primary role in limiting populations of different tree species.

The role of pests in maintaining the diversity of tropical trees was demonstrated in humid seasonal forest, but pest pressure is probably more intense in more nearly everwet forests, causing their higher tree diversity. First, dry season depresses pest populations, so flushing leaves before the rains begin reduces herbivory (Aide, 1992). In the tropical dry forest of south India, with 1200 mm year^{-1} of rain and a 5-month dry season, trees flush edible new leaves several weeks before the rains begin, thereby reducing losses to insect herbivores (Murali and Sukumar, 1993). By the time rains bring out the insects, these leaves are tougher and harder to eat. Everwet forests, however, offer no opportunity for this ploy. As we have seen, in less seasonal forests mature leaves are tougher and less nutritious, as if deterring pests were a more urgent priority in less seasonal forest. Finally, Alwyn Gentry showed that in forests with weaker dry seasons a higher proportion of tree species attracted mammals to disperse their seeds as if, in less seasonal forests, it was more urgent to disperse seeds further from their parent and its pests (Leigh, 1999, p. 192).

Mildly and Strongly Seasonal Humid Forest

Humid seasonal tropical forest can be separated into mildly seasonal forest, limited more by light than water, and strongly seasonal, primarily water-limited forest. Using various remote-sensing indices, Guan et al. (2015) inferred that in most tropical forest with >2000 mm rain year^{-1}, monthly gross production (total photosynthesis) is at least as high during the dry as the rainy season. This is untrue for the wettest (2671 mm year^{-1}) of the sites compared in **Fig. 1** of Wu et al. (2016), judging by eddy flux measurements of gross production. On the other hand, at all three sites there with >100 mm rain in the year's driest quarter, gross production drops in the latter part of the rainy season, and rises again all through dry season, unhindered by lack of water. Here, leaf flush, and probably flowering, increases in the dry season (van Schaik et al., 1993). In sum, the remote sensing criteria of Guan et al. (2015) probably suffice to distinguish mildly from strongly seasonal forest. If so, most of South America within 5° of the equator, and all Malaysia, Sumatra and Borneo, are everwet or mildly seasonal (Guan et al., 2015).

Strongly seasonal humid forest is primarily water-limited. They cannot benefit from increased dry season light, especially later in the dry season, so total monthly photosynthesis will be lower in the dry season, especially later in that season, than during the rainy season. Guan et al. (2015) infer from their remote sensing indices that most forests with <2000 mm rain year^{-1}, including those on the southern margins of Amazonia, nearly all African forest, and most Thai, and Burmese forest, is strongly seasonal. Eddy flux data from Jaru Reserve, Brazil, with 2040 mm rain year^{-1} but <70 mm during its driest quarter, and from Thai dry forests with 5-month dry seasons, averaging <10 mm during the year's driest 2 months—dry deciduous forest with 1680 mm rain year^{-1} and dry evergreen forest with 1240 mm year^{-1}—gross production declines or reaches its nadir during the dry season (Wu et al., 2016, Fig. 1; Huete et al., 2008, Figs. 2–4). In strongly seasonal forest, shallow-rooted trees should flower and flush leaves when the rains begin, deep-rooted trees in dry season when light is most available (van Schaik et al., 1993).

Of course, whether a forest is mildly or strongly seasonal depends not only on annual rainfall or its seasonality, but on the depth and water-holding capacity of the soil and the rooting depth of its trees. Amazonian forest near Paragominas, Brazil (3°S) averages 1803 mm year^{-1}, 260 mm during its 6-month dry season, and <100 mm during its driest quarter, yet it is not only evergreen, but mildly seasonal. During a 4-year period, evapotranspiration, which is proportional to gross production, averaged 694 mm during the wet, and 821 mm during the dry, half-year. This period, which included the 1992 El Niño year with only 1100 mm, averaged 1550 mm year^{-1}, insufficient to sustain such transpiration indefinitely. This transpiration rate is sustainable with 1800 mm rain year^{-1}, for the tree's deep roots (up to 18 m) allow them to draw water from the top 10 m of soil, which the following rainy season's excess suffices to replenish (Jipp et al., 2008).

The Distinction Between Humid and Dry Seasonal Forest

No clear-cut Kangar-Pattani line separates humid from dry seasonal forest along a gradual climatic gradient. Moreover, dry forests on different continents differ markedly enough to render a universal definition difficult to attain.

Neither the Americas nor Madagascar have long been settled by human beings, and their dry forest trees are not adapted to surviving fire, although fire-prone savanna appeared in South America >7 million years ago (Simon and Pennington, 2012). Indeed, fires mostly stop at the edge of these forests. In these regions, dry forests are characterized by a higher proportion of deciduous trees. This proportion however, is a continuous variate (**Table 3**): distinguishing humid from dry seasonal forests is an arbitrary business.

Trees in these dry seasonal forests differ greatly in how long they are leafless (Pichon et al., 2015) and in the ways they cope with water stress—whether by strong xylem vessels and deep roots, or by storing water in their trunks, shedding their leaves in the

Table 3 Seasonality and deciduousness

Site	*P*	N_{dry}	P_{dry}	P_3	f_d (%)	f_{bd}
Barro Colorado, Panama	2551	3	131	131	12	No data
Santa Rosa, Guanacaste, Costa Rica	1668	5	42	8	~70	No data

Badrala, Madagascar	1425	7	75	0	80	17%
Kirindy, Madagascar	799	8	100	3	96	7%
Chamela, Jalisco, Mexico	700	8	150	0	96	No data

Annual rainfall *P*(mm), number of consecutive dry months with <100 mm rain N_{dry}, total dry season rainfall P_{dry}, rainfall during the year's driest quarter P_3, fraction of tree species at least briefly deciduous f_d, and fraction of brevideciduous trees (leafless for ≤ 10 days) f_{bd}.

Data for Kirindy are from Sorg and Rohner (1996); data for Badrala from Pichon *et al.* (2015); rainfall data for Barro Colorado and Huai Kha Khaeng are from Leigh (2004); rainfall data for Santa Rosa, Guanacaste are from the Instituto Meteorological Nacional, Costa Rica, Departamiento de Informacion; data on deciduousness at Huai Kha Khaeng are from Williams *et al.* (2008); data on deciduousness in other forests and climate data for Chamela (Jalisco) are from Reich (1995).

Table 4 Impact of fire on the density of small stems

Number of stems ha^{-1}	*Rainforest*	*Thailand dry forest*	*India dry forest*	*Miombo*	*Humid forest*
≥ 1 cm trunk diameter	6707	1450	363	<888	8112
≥ 5 cm trunk diameter	1375	738	272	530	1301
≥ 10 cm trunk diameter	531	438	252	266	438
≥ 30 cm trunk diameter	76	128	110	38	77

Density of stems of various sizes in everwet Malaysian rainforest, fire-prone Thai and south Indian dry forest, and miombo woodland and fire-free humid seasonal forest in the Democratic Republic of the Congo (DRC).

Data for rainforest are for Pasoh, Thailand dry forest for Huai Kha Khaeng, and humid forest for Ituri (Edoro) are from Losos *et al.* (2004); data for miombo are those for Kaspa in Malaisse (1978); data for Indian dry forest are from Sukumar *et al.* (2005).

dry season, and or photosynthesizing with CO_2 respired by the bark without releasing water vapor to the atmosphere (Santiago et al., 2016). The same strategy may be deployed in many climates. Magnificent tall baobabs, *Adansonia* spp. (Malvaceae, Bombacoideae) grow under ~800 mm rain year^{-1} on Madagascar's west coast. They store water in their trunks which they use only to flush new leaves, in response to increasing photoperiod, before the rains come. A look-alike on Barro Colorado Island, Panama, with ~2600 mm rain year^{-1}, the cuipo *Cavanillesia platanifolia* (Bombacoideae), does likewise, as does this island's *Pseudobombax septenatum* (Bombacoideae), which also has vertical green stomate-less stripes on its trunk for photosynthesizing CO_2 respired by the bark (Ávila-Lovera and Ezcurra, 2016). Nitrogen-fixing bacteria enable dry forest trees of the families Papilionaceae and Mimosaceae to both increase water use efficiency and produce more effective anti-herbivore compounds than competitors which lack such bacteria (Pellegrini et al., 2016).

South Asian dry forests, where human beings have lived for a million years, are distinguished by the frequency of forest floor fires (>1 per decade) and their trees' tolerance of these fires (Bunyavejchewin et al., 2011). Fires reduce the density of smaller stems in these forests well below those in humid seasonal forest (**Table 4**).

Many of these forests are largely evergreen, because their poor soil does not provide enough nutrients to renew leaves every year. Yet evergreen and deciduous forests seem equally productive: Huete et al. (2008) found that in Thailand, a mixed deciduous forest on good soil with 1650 mm rain year^{-1} and a dry evergreen forest on poor soil with 1240 mm rain year^{-1}, both with 5-month dry seasons and <20 mm during the year's driest 2 months, have nearly equal gross production, ~ 27.5 tons (Mg) carbon ha^{-1} year^{-1} compared to 34 in everwet forest 60 km N of Manaus (Wu et al., 2016, Fig. 1).

The dry forest at Mudumalai in south India suffers several fires per decade, thanks to its grassy understory. These fires reduce the density of smaller stems well below the levels of dry forest in Thailand (**Table 4**). Sukumar et al. (2005) found that the Mudumalai region averages two elephants km^{-2}: they sometimes inflict great mortality on stems ~5 cm in diameter. As reproduction is so difficult, canopy trees are adapted to live long: mortality of trees over 30 cm trunk diameter is 0.6% year^{-1} at Mudumalai (Sukumar et al., 2004, Table 33.7), compared to 2% year^{-1} on Barro Colorado (Leigh et al., 2004, Table 24.7, 1985–95) and 1.9% year^{-1} at Thailand's Huai Kha Khaeng (Bunyavejchewin et al. 2004, Table 27.7). Like Thai forests with herbaceous or grassy understory, Mudumalai supports high mammal biomass (10 tons (Mg) km^{-2} compared to 1.4 tons km^{-2} at Peru's Manu, Leigh, 1999, p. 164). These mammals support tigers, leopards, and dholes (wild dogs) (Sukumar et al., 2004). Indeed, Mudumalai's ecosystem is one of the most intact known, extraordinarily so for an area so long frequented by human beings.

Dry forests in Africa also burn, on the average, nearly ten times more often, about once per 12 years, than equally dry South American forests (Pellegrini et al., 2016). In Africa, Menault et al. (1995) distinguished two types of dry forest, fire-sensitive "true dry forest," forêt dense sèche, and fire-tolerant woodlands, forêt claire. Both types normally have deciduous canopies. True dry forest also has a layer of understory trees, and casts enough shade that the herb layer is too sparse to carry a fire. The continuous canopy of woodlands, even when

fully leafed, lets through enough light to support a dense herb layer that can carry a fire when dry. Near Lumumbashi, Democratic Republic of the Congo, Malaisse (1978) compared forêt claire, there called miombo, with forêt dense sèche, there called muhulu. Miombo differs far more than muhulu from humid seasonal forest. Miombo lets 27% of the incoming light reach the herb layer, compared to muhulu's 2.3%; its average diurnal temperature range is 17°C, compared to muhulu's 10°C. Although dry forest at Mudumalai. South India, has a thick fire-prone grassy understory, it has three times the miombo's density of trees over 30 cm trunk diameter (**Table 4**). Yet tree diversity is higher in miombo than muhulu. Miombo presumably evolved millions of years ago, before human beings started burning vegetation.

The Importance of Humid Seasonal Forest

Humid seasonal forests have served as essential guides to understanding more diverse everwet forests. In seasonal forest, tree diversity is high enough to challenge explanation, but not high enough to overwhelm the mammologist who needs to know what his study animals are eating or the ethologist who needs to learn what plants her fascinatingly social bees are pollinating, and from what plants—and why these?—they are robbing nectar.

At Barro Colorado Island, Panama, work by independent researchers pursuing questions of their own design developed understanding of its ecosystem's organizing processes. There, biologists could discover how seasonal shortages of fruit and new leaves help regulate populations of vertebrate herbivores, what climate fluctuations cause the occasional famine, and what role birds and bats play in limiting populations of herbivorous insects (Leigh, 1999; Wright et al., 1999; Kalka et al., 2008). Field and laboratory techniques were developed there for analyzing the trade-off between growing fast in bright light and surviving in shade (Leigh, 1999, p. 188; Wright et al., 2003). Studies there on selected pest-limited plant populations (Leigh, 1999, p. 192) prompted Stephen Hubbell and Robin Foster to establish a 50-ha plot where all free-standing woody plants at least 1 cm in trunk diameter were censused. The first census, completed in 1983 took 3 years, and would have taken much longer, had the flora been less well known. This census found 305 species among 235,000 "trees" at least 1 cm stem diameter (Leigh et al., 2004). The plot was recensused every 5 years from 1985 on to track growth, mortality and recruitment. Combining plot data with seedling data from small subplots allowed Comita et al. (2010) to show that a tree species's relative abundance on the plot was greatly influenced by its sensitivity to near neighbors of the same species. Barro Colorado's 50-ha plot inspired similar plots around the world, in everwet, humid seasonal, and dry seasonal forests (Losos and Leigh, 2004): they provided many of this article's data. Plots in continental everwet forest reveal their formidable diversity. A 25-ha plot 80 km N of Manaus, Brazil, has 1302 species among 150,000 "trees" at least 1 cm stem diameter, and 930 species among 13,345 trees at least 10 cm trunk diameter (Duque et al., 2017). Even so, thanks to the unparalleled dialogue between Barro Colorado's 50-ha plot directors and independent biologists with varied interest and expertise, this plot remains a primary source of ideas on new data to collect and new questions to pose these data.

Another, somewhat less seasonal, much more diverse humid forest that has attracted effective question-driven research by different independent investigators is the Cocha Cashu Research Station in southeastern Amazonian Peru's Parque Nacional Manú. As at Barro Colorado, research at Manú is devoted to studying processes that organize its ecological community. Manú's community is more complete than Barro Colorado's in its variety of habitats and its assemblage of larger predators such as jaguars, pumas and harpy eagles. Work there has demonstrated the roles of predation and habitat diversity in governing mammal populations (Terborgh, 1983, 1990). Question-oriented work has also revealed the role of migration in organizing the savanna ecosystem of the Serengeti (McNaughton, 1985). Studies focused on a particular site are particularly fruitful for they often set each other in enlightening perspective.

Study of whole tropical forest communities, including animals, is essential for a proper understanding of their trees. Animal pollinators allow tree species to maintain high genetic diversity even when pests keep them rare. Animals dispersing seeds of rare species allow some of the resulting seedlings to escape their pests until they have grown big enough to resist them. These animals allow plants to shift resources from anti-pest defense to fast growth, thus promoting tropical forest productivity (Leigh, 1999), as does the intense predation on herbivorous insects by birds and bats. Steinberg et al. (1995) graphically illustrated how profoundly predators can shape the properties of plant communities. In the Aleutians, sea otters historically ate enough sea urchins—principal consumers of kelp—to keep shallow-water kelps nearly urchin-free. These kelps can thus severely reduce their anti-herbivore defense, fueling fast growth, whereas their New Zealand counterparts must invest heavily in urchin-deterring toxins because they have no sea otters to protect them. Steinberg *et al.*'s findings are a clear and urgent lesson for tropical forest ecologists: ignoring animals is not the way to understand tropical forest.

Tundra☆

R Harmsen and P Grogan, Queen's University, Kingston, ON, Canada

Introduction

Tundra ecosystems are widely distributed over all continents. Tundra is characterized by climatic stress consisting of low temperatures, strong winds, low precipitation, frost action, and long periods of shortage of liquid water caused by freezing and/or drought. These stresses combine to create what is called the periglacial environment, which is defined by repeated effects of freezing and thawing on soils and water bodies. There are many different kinds of tundra. The two main categories are arctic and alpine tundra. Each of these can be divided into subcategories or can be seen as gradients from a richly vegetated tundra with tall shrubbery adjacent to the 'tree line' through categories with less vegetation to barren areas with only a minimum of vegetation adjacent to icefields and permanently frozen polar or alpine areas. Included in the tundra biome are tundra ponds, lakes, streams, marshes, and other wetlands.

Since tundra is found at the cold limit of life forms on Earth, climatic changes of the past have had major effects on tundra ecosystems and the plant and animal species of these systems. With each Pleistocene ice age, big areas of arctic tundra were eradicated, while others shifted southward and areas of forest or prairie became tundra, only to be reversed during the subsequent interglacial warm periods. Similar changes would have occurred in mountainous regions. These major changes resulted in the local extinction of species and in the disruption of coevolved, interactive plant and animal assemblages. These changes in tundra communities persist today, resulting in low species diversity and relatively simple food webs compared to lower latitude ecosystems. During the current interglacial, many areas that were pushed down by the weight of the ice were first flooded by the rise in sea level, but have subsequently, in part at least, rebounded and developed into tundra. Some parts of Beringia (eastern Siberia, lowland Alaska, and the Yukon) were not glaciated, and remained tundra during the last glacial period. Species of plants and animals that now form arctic tundra communities survived the ice ages either south of the glaciated land area or in unglaciated refuges such as Beringia.

The Periglacial Environment

Periglacial conditions are the result of current or geologically recent frost and ice formations on a landscape. Glaciers affect landscapes in major ways, which can have long-lasting effects on geomorphology, drainage systems, and soils. But even temperature regimes that cause frequent freeze–thaw cycles – for example, annually in the high arctic and daily on high tropical mountains –have not only direct effects on plants and animals, but also indirect effects on soils and water, which results in specific types of erosion and the formation of characteristic landscapes. Furthermore, the presence of permafrost under tundra ecosystems is of critical importance, in that it forms an impenetrable floor, preventing biological penetration and vertical movement of water and nutrients.

Freeze–thaw cycles cause expansion and contraction of soils and water, while the gradual freezing of wet soils will also cause a nonrandom redistribution of water into ice lenses and ice wedges. These processes can result in frost heave and long-term vertical and horizontal movements of soils, debris, and even large rocks, creating typical landscape features (such as polygons), frost mounds (such as palsas and pingos), slope solifluction, and others. These characteristic land forms in turn affect the vegetation and all other life forms.

Permafrost is defined as ground that has been continuously frozen for at least 2 years, and it is very common in the arctic tundra, but less frequently found in alpine tundra sites, as alpine landscapes are more diverse and the summers are warmer. It is not found in any but the highest tropical mountains. During spring, the thawing of the soil starts from the surface down, gradually releasing the vegetation from the grip of the frozen soil. There is usually an overlap between snow melt and the thawing of the soil, especially in undulating landscapes. All melt water must run off, accumulate in low areas, or evaporate, as no vertical movement of water is possible due to the impervious permafrost. This can cause erosion, affecting plants and small animals. During the summer, thawing of the soil above the permafrost continues till autumn, when the surface may already have started to refreeze. During later autumn and early winter, the frost will penetrate deeper into the soil from the surface, as it also comes up from the main body of the permafrost. This process can cause considerable expansion and result in frost heave and can cause much damage to root systems and animal burrows. In many areas, nutrient supply from tundra soils is low because soil decomposition is limited by the cool temperatures and high moisture contents resulting from the impenetrable permafrost below.

Some lakes (e.g., kettle lakes and moraine lakes) have their origins in major ice formations dating from the latest ice age, while others are recent formations. Tundra lakes and ponds are severely affected by annual freezing, especially those lakes that freeze each winter right to the bottom and beyond to the permafrost. Freezing of lake ice causes expansion and results in the shoreline with its vegetation being elevated above the surrounding lowlands. Lake sediments are often high in inorganic matter from spring runoff, but low in organic matter due to low productivity, reflecting low nutrient levels. Frost action and wind effects on ice tend to disturb lake sediments in shallow lakes.

☆*Change History:* February 2013. R Harmsen updated all sections and the Reference List.

Landscape and Species Diversity

Many parts of the arctic tundra are flat, especially in areas adjacent to the sea. These areas are often covered with ponds and shallow lakes, separated by marshes and connected by meandering streams and rivers. These areas can accumulate peat and develop into fens. Along the seashore, these habitats tend to merge into salt marshes, brackish lagoons, and beach ridges. On higher ground, with hills and rock outcrops, the landscape diversity is much greater, especially because north and south facing slopes have very different microclimates, and hence, very different biological communities. Here one can also find deep lakes and fast-flowing rivers. Both erosion and the underlying rock type also add to the ecosystem diversity. In mountainous areas, the low altitude arctic tundra merges at higher altitudes into a more alpine version.

The diversity of alpine tundra worldwide is enormous, as it is found on all continents and in many climatic zones. Snow accumulation during winter, combined with slope, wind, and summer climate affects the length of the growing season of alpine tundra ecosystems. Tropical alpine tundra occurs only at very high altitudes, with unique climates varying from desert to some of the wettest conditions on Earth (Fig. 1). It should also be noted that many of the alpine tundra zones are isolated from other such zones by hundreds or even thousands of kilometers, so their flora and fauna have undergone independent evolution. Especially, geologically old high mountains contain many endemic species derived from local forest or savannah species. For instance, the Southern Alps of New Zealand have over 600 species of alpine plants, very few of which are found elsewhere on Earth.

Roughly 5% of Earth's surface is covered by arctic vegetation and 3% by alpine vegetation. The alpine tundra worldwide, as well as per hectare for most alpine systems, has a much higher biodiversity than the arctic lowland tundra. Species richness declines with altitude on mountains and with latitude in the arctic, and is also dependent on local climatic conditions, nutrient availability, etc.

Vegetation and Succession

Whether one climbs a mountain and crosses the timberline, or travels northward in the arctic and crosses the tree line, one enters the low tundra, which is characterized by shrubs. A combination of low temperatures, shallow soils, and strong winds prevents tree growth, but a tight shrub cover manages to thrive under such conditions. On each mountainous area on Earth, shrub tundras can be found, which are superficially quite similar to other isolated alpine shrub tundra communities; even many of the individual species have a remarkably similar appearance. However, mostly unrelated species form such shrub communities in different parts

Fig. 1 Mount Kenya, tropical Africa. High tropical alpine tundra. In the foreground, a boulder moraine with lichens, mosses, scattered tussock grasses, and a few rosettes of the large *Seneciodendron keniensis*. In the middle ground, a sparse stand of the yet larger *Seneciodendron keniodendron*. The genus *Seneciodendron* is endemic to the east-central African mountains. Fig. 2 Hudson Bay Lowlands, Northern Manitoba, Canada, 60°N. Low arctic willow (*Salix* spp.) and graminoid tundra. Note the radio collar on the polar bear.

of the world. For instance, most of the species of the shrub vegetation on East Africa's Mount Kenya, New Guinea's Mount Wilhelm, and Pico Mucuñuque of the Venezuelan Andes belong to different families. This is a good example of convergent evolution acting on divergent taxa, causing similar adaptation to a specific environment in distantly related taxonomic groups. The shrub zone in the Canadian arctic has a more impoverished vegetation than the shrub zones on tropical mountains. It is dominated by several species of willow and birch, and a smattering of other species (Fig. 2). Again, the arctic tundra in Greenland, Scandinavia, or Siberia also looks very similar, but in this case the species are all close relatives or even the same circumpolar species on the different continents. Another difference is that on tropical mountains there are a lot of shrub species that are not found below the tree line, whereas in the arctic many of the shrub species are also found south of the tree line. These differences are the result of the different effects of the ice ages, which on mountains merely caused the vertical movement of more or less entire plant communities up and down alpine valleys and slopes, while in the arctic, changes in the climate can cause north–south displacements of the conditions suitable for shrub tundra over hundreds of kilometers.

The more typical graminoid, forb, and moss tundra found higher up the mountains and further north in the arctic is adapted to extreme cold, long periods of temperatures permanently below freezing (and permanent darkness in the arctic), and strong winds. It is the strong winds blowing ice crystals that abrade any vegetation above snow level, combined with desiccation that makes tree and tall shrub growth impossible in high arctic and alpine tundra. Especially in arctic deserts, where snow cover is low, vegetation remains low, very close to the ground (Fig. 3). For instance, on Banks Island at 70°N, arctic willow (*Salix arctica*) grows horizontally along the ground, forming matted areas of intertwining branches that form catkins and leaves in summer. One such willow can live and grow for decades. All grasses, sedges, and forbs die in autumn and survive the winter as below-ground root masses, or as ground-hugging rosettes.

One advantage of being a plant in a dense, close-to-the-ground plant community is that on cool, sunny summer days, radiant heat from the 24 h solar radiation is trapped within the air between the plants, keeping temperatures high enough for growth and maturation of seeds. There are very few annual plants in the high arctic tundra, because the season is not long enough for them to germinate, grow, and reproduce. A few very small species, such as *Koenigia islandica* and *Montia lamprosperma*, maintain an annual life strategy. Uniquely, a few species of semiparasitic members of the Scrophulariaceae, such as *Euphrasia arctica*, do so as well. These species have a distinct early season advantage, being able to grow very rapidly by gaining nutrients and photosynthate from neighboring perennials.

The frequent disturbances due to the freeze–thaw cycles often lead to local eradication of vegetation. This creates openings for reinvasion and subsequent succession. One of the most interesting examples of this is the result of solifluction of soil clumps on south-facing slopes in the arctic. Soil clumps with vegetation surrounded by clefts get heated by the sun on the downslope side, causing them to thaw out and slump downwards, burying the lowest vegetation, while at the same time exposing a small strip of upslope bare soil (Fig. 4). It takes up to 30 years for the clump to make one entire downhill rotation. On each clump, one can see a successional sequence of plant maturity, species composition, and diversity, as the oldest community gets buried and an opening appears at the top end for reinvasion. Succession on a larger scale occurs after slope collapses, frost mounting, stream erosion, mud deposits after flooding, etc.

Ecosystem Structure and Function

Very few species remain active within arctic tundra ecosystems during the winter. Only mammals such as the muskox (*Ovibos moschatus*), the reindeer (*Rangifer tarandus*), the arctic hare (*Lepus arcticus*), lemmings, and the wolf (*Canis lupus arctos*) remain fully active. A few birds, for example, the raven (*Corvus corax*) and the rock ptarmigan (*Lagopus mutus*), manage as well. During the autumn and early winter months, soil microbial metabolic activity continues down to at least $-12\,^{\circ}C$. The vast majority of

Fig. 3 Banks Island, Northwest Territories, Canada 70°N. Upland high arctic tundra, also described as arctic desert. The vegetation is dominated by mountain avens (*Dryas integrifolia*), various species of arctic vetch (*Oxytropis* spp. and *Astragalus* spp.), and scattered clumps of small graminoids. In the background is the Thomsen River valley with sedge meadow tundra and tundra ponds.

Fig. 4 Banks Island, Northwest Territories, Canada 70°N. Two types of high alpine tundra. In the foreground, a wet graminoid tundra fed by snowmelt water. On the opposite slope, a sparsely vegetated dry tundra showing solifluction. The muskoxen feed primarily on the graminoid slope, but will venture onto drier tundra types to feed on high nitrogen species such as arctic vetch.

organisms that spend the winter on the tundra do so in some form of dormancy. Alpine tundra, being much more diverse, and much of it having periods of daylight throughout the year, varies greatly in the degree of winter activity of the fauna. The brief summer on the tundra is enormously productive and provides food for a wide variety of organisms. The vegetation starts to bloom and grow as soon as the snow starts to melt. At that time of year the sun hardly sets, if at all, and temperatures rise quickly. Dormant overwintering insect larvae start to feed and eggs eclose to add innumerable larvae in the snow melt ponds, in the soil, and on the new vegetation. The ecosystem seems to burst into active life. High availability of edible vegetation, exploding insect, bird and rodent populations, and young birds lasts till just before the freeze-up in autumn (**Fig. 4**).

Many bird species migrate annually from more southerly wintering sites to the tundra to breed, taking advantage of, and adding to, the burst of summer productivity. Some of these species arrive in extremely large numbers. Most of these birds are insectivorous or feed on pond crustaceans; some such as loons and grebes are piscivorous, falcons and hawks are predators, and geese are herbivorous. The colonially nesting geese, especially, can have major destructive effects on the vegetation, which in turn can affect many other species.

In some tundra ecosystems, some small mammals, especially two species of lemmings, show extreme oscillations in population density, making them keystone species in the tundra ecosystem. For instance, on Banks Island in northern Canada, both the collared lemming (*Dicrostonyx torquatus*) and the brown lemming (*Lemmus sibiricus*) undergo sharp population oscillations within a 3–5-year period. At peak populations the lemmings are all over the place, whereas the year after it is hard to find a single lemming. During the outbreak phase, several predatory birds, including snowy owls (*Nyctea scandiaca*), rough-legged hawks (*Buteo lagopus*), and jaegers (*Stercorarius* spp.), migrate long distances and concentrate in the regions with high lemming populations. They lay large clutches and raise many young, only to disperse to other areas when the lemming population collapses (**Fig. 5**). Mammalian predators are not as able to respond by migration. Arctic foxes (*Alopex lagopus*) and ermines (*Mustela erminea*) are the main mammalian predators; they also take advantage of lemming outbreaks with large litters. However, this leaves relatively dense populations of these predators after the collapse of the

Fig. 5 Nest of snowy owl (*Nyctea scandiaca*) with six eggs and one hatchling. Snowy owls start incubating as soon as their first egg is laid so that the young are hatched sequentially. Note the seven dead lemmings surrounding the nest, intended as food for the hatchlings. Later that summer, the lemming population crashed. Only the two eldest hatchlings survived to fledge, the others being eaten by the older ones.

lemming population. This has a major feed-forward effect in that the half-starved predators exert a strong negative effect on other less favored prey species, mostly birds, from small passerines to ducklings and even goslings. Only after the predator population has collapsed can the lemming population start to grow again.

The ultimate cause of the collapse of the lemming population is not the predation pressure, but the exhaustion of quality vegetation and a delay in nutrient cycling. However, once the lemming population has collapsed, the subsequently declining predator population can drive the lemming population further down to its minimum. The vegetation, litter layer, and soils are strongly affected by the lemming cycles. This is shown by the enormous difference between the tundra in northern Canada and central Greenland, as in Greenland there are no lemmings, much more accumulated litter, differences in relative abundance of plant species, and far fewer predators. Exclosure experiments in Canadian tundra have produced similar results.

Special Adaptations to Tundra Conditions

Many species have evolved special adaptations to the rigorous, but often predictable, conditions of the tundra. This article presents four cases of such adaptations as examples of this phenomenon: the muskox, two species of arctic bumblebee, an alpine lobelia, and two congeneric alpine beetle species.

The Muskox of Banks Island in Canada's Northwest Territories

The muskox (*Ovibos moschatus*) is a surviving species of the Pleistocene megafauna; it survived the ice age both in Beringia and south of the ice sheet in what is now southern Canada and the northern United States. It has a very long adaptive history in arctic conditions, which shows in a number of very effective adaptations to extreme cold. Besides the obvious anatomical features such as the extremely effective insulating wool under the shaggy guard hair and the front hooves that are perfectly shaped to scratch the hard arctic snow to expose vegetation, this animal has a set of integrated physiological and behavioral traits making up a unique reproductive strategy. A muskox cow responds to her nutritional condition in autumn by not going into a reproductively active phase when in poor condition, and only doing so early in the rutting season when she is in excellent condition. This means that cows in poor condition, which would not have been able to survive the winter and produce a calf the next spring, will live and have another chance at reproduction the next year. The cows that do get pregnant, when faced with a bad winter will either abort their fetus or abandon the calf after birth. Since most calves are born well before the snowmelt and reappearance of new fodder, the cows have to be in good shape to not only carry the calf to birth, but also lactate for several weeks. However, only calves born early in the year have a good chance of gaining enough weight and reserve fat to survive their first winter.

Integrated with this strategy are some significant traits. At birth, the calf weight over cow weight ratio is one of the lowest among ungulates, making abortion or abandonment a relatively minor cost for the cow, which can then cut lactation. Once the calf is born and the cow is lactating, she licks the calf when it urinates and swallows the urine. The urea of the urine is rebuilt into protein by the cow's gut flora and will eventually be available for milk production. This is important because storage of protein over the winter is difficult, and late winter forage is scarce and low in protein. As soon as new forage is available during snowmelt, the cows graze selectively on high-protein vegetation, such as willow catkins and sprouting rosettes of arctic vetch (*Oxytropis* spp.). In far northern parts of their range, muskox cows live long lives, but reproduce only every second or third year and still lose some of their calves.

Two Species of Bumble Bee from the Canadian Arctic

The first author has a personal recollection of working in early July on the tundra on northern Banks Island when in the middle of a snow squall a bumblebee flew by. This seemingly incongruous event is explained by the fact that the common large bumblebee (*Bombus polaris*) has an unusually well insulated thorax, which allows it to keep its flight muscles at $\sim 30\,^{\circ}C$ even when the ambient temperature drops to the freezing point. What is even more special about this species is that the queen also keeps her abdomen near 30 °C, which presumably allows the eggs to develop faster. However, early in the season the queen also warms her eggs and larvae in the nest by inserting her abdomen into the middle of the nest and producing heat by vibrating her flight muscles and circulating the heat to her abdomen. After she has overwintered, the queen builds the nest, often in an abandoned lemming burrow, using bits of dead vegetation and muskox wool. There she raises one brood of workers before switching to start raising reproductive bees for the next year. The other species of bumblebee (*B. hyperboreus*) found on Banks Island is an obligatory brood parasite of *B. polaris*. The queens of this species lay eggs only for reproductives, and lay them in the nest of their host species. This strategy is obviously adapted to the very short summer season in the high arctic tundra, but it also depends on the presence of *B. polaris*. The ratio of the densities of the two species is stabilized by frequency-dependent selection.

Flightless Beetles of the Genus *Parasystatus* on Mount Kenya

In the tussock grass alpine tundra of Mount Kenya between 3200 and 4000 m, there are six described species and at least one undescribed species of the genus *Parasystatus*. These large beetles must be adapted to the diurnal extremes of the climate, which has been described as summer each day and winter each night. Two of these species, *P. elongates* and one undescribed species, have been studied in some detail as to their adaptation to the nightly frost of that zone. *P. elongates* spends its entire larval and pupal development inside a tussock of the grass *Festuca abyssinica*, where it is not affected by the nightly frost. As an adult beetle, it is active by day, shielded from the intense solar radiation by inflated elytra and a shiny, reflective outer cuticle. At night, the beetle hides under vegetation to avoid the worst of the frost; it has an ineffectively high supercooling point (Cooling a liquid to below its freezing point without phase transition; here pertaining to the avoidance of ice formation due to the presence of antifreeze substances and/or the absence of crystallization nuclei.), but an effective freeze tolerance. The other species of the same genus is active well into the night, and protects itself with a much lower supercooling point, but is freezing sensitive. These two different physiological adaptations to nightly frost within one genus indicate that the two species have independently invaded the alpine tundra, rather than having arisen through speciation in the alpine zone. Their being flightless – a typical adaptation to mountain top ecosystems – also rules out invasion from another mountain.

The Giant Lobelia and Its Insect Commensals on Kilimanjaro

Between 3000 and 4000 m on the slopes of Mount Kilimanjaro, the giant lobelia (*Lobelia deckenii*) also has to face the stress of nightly frost, which can be severe due to parts of the Kilimanjaro alpine tundra being relatively dry. The plant has evolved into a ball-shaped rosette consisting of a fleshy center surrounded by concave spiky leaves, which are arranged in such a manner as to trap rainwater. A single plant can contain, trapped in its rosette, a compartmentalized mass of several liters of water. This volume is large enough to prevent it from freezing right to the middle in any one night. Indeed, the center of the plant where the growing tip is located maintains a very even temperature throughout the diurnal cycle. Not surprisingly, this water mass of the lobelia plants with its relatively even temperature has become the breeding environment for a few species of insects with aquatic larvae, the most abundant of which is a chironomid midge. The water in the lobelias also contains microorganisms, which feed on decomposing debris and are in turn food for the insect larvae.

Global Warming and Other Anthropogenic Effects

Extensive research in the arctic and alpine regions including ice core analysis, paleolimnology, palynology, and geomorphology has provided a detailed picture of the climatic history of these regions. This allows us to conclude that, as well as the major changes at the end of the last ice age, frequent climate oscillations have subsequently occurred that caused major changes in tundra ecosystems. Furthermore, there have been times when tundra types existed that are no longer extant. The species complexes that now exist consist of species that have been sufficiently flexible and/or dispersible to have survived the climatic and landscape oscillations of the past. However, this does not necessarily bode well for the future of tundra ecosystems and species, as anthropogenic changes are certain to be increasingly imposed on Earth. Already, the most likely reason for the extinction of most of the Pleistocene arctic megafauna is a combination of climate change and human hunting. The disappearance of the large herbivores at this time caused a major switch in plant dominance on tundra ecosystems from graminoids to mosses, with concomitant changes in long-term soil and peat formation. We must expect similar major changes in the coming century, associated with at least some extinctions. Climate change will be severe and direct human effects will also increase. Already, several species are declining due to pollution and overhunting. Some of the most at-risk tundras (and associated endemic tundra species) will be isolated alpine tundra systems on relatively low mountains, where climatic warming will cause the entire system to be replaced by forest.

Climate change in the arctic is already causing major effects on the tundra ecology. The mean annual air temperatures in the arctic have risen by 2 °C since the 1960s. The sea-ice cover on the Arctic Ocean and the water ways adjacent to islands and continental shores have been declining at a rate of 18% per decade since 1979. By 2012, it was at only 50% of the 1979–2000 average. The two measures, sea-ice cover and air temperature are strongly interdependent, as ice-free water absorbs more solar radiation than ice, causing warming, which in turn melts more ice. Open water also evaporates faster than ice, resulting in more precipitation over adjacent land. Warmer temperatures are increasing the growth of vegetation – especially of shrubs, leading to a 'greening' of the arctic. This in turn has a major effect on the community structure and species composition of the various tundra ecosystems.

The cultural practices of native northern peoples are being affected by earlier breakup and melting of ice in spring, which affects their ability to travel to hunting grounds. In *Inuktituk* (the Inuit native language), the word for 'July' means 'the time of the lake ice breaking,' but the ice now often breaks in June. There is little doubt that the people and the ecology of the arctic are already being significantly affected by the climate warming caused by the anthropogenic fossil fuel emissions that almost entirely derive from the activities of people further south.

Upwelling Ecosystems

TR Anderson and MI Lucas, National Oceanography Centre, Southampton, UK

Introduction

Throughout the world's oceans, phytoplankton community structure and rates of primary production are determined by the interplay between available light and nutrient supply (NO_3^-, Si, PO_4^{2-}, dissolved Fe) as well as by grazing. Winds blowing over the ocean create a surface mixed layer, the depth of which is of great importance for production by phytoplankton. If mixing is vigorous, as is often the case at high latitudes, then nutrients are plentiful but plankton circulating within a mixed layer that may be hundreds of meters deep are exposed to low average light intensities. In contrast, mixing is inhibited in warm stratified waters such as those of the vast subtropical gyres that cover 40% of the surface ocean, in which case light is plentiful and limitation is instead by nutrients. The unique physical circulation of upwelling systems leads to conditions that, to varying degrees, provide both light and nutrients together in quantities that considerably exceed rate-limiting requirements for sustaining maximal growth rates of phytoplankton. As a result, upwelling ecosystems are among the most productive in the ocean.

Upwelling Circulation

The Coriolis effect, whereby the Earth's rotation causes moving bodies at its surface to be deflected, means that wind-driven ocean currents turn right in the Northern Hemisphere, and left in the Southern Hemisphere. The result is horizontal flow at the ocean surface in the so-called Ekman layer, typically tens of meters deep. Upwelling occurs in areas where this flow diverges, the Ekman flow or divergence, so that water displaced at the surface must be replaced by deeper water from beneath. Depending on the nature of this divergence, two major types of upwelling systems can be distinguished.

First, coastal upwelling systems occur where the Ekman layer is directed offshore resulting in flow divergence near the coast. Such systems tend to occur on the eastern boundary of ocean basins, major examples being the Canary, Benguela, Humboldt (Peru), and California Current systems (**Fig. 1**). Offshore Ekman flow in eastern boundary current (EBC) systems is driven by local equatorward winds associated with the pressure gradient between the quasi-stationary atmospheric high-pressure systems over the subtropical oceans relative to adjacent continental low-pressure atmospheric systems. Seasonal north–south progressions of these high-pressure systems (poleward in spring, summer) cause increased upwelling and nutrient supply that, along with increased day length and light, drive latitudinal shifts in phytoplankton biomass and productivity. The other major coastal upwelling system is the Somali Current, driven by seasonal monsoon winds of the Arabian Sea. Coastal upwelling is often enhanced by topographical features such as capes or canyons where local upwelling cells form.

Second, upwelling occurs in the open ocean, being most marked where easterly trade winds give rise to Ekman divergence north and south of the equator. The resulting area of equatorial upwelling in the Pacific is vast, extending westwards from the coast of South America to beyond the international date line. A smaller belt of upwelling occurs in the equatorial Atlantic. In the Southern Ocean, the Antarctic Circumpolar Current contains another zonal upwelling region, most vigorous between 50° and 60°S, driven by northerly Ekman flow that is generated by the strongest prevailing westerly winds in the 40–50° latitudes.

General Characteristics

Nutrients are present in high (e.g., NO_3^-, 35; Si, 30–60; PO_4^{2-}, 1–2 $\mu mol\ l^{-1}$) concentrations in subsurface waters of the global oceans. Upwelling brings them to the surface, fertilizing the resident phytoplankton assemblage. Stratification of the surface mixed layer between the strongest upwelling pulses provides favorable light conditions for algae to grow and take up the nutrients at their disposal. Resulting rates of primary production are often among the highest seen in marine systems. Coastal upwelling systems, for example, occupy just 0.5% of the ocean surface area, yet contribute to 2% of global marine primary production. Supporting an abundance of higher trophic orders such as fish, birds, seals, and whales, they also contain some of the world's major fin-fisheries.

Intermittence is a key feature of upwelling systems. Upwelling intensity is seasonally episodic in systems such as the Canary Current, Benguela, and Somali systems, whereas in others such as the Humboldt and Southern Ocean, upwelling is semi-continuous all year round. In all systems, wind strength varies on shorter timescales of days to weeks, leading to periods of strong and weak upwelling, or times when upwelling ceases altogether. Organisms must be able to tolerate these changes in upwelling intensity and the resulting impact on nutrient supply and spatiotemporal variation in food resources, as well as variations that may occur from year to year and on longer timescales. In addition, they face the prospect of either themselves, or their reproductive products, being swept away in the Ekman layer toward less-favorable habitats. A key feature of these organisms, including phytoplankton, zooplankton, and fish, is that their life histories and behavior are specifically geared toward maintaining populations in the regions of the upwelling centers.

Understanding the ecosystem structure and functioning of upwelling systems, and in particular how they are influenced by climate variability, is increasingly recognized as essential to the management of sustainable fishery resources.

Primary Production and Lower Trophic Levels

Primary Production

The EBC systems provide a highly favorable combination of light and nutrient supply for primary production by virtue of a strongly shoaling pycnocline (the density gradient that signifies the base of the mixed layer) toward the coast and a relatively shallow (<500 m) shelf environment. A near-surface pycnocline has the dual effect of facilitating the injection of nutrients into surface waters and maintaining phytoplankton in a shallow (usually <50 m) well-lit euphotic layer environment. Shallow shelf sediments augment the nutrient concentration of deeper upwelling source waters. As the four major EBC systems lie predominantly in mid-latitudes (40° N/S to 10° N/S), insolation rates are seasonally high, providing both the light and necessary surface warming and stratification to optimally drive photosynthetic carbon fixation supported by a nutrient-replete environment. Taken together, they have a combined productivity estimated to be ~ 1 Gt C yr^{-1}. Chlorophyll concentrations typically exceed 2 mg m^{-3} but can reach up to 50 mg m^{-3} locally where intense dinoflagellate blooms are present. Highest production rates are consistently found in the Humboldt system (2–6 g C m^{-2} d^{-1}) due to a higher average irradiance and a less-fluctuating nutrient environment associated with relatively consistent upwelling.

A key feature of primary production in upwelling ecosystems is that it is fuelled by large amounts of NO_3^- that is `new' (i.e., allochthonous) to the euphotic zone. Phytoplankton production based on nitrate uptake is therefore termed `new production'. Nitrate arises almost entirely from remineralization of organic matter below the pycnocline, notably from dead phytoplankton and other material that had earlier `rained' down from surface waters. In contrast, `regenerated production' is based on nitrogen (NH_4^+, urea, and dissolved organic nitrogen) excreted by organisms within (i.e., autochthonous) the euphotic zone. The relative importance of new production is often stated by expressing it as a fraction of total phytoplankton production (i.e., the sum of new and regenerated production), this fraction being known as the *f*-ratio. Values for the *f*-ratio are usually high (~ 0.5–0.7) in most EBC upwelling ecosystems, although in seasonally pulsed upwelling systems such as the Southern Benguela, the yearly averaged *f*-ratio is lower (~ 0.3). High rates of new production make available carbon and nutrients for transfer to higher trophic levels and are the fundamental reason why EBC systems can sustain productive fisheries. They also provide the potential for large downward fluxes of sinking particles from the euphotic zone in the event that phytoplankton are inefficiently grazed. In contrast, systems based on regenerated production gradually run downhill unless there are new inputs of nitrogen because nutrients are never recycled with 100% efficiency.

Phytoplankton Community Structure

A characteristic succession is seen in the composition of phytoplankton communities of coastal upwelling ecosystems. This succession is driven by changes in the nutrient and light environment, linked closely with upwelling frequency and the three-dimensional (3D) circulation of water as it flows away from the upwelling centers. Large individual (20–200 μm), colonial, and chain-forming diatoms of up to 500 μm in length proliferate as newly upwelled water arrives and stabilizes in the sunlit surface layer. Analogous to weeds, these algae grow quickly because of intrinsically fast growth rates and an ability to take up nutrients rapidly, provided that concentrations remain sufficiently high. Cell division rates of 2–4 d^{-1} quickly result in population growth

that outstrips zooplankton herbivory, leading to extensive diatom-dominated blooms. The accumulating chlorophyll biomass can exceed 6 mg m^{-3} in just a few days, high enough to be easily visible in ocean color satellite imagery (Fig. 2).

Most diatom species within EBC systems are adapted to avoid lateral dispersal in surface currents away from the upwelling centers. Many species trigger a resting stage in their life cycle in response to diminishing nutrient availability. Spores are formed that sink rapidly and become entrained into deeper shelf-edge waters and surface sediments. Sinking of vegetative cells, or chain-formation that increases sinking rates, provide alternative strategies to counteract dispersal. Spores and physiologically inactive diatoms remain within the sediment–water interface layer and await the next upwelling event that will entrain them back into near-shore and nutrient-rich sunlit surface waters, so initiating another bloom event. The construction of silica tests and spiny frustules from dissolved silicate, along with their large size and ability to form chains and colonies, offer initial protection from herbivorous zooplankton such as copepods. The efficacy of grazers is further weakened in pulsed upwelling systems that do not settle into steady state. As initial exponential growth rates of diatoms are much faster (hours, days) than those of herbivorous copepod consumers (weeks), episodic and short-term upwelling events (days) produce a `mismatch' between phytoplankton and zooplankton, the former breaking free from top-down grazer control that might otherwise prevent blooms from occurring. Nevertheless, the grazing that does occur permits carbon to be efficiently transferred to pelagic fish in a short two-step food chain (diatoms $\Rightarrow$ mesozooplankton $\Rightarrow$ pelagic fish).

A shift in phytoplankton community structure occurs as nutrients become depleted in the well-stratified surface waters downstream of coastal upwelling centers. Diatoms give way to smaller cells such as nanoplanktonic phytoflagellates (2–20 μm) as well as other smaller picoautotrophs (<2 μm) that do not require Si and are better able to scavenge nutrients at low concentrations because of their high surface area to volume ratio. As nutrients in the surface layers are scarce, these small phytoplankton primarily occupy the thermocline where nutrients diffuse slowly from below. A deep chlorophyll maximum (DCM) develops that involves a delicate tradeoff between maximizing nutrient availability, but having sufficient light in a near light-limited environment. Microzooplankton grazers keep the numbers and biomass of these small phytoplankton in check (<0.5–1 μg chl *a* l^{-1}). Within this `microbial loop', particulate organic nitrogen (PON) is efficiently recycled via microzooplankton and bacteria into NH_4^+ and urea to support further phytoplankton growth. As nitrogen remineralization is usually balanced by the rapid uptake of such regenerated nitrogen by phytoplankton, concentrations of these nutrients remain low (<0.5–1 μmol l^{-1}). Paradoxically therefore, grazing pressure is essential to support further algal growth. Carbon is only inefficiently transferred along

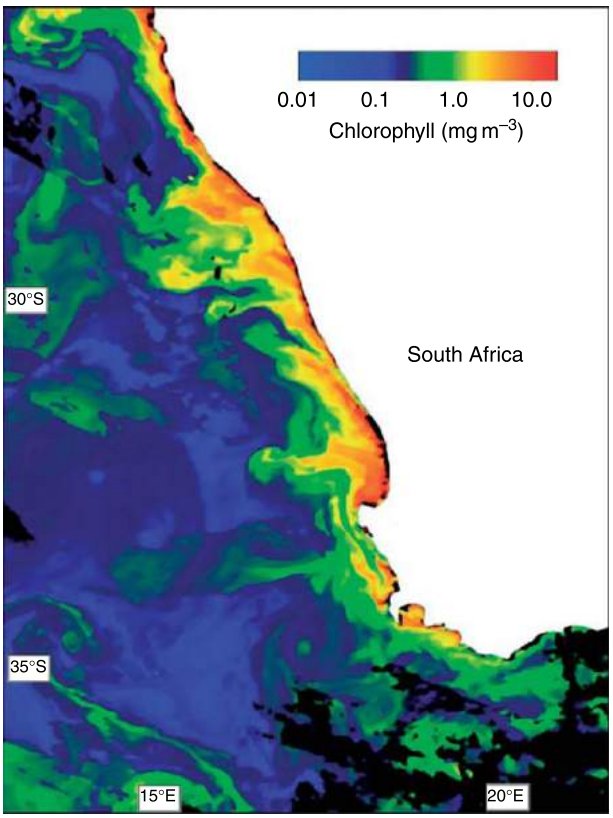

Fig. 2 Satellite image of chlorophyll biomass in the Southern Benguela region. Note high chlorophyll concentrations inshore where upwelling of nutrient rich water is strongest, and also offshore filaments in the chlorophyll signal which weakens offshore as nutrients become exhausted. Courtesy Stewart Bernard, Univ. Cape Town.

an extended food chain (pico-, nanoplankton ⇒ microzooplankton ⇒ mesozooplankton ⇒ fish) because, at each step, something approaching 90% of the transferred carbon is lost through respiration.

Oxygen Depletion

Dead and decaying material is a feature of all ecosystems, those of upwelling areas being no exception. Detrital particles are produced in abundance, either as senescent phytoplankton or as zooplankton fecal material. A `rain' of sinking particulate organic material (`marine snow') is exported from the euphotic zone and decomposed either in mid-water by heterotrophic bacteria, or by both benthic organisms and bacteria on the seafloor. Large quantities of oxygen are consumed, creating an oxygen minimum zone (OMZ) in the sediments and the overlying water. The resulting oxygen concentrations of <0.5 ml l^{-1} are inhospitable to many animals, pelagic and benthic alike.

Coastal upwelling systems are particularly susceptible to hypoxic (<0.5 ml l^{-1}) or anoxic (near-zero O_2) events because of the high rates of diatom-dominated phytoplankton productivity that quite suddenly become nutrient-limited and therefore senescent. The oxycline may often extend to near the surface (<50 m). Most zooplankton that can actively migrate often do so in order to maintain their position in the oxygenated waters near the surface. Others, such as *Eucalanus inermis* in the Humboldt system, are able to withstand low oxygen concentrations, and indeed are known to congregate in the OMZ, perhaps exploiting it as a refuge from predation. In similar fashion, juvenile hake (*Merlucius capensis* and *M. paradoxus*) in the northern Benguela system off Namibia are known to exploit the OMZ as a refuge from their cannabilistic parents!

Oxygen consumption in upwelling areas leads to extensive seafloor habitats subject to permanent hypoxia. Diversity is low, but those animals that tolerate low-oxygen conditions are abundant. Calcareous foraminiferans, nematodes, and annelids utilize the influx of organic material from above, but rely on anaerobic metabolism to do so. Chemoautotrophic bacteria use NO_3^- and sulfur as terminal electron acceptors instead of O_2, first stripping the anoxic water column of NO_3^- (denitrification) before specific anaerobic sulfur and sulfate-reducing bacteria release sulfurous and foul-smelling H_2S into the water column creating so-called `black-tides' and `sulfur eruptions'. However, it appears that some nitrogen losses previously ascribed to denitrification should instead be linked to the process of ammonium oxidation `annamox', first described in Dutch sewerage works.

Offshore hypoxia can have profound effects on the near-shore intertidal environment. When gentle upwelling begins, low-oxygen water is driven into the near-shore and intertidal zone, killing all before it except those most resistant to hypoxia. In the Benguela system, crayfish `walkouts' by animals fleeing from low-O_2 water can leave thousands of tons of crayfish stranded on the beaches in sheltered embayments.

Zooplankton

Great variety is seen in the zooplankton of upwelling ecosystems. Smallest are the microzooplankton, including ciliates, heterotrophic dinoflagellates, and flagellates (typical size 2–5 μm) that efficiently graze the smallest phytoplankton. Reproducing by cell division, their high growth rates (e.g., 1.0 d^{-1}) are similar to those of their algal prey such that their grazing is sufficient to prevent small phytoplankton cells from blooming. Microzooplankton do not fit the general paradigm that organisms eat prey items significantly smaller than themselves. Instead, they have evolved various specialized feeding mechanisms including direct engulfment, tube feeding in which a feeding tube, the peduncle, pierces prey which then has its insides sucked out, and pallium feeding, where a feeding veil envelops and digests prey *in situ*. Prey items as large as, or larger than, the microzooplankter's own body size can be consumed using these adaptations. It has been suggested, for example, that heterotrophic dinoflagellates are able to compete with copepods for diatom prey, although the extent to which this competition operates in marine ecosystems is as yet poorly known.

It is the larger mesozooplankton ($\sim$0.2–2 mm), notably copepods and to a lesser extent euphausiids, that are the major grazers of diatoms and which form the main trophic link with fish and other higher trophic levels. Phytoplankton are captured by filter-feeding or by selective particle capture (raptorial feeding) based on size and/or palatability. *Calanus* is the dominant copepod genus in upwelling ecosystems. Although not reproducing as fast as microzooplankton, it may achieve as many as ten generations per year, each with its own life cycle of eggs, nauplii, copepodites, and adults. When food conditions are favorable, fecundity is high and egg production is rapid. Upon hatching, the planktivorous juvenile stages are swept along in the Ekman layer and will starve if they do not encounter suitably dense patches of appropriately sized food particles. For adults, survival is enhanced by the storage of energy reserves in the form of lipids. Given their size, copepods are unable to maintain their position within upwelling systems by swimming against lateral advection that is often offshore. This problem is overcome by diel vertical migration. Offshore surface Ekman flow is balanced by deeper shoreward flow onto the shelf. By migrating into this deeper layer by day, copepods utilize the natural circulation pattern to maintain their inshore position where food resources are richest.

Euphausiids are also a significant component of the zooplankton community in upwelling ecosystems, for example, *Euphasia lucens* in the Benguela system. They are much larger (1–2 cm) than copepods and have a longer life span of about a year. This longevity, along with an omnivorous diet, means that euphausiids are better able to cope with the fluctuating food conditions of upwelling ecosystems than are copepods. Nevertheless, physical transport away from upwelling centers remains a problem, and these animals also employ diel vertical migration into the subsurface countercurrent to maintain their position in the flow field. Their larger size makes euphausiids a key prey item for larger zooplankton consumers, including baleen whales that are often temporary residents of upwelling systems.

Open-Ocean Upwelling Systems

The general principles and characteristics that govern productivity in EBC regions apply also to the major open-ocean upwelling systems (Equatorial Pacific, Equatorial Atlantic, and Southern Ocean). There are nevertheless key differences, notably that upwelling strength tends to be lower and there is no influence of the seabed (e.g., in supplying iron) on euphotic zone processes, now that it is 3000–4000 m beneath the ocean surface.

The Equatorial Pacific is a vast upwelling system, as well as being a good example of a so-called high-nutrient low-chlorophyll (HNLC) ecosystem. Phytoplankton biomass is generally low and relatively constant ($\sim$0.2–0.4 mg chl *a* m^{-3}) which, along with low productivity of $\sim$0.1–0.5 g C m^{-2} d^{-1}, occurs despite the presence of sufficient macronutrients (NO_3^-, Si, PO_4^{2-}) and light. Iron, however, is in short supply. This micronutrient is needed by phytoplankton to harvest light using their photosynthetic machinery (photosystems I and II), as well as by the enzymes nitrate and nitrite reductase to reduce NO_3^- within cells to NH_4^+. Without a sedimentary source, aeolian supply is the primary source of Fe to the open ocean. However, most aeolian dust supply is from the Saharan desert, far-distant from the Equatorial Pacific. The resulting shortage of iron impacts most severely on large cells, notably diatoms, because of their inability to compete with smaller phytoplankton at low nutrient concentrations. In the western basin, phytoplankton biomass is dominated by small solitary picoplanktonic cells (0.2–2 μm) within a DCM comprising prochlorophytes, *Synechococcus*, and small eukaryotes. These cells utilize what little iron supply there is from the waters upwelled from below, starving the surface ocean of this element. Diatoms are more abundant ($\sim$6%) to the east of $\sim$140 °W where deep nutrient-rich upwelling outcrops at the surface but, nevertheless, the overall biomass is still picoplankton dominated. Grazing by microzooplankton keeps phytoplankton stocks in check, but small natural enhancements of iron that occur in the Equatorial Pacific in response to the passage of tropical instability waves promote transient increases in primary production.

The upwelling region at the Antarctic Polar Front is another HNLC system with low Fe concentrations. Chlorophyll biomass is typically $\sim$0.5 mg m^{-3} in the austral summer with a productivity of $\sim$0.5–1 g C m^{-2} d^{-1}. Unlike the Equatorial Pacific, however, winter gales drive deep mixing that entrains nutrients, including Fe, into surface waters. This is sufficient to initiate short diatom-dominated blooms in the early spring (September, October) as the light environment improves. Iron limitation throughout the rest of the year opens the way for a more typical HNLC community of pico- and nanoplanktonic phytoflagellates that are microzooplankton controlled. Populations of the prymnesiophyte *Phaeocystis antarctica* may also develop, an organism that exists both as solitary cells and mucilaginous colonies, and which is the main producer of volatile organic sulfur (dimethyl sulphide, DMS) in the region.

The Equatorial Atlantic is unique among open-ocean upwelling systems both in terms of its hydrography and because of its close proximity to aeolian dust sources from the Sahara meaning that productivity is far less Fe-limited than in other open ocean systems. Between June and January, water flowing from the Amazon basin floods eastwards (the North Equatorial Counter Current) across the northern margin of the equatorial upwelling region. Stripped of nutrients as it crosses the Amazonian shelf, this fresher, buoyant water forms a layer $\sim$40 m deep that caps the nutrient-rich water below and also limits light penetration. A DCM forms at the juncture of these two water types, the low light intensities being particularly well exploited by the cyanobacterium *Prochlorococcus*. The nutrient-depleted waters above are home to a separate community in which nitrogen fixers such as *Trichodesmium* utilize atmospheric nitrogen as a nutrient source. The aeolian flux of dust plays an important role since nitrogen fixers have a particularly high requirement for Fe.

Between February and May, the Amazonian outflow diverts northwards toward the Caribbean. Phytoplankton now find themselves $\sim$40 m closer to the surface in a higher light environment and productivity increases but, as the rate of upwelling is weak, the upward flux of nutrients is insufficient to support diatom blooms except in the eastern basin near the African coast.

In addition to the major upwelling systems described above, the upper ocean contains numerous mesoscale eddies - whirling current systems analogous to weather systems in the atmosphere but only about a tenth of the size (tens instead of hundreds of kilometers across). Produced through the conversion of potential energy to kinetic energy as part of the ocean's annual energy cycle, both cyclonic and anticyclonic eddies (depending on the vertical structure of the water column) can result in the localized doming of isopycnals (constant density surfaces) and upwelling of nutrient-rich waters into the euphotic zone as they form. Eddies themselves then decay as they release their potential energy over periods of weeks to months, vertical motions both upward and downward occurring on their periphery during this time. Primary production is generally stimulated through nutrient enrichment. As in other upwelling systems, regions of higher nutrients and shallower mixed layer depth associated with eddies tend to promote the growth of larger phytoplankton cells such as diatoms, their concentrations typically being higher within eddies than in surrounding waters. Ubiquitous in nature, eddies provide a significant vertical transport mechanism for nutrients throughout much of the world's oceans.

Fish and Higher Trophic Levels

The EBC upwelling ecosystems of the world support major commercial fisheries based on the shoals of sardine, anchovy, and mackerel that thrive on the abundance of phytoplankton and zooplankton food. In the Humboldt system alone, for example, catches have been around 12 million tons in peak years, although this decreases by >50% during unfavorable conditions. Indeed, stocks of different fish species have been highly variable over the years, suggesting a remarkable responsiveness in ecosystem structure to changing conditions. Understanding the links between fish, lower and higher trophic levels, and environment is essential to ensuring the sustainable management of these important fish resources.

Small Pelagic Fish

The food chain of upwelling systems embraces phytoplankton and zooplankton at its base, linking to small pelagic fish which are in turn consumed by higher predators such as piscivorous fish, birds, and seals (Fig. 3). A curious aspect of this trophic network is that there are many species at low (phytoplankton, zooplankton) and at high trophic levels, but only a few species of small pelagic fish in between. Indeed, the fish biomass of coastal upwelling systems is typically dominated by either a single species of sardine (*Sardinops*) or a single species of anchovy (*Engraulis*) at any one time.

Although food resources are generally favorable, the 3D circulation makes upwelling systems a hazardous environment for fish. Losses of eggs and juvenile stages may occur due to offshore transport or because of starvation when being carried by currents from the spawning to nursery areas. Spawning grounds are therefore often strategically positioned in quieter areas surrounding the upwelling centers such as downstream of capes in sheltered embayments. The result is a complex network of spawning grounds, transport pathways, and migration patterns, a typical example being the Benguela system (Fig. 4). Anchovy spawn on the Western Agulhas Bank in spring and summer (with a maximum in November), while sardine have a longer spawning season in the same area, peaking in both October and March. Once fertilized, eggs and larvae drift northwards in the Benguela `Jet'. Larvae feed selectively on small particles and juvenile fish recruitment occurs at several locations north of St. Helena Bay on the West Coast. There, anchovy recruits feed primarily on larger zooplankton (copepods) as they slowly migrate southwards, returning as 1-year-old adults to the Agulhas Bank to spawn in the following austral spring/summer.

The survival of small pelagic fish is thus determined to a large degree by direct physical factors such as circulation patterns and the intensity and duration of upwelling that simultaneously control egg and larval survival, recruitment success, and food supply. Population control is therefore neither exclusively `bottom-up' via primary producers nor `top-down' by higher predators. Instead it is from the `waist', both up and down, the so-called `wasp-waist' hypothesis. Small pelagic fish provide higher tropic levels such as birds and seals with food, while at the same time keeping phytoplankton and zooplankton numbers in check. As a result, ecosystem functioning as a whole may be remarkably sensitive to fluctuations in pelagic fish numbers. Direct environmental forcing or commercial fishery exploitation of `wasp-waist' populations may cause disruption to these ecosystems by undermining the stability of the entire food web.

Bottom-up and top-down controls of small pelagic fish populations are nevertheless by no means unimportant. Sardines and anchovy, for example, have different feeding strategies. Sardines are mostly indiscriminate filter feeders on phytoplankton and smaller zooplankton, including small cyclopoid copepods, whereas anchovy use biting behavior to selectively ingest individual particles such as larger ($\sim$2 mm) copepods and euphausiids. Strong upwelling should therefore favor anchovy by promoting the diatom growth that supports larger zooplankton. In contrast, the more nutrient-depleted waters present during periods of weaker upwelling favor smaller phytoplankton and consequently smaller zooplankton that are preferred by filter-feeding sardines.

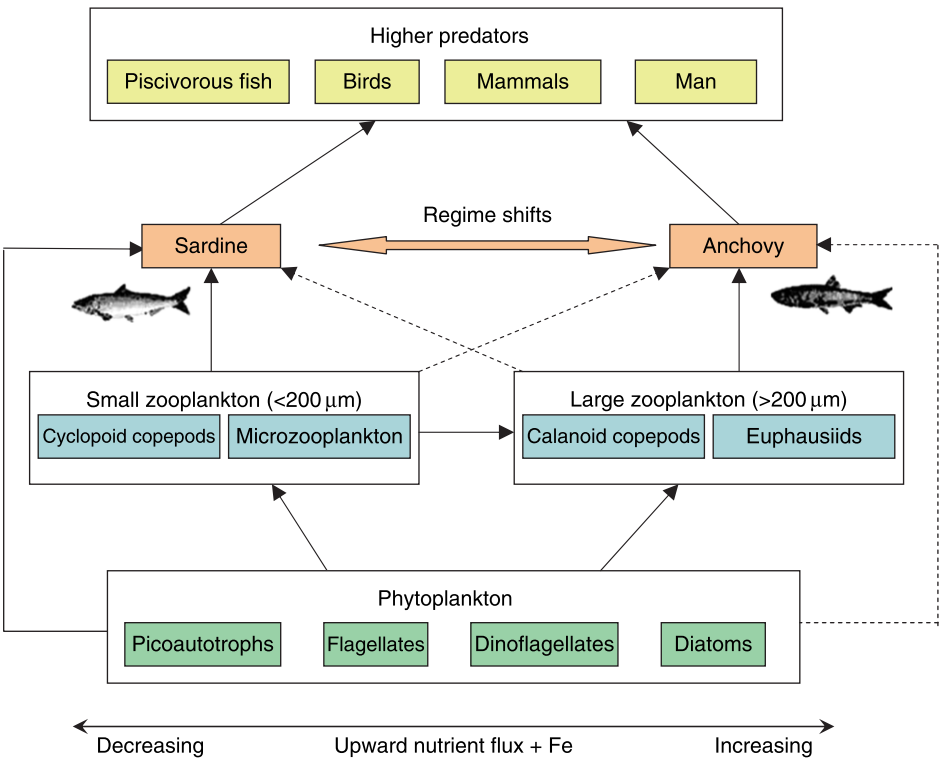

Fig. 3 Idealized flow diagram for an upwelling ecosystem food web. Dashed arrows indicate weak flows.

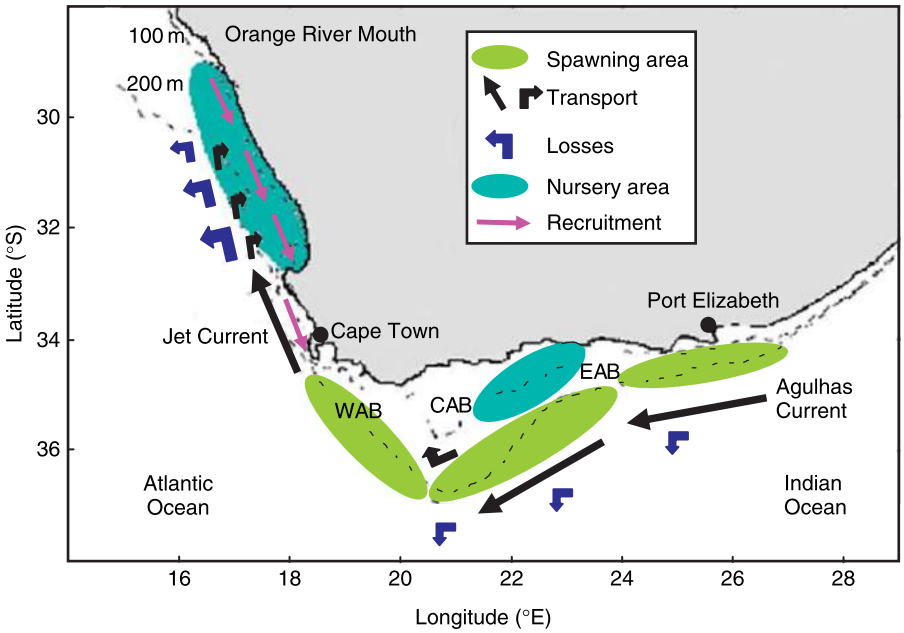

Fig. 4 Map of the Southern Benguela off South Africa showing the locations of small pelagic fish spawning and nursery grounds and transport and loss processes that impact on eggs and larvae. WAB, CAB, and EAB indicate the Western, Central, and Eastern Agulhas Banks, respectively. Redrawn from Lehodey, P., Alheit, J., Barange, M., et al., 2006. Climate variability, fish and fisheries. Journal of Climate 19, 5009–5030.

Variability in small pelagic fish populations has consequences for their predators. Evidence from the Benguela region shows that during periods of pelagic fish abundance populations of piscivorous fish (e.g., snoek, hake), seals and birds (gannets, cormorants) generally increase and, in doing so, begin to exert a stronger top-down control on the small pelagic fish. This in turn relaxes anchovy predation pressure on copepods and so mesozooplankton numbers recover, in turn exerting a higher grazing pressure on phytoplankton. Not only does top-down predator control on small pelagics equal or exceed that by commercial fishermen, it can substantially shape community structure right down to the level of primary producers.

Fish Production

High primary production fuelled by new nutrients undoubtedly contributes to the prodigious fish production of coastal upwelling systems. Back in 1969, John Ryther proposed that high fish yield should be expected where phytoplankton cells are large, or exist as colonies or chains, thereby leading to only one or two trophic links from primary producers to fish. The greater number of trophic links stemming from smaller phytoplankton cells should lead instead to greater respiration losses and recycling of organic matter.

Fish catches vary markedly between EBC systems, typical values being 0.05%, 0.09%, and 0.16% of primary production for the Canary, Benguela, and Humboldt Current systems respectively. Much of this variation may be due to differences in upwelling intensity and frequency that impact on lower trophic levels and fish recruitment, although intensity of fishing may also play a part. The strongly seasonal and pulsed nature of upwelling in the Canary and Benguela systems, for example, leads to temporal mismatches between primary producers and copepods, depressing their fecundity and therefore population size, so reducing the food supply for fish. In contrast the Humboldt system experiences less variation in the intensity of upwelling, leading to tighter coupling between phytoplankton and copepods, greater zooplankton production, and ultimately higher fish production. The low fish catch per unit primary production of the Canary system relative to that of the Benguela is due to its narrow continental shelf (20 km; the Benguela's is ~85 km), such that proportionately more primary production may be advected offshore away from the main zones of fish production.

The impact of environment on the reproductive success of fish in upwelling ecosystems can be thought of in terms of a fundamental triad of processes: enrichment (nutrient supply for primary production), concentration processes (convergence, water-column stability), and retention (within favorable habitat). Acting at the base of the food chain, nutrient enrichment via upwelled water fertilizes primary producers, although excessive wind may deepen the surface mixed layer, leading to light limitation. Upwelling also stimulates small-scale turbulence, increasing encounter rates between both zooplankton and fish larvae and their prey. On a larger scale, convergence promotes food particle aggregation, but divergent upwelling flow will tend to dissipate particles offshore. Based on these pros and cons, an optimal level of upwelling intensity can be defined, the `optimal environmental window' (OEW), that maximizes fish yield (Fig. 5). When on the left side of the OEW (too little wind) upwelling is weak and primary production, and hence also food for fish, is restricted by insufficient nutrient supply. On the other hand too

much upwelling (right side of the OEW) leads to dispersal of organisms away from upwelling centers and provokes light limitation in phytoplankton as they are mixed deeper into the water column because stratification is not established.

Higher Trophic Levels

The abundance of zooplankton and small pelagic fish in coastal upwelling systems provides food for a range of higher trophic levels including piscivorous fish, seabirds, pinnipeds, and cetaceans. Predatory fish such as horse mackerel and deep-water hake are themselves important fishery resources, the latter being caught by mid- and deep-water trawling. Another economically viable product of upwelling systems, particularly in the Humboldt and Benguela, is the production of bird droppings, guano, which is prized as a fertilizer because of its high N and P content. The so-called `guano birds' such as the guanay cormorant, Peruvian booby, Chilean pelican, Cape cormorant, and Cape gannet are part of resident seabird populations that breed along the coast and on adjacent islands feeding on small pelagic fish such as anchovies and sardines. Both the Benguela and Humboldt systems also support populations of small-sized penguins. The African Penguin (*Spheniscus demersus*) extends from central Namibia to Algoa Bay on the south coast of South Africa. Its population has dwindled from more than one million in 1900 to about 200 000 now, feeding mainly on a diet of pelagic schooling fish (anchovy, sardine, redeye). Reasons for the declining population are ecologically complex, but include competition with commercial fisheries for food, habitat degradation because of removal of guano from islands that they burrow into for nesting, pollution (oiling), and predation by seals. The Humboldt Penguin (*Spheniscus humboldti*) breeds mainly from 5 to 33 °S along the Peruvian and Chilean coast, with another small colony at 42 °S. Like the African Penguin, it also feeds on small pelagic fish, and its population has declined to around 30 000 for similar reasons.

Because of the episodic nature of upwelling, higher predators must endure large seasonal or interannual fluctuations in prey availability, for example, in response to El Niño events (see below). Resident seabird and pinniped populations are particularly susceptible. In catastrophic instances, starvation may cause adult seabirds to die, although more often food scarcity affects breeding success by decreasing the proportion of adults breeding and the growth rate of the hatchlings. In similar fashion, there is often a high incidence of seal pup mortality during food shortages, the adult females being unable to provide enough milk for their survival. Seabirds and pinnipeds are able to employ various strategies to compensate when food resources are in short supply including increasing the time and/or distance spent foraging for offspring, delaying reproduction until such time that food becomes available, or ceasing breeding efforts altogether. Others may target alternative food resources, such as squid, or migrate to other regions within the system where food resources are more plentiful.

Many migratory species are attracted to the high productivity of upwelling systems. Blue whales, for example, feed on dense swarms of euphausiids that exist in the California Current system. Many birds that nest elsewhere also benefit from the abundance of food in upwelling areas. The California Current system, for example, is visited by sooty shearwaters, which breed off South America, and red-necked phalaropes which nest in the Arctic. Arctic terns migrate to the Southern Hemisphere in austral winter, feeding in the Benguela and Southern Ocean upwelling systems.

The catch of pelagic anchovy and sardine by the predators described above is generally considered to surpass that by commercial purse-seine fishermen, even in the Humboldt which is heavily exploited. Seals in particular are unpopular competitors, not least because they cause damage to nets and generally interfere with fishing operations. Nevertheless, the potential consequences of overfishing in upwelling ecosystems should not be underestimated. Over the last few decades the fishing industry has progressively concentrated on species at relatively low trophic levels, with emphasis on small pelagic species such as sardine and anchovy with decreased catches of predatory fish such as hake and horse mackerel. An apparent consequence of this `fishing down marine food webs' has been a decline in pelagic fish and a proliferation of jellyfish that occupy the vacant niche, the two utilizing the same food resources. Jellyfish biomass in the northern Benguela off Namibia, for example, is now thought to exceed that of commercially

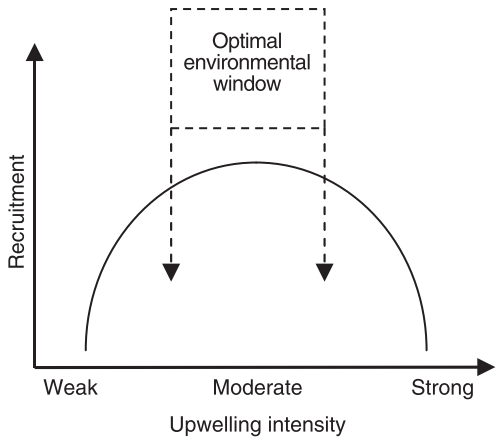

Fig. 5 Optimal environmental window for fish recruitment. Reproduced from Cury, P., Roy, C., 1989. Optimal environmental window and pelagic fish recruitment success in upwelling areas. Canadian Journal of Fisheries and Aquatic Sciences 46, 670–680.

important fish stocks. Once established, this regime shift may be difficult to reverse because jellyfish are predatory on fish eggs and juveniles.

Climatic Forcing

Changes have occurred in the dominant fish species of upwelling ecosystems, from year to year, over decades and indeed centuries. Worldwide, populations of anchovy and sardine have exhibited `flip-flops' in which one species is replaced by the other. Fishing is one factor that may influence these changes. Comparison of the fish catches of different upwelling systems, however, reveals a remarkable synchronicity in their behavior (Fig. 6) suggesting a climate linkage via global `teleconnections'. The implication is that fish populations are driven primarily by natural climate variability and its influence on ecosystem structure and recruitment success. Short-term events such as El Niño cause calamitous declines in fish stocks that lead to hardship for wildlife such as bird and seal populations, and of course fishermen. Superimposed on this short-term variability are longer-term trends that occur in response to factors such as climate change. Understanding these variations and their causes is crucial to the maintenance of sustainable fisheries in upwelling areas.

El Niño

The El Niño Southern Oscillation (ENSO) is the most important example of a relatively short-term impact of climatic forcing on upwelling ecosystems, with a typical periodicity of 3–5 years. In normal (La Niña) years, easterly trade winds blow across the surface of the equatorial Pacific from Peru/Chile to Indonesia creating the general divergent open ocean upwelling that occurs

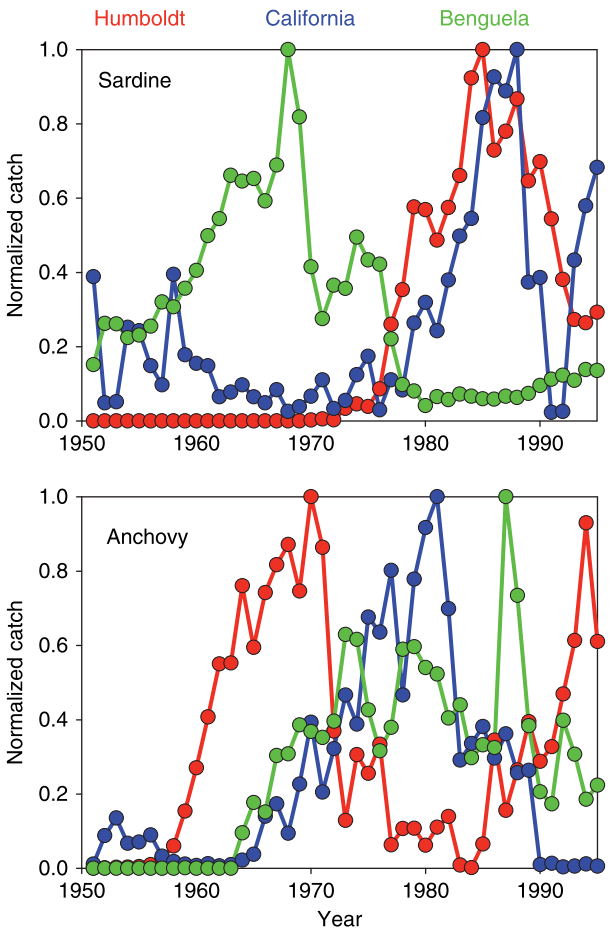

Fig. 6 Comparison of sardine and anchovy catches in the Humboldt, California, and Benguela systems. Data are normalized to maximum catch (million tons): sardine: 5.62, Humboldt; 0.29, California; 1.51, Benguela; anchovy: 12.9, Humboldt; 0.32, California; 0.97, Benguela. Reproduced from Schwartzlose, R.A., Alheit, J., Bakun, A., et al., 1999. Worldwide large-scale fluctuations of sardine and anchovy populations. South African Journal of Marine Science 21, 289–347.

across the eastern half of the equatorial Pacific. This process sets up a surface temperature gradient of $<20\ ^{\circ}C$ in the east to $>30\ ^{\circ}C$ in the west, resulting in a shallow thermocline ($\sim$20 m) in the east, but a much deeper one ($\sim$80 m) in the west. At its eastern end, along-shore winds off Peru and Chile drive the coastal upwelling of the Humboldt Current System. El Niño occurs when the easterly trade winds lose intensity, allowing warm water from Indonesia and eastern Australia to flood eastwards across the Pacific, `capping' the deeper nutrient-rich waters that lie below (Fig. 7). The coastal winds that drive upwelling in the Humboldt System possess insufficient energy to erode and mix this stratified surface layer.

Upwelling continues during El Niño but the water arriving at the surface is depleted in nutrients with drastic consequences for marine life. Diatom blooms are suppressed with a dramatic shift to a community structure dominated by the small cells of the microbial loop. Fish stocks collapse in response to the low availability of food, the starvation of adults and/or larvae leading to recruitment failure. High mortality rates are also seen in top predators. Major ENSO events occurred in 1972 and 1976, as well as in later years, economic disaster following in their wake. For example, revenue losses to Chile and Peru resulting from decimated fish stocks were about $8 billion for the 1997–98 ENSO event.

Further afield, the effects of ENSO events are felt throughout the Southern Hemisphere, and indeed the globe. The warm waters of El Niño in turn affect atmospheric circulation, the resulting teleconnections instigating changes in other upwelling systems. For example, so-called `Benguela Niño' events occur about 6 months after the onset of activities in the Pacific. During these events, the Angola-Benguela front moves southwards by several hundred kilometres, bringing low-oxygen warm water into the Namibian upwelling region that results in a southward displacement of pelagic fish stocks.

Long-Term Climate Variability

Having high fecundity, small pelagic fish are able to recover from events such as El Niño within a year or two. Yet the observed anchovy–sardine flip-flops persist over many years suggesting that climatic factors operating on longer timescales play an important role in structuring coastal upwelling ecosystems and fish stocks (Fig. 6).

Anchovy were the dominant fish species in the Humboldt Current System until the mid-1970s. Catches peaked at about 12.9 million tons in 1970, but were followed by a severe decline that may have been precipitated by the major El Niño of 1972. Recovery of the anchovy stock did not occur until the mid-1980s, sardine being dominant during the interim period. The variability of fish catches appears to have followed cycles of around 55–65 years over the last century. Analysis of atmospheric circulation patterns (e.g., the `atmospheric circulation index', ACI) reveals that the dominant direction of air masses has also changed on similar timescales. Fish scales preserved in anoxic and undisturbed shelf sediments off California and off Namibia reveal 50–70 year cycles of anchovy and sardine abundance that are linked to changes in sea surface temperature over the last 1600 years. In the Humboldt system, regime shifts appear to correlate with lasting periods of warm or cold temperature anomalies related to the approach and retreat of warm subtropical water toward the coasts of Peru and Chile. Sardine are favored during periods of warm water intrusion (1970–85) whereas the anchovy fishery prospers during periods when temperatures remain relatively cool (1950–70, 1985 to present). Resolving the underlying, probably basin-scale, physical processes that lead to such patterns, along with teleconnections linking different upwelling systems, remains a priority for scientific investigation.

Changes in local atmospheric pressure gradients with global warming might be expected to increase upwelling frequency and intensity, with accompanying changes in the structure and function of ecosystems. Nutrient concentrations have for example

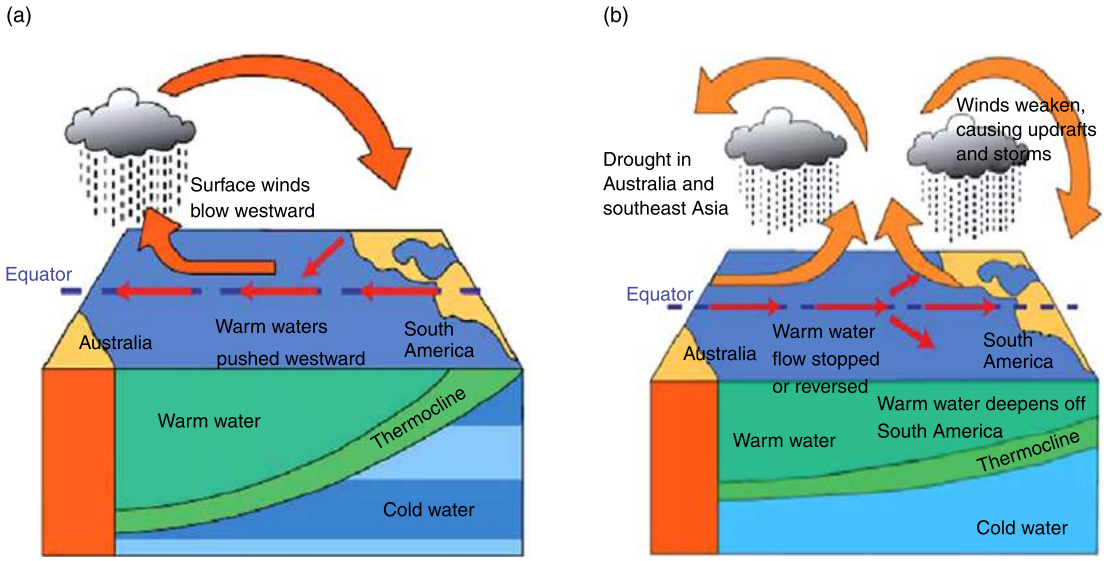

Fig. 7 Atmospheric and ocean circulation patterns associated with La Niña (a) and El Niño (b). Reproduce from SEPM Photo CD-5, *Oceanography Series* (edited by Peter A. Scholle), with permission from Society for Sedimentary Geology (SEPM).

increased in the Benguela region over recent decades, suggesting an increase in upwelling. There has at the same time been a shift from sardine prior to the mid-1960s, to anchovy in subsequent years. The recent dominance of anchovy has impacted on the zooplankton population by selective predation pressure on larger zooplankton, so that smaller cyclopoid copepods become dominant.

Variability in the trophic structure of upwelling ecosystems, be it short-term regime shifts or longer-term trends, occurs as a consequence of a range of processes operating via both environment and man's direct intervention by fishing. Understanding these interactions in order to predict the response of upwelling ecosystems to climatic forcing and fishing strategies involves unravelling a multiplicity of factors that affect primary production, zooplankton and fish recruitment, a challenging task for the scientific community.

Adaptation☆

David J Booth and Peter Biro, University of Technology, Sydney, NSW, Australia

Introduction

A biological adaptation is a structure, physiological process, or behavioral trait of an organism that has altered incrementally, mainly through natural selection in response to increases in reproductive success in the organisms that showed those traits most strongly. Four major types of adaptations affect population dynamics, and in turn are shaped by population dynamics. Structural adaptations are special body parts of an organism that help it to survive in its natural habitat, for example, its skin color, shape, and body covering. Behavioral adaptations are ways in which a particular organism behaves to survive in its natural habitat. Physiological adaptations are systems present in an organism that allow it to perform certain biochemical reactions optimally, while life-history adaptations are parameters affecting growth and reproduction such as age at sexual maturity, reproductive investment, body size, and longevity.

Here, we will not distinguish adaptations (features produced by natural selection for their current function), from exaptations (features that perform functions, which were produced by natural selection, but not for their current use). We will emphasize the fact that adaptations are both a cause and a consequence of population dynamics. "Most behavioral and life-history theory assumes populations with stable dynamics, yet considerable empirical work shows that natural selection constantly changes population structure, resulting in disequilibrium, and hence unstable population dynamics." Adaptations can be relatively fixed (genetically based and slow to evolve), or highly plastic (changing from moment to moment, or evolving quickly), or both.

Processes of Evolutionary Adaptation

Adaptation (changes within a species over time) and speciation (in which new species arise) are two main processes that explain the observed diversity of species. For these to occur through evolution (natural selection) an organism must be viable at all stages of its development which places constraints on the rate and form of development, behavior and structure of organisms. Since adaption are to the local environment, a species may differ considerably across its distributional range, or across any climate boundaries.

Types of Adaptations

Structural Adaptations

Adaptations of feeding, antipredator, and reproductive morphology can directly affect population demography, and if they vary in space or time, can consequently drive variation in population demography. Alternative feeding morphologies in response to increased competition may increase population size but with reduced growth. Considerable variation in morphology associated with resource use is a classic example of local adaptation to the environment, and can therefore lead to variable population dynamics. Alternatively, structural adaptations may reduce variation in population dynamics. For instance, inducible defenses (spines in plankton, body shape in frogs, etc.) that evolve as adaptations to predation intensity, may stabilize dynamics by reducing mortality rates and therefore the likelihood of density dependence. Classic examples of structural plasticity reducing variation in predation rate include the evolution of head spination in cladocerans such as *Daphnia* species only in lakes which have high predator densities. Predators in turn may vary their morphology in response to prey type or abundance. Populations of freshwater roach fish such as Crucian carp (*Carassius carassius*) may exhibit local adaptation to zooplankton prey size and structure by altering the morphology of their gill rakers which are used to sieve plankton. Two species of Darwins' finches in the Galapagos have been

☆*Change History:* December 2017. D.J. Booth made minor changes to the text and references.

shown to vary in body size and bill shape over the last 30 years in response to changes in food supply. Tadpoles of some frog species develop deeper tails in ponds with predators, and there are many other examples of "inducible defenses."

Life-History Adaptations

A whole suite of different life-history characters can vary and adapt according to fluctuations in an animal's own abundance, feeding opportunities, predation, and environmental conditions. In turn, variation in life-history characters can affect spatial and temporal variation in the population abundance. Often these characters have a genetic basis and can evolve (sometimes rapidly), or they can be quite plastic within the individual, or even both. The most frequently considered and important life-history characters include growth rate, age at maturity, reproductive investment, reproductive strategy, body size, and longevity. Although they can be considered in isolation, they are often tightly correlated with one another. For example, greater growth is often associated with delayed age at maturity, greater reproductive investment, and larger body size.

Effects of changing population density on life history through competition and predation are perhaps most important and widely studied. Generally speaking, increases in population density result in decreases in age at maturity, reduced energy investment toward reproduction, smaller body size, and adoption of alternative reproductive strategies. Increased competition for food among conspecifics is a common underlying cause, though risk of cannibalism/predation can also indirectly cause such effects by confining and concentrating vulnerable individuals to refuges where feeding opportunities become limited. If so, then competition and predation are not independent factors affecting behavior and life history as so much of the literature would imply. Such "density-dependent" reductions in age at maturity and reproductive investment frequently result in smaller numbers and sizes of offspring, resulting in reduced survival and density-dependent mortality which tend to stabilize population fluctuations. Such delayed mortality is often termed "delayed density dependence" and is generally viewed as an important mechanism for stabilizing population dynamics. As suggested above, competition and predation can interact to affect changes in population dynamics through short-term effects on reproductive investment and juvenile survival in prey populations. For instance, density-dependent limitation of food resources reduces condition in young hares in Northern Canada and, in combination with predation, is thought to initiate the decline phase of their fluctuating population dynamics.

Adoption of alternative reproductive tactics is another life-history adaptation to strong reproductive competition. Examples include adoption of sneaking versus territorial/aggressive mating tactics in several fish species, for example, the bluegill sunfish (*Lepomis macrochirus*) whereby small and early maturing males become "sneakers" that dart-in and ejaculate over the eggs of a copulating pair of large individuals. This alternative "sneaking" life history (early maturing, small body size) is thought to increase fitness in fish and mammal populations where reproductive success is normally size based. Such alternative reproductive tactics serve to compensate, at least in part, for reduced reproductive success in early maturing individuals. Some of the best-known life-history responses to variation in feeding and predation conditions come from guppy populations in Trinidad, where greater predation rates result in compensating increases in reproductive investment (more eggs), earlier maturity, rapid juvenile growth, decreased coloration, and smaller population sizes than populations from streams with few or no predators. These changes in life history should serve to mitigate effects of predation mortality and prevent extinction, though its effect on population dynamics is unclear. Similar in its effect to that of natural predators, commercial fishing can alter life-history parameters. For instance, in Atlantic cod (*Gadus morhua*) and other species, "longevity overfishing" (preferential removal of the oldest, largest, and most fecund individuals) may cause a shift in phenotype to smaller body size, fewer eggs, early maturity, and consequent lower population productivity and fishery value. These changes make it difficult for the population to rebound from low numbers, and therefore increase the risk of local extinction due to the low numbers of adult fish remaining in combination with fewer young being produced which are small and less fecund than larger ones.

Variation in climatic conditions can also directly select for life-history traits that increase probability of survival in harsh environs, stabilize dynamics, and allow persistence. For instance, fish have been shown to evolve more rapid growth rates with increasing latitude and mammals evolve larger body size with increasing latitude. More rapid juvenile growth rates in fish increase the probability of surviving their first winter by accumulating body reserves and fat for the longer winters at northern latitudes. However, more rapid growth often requires greater feeding effort, increasing exposure to predators, resulting in a significant mortality cost for rapid growth rates. This may result in lower initial recruitment, but may be offset by the benefits of greater overwinter survival. Larger absolute body size in mammals at northern latitudes is thought to decrease the ratio of exposed body surface area to body mass, thus decreasing mass-specific metabolic expenditures required to keep warm during long northern winters (following Bergmann's rule). Rapid growth to accumulate resources and larger body size to minimize heat loss are both mechanisms that minimize environmentally related mortality and allow persistence and stability in these extreme environments.

Sex-ratio adjustment can also buffer a population against fluctuations. Birds and wasps in particular may use selective infanticide to maximize survival, while turtles and lizards have temperature-dependent sex determination. In the Australian water dragon lizard, for example, females are produced at hot and cool temperatures, and males at intermediate temperatures. Females take control of sex determination through changes in their nest site selection latitudinally and altitudinally and adjust sex ratios.

It should be noted that not all life-history adaptations will act to stabilize population dynamics, and there is current debate in this area. Adaptive food choice by consumers has been suggested as a major factor in population and community stability. However, a review of reproductive traits suggested that, while adaptive timing of reproduction could lead to stability, adaptations in reproductive investment and allocation of reproductive investment to offspring should destabilize population dynamics. Whether adaptive life-history strategies stabilize or destabilize population dynamics depends on the combination of optimized traits under some tradeoff.

There is surprisingly little direct evidence that intraspecific genetic variation can influence population growth and life history. However, one recent study of the Glanville fritillary butterfly (*Melitaea cinxia*) in Finland showed that variants of one gene (*Pgi*) influence population growth in a complex and habitat-dependent manner. The *Pgi* gene has several alleles: one of the homozygotes and one of the heterozygotes are common, and are linked to a higher flight metabolic rate and to be more fecund than the other heterozygotes. In small meadows, growth was highest when the two former genotypes predominated, but in larger meadows, the latter genotype was favored, possibly because butterflies with it mature later but also die later, allowing them to exploit a larger habitat more thoroughly.

Local adaptations to specific environments are well documented, and have important effects on overall population dynamics. For instance, pathogen–host populations, such as those associated with the rabies virus, illustrate the interaction between life-history dynamics, spatial spread, and evolutionary changes in infectious diseases. This is of critical importance for understanding extant epidemiological patterns and is prerequisite to constructing a predictive theory of disease emergence.

Behavioral Adaptations

In response to fluctuations in the abundance of competitors, food, and predators, individuals adapt behaviorally through changes in territoriality, reproductive behavior, foraging activity, and habitat use. By doing so, individuals can mitigate some of the negative effects of increased competition, decreases in food abundance, and predation. Density-dependent behavioral variation is most likely to directly affect population dynamics, primarily by promoting stability through reductions in survival at high density which dampen oscillations. In contrast with life-history characters, behavior can be extremely plastic and change from moment to moment with varying conditions. However, behavior also has a genetic basis allowing longer-term evolution of less plastic variation in behavior. Below we discuss some important behavioral adaptations to dynamic changes in competition and predation, emphasizing the importance of highly plastic behavior as well as less flexible behavioral adaptations.

For instance, territoriality has been shown to be a direct mechanism for density-dependent losses of young animals from natal habitats and linked to density-dependent rates of recruitment and adult population size. Given a minimum territory size, increases in conspecific density must therefore result in the aggressive exclusion of individuals into available habitats which are likely to be less favorable for growth and protection from predators. However, increases in food abundance can moderate these competitive effects. When territorial defense involves significant energy expenditure, increases in food abundance can result in decreases in territory size and therefore permit an increase in local population density. Thus, territoriality is flexible and variation in local density and food abundance interact to affect changes in territorial behavior that in turn affects local density. As individuals grow and energetic demands increase, territory size should also correspondingly increase and result in delayed density-dependent emigration of individuals and local "population regulation."

Animals that are not territorial or under circumstances which do not favor territorial monopolization of resources (e.g., unpredictable resources) frequently respond to increases in density with increased rates of foraging activity and space use. When individuals deplete food resources with increases in density, then mobile animals must increase activity rates and/or use of space to search out and find new sources of food. Increases in activity with density have been shown to compensate (at least in part) for low local food abundance to maintain growth rates (a benefit), but greater activity rates also increase encounter rates and visibility to predators (a cost). Density-dependent rates of foraging activity by prey, and corresponding activity-dependent vulnerability to predation has been demonstrated for taxa ranging from aquatic insects to large ungulates and appears to be a common mechanism for delayed density dependence and potentially stabilizing effects on population dynamics. For instance, increases in density and/or decreases in food abundance results in increases in foraging activity in tadpoles and fish and greater spacing of individuals in groups of shorebirds, resulting in greater vulnerability to predators and elevated mortality rates. Increased competition due to high density, in combination with two or more very distinct sources of food, can also combine to select for divergent foraging behavior (activity and habitat use) among individuals within a population. In this scenario, a population may diverge into distinct pools of active and sedentary individuals that specialize on different food items located in different habitats. In marine environments, most species produce propagules that disperse large distances in open ocean. For marine invertebrates and fishes, arrival at adult habitat (settlement) is characterized by larvae choosing to settle with resident conspecifics. This choice affects rate of conspecific aggression, group and individual survival, growth, and reproductive success.

Although behavior is usually thought of as being plastic and highly adaptable, recent work has begun to highlight the fact that behavioral tendencies exist (termed "behavioral syndromes"), analogous to human personality. It is thought that behavior that is not completely flexible evolves in response to unpredictable fluctuations in biotic and environmental conditions. Because fluctuations in conspecific and predator abundance are often unpredictable and change over long time intervals, it is unreasonable to expect that an animal can integrate current and future conditions to make optimal choices that maximize fitness. Rather, an inflexible component to behavior with a genetic basis can allow natural selection to optimize (over the long term) behaviors which allow persistence and fitness maximization in the face of fluctuations in competition, predation, and environmental conditions. Indeed, many animals ranging from insects, frogs, fish, mammals, and primates all display individual behavioral tendencies, such as consistent tendencies to be active and aggressive across many situations and contexts. Thus, individual behavior has a tendency or trajectory that is genetically determined, but also possess flexibility to current conditions. Maintenance of variation in behavioral tendencies then may be a mechanism for ensuring persistence over the long term, rather than short-term fitness maximization. For instance, animal populations on predator-free islands have evolved to become "tame," because antipredator behavior no longer represents a long-term persistence mechanism and reduces feeding rates in the short term. Similarly, evolution of different dispersal propensity in response to increased competition and reductions in food and/or predators can have effects on populations and their

growth (range expansion). For example, cane toads are an exotic pest species that appear to be evolving a greater propensity to be active dispersers at the front of their invasive distribution in northern Australia. Those at the "front" appear to be more active, move in a directional manner, and have longer legs than those at the point of introduction a few decades earlier.

Physiological Adaptations

Clearly, physiology of organisms limits scope for their populations to occupy habitats, grow, disperse, etc. At a gross level, physiology delimits occupation of aqueous versus aerial habitats, but more subtly, individual variation in physiological responses to the abiotic (e.g., rainfall, water quality) and biotic environment (e.g., scope to escape predators) can bear directly on population distribution, growth rate, and fecundity.

Ambient temperature is a key factor determining geographical distribution and energy budget, especially of ectothermic animals. Climate change will, therefore, cause changes in the population dynamics of organisms. In trout, for instance, adaptation leads to optimal growth when temperatures are within normal range, but can result in smaller population size when temperatures deviate substantially from the norm. This occurs primarily because metabolism increases exponentially with temperature, and because consumption is also reduced, thus reducing growth rates. More generally, when temperatures are greater than or less than optimal, individual "scope for growth" is reduced, leading to often negative effects of slower growth and smaller body size. Another example is where timing of breeding in birds does not adjust to increases in temperature due to climate warming leading to poor chick survival and reduced population size.

Energy allocation to growth and reproduction may also closely respond to local environments, with anticipated harsh conditions (e.g., freezing lakes, food shortages, long-distance migration) often preceded by buildup of storage lipids in many taxa. This may remove energy from growth and reproduction in the short term but improve lifetime success. A species that occupies a large latitudinal range, for instance, may vary its "energy budget" in response to temperatures. For example, northern Atlantic forms of silverside fishes allocate more energy to lipids than southern populations, and animals may channel energy to growth (when small and vulnerable as juveniles) and later allocate energy to fat reserves for periods of resource shortage and to reproduction.

Evolutionary Adaptation Under Human-Caused Climate Change

Evolutionary adaptation can be rapid and potentially therefore help species counter stressful conditions or take ecological opportunities arising from climate change. This means that within a community, there may be climate-change winners and losers, depending for instance on a species' adaptive capacity near its physiological limits. For example, corals exist at water temperatures often at their physiological upper thermal limits, and different rates of adaptation of co-occurring species may predict which corals will survive, if any, in the face of unprecedented global ocean warming.

Conclusion

Natural selection works through responses of individuals within populations to different environments. Therefore, population dynamics is intimately linked to natural selection, and speciation may have its foundations in within-species polymorphisms for resources. Adaptations may serve to either enhance population stability or lead to increased variation in demographic parameters, and are key to species performance across a wide range of environments, such as across latitudes. A new suite of methods, such as structurally dynamic modeling, are required which take into account the consequences of adaptations at the population level (such as plankton size shifts) to model responses of ecosystems to changed impacts. Evolutionary processes such as adaptation need to be incorporated into management programs, for instance those designed to minimize biodiversity loss under rapid climate change.

Allee Effects

John M Drake, University of Georgia, Athens, GA, United States
Luděk Berec, Institute of Entomology, České Budějovice, Czech Republic
Andrew M Kramer, University of South Florida, Tampa, FL, United States

Glossary

Allee effect Positive association between individual fitness and population size or density.
Allee threshold Critical population size below which average lifetime reproductive output is less than one.
Anthropogenic rarity Species rarity caused by human activity.
Component Allee effect Positive association between a vital rate and population size or density.
Demographic Allee effect Positive association between per capita population growth rate and population size or density.
Evolutionary suicide An adaptive process leading to extinction.
Inverse density dependence Positive association between per capita population growth rate and population density; also called "positive density dependence."
Strong Allee effect An Allee effect that is sufficiently large to cause an unstable equilibrium at some small, non-zero population size; this critical population size is called the "Allee threshold."
Weak Allee effect An Allee effect that is too small to cause an unstable equilibrium.

Theory of Allee Effects

Summary

Allee effects are an individual and population-level phenomenon in which the expression of reproductive output or other measures of fitness increases with density over some interval of small population sizes. Because of this positive association, Allee effects are sometimes called *inverse density dependence* or *positive density dependence*, in contrast to the negative density dependence caused by intra-specific competition. Population-level phenomena due to this density-dependent process include accelerating invasions, the appearance of critical phenomena, and evolutionary suicide.

Population Dynamics

The dynamics of populations subject to Allee effects are typically studied by translating average individual fitness into a per capita intrinsic rate of population increase. Denoting the population size or density by n, we suppose that the vital rates of the population may be represented in terms of a per capita birth rate, $b(n)$, and a per capita death rate, $d(n)$, each of which is expressed in terms of individuals per time. The balance of vital rates gives the per capita rate of increase $g(n) = b(n) - d(n)$. A *component Allee effect* may be expressed in either term, that is, a component Allee effect occurs if $b(n)$ is an increasing function of n or if $d(n)$ is a decreasing function of n. The existence of a component Allee effect does not guarantee the existence of a *demographic Allee effect*, defined to occur when the per capita growth rate $g(n)$ is an increasing function of n (over some interval), because density may affect both reproduction and mortality simultaneously. Examples are shown in **Fig. 1**. Scenario 1 shows a component Allee effect in the death rate (*green line* decreasing) resulting in a demographic Allee effect (*blue line* increasing). Similarly, Scenario 2 shows a component Allee effect in the birth rate (*black line* increasing) resulting in a demographic Allee effect (*blue line* increasing). In contrast, Scenario 3 shows a component Allee effect in the death rate (*green line* decreasing) but no demographic Allee effect (*blue line* decreasing) due to a countervailing effect in the birth rate (*black line* decreasing faster than *green line*). Likewise, Scenario 4 shows a component Allee effect in the birth rate (*black line* increasing) but no demographic Allee effect (*blue line* decreasing) due to a countervailing effect in the death rate (*green line* increasing faster than *black line*).

To obtain the rate of growth or decline for the population as a whole, the per capita population growth rate is multiplied by the population size n. It is conventional to write this growth rate as a differential equation, that is,

$$dn/dt = ng(n) = n(b(n) - d(n)).$$

For instance, Dennis (2002) considers a model where mate encounter limits reproduction at small population sizes. In this model, the birth rate is given by

$$b(n) = \lambda n/(\theta + n),$$

where λ is a maximum per capita growth rate and $n/(\theta + n)$ reflects the suppression of reproduction due to mate limitation. In this

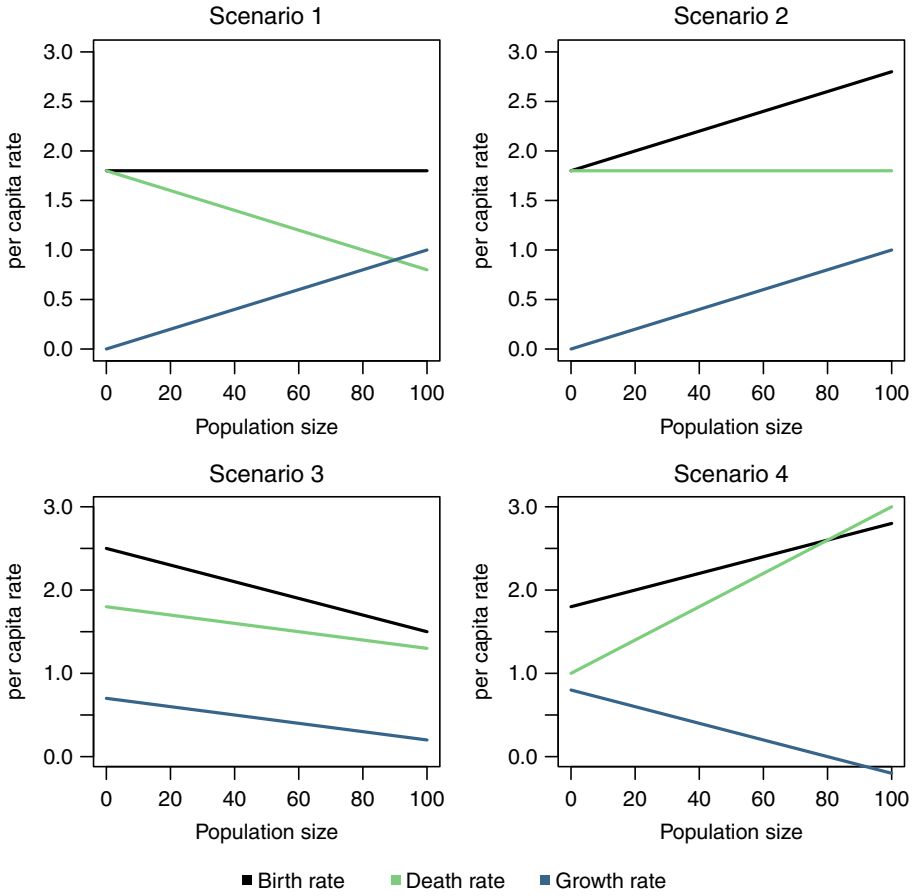

Fig. 1 Component and demographic Allee effects. Scenario 1: component Allee effect in death rate (*green line* decreasing) resulting in a demographic Allee effect (*blue line* increasing). Scenario 2: component Allee effect in birth rate (*black line* increasing) resulting in a demographic Allee effect (*blue line* increasing). Scenario 3: component Allee effect in death rate (*green line* decreasing) but no demographic Allee effect (*blue line* decreasing) due to a countervailing effect in the birth rate (*black line* decreasing faster than *green line*). Scenario 4: component Allee effect in birth rate (*black line* increasing) but no demographic Allee effect (*blue line* decreasing) due to a countervailing effect in the death rate (*green line* increasing faster than *black line*).

model, θ is a half saturation constant corresponding to the population size at which the per capita birth rate is half what it would be if matings were not depressing population growth (**Fig. 2**).

If we take the death rate to be a constant, μ, this gives rise to the mate limitation model of population dynamics

$$dn/dt = ng(n) = n(\lambda n/(\theta + n) - \mu n).$$

If $\lambda > \mu$, this model has a positive, unstable equilibrium, called the *Allee threshold*, at $n^* = \theta\mu/(\lambda - \mu)$ as shown in **Fig. 3**. A population with such an unstable equilibrium is called a *strong Allee effect*. In contrast, a model with an acceleration in population size, but where the unstable equilibrium is at extinction ($n^* = 0$) is called a *weak Allee effect*.

This model does not exhibit any negative density dependence, even at large population sizes. Dennis (2002) has shown how a logistic model for population regulation can be modified to include an Allee effect. The resulting model is

$$dn/dt = ng(n) = n(r - rn/k - \lambda\theta/(\theta + n)),$$

where r is the intrinsic rate of increase and k is the carrying capacity. This model has the shape in **Fig. 4**. A cubic model that gives a similar shape is the function.

$$dn/dt = ng(n) = n(r(n/a - 1)(1 - n/k)),$$

where the new parameter a governs the location of the Allee threshold.

This theory has been extended to a variety of more complicated models, including models of demographic stochasticity and extinction (Dennis, 2002), spatial models (Lewis and Kareiva, 1993; Kanarek and Webb, 2010), age-structured models (Cushing, 1994), discrete-time models (Veit and Lewis, 1996; Allen *et al.*, 2005), and models structured by two sexes that represent mate limitation directly (Engen *et al.*, 2003). These models make a range of theoretically testable predictions. For instance, a strong Allee effect gives rise to a sigmoidal relationship between initial population size and the chance of extinction (Dennis, 2002; Kaul *et al.*, 2016). A strong Allee effect coupled to spatial diffusion gives rise to a critical patch size that must be occupied by an incipient

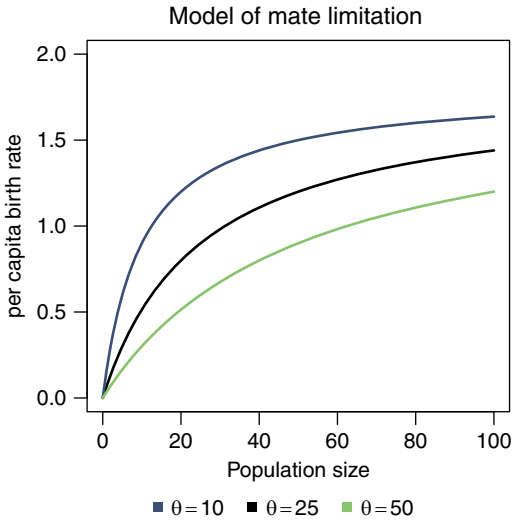

Fig. 2 Mate-limited Allee effects. The mating function $n/(\theta + n)$ causes the per capita birth rate to increase with population size until it reaches an asymptote.

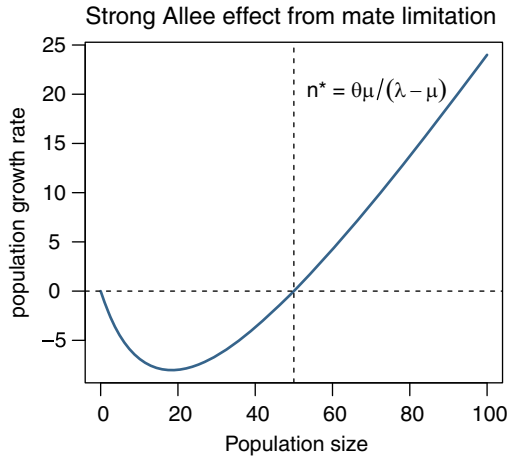

Fig. 3 Strong Allee effect. A strong Allee effect occurs when there is a non-zero population size below which the population growth rate is negative and above which it is positive. This Allee threshold, here shown at $n^* = 50$, is a critical population size below which the population cannot persist.

population to invade and an accelerating invasion wave (Lewis and Kareiva, 1993; Vercken *et al.*, 2011). And, in populations that reproduce through mating of two sexes, fluctuations in the sex ratio can give rise to an additional source of demographic noise, increasing the risk of extinction (Engen *et al.*, 2003). Thus, the theory of Allee effects gives rise to predictions that may be empirically tested in field populations. Nevertheless, at this time, the theory of Allee effects is much more advanced than the empirical study of Allee effects in nature.

Evidence for Allee Effects

Overview

Following two reviews in the late 1990s (Courchamp *et al.*, 1999; Stephens and Sutherland, 1999), however, there was a rapid increase in studies of Allee effects in natural populations, as well a retrospective examination of previous studies that had been overlooked (Courchamp *et al.*, 2008; Kramer *et al.*, 2009). The majority of the new work was driven by applications in species conservation, invasive species management, biological control, pest outbreak and harvest (Kramer *et al.*, 2009). By the end of the 2000s, component or demographic Allee effects had been detected in plants, terrestrial arthropods, aquatic invertebrates, fish, birds, and mammals, totaling >60 species (Kramer *et al.*, 2009). Each taxonomic group is discussed in more detail below.

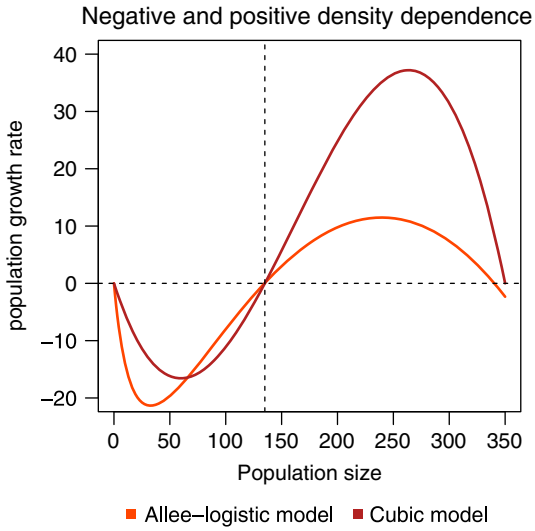

Fig. 4 Models with both positive and negative density dependence. Models with both positive density dependence at small population sizes (Allee effects) and negative density dependence (at large population sizes) are needed for understanding the long-run dynamics of populations subject to Allee effects, for instance to calculate extinction probabilities or the critical patch size of an invading population.

The diverse group of affected species and numerous mechanisms documented to cause Allee effects show these effects to be common in nature and with potential for widespread influence on population dynamics (Courchamp *et al.*, 2008). Most cited evidence was based on researchers detecting component Allee effects, primarily from mate limitation, predator satiation, and mechanisms related to social cooperation (Gascoigne and Lipcius, 2004; Gascoigne *et al.*, 2009; Kramer *et al.*, 2009). Whether these mechanisms commonly cause positive density dependence in natural populations is still actively debated. Kramer *et al.* (2009) found that only 23 studies showed any evidence for a demographic Allee effect, but also that most studies were not designed to detect demographic Allee effects. Convincingly identifying critical thresholds due to a demographic Allee effect was even rarer, occurring in only 7 of the 23 studies. Several meta-analyses have approached the question of the prevalence of demographic Allee effects by assembling data on multiple populations and applying a consistent method to detect positive density dependence in these large datasets. Gregory *et al.* (2010) fit several population models with and without Allee effects to 1198 time series of population abundance. The models with Allee effects were rarely the top-ranked model (1.1%) and had a combined support of 12% (Gregory *et al.*, 2010). This limited evidence for Allee effects was similar to low detection rates in previously published meta-analyses (Myers *et al.*, 1995; Sibly *et al.*, 2007). More recent reviews of insect (Fauvergue, 2013) and fish (Keith and Hutchings, 2012) populations also found only limited evidence of demographic Allee effects.

Causal explanations for these findings include (i) that demographic Allee effects do not occur regularly in natural populations due to fitness tradeoffs, and (ii) that Allee effects operate only at densities well below those exhibited by most populations. Alternatively, these results may also be a consequence of the difficulty of detecting positive density dependence in the presence of short time series, climatic variability and measurement error (Gregory *et al.*, 2010), that is that the failure to detect Allee effects is a measurement problem. Given the inherent difficulties in detecting and censusing sparse populations, it is not surprising that most meta-analyses have used purpose-built or specially adapted statistical methods to detect Allee effects with the goal of achieving higher statistical power. These include least squares model fits to population models (Gregory *et al.*, 2010) and Bayesian analysis of variance applied to the standardized number of recruits (Keith and Hutchings, 2012). The most heavily analyzed datasets have been marine fisheries datasets (reviewed in Hutchings, 2015), which have reported divergent findings depending on method used. Confirming the presence of a critical threshold for positive population growth is even more difficult, but has been accomplished for individual species or populations by quantifying the relationship between population growth rate or per capita growth rate and population density (Kramer *et al.*, 2009). An alternative method for detecting demographic Allee effects depends instead on comparing probability of establishment and extinction to population density (Hopper and Roush, 1993). Rigorous application of this approach relies on the theoretically conjectured differences in pattern between extinction risk due to demographic stochasticity and risk due to positive density dependence (Dennis, 2002). This method can be particularly powerful for experimental tests of Allee effects using replicate populations (Kaul *et al.*, 2016).

Evidence in Vertebrates

Component Allee effects have been detected in mammals, birds, and fish (Courchamp *et al.*, 2008; Kramer *et al.*, 2009). Examples in amphibians or reptiles are presently undocumented. Mechanisms confirmed to induce Allee effects include mate limitation, cooperative defense, cooperative breeding, cooperative feeding, predator satiation and dispersal (Courchamp *et al.*, 2008, Kramer *et al.*, 2009). Cooperative and predator-dependent methods are the most common, whereas mate limitation has been studied (and

detected) less often for vertebrates, perhaps not surprising since most vertebrates are highly mobile and often exhibit advanced social organization and signal-based communications among individuals. Multiple studies on vertebrates have provided clear evidence for the importance of Allee effects to managed populations and those of conservation concern (e.g., Angulo *et al.*, 2007), including the detection of critical thresholds for population persistence (e.g., Wittmer *et al.*, 2010).

The influence of Allee effects on the dynamics of fisheries has been of particular interest, resulting in competing conclusions for and against the relative importance of positive density dependence compared with compensatory dynamics (reviewed in Keith and Hutchings, 2012, Hutchings, 2015). However, because Allee effects appear to be a possible explanation for multiple cases where overfished populations have failed to recover following the removal of fishing pressure, continued work on fisheries data has led to innovative methods for detecting Allee effects. Outcomes of this research include recent attempts to estimate approximate rules for what level of population depletion leads to impaired recovery, with estimates of 10% of maximum population size for marine fishes, 15% of maximum population size for terrestrial mammals and 19% of maximum population size for marine mammals (Hutchings, 2015).

Evidence in Invertebrates

Studies detecting Allee effects in invertebrates are similar in number to those for vertebrates (Kramer *et al.*, 2009). These detections include terrestrial arthropods, aquatic arthropods, and aquatic molluscs subject to mate limitation, dispersal, cooperative feeding, cooperative defense, and predator satiation (Courchamp *et al.*, 2008; Kramer *et al.*, 2009). Mate limitation is the dominant causal mechanism in terrestrial and aquatic invertebrates. While this may be due partly to study bias, it strongly suggests that invertebrates experience a relatively greater challenge to mate-finding than vertebrates, and that variation in traits facilitating mate encounter is likely to be an important aspect of extinction and invasion risk in these species. One well-studied example of Allee effects in wild populations is the invasion of Gypsy moth (*Lymantria dispar*) in North America. The speed of gypsy moth spread and population dynamics where programs to monitor and slow that spread have been deployed provide evidence that (i) Allee effects may be expressed in landscape-level features of population biology (Vercken *et al.*, 2011), (ii) that there exist critical population thresholds for population establishment, and (iii) that these thresholds are spatially and temporally variable (Tobin *et al.*, 2007, Fauvergue, 2013).

Evidence in Plants

Allee effects have not been as widely considered in studies of plant populations, but have been shown to be important in populations of conservation concern (van Tussenbroek *et al.*, 2016) and invading species (Taylor *et al.*, 2004). Pollen limitation (a kind of mate limitation) is nearly universally implicated in these studies. The constraint of pollen limitation has often been hypothesized as the primary driver in the evolution of selfing in plants (see section on "Evolutionary Ecology of Allee effects"). Most of these studies document only the component Allee effects, but Groom (1998) found experimental support for reduced persistence in isolated patches due to pollen limitation.

Evidence in Microorganisms

There has been very little research on Allee effects in microorganisms. Two possible reasons are (i) the predominance of asexual reproduction removes the mechanism of mate limitation from consideration, and (ii) the numerically "large" population sizes of microbial populations begs questions about the relevance of theory exclusively concerned with "small" populations. Recently, Allee effects have been engineered in *Escherichia coli* (Smith *et al.*, 2014), and detected in experimental population of *Vibrio fischeri* (Kaul *et al.*, 2016). In both cases, the circumstances under which Allee effects were detected were highly contrived experimental settings. In another example, the social bacterium *Myxococcus xanthus* exhibits density-dependent spore production in laboratory populations (Kuspa *et al.*, 1992), resulting in heightened extinction risk at low densities and when the population is dominated by genotypes that do not contribute to fruiting body formation (Fiegna and Velicer, 2003). Further research is required to determine when analogous conditions occur in nature. We anticipate that the number of examples where positive density dependence and component Allee effects in microorganisms are demonstrated will increase as techniques for studying these populations improve.

Evolutionary Ecology of Allee Effects

Density-Dependent Selection

The presence of an Allee effect in any population is due to the fitness consequences of sparsity. For this reason, many species are presumed to have acquired adaptations expressed at small population sizes to mitigate these fitness consequences (Courchamp *et al.*, 2008; Berec *et al.*, 2018). For instance, mate-finding adaptations include the ability to move faster or more efficiently when rare, the evolution of signaling systems such as sex or aggregation pheromones, or shifts in mating system such as the facultative appearance of hermaphrodites or clonally reproducing individuals in sparse populations (Gascoigne *et al.*, 2009). Even once acquired, such adaptations may not cause the complete disappearance of demographic Allee effects, however. For instance, gypsy

moth *Lymantria dispar* (Tobin *et al.*, 2011) and the large copepod *Hesperodiaptomus shoshone* (Kramer *et al.*, 2008) both exhibit demographic Allee effects due to reduced mate encounter when rare, despite the evolution of sophisticated communication systems for mate-finding involving female-produced chemical signals that increase the encounter rate with males. Determining the etiology of traits that affect the expression of Allee effects is complicated, however, by the existence of unknown historic environments in which evolution occurred. For instance, the pheromone systems used by these species for signaling may be an evolutionary adaptation for alleviating the mate-finding Allee effect. Alternatively, it could be an adaptation acquired to signal mate quality at high densities but co-opted to facilitate mate encounter at low densities. In general, a challenge for evolutionary biology is to understand which adaptations have evolved to counteract the effects of low density and which to provide an advantage when many competitors are available.

It is further possible that dense populations of individuals may acquire traits that cease to be advantageous if those populations are reduced in size. This kind of density-dependent selection has been observed in the gamete morphology and reproductive performance of three congeneric sea urchins (Levitan, 2002). The species that commonly lives at the lowest density, *Strongylocentrotus droebachiensis*, has evolved relatively larger eggs and slow, long-lived sperm, gametes that perform best under sperm limitation. In contrast, the urchin *S. purpuratus* that lives at the highest density evolved smaller eggs and fast, short-lived sperm, gametes that perform best under sperm competition. The urchin *S. franciscanus*, which is typically found at intermediate densities, has gametes with intermediate traits. More generally, Berec *et al.* (2018) found that density-dependent selection in mate-finding traits resulted in higher Allee thresholds in populations kept at higher densities under a variety of realistic scenarios in a simulation model. In interpreting these results, it is important to keep in mind that most documented Allee effects in nature occur in species that are *anthropogenically rare* because they have been reduced in abundance by recent human activity (Courchamp *et al.*, 2008; Gascoigne *et al.*, 2009; Kramer *et al.*, 2009). Density-dependent selection thus offers an explanation for the relatively high frequency of demographic Allee effects in anthropogenically rare species.

Trait Evolution

Given the difficulty of experimentally studying demographic Allee effects and the time scales over which major innovations in mating system, gamete structure, or social behaviors are expected to evolve, it is not surprising that there is a great deal more theory than empirical evidence about the relation of Allee effects to biological evolution. The theory can be roughly divided into two nonexclusive categories: (i) theories about how Allee effects respond to the evolution of traits that shape them, and (ii) theories about how various traits evolve in populations not exposed versus exposed to Allee effects. Models of both kinds provide important insights into how populations may persist at low densities, and whether they may escape from chronic rarity.

One leading line of work suggests that when there is sufficiently large phenotypic variation in a trait that affects the strength of a demographic Allee effect, populations below the Allee threshold may escape extinction through an *evolutionary rescue*, a process of frequency dependent selection in which traits are acquired that prevent a declining species from going extinct (Gomulkiewicz and Holt, 1995). Under such circumstances, even though the population declines initially, genetic adaptation causes the Allee threshold to decline at a faster rate, eventually falling below the realized density in the population, in turn preventing population extinction (Kanarek and Webb, 2010; Cushing and Hudson, 2012; Cushing, 2015). This process may increase the chance that a population subject to an Allee effect invades a novel habitat, but its real effect is likely to be dominated by additional immigrations that sustain the initially small invading population (Kanarek *et al.*, 2015).

Another line of theory suggests that evolution also affects the strength of Allee effects in populations expressing strong Allee effects (i.e., populations on the path to extinction). Since Allee effects are intimately related to individual fitness, any mutation in a trait shaping a component Allee effect may be affected. Outcomes of such evolution may vary greatly. For example, rare plants capable of selfing may face two opposing selection pressures: inbreeding (when selfing dominates) and pollen limitation (when selfing is rare). When inbreeding depression is weak, small or low-density populations of outcrossing plants may avoid a component Allee effect due to pollen limitation by evolving selfing, while evolution may lead plants to become completely non-selfing under strong inbreeding depression despite the requirement for pollen-ovule encounter to achieve fertilization (Cheptou, 2004). Inbreeding depression is a fitness cost of selfing and may itself induce a component Allee effect if selection is weak and deleterious mutations are not purged sufficiently fast (Courchamp *et al.*, 2008; Luque *et al.*, 2016). Such antagonistic Allee effects can also arise in animals, for instance when a mate-finding Allee effect is combined with a predation-driven Allee effect, or if Allee effects due to foraging facilitation and anti-predator defense behavior affect viability of a species (Berec *et al.*, 2007). One or the other Allee effect then dominates, depending on ecological and evolutionary context.

Selection for selfing may also lead to *evolutionary suicide* (Cheptou, 2004), however, when an individual fitness increase due to trait change is accompanied by a decrease in the population size or density such that at some point the population collapses and goes extinct (Webb, 2003; Rankin and López-Sepulcre, 2005). Allee effects are a common ingredient of evolutionary suicide: the population goes extinct after it falls below the Allee threshold (which may itself increase in size as a result of the trait evolution; Parvinen, 2007; Courchamp *et al.*, 2008). The social bacterium *Myxococcus xanthus* appears to represent one of a few observed cases of evolutionary suicide, in this case triggered by a strong demographic Allee effect (Fiegna and Velicer, 2003).

A relatively new line of theoretical inquiry investigates traits of mate search rate. When search rate evolves and shapes a mate-finding Allee effects, mating systems, fitness trade-offs and the searching sex are all predicted to have a crucial role in determining

the Allee threshold (Berec *et al.*, 2018). Specifically, costs imposed by mate search may be crucial to determining how density influences the evolution of Allee effects. In a simulation study, Berec *et al.* (2018) found that when viability declines in fast searchers, the attained trait value commonly minimizes the Allee threshold irrespective of population density. However, density-dependent selection arose when a search-fecundity trade-off was imposed, leading to mate search rates that result in lower Allee thresholds in populations kept at lower densities. Further, the final outcome was sensitive to mating system. When there were no costs to mate search, runaway selection on mate search rate gave rise to evolutionary suicide with males as the searching sex, but not with females as the searching sex (Berec *et al.*, 2018).

A number of theoretical studies consider demographic Allee effects as a selection pressure on evolution of various traits, and explore whether populations subject to Allee effects evolve different characteristics as compared with those that are not subject to it. For instance, demographic Allee effects were shown to greatly facilitate local adaptation to sink environments (Holt *et al.*, 2004). They were also found to modify propensity of individuals to disperse, such as to reduce the distance that individuals move (Travis and Dytham, 2002) or to reduce sex-bias in dispersal (Meier *et al.*, 2011). However, evolution may also act to speed up the rate at which populations subject to a mate-finding Allee effect spread, in spite of diluting the population and making mate finding more difficult (Shaw and Kokko, 2015). This and other somewhat counter-intuitive evolutionary outcomes affected by and/or shaping Allee effects (some of which are mentioned above) underscore the need for theory to illuminate the evolutionarily counter-intuitive properties of mate-limitation and other population phenomena induced by sparsity as well as the need for empirical studies.

Conclusion

Allee effects are one of the classic phenomena of population ecology. The existence of a threshold size for the viability of populations subject to a strong Allee effect gives rise to a wide range of consequences for the establishment and extinction of biological populations, the speed of spread, and the expected persistence over long times. Despite the rich body of dynamical theory that elaborates on these predictions, the evidence for Allee effects in nature is relatively weak. Possible reasons for this include that population processes that give rise to Allee effects such as mate limitation are genuinely rare, that Allee effects are common but difficult to detect, and that populations that would otherwise be subject to Allee effects quickly evolve adaptations that prevent the expression of low fitness at small population sizes. Current research is seeking to illuminate which, if any, of these explanations is correct.

Association☆

Christine Angelini, University of Florida, Gainesville, FL, United States

Glossary

Association Term used for a wide range of situations where different species occur together.
Community All types of organisms found together at a given place and time.
Facilitation Interaction among species in which one improves environmental conditions or enhances resource availability to support the other.
Mutualism Interaction among different organisms in which both partners benefit.
Parasitism An interaction among different organisms in which one partner benefits at the expense of the other.
Symbiosis An interaction between two different organisms living in close proximity to one another that typically benefits both organisms.

Introduction

The most general definition of associate is "to keep company with," and the term association has accordingly been used in ecology for a wide range of situations in which different species occur together. In the early 20th century, the term was first used to refer to a group of plant species that occurs predictably together under a given set of environmental conditions, for example, the oak-hickory forest of the southeastern United States. The plant association was the forerunner of the modern concept of the ecological community, which includes all types of organisms found together at a given place and time. Ecological associations vary in both the intimacy of interaction between the species and in the types of benefits accruing to them (Fig. 1). In general, associations between species can be understood in terms of the timescales over which species interact as well the dynamic balance between fitness costs and benefits to the parties involved. Casual and intimate associations, as well as parasitic and mutualistic associations, are points along complementary continuums. Importantly, changes in environmental conditions or evolutionary changes in the interacting species can cause a given association to shift along each continuum to a new position.

Types of Associations

Intimacy: Casual to Obligate Associations

Associations between species vary from casual and fleeting to mutually obligatory and coevolved (Fig. 1). At the casual end of this spectrum, associations may arise with little or no interaction, simply because species have similar environmental requirements and tolerances, a view championed in the 1920s by Henry Gleason in his individualistic concept of plant associations. A variety of essentially fortuitous casual associations among species can enhance the fitness of one or both parties. For example, among both terrestrial plants and seaweeds, toxic or otherwise herbivore-resistant species can provide small-scale refuges for the germination and growth of other, more palatable species that would otherwise be eaten. Although both herbivore-resistant and edible species have equal or greater fitness when living alone in appropriate environments, such associational defenses broaden the range of conditions under which the edible species can thrive, often increasing diversity in the immediate vicinity of the well-defended plant.

Among animals, casual associations form when one species enhances food availability or reduces risk of predation or parasitism to benefit the other species. For example, birds foraging in mixed-species flocks can facilitate higher food intake by individual birds as the activities of one species flush out prey or open up tough foods (nuts, vertebrate carcasses) that are then available to others, and can provide predator protection as wary, alert species provide warning calls to alert other birds of the presence of predators. A more specialized association occurs between oxpecker birds and African ungulates: by removing ticks from their hosts, oxpeckers get a steady source of food, while the host gets relief from parasitism. A similar relationship holds among cottonmouth snakes and roosting birds where the presence of snakes protects birds and their chicks from rodent nest predators, like raccoons and rats, and the birds drop scraps of fish and other food to feed the snakes. In these specialized cases, the fitness of both partners increases as a result of this casual association.

More persistent and regular interactions among species can lead to the evolution of obligate associations, often involving adaptations in one or both of the interacting species. At the far end of this gradient of intimacy is symbiosis ("living together")

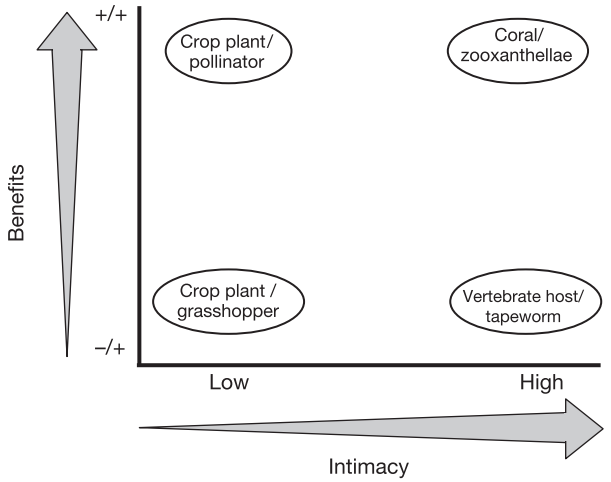

Fig. 1 Schematic illustration of the two axes of association, and the positions of some common associations in this space. The "benefits" axis ranges from parasitism (positive fitness consequences for parasite and negative for host) to mutualism (benefits to both parties). The "intimacy" axis ranges from casual and fleeting to intimate and obligatory for at least one of the associates.

between species that live in close association for most or all of their lives. The most extreme case of symbiosis is the eukaryotic cell itself, which is the product of an ancient association among formerly free-living prokaryotes that have become fully integrated physiologically and genetically and now reproduce as a single organism. Another conspicuous example of an intimate association, noted by Darwin, is the coevolution of tubular flowers (i.e., those that are shaped like trumpets and are typically nectar-rich) with hummingbirds and long-tongued insects. Similarly, reef-building corals have evolved to become dependent on their symbiotic algae; while the corals provide protection and habitat for the algae, the algae provide sugars derived from photosynthesis for their coral hosts. When bleaching events force corals to expel their algae, the corals can die of starvation if not rapidly recolonized their algae symbionts.

Benefits: Parasitism to Mutualism

A second gradient of association involves the symmetry of benefits to the interacting species (Fig. 1). Associations range from parasitism, in which one party benefits at the expense of the other through mutualism, in which both parties benefit. Between these extremes lies commensalism, in which one party benefits while the other is unaffected.

Parasites include microbes, intestinal worms, and invertebrates as well as plant- and animal-feeding insects, which are estimated to make up more than half of all animal species. The most familiar parasites associate closely and permanently with their hosts, and are strongly adapted to maintain their host-dependent life cycles. For instance, castrator barnacles are adapted to shed their hard-shells when they make contact with a crab host and squeeze through chinks in the crab's claw joints before forming tendrils, or roots, that wrap around and leach nutrients from its host's organs. Once the barnacle reaches sufficient size, it alters its host's hormone levels, rendering its host infertile while it produces an egg mast that soon releases larvae into the water column. Thus, all stages of the castrator barnacle's life cycle have evolved to enable this parasite to maintain its obligate association with its host. A similar relationship forms between mistletoe, which are a diverse group of obligate hemiparasites, and the trees they utilize as hosts where the mistletoe root into and then draw water and nutrients from their tree host. Thus, while the mistletoe fitness benefits, the host tree fitness suffers, from this parasitic association. But other parasites have a less intimate association with their hosts. Among the more bizarre such parasites are certain cichlid fish of the African Great Lakes that feed solely on the scales or eyes of other fish, which they obtain by surreptitiously attacking and sucking from the living victim.

Many associations in nature are commensal, benefiting one party with little or no impact on the other. Commensalism commonly involves a larger host species and a much smaller guest species that exploits the host's organic products or structure. Examples include many animals that live on plants or corals, as well as certain microbes that associate with the human gut or skin with no appreciable effect on the host's fitness. Epiphytes, for instance, are a highly diverse group of plants that live opportunistically on the surface of other plants, but do not extract water or nutrients from them. Spatially dominant organisms whose physical structure provides habitat and ameliorates environmental stress, such as trees, kelps, or corals, are referred to as foundation species and support many other plant and animal species that may have little to no reciprocal effect on the foundation species.

Mutualistic associations, like parasitic ones, take a variety of forms, from casual to obligate, and provide a variety of benefits including food, protection, and dispersal. The foraging mutualisms among mixed-species flocks and birds and snakes mentioned above represent the casual end, while the symbiotic associations between plants and their mycorrhizal fungi, certain insect groups and their mycetomes, corals and their algae (zooxanthellae), giant tube-worms of hydrothermal vents and their chemosynthetic bacteria, and the complex microbial ecosystems housed within the gut of ruminant ungulates fall out on the obligate end of the continuum. Among the most familiar mutualisms and those that are perhaps most important for sustaining human societies are those between flowering plants and the insects and other animals that pollinate them. Although not symbiotic due to the mobility

of many pollinators, many plant–pollinator associations are highly specialized and coevolved, and have profound effects on terrestrial ecosystem structure and functioning.

Mutualisms based on protection from enemies are also common, especially in tropical ecosystems where predation pressure is generally stronger than in temperature or artic systems. In coral reefs, for example, certain crabs and shrimp live only within the protective, stony branches of their coral hosts where they feed on the coral's secretions. In return, the crustaceans attack predatory starfish that attempt to eat their coral hosts. Thus, both mutualist partners provide predator protection to the other. A similar mutually beneficial relationship arises between ants and Acacia trees in African savannas browsed by large grazers, including giraffes and elephants. While the ants aggressively attack these grazers to protect their Acacia hosts, the hosts provide housing and carbohydrates to the ants, which create domatia within the tree. In areas where large grazers have been removed due to poaching or experimental exclusions, this mutualism can fall apart however, indicating that cooperation in such partnerships can be highly sensitive to shifts in environmental conditions.

Evolution of Associations

Selection for Association

Theory predicts that mutualistic associations should be most favored under conditions where risk of mortality from abiotic stress or predation is high, or in nutrient-poor environments where the symbiosis provides the host with nutritional benefits. Under such conditions association can provide escape from mortality or starvation that outweighs the costs imposed by competition for resources with the associate. These predictions are generally consistent with evidence from the distribution of mutualistic and commensal associations. For example, predation pressure is generally higher, and nutrient availability is generally lower, in tropical than in temperate marine waters. Accordingly, symbiosis with photosynthetic algae is much more common in tropical corals than in temperate species, and protective commensalisms between corals and sedentary invertebrates is much more common among tropical than temperate shrimp. Protective mutualisms between plants and ants, like those described among Acacia and ants in savannas, also occur primarily in the tropics. In temperate latitudes, mutualistic associations also arise, typically within more physically stressful areas. On cobble beaches characteristic of the shorelines of northeastern North America, for instance, the dominant plant *Spartina alterniflora* stabilizes and shades the cobbles, allowing numerous other plant species to colonize and thrive where they could otherwise not establish due to the heat and mobility of the cobbles.

The Coevolutionary Arms Race

When associations produce fitness benefits and/or costs to the organisms involved, their interactions will generate natural selection on one another, potentially producing evolutionary changes in one or both species. Because parasites reduce host fitness, they impose selection on the host to defend itself. In turn, parasites experience selection to overcome host defenses, which then generates selection for more effective host defenses and so on. This reciprocal selection is termed a coevolutionary arms race. Arms races also occur between predators and their prey as occurs between shell-crushing predatory crabs and snails where the crabs have evolved increasingly powerful and complex claws in response to the snails evolving increasingly thick or spiked shells.

Animals and plants have evolved a wide range of biochemical, behavioral, and life history adaptations that reduce the impacts of enemies. That such defensive features are in fact evolutionary responses to enemy pressure is supported by their geographic distribution. For example, waterfleas (*Daphnia*) from lakes with predatory fish show genetically determined predator avoidance behavior that is not present in conspecifics from fishless lakes. Many seaweeds from the tropics, where herbivore pressure is generally intense, are better defended against grazing than their relatives from more temperate areas. Conversely, selection on parasites to circumvent host defenses is illustrated by parasitic flukes that infest snails in New Zealand lakes. The flukes are better able to infect snails from their own than from other lakes, suggesting that they have adapted to the traits of the local hosts with which they have experience. Such local adaptation between hosts and parasites is common.

Specialization

Specialized associations are surprisingly common among animal species, particularly among parasites that must complete development on a single individual host. In such associations, the host constitutes the entire environment of the parasite. Detailed studies of tropical plant-feeding insect species have demonstrated that more than half are extreme specialists, feeding on only one or a few closely related species of plants. Surveys of coral-reef shrimps symbiotic with sponges yield a similar pattern. Moreover, phylogenetic analyses reveal that association with plants has strongly enhanced the evolutionary diversification of insects. Hence, the tendency of organisms to form specialized interactions with other species has been a major generator of Earth's biological diversity.

Ecology of Associations

Context Dependency

The nature of the relationship between associated species is dynamic in both ecological and evolutionary time, and subject to shift with changing conditions. The fluidity of transition between parasitism, commensalism, and mutualism at evolutionary time scales is hinted at by fungi in the family Clavicipitaceae, several of which grow within the tissues of grasses. Some species are parasites, producing diseases such as ergot in rye. Other species are commensal, with little appreciable impact on the grass host, and others still are mutualistic, producing toxic alkaloids that protect their grass hosts from grazing. Similarly, among yucca moths, most species form obligate pollination mutualisms with their yucca hosts, but several species have become parasitic; laying their eggs in yucca fruits they have not pollinated and thereby exacting a heavy cost on the host. Both the Clavicipitaceae fungi and yucca moth examples highlight that over evolutionary time scales associations can diverge in ways that can significantly affect the distribution and fitness of both associated species.

On shorter time scales and at smaller, landscape-scales, the relationship between associated species can also change in response to natural and anthropogenic shifts in environmental conditions. Global warming in particular is now recognized as an important mediator of the strength and prevalence of associations among microbial parasites and their hosts. An alarming example of this trend is the prolonged, and widespread, outbreak of a chytrid fungus, parasitic in amphibians, in Central America since the late 1980s. The epidemic, which appears responsible for the extinction of over 70 species of frogs and toads in the region, has recently been linked to improved conditions for the fungus resulting from warming temperatures. Additionally, during increasingly frequent and severe droughts, the relationship between ribbed mussels that form dense aggregations in salt marshes and cordgrass that dominants marsh landscapes shifts from a facilitative mutualism where the cordgrass benefits from, but does not depend on the mussels, to an obligate mutualism. This is because the mussel enhance water storage and reduce soil salinity stress to protect the vegetation from otherwise lethal soil conditions during the drought events.

Importantly, the nature of associations between species is also dynamically changing as a result of sifts in species' distributions due local or total species extinctions or introductions. For example, overfishing of predatory fish and crabs in New England salt marshes has opened the door for European green crabs to invade these marshes, a generalist predator which is unexpectedly benefiting marsh cordgrass by suppressing herbivore densities. Rebounding sea otter populations in coastal California is similarly reestablishing positive interactions between the sea otters and the dominant seagrass in the region as a result of the sea otters strongly suppressing previously abundant herbivore populations. Thus, associations should be considered dynamic and sensitive to changes in environmental conditions at ecological and evolutionary time scales.

Community and Ecosystem Consequences

In general, mutualistic associations expand the range of conditions beyond those in which either species could live alone, whereas parasitism tends to restrict the range of conditions under which the host can live. Consequently, associations have strongly influenced the distribution and abundance of organisms, and indeed the basic structure of ecosystems. Mutualistic associations have allowed associated species to dominate their environments, and to colonize new environments that would be unsuitable for either species alone. As a result, mutualistic and parasitic associations profoundly influence community structure, or the composition of species in an ecosystem, and the ways in which these species then control nutrient, water, and energy flows.

Perhaps most dramatically, the evolutionary diversification and dominance of terrestrial ecosystems by flowering plants has been aided by several such associations. Insects and other animals pollinate flowers much more efficiently than does the wind, and the specificity of their behavior has fostered reproductive isolation and diversification of plant species. Once pollinated, many plants produce fruits or nuts whose movement through the environment is commonly aided by a diverse collection of mammal and invertebrate dispersers that play a secondary role in mediating patterns in plant distribution. Concurrently, the roots of most terrestrial plants are intimately associated with mutualistic fungi (mycorrhizae) that can enhance their uptake of nutrients and water from the soil. One of the most ecologically important mutualisms between plants and microbes involves the fixation of organic nitrogen by bacteria (rhizobia) in the roots of legumes. By introducing new usable nitrogen into soils, this association is important in facilitating plant succession, mediating community organization, and providing a source of limiting nitrogen to grazing livestock and other animals. Reef-building corals similarly thrive in extremely nutrient-poor ocean waters, and form the foundation of the most diverse marine ecosystems on Earth, as a result of the tight recycling of nutrients by their endosymbiotic algae.

Mutualisms have also promoted dominance of certain mobile consumers. Leafcutter ants are the major herbivores of the New World tropics because their elaborate farming of fungi on harvested foliage allows them to use virtually any plant species as nourishment, in stark contrast to most herbivorous insects, which use one or a few closely related plant species as food. In lower termites, symbiotic bacteria and protists within the gut produce cellulases that allow them to feed on one of the poorest food sources in the world: wood. Similarly, the mutualistic gut flora of ruminant grazers such as wildebeest, bison, and many domestic livestock contribute to their high densities despite relatively poor nutritional quality of their forage. These densities in turn cause large grazing vertebrates to play a key role in determining the structure and functioning of their ecosystems.

Human welfare is critically dependent on associations with certain beneficial organisms, and is threatened by its association with others. Over the last few thousand years, various crop plants, livestock, and household animals have been domesticated as humans selectively bred them for characteristics we consider desirable. The food security and physical power provided by our association with these domestic organisms has been central to making humans the most abundant and powerful species in Earth's history. Remarkably, similar agricultural associations have also evolved in several groups of insects, helping them dominate their environments.

Body Size, Energetics, and Evolution

FA Smith, University of New Mexico, Albuquerque, NM, USA

Introduction

Living things vary tremendously in their characteristic body size. The range of mass spans more than 21 orders of magnitude, from the smallest known organisms (mycoplasm) at $\sim 10^{-13}$ g to the largest (blue whale) at 10^{8} g (180–200 t). Even insects, a group typically thought of as relatively diminutive, have body sizes ranging over more than three orders of magnitude (**Table 1**). This includes feather-winged beetles, which readily could move through the eye of a needle, and the Goliath beetle from Africa, which is bigger than a typical dinner plate. The body mass span is extended considerably if one considers extinct insect species such as Meganeura with wingspans of ~ 70 cm. For centuries, biologists have been interested in what underlies this incredible diversity; why organisms evolve a certain size; and what the ecological and evolutionary consequences and tradeoffs are of each.

Body Size Matters

How animals interact with their environment is strongly influenced by their body size: the relative importance of forces like the surface tension of water, and the influence of gravity and temperature differ greatly depending on the absolute size of organisms. A cat cannot walk on water or up a wall, but some insects or lizards can. Likewise, both tree trunks and the limbs of terrestrial animals must be strong enough to provide support against the force of gravity but not so large that they are crushed under their own weight, or interfere with efficient functioning (transport of water and nutrients in the case of a tree, locomotion in the case of the animal). For a quadrupedal animal, ~ 140 t is the estimated maximum mass before the width of the limbs would have to be so large as to support the weight of the animal without interfering the movement; this value is close to that estimated for the sauropod *Argentinosaursus*, the largest known terrestrial animal (~ 100 t). Aquatic organisms face different constraints. Although the influence of gravity is ameliorated, allowing the evolution of much larger size (~ 200 t in the case of the blue whale), water has ~ 24 times the heat conductance of air (0.58 vs. 0.024 $\mathrm{W\,m^{-1}\,K^{-1}}$). In practical terms, this means that endotherms (animals maintaining a constant body temperature) must expend considerably more energy maintaining homeostasis. This likely limits the minimum body size; the smallest truly aquatic endotherms are ~ 100 kg, a mass that reflects selection on the ability of neonates to successfully thermoregulate. Because neonate mass is tightly correlated with maternal mass, an adult mass less than 100 kg results in offspring too small to successfully thermoregulate in water.

Biological Scaling

Not only do the structure of organisms and their dimensions change in a regular way with size, but many fundamental physiological, ecological, and evolutionary factors also scale in predictable ways. If the relationship is linear or geometric with body mass with a slope of ~ 1, the scaling is termed isometric (iso = same, metric = measure); the gut capacity of animals is an example of a trait that scales isometrically with body mass. Many relationships scale nonlinearly with body mass, with slopes less than or greater than 1; these are known as allometric relationships (allos = different, metron = measure; **Fig. 1**), a term coined by Julian Huxley and Georges Teissier in 1936. Allometric relationships were first noted in the late 1890s by Eugene Dubois and Louis Lapicque working independently on the relationship between brain and body mass, and have been extensively explored in paleontology, physiological ecology, and other disciplines.

Among traits that scale allometrically are many fundamental physiological processes such as metabolic rate, fecundity, home range, and cost of locomotion. Allometric or isometric relationships with body size are often formulated as power functions:

$$Y = aM^{b}$$

where Y is the variable of interest, M is body size, b is the slope of the relationship (representing how the variable of interest changes with differences in body size), and represents a taxon-specific constant, sometimes referred to as the normalization or proportionality constant (the intercept at unity body mass when $M = 1$). Power laws are often logarithmically transformed such that

$$\log \mathrm{Y} = \log a + b\log M$$

because the exponent becomes the slope of a straight line, facilitating computations and comparisons. The intercept often varies in a regular way among groups; marsupials, for example, have a metabolic rate 30% lower than other mammals, which is reflected in the value of their normalization constant. These body size relationships allow comparisons within and among species at different taxonomic levels and also allow reasonably accurate predictions of many biological rates and times. Often what appear to be

Table 1 Examples of the range of body size seen in various taxa

Taxa	*Smallest*		*Largest*		*Orders of magnitude*
Mammal	*Suncus etruscus* (pygmy shrew)	~1.8 g	*Balaenoptera musculus* (blue whale)	~180 t	8 (mass)
Bird	*Mellisuga helenae* (Bee hummingbird)	6.2 cm, ~1.8 g	*Struthio camelus* (North African ostrich)	~2.75 m, ~156 kg	2 (length)
Tree	*Salix herbacea* (dwarf willow)	1–6 cm tall	*Sequoiadendron giganteum* (giant sequoia)	83.8 mtall	3 (length)
Fish	*Paedocypris progenetica*	~7.9 mm long	*Rhincodon typus* (whale shark)	12.6 m long	4 (length)
Frog	*Eleutherodactylus iberia*	~9.8 mm	*Conraua goliath* (Goliath frog)	~32 cm, 3.3 kg	~1–2 (length)
Spider	*Patu marplesi* (Samoan moss spider)	0.3 mm	*Theraphosa blondi* (Goliath bird-eating spider)	28 cm170 g	4 (length)
Insect	*Nanosella fungi* (Feather-winged beetle)	0.25 mm	*Goliathus goliatus* (Goliath beetle)	>110 mm	3 (length)

For roughly cylindrical organisms, mass scales as the cube of length, so a difference of one order of magnitude in length equates to a three-order difference in mass.

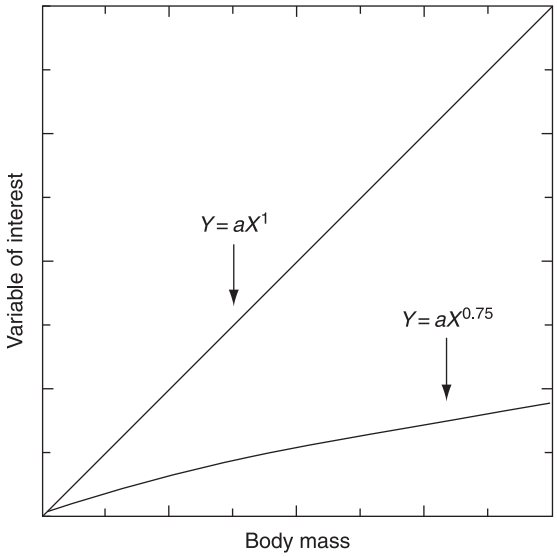

Fig. 1 Difference between isometric and allometric scaling in arithmetic space. Such relationships are typically logarithmically transformed to obtain a linear slope for ease in computation and take the form $\log Y = \log a + b \log X$.

significant differences among organisms are a simple consequence of scaling effects. True deviations from predicted values can provide important insights into evolutionary history and adaptation. Considerable research has gone into formulating and comparing allometric relationships for a whole variety of traits and taxa.

Body Size, Energetics, and Food Acquisition

All organisms require energy for the essential activities of survival, reproduction, and growth. Consequently, knowledge of energetics is central to an understanding of the selective forces that shape an organism's physiology, natural history, and evolution. The environment imposes intense selective pressures on organisms over both short and long time intervals. The occupation of novel environments, or abrupt environmental alterations, for example, can radically alter the pattern of energetic allocation between the essential activities of survival, reproduction, and growth.

The rate at which energy (E) is acquired, transformed, and used is known as the metabolic rate (MR); it drives the rate of all biological activities of and within the organism. Biologists often measure metabolic rate in calories (cal; defined as the energy required to heat 1 g water by 1 °C) or joules (1 cal = 4.1840 J). More fundamentally, the metabolic rates of organisms reflect their energetic demands or footprint on the environment. Strikingly, the metabolic rate of mammals scales consistently with body size with an exponent of 3/4 (**Fig. 2**); this is often referred to as the 'mouse to elephant curve'. The 3/4 scaling relationship between metabolic rate and body size was first proposed by Max Kleiber in 1932 and has been the object of intense debate and study. Much of the controversy centered on whether the relationship was related to surface area, which would result in an exponent of 2/3, or whether it reflected other constraints. Several comprehensive studies have firmly demonstrated a 3/4 scaling exponent and extend

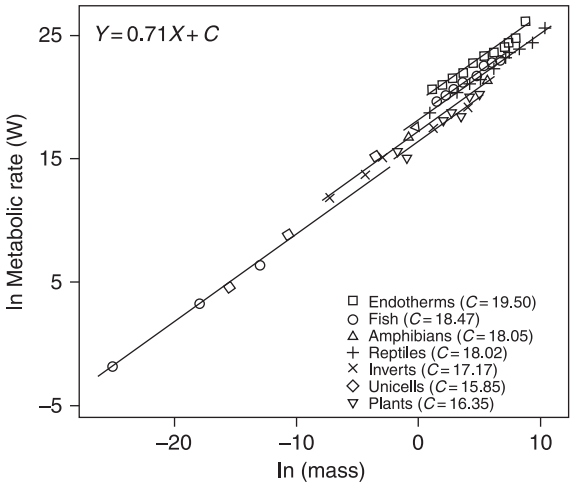

Fig. 2 The logarithmic relationship between temperature-corrected metabolic rate (in watts) and body mass (in grams) for various taxa, ranging from unicellular organisms, invertebrates, and different groups of vertebrates, to plants. The overall slope provides an estimate of the allometric exponent; the intercepts are the normalization or proportionality constants for each group (see text). Differences in the intercepts reflect taxon-specific biology. The observed slope of 0.71 ± 2 is close to the predicted value of 3/4. Drawn with permission from Brown JH, Gillooly JF, Allen AP, Savage VM, and West GB (2004) Toward a metabolic theory of ecology. *Ecology* 85: 1771–1789.

the relationship to organisms as diverse as microbes, invertebrates, to the largest mammals and trees. Over 90% of the variation in metabolic rate across species can be explained by body mass, with the residual variation reflecting unique evolutionary or biological adaptations specific to particular groups. Although still somewhat controversial, recent studies convincingly demonstrate that the underlying constraints are a result of the design properties of the vascular system. Specifically, the mechanism involves limitations on rates of uptake of resources across surfaces and rates of distribution across fractal-like branching networks within organisms.

The ecological and evolutionary consequences of allometric scaling of metabolism are profound. In practical terms it means that each gram of an animal the size of a mouse or shrew uses 20 times more energy than a gram of elephant or giraffe. Thus, food acquisition, processing, and passage rates are typically much more rapid for small animals (**Fig. 3**), and the type of digestive strategy that can be utilized is heavily influenced by body size. True herbivory – that is, the ability to obtain energy from plant structural materials as opposed to relying largely on the easily digestible cell contents – is largely controlled by residence time in the gut or fermentation chamber. If passage rates are rapid as they are for small animals, insufficient time may elapse for the microbes to ferment plant materials and consequently limited energy can be obtained from this digestive strategy. Some small herbivores have evolved specialized adaptations to get around these constraints. These include a highly convoluted cecum and microvilli (increasing surface area), or shunts for selectively retaining materials to effectively increase residence time. While such adaptations may allow more efficient use of plant structural materials, the consequence is that small herbivores are often energetically limited, which in turn influences other essential activities such as reproduction. Most small animals are much more selective and forage on higher quality resources.

The Influence of Temperature

Temperature plays a crucial role in energetics. The total energy required by an animal is not only a function of size, but is also dependent on whether it maintains a constant body temperature, that is, whether it is endo- (endo = inside) or ectothermic (ecto = outside, thermic = to heat). Endotherms maintain their body temperature within a narrow range by means of heat generated by their metabolism. Maintaining homeothermy (a constant body temperature) consumes ~90% of the energy intake of the animal, but allows activity largely independent of environmental temperatures. Only birds and mammals have adopted this evolutionary pathway – mammals typically maintain core temperatures of ~37–40 °C, while birds maintain slightly higher core temperatures of ~39–43 °C. Ectotherms, such as reptiles, fish, and other taxa, do not utilize metabolic energy to maintain a constant body temperature. Consequently, their absolute energy requirements are considerably less. However, ectotherms are generally incapable of intense activity over sustained periods of unfavorable environmental temperatures. Moreover, the metabolic rate of ectotherms is influenced by ambient environmental temperatures. Some ectotherms behaviorally thermoregulate by shifting among different microclimates to maintain a more consistent core temperature. The thermal inertia resulting from huge body masses achieved by sauropods in the Mesozoic probably meant that they were, for all practical purposes, homoeothermic. The implications of endo- versus ectothermy go beyond differing metabolic requirements. In general, ectotherms grow slower and mature at a larger body size in colder environments. Fecundity is related to adult body size, with larger individuals having larger clutches.

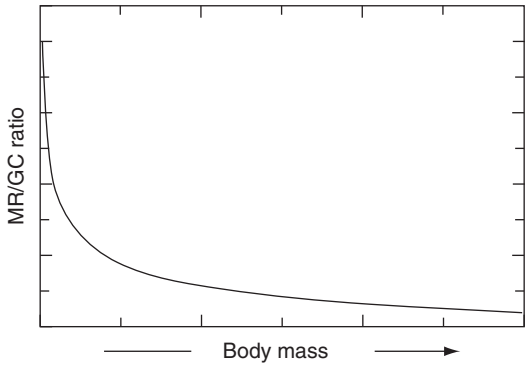

Fig. 3 While metabolic rate scales allometrically with mass to the 3/4 power, gut capacity is isometric with body mass. Thus, the ratio of metabolic rate to gut capacity scales negatively with mass to the 1/4 (e.g., $M^{0.75}/M^{1} = M^{-0.25}$). This fundamental constraint mandates higher-quality food and/or high passage rates for small animals to meet their higher per gram metabolic requirements. Food that takes longer to process (i.e., plant structural materials such as leaves) becomes progressively more difficult to handle and digest. Consequently, the smallest vertebrates are insectivores, subsisting on a ubiquitous and high-energy food source that is relatively easy to process.

It is well known that rate of biological activity rises exponentially with temperature. Mechanistically, this is because the increase in the kinetic energy of molecules results in substrates colliding with active sites more frequently. Physiologists express the relationship between metabolic rate and temperature as the Q_{10}, the rate increase for each 10^0 rise in temperature. A Q_{10} of 2, for example, means that the metabolic rate doubles for each 10^0 rise.

Recently, investigators have incorporated the important influence of temperature on metabolic rate (MR) by adding the Boltzmann factor to the allometric equation relating it to body size. In this formulation, the relationship is stated:

$$\mathrm{MR} = M^{3/4} e^{-E/kT}$$

where E represents the activation energy, k is the Boltzmann's constant, and T is the absolute temperature in degrees kelvin. Similarly, the rates of many other fundamental life-history traits demonstrate temperature dependence. Thus, the addition of the Boltzmann factor into allometric relationships allows comparisons across the entire range of living organisms, regardless of thermal regulation regime, life history, or size (**Fig. 2**). The robust relationships found suggest that the combined effects of body size, temperature, and resource supply constrain metabolic and other fundamental biological rates for all taxa.

Factors Influencing Body Size over Space and Evolutionary Time

Regular patterns of morphological variation with abiotic factors (especially temperature) have been observed repeatedly over time and space. These 'ecogeographic' gradients often involve body size, although coloration or dimensions can be influenced as well. The existence of ecogeographic patterns across space demonstrates the ability of species to adapt to fluctuating abiotic conditions, as well as underscoring the strong selection imposed on organisms by their environment.

Bergmann's Rule

Bergmann's rule is the principle that within a broadly distributed genus, species of larger size are found in colder environments, and species of smaller size are found in warmer areas. Although originally formulated in terms of species within a genus, it is often recast in terms of populations within a species. The rule (named after the German physiologist, Carl Bergmann) appears to be valid for the majority (62–83%) of vertebrates (**Fig. 4**). This includes endotherms (e.g., birds and mammals) as well as numerous species of ectotherms (bacteria, protests, plants, insects, marine organisms, and turtles). The most notable exceptions include lizards and snakes. There may be a tendency for larger-bodied animals to conform to the rule more closely than smaller bodied animals, perhaps reflecting a reduced ability to avoid stressful environments by burrowing or other means. In addition to being a general pattern across space, Bergmann's rule has been observed in populations over historical and evolutionary time when exposed to varying thermal regimes (**Fig. 5**).

Environmental temperature directly influences the energetic relationships and physiology of animals. Consequently, Bergmann's rule is often interpreted as a direct response to temperature. As organisms increase in body size, surface area increases more slowly than does volume (surface area $\propto$ length^2, vs. volume $\propto$ length^3), such that SA scales as $\sim V^{2/3}$. Because heat loss is proportional to surface area, this means that larger animals lose less heat per unit mass than smaller animals and are at an advantage under cold environmental conditions. Conversely, smaller animals have a greater surface to volume ratio and are more capable of dissipating heat under thermally stressful conditions. Numerous other mechanisms have also been postulated to

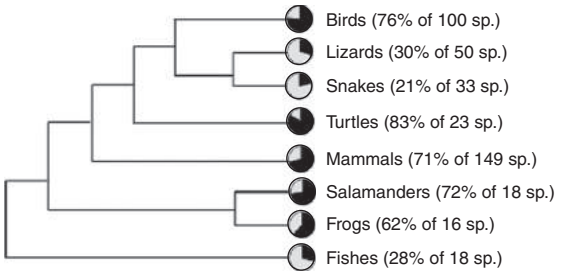

Fig. 4 Percent of various vertebrate groups that conform to Bergmann's rule. Although endothermic vertebrates demonstrate a strong body size-cline with temperature, ectotherms are much more variable in their adherence to the rule. Fig. 5 Third-order regression equations fitted to data for woodrat body size and environmental temperature over the Late Quaternary illustrating adherence to Bergmann's rule over evolutionary time. (a) Mean body size of woodrats from various locations across the southwestern United States plotted as a function of radiocarbon date and expressed relative to the size of the animals at the same sites today. (b) Simulated July temperature anomalies from the National Center for Atmospheric Research Climate Circulation Model (NCAR-CCMO) expressed as deviations from modern temperature. (c) Mean annual temperature as estimated from deuterium isotope ratios measured in fossil leaves. All regression equations were constrained to yield contemporary values (as indicated by the dotted line in each panel) at 0 years BP. Drawn with permission from Smith FA, Betancourt JL, and Brown JH (1995) Evolution of body size in the woodrat over the past 25 000 years of climate change. *Science* 270: 2012–2014.

explain the size-cline, including productivity gradients, selection on life-history characteristics, development rates, and other factors related to thermal characteristics of the environment. Although the validity of the rule is generally accepted, no general consensus has yet been reached about the underlying mechanism(s) generating the gradient in size.

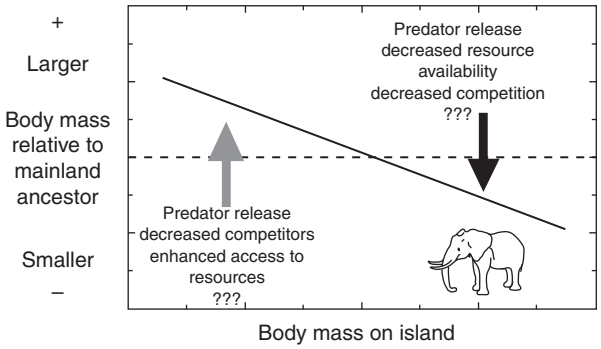

Fig. 6 Schematic of body size changes in insular habitats leading to dwarfing or gigantism. Some of the selective forces postulated to be important factors in insular habitats are indicated; these may or not apply (and depending on the taxa may select for or against larger body size). These are not meant to be inclusive list. The magnitude of evolutionary shifts is known to be dependent on the size of the island and on the degree of isolation.

Island Rule

The island rule, or Foster's rule, is the general principle that larger vertebrates isolated on islands tend to become smaller, and small ones tend to become larger. It was originally proposed by J. Bristol Foster in 1964 in an analysis of islands of the coast of western North America and Europe. Over the past few decades, considerable research has gone into establishing the fundamental patterns and proposing a variety of underlying casual mechanisms. The island rule has been amply demonstrated for many groups of mammals and reptiles, although whether mammalian carnivores conform to this pattern is still unclear. The fossil record is replete with examples of both gigantism and dwarfism on islands: during the Pleistocene the Mediterranean islands contained numerous pygmy species of elephants, rhinos, deer, as well as giant rabbits, shrews, and mice. Pygmy mammoths occupied the Channel Islands off the California coast and giant hutias ranged on islands in West Indies, with one species reaching masses of 50–200 kg. Giant birds related to the pigeon were found on Fiji and the Mascarenes, and giant tortoises ranged on numerous islands in the Indian Ocean. Many of these large animals have subsequently gone extinct, in large part due to human exploitation.

Classical explanations for the island rule focus on energetics. Island communities are typically relatively depauperate compared to mainlands. The reduced species diversity often results in few or fewer competitors or predators. With the removal of constraints imposed by the diverse mainland suite of predators and competitors, organisms evolve to a size that increases the net energy that they can obtain in the insular habitat. For large animals, where large size no longer ameliorates predation pressure, this may result in dwarfing of body size. For small animals gigantism may be favored because of increased ecological or physiological access to food resources (Fig. 6). The degree of dwarfing or gigantism may be related to the reduction in overall species diversity as well as resource availability. Note that the distinctive selective pressures on islands have also resulted in other major evolutionary transformations, such as the tendency for a loss of flight in birds, and reductions in the dispersal ability of plants.

Cope's Rule

Cope's rule is an avowed tendency for lineages of organisms to become larger over evolutionary or geologic time. Named for Edward Drinker Cope, a prominent paleontologist who first proposed it in 1896, it remains unclear whether it is a valid phenomenon or an artifact of sampling or investigator biases. Studies of several vertebrate groups such as mammals and dinosaurs appear to have generally upheld the tendency for descendent lineages to be larger than ancestral ones. Other studies, including those of marine organisms have not. Moreover, no clear underlying causal mechanism has yet been accepted to explain why an evolutionary trend toward larger body size should be favored over geologic time. Larger body size can increase the fitness of an organism if it results in a net increase in the ability to acquire resources and energy from the environment. Several traits such as foraging ability, predator avoidance, reproductive success, and thermal efficiency may be positively related to larger size. Although the fitness of the individual may increase with size, there are considerable disadvantages to large body size at the population, species, or clade level. Significant among these is that longer generation times and lowered population densities concomitant with large size might render organisms more susceptible to environmental perturbations and/or extinction events.

Patterns at Higher Taxonomic Levels

Because body size so strongly constrains the energetic demands of organisms and their interaction with the environment, it is not surprising that it also influences space and home range requirements, population densities, and other important population and community level characteristics. The statistical study of broad, consistent patterns between organisms and their environment is called macroecology, a term coined by James Brown and Brian Maurer in 1989. For example, the population density of mammals scales negatively with body mass, with about the same exponent, as does the positive scaling of metabolic rate. The coupling of these relationships results in a well-known macroecological pattern dubbed the 'energetic equivalence rule', which suggests that

the energy used by a local population of a species in a community is largely independent of its body size. Similar allometric relationships have been observed between abundance and body size for other groups including algae, terrestrial plants, and marine phytoplankton. Evidence from recent research suggests that there may well be general mechanisms that link the metabolism of individuals to higher-order emergent properties of communities and ecosystems. Thus, the study of body size is likely to continue to be a fruitful area of research in years to come.

Clines

EE Sotka, College of Charleston, Charleston, SC, USA

A cline is a gradient of a phenotypic or genetic character within a single species. The geographic distances across which characters shift can range from meters to thousands of kilometers. Clines are especially frequent within geographically widespread species. There is strong evidence that natural selection plays a central role in maintaining clines, in part because much of the spatial variation in a given trait reflects shifts in the biotic and abiotic environments. Clines are known as `taxonomist's nightmares and evolutionist's delights' because their evolution informs several contentious issues in ecology and evolution, including the degree and nature of natural selection, the process of dispersal and gene flow, historical demography, and speciation. Below, we briefly describe a few examples of clinal variation, outline the theoretical frameworks that underlie modern analyses of genetic clines, and describe the role of clines in understanding parapatric speciation.

Cline Examples

Though clines were formally defined as recently as 1938 by Julian Huxley, the gradual change of characters within species has been observed by naturalists for centuries. Consequently, the number of published examples of clinal variation is staggering and include clines in morphology, physiology, behavior, and genetic loci. Some morphological clines are so common as to be cited as a `rule' of nature. The oldest and most contentious of these clines is Bergmann's rule, which posits that body size increases with latitude. The pattern is widespread within and among species of mammals, birds, and some insect groups (e.g., Drosophilids; **Fig. 1**). It appears likely that selection must act on the latitudinal cline in body size because the pattern has evolved within multiple lineages of organisms and on several continents. Further, some of these clines develop over extremely short periods of time. For example, the invasive populations of the fruit fly *Drosophila suboscura* in North America has evolved a latitudinal cline similar to that seen in native Europe in less than 20 years (**Fig. 1**). As with many published clinal patterns, however, the selective mechanisms underlying Bergmann's rule are unclear. Air temperature sharply declines with latitude and represents the most obvious environmental factor operating on body size, but the exact manner in which temperature drives body size evolution remains unsolved. Other common morphological clines include Allen's rule (populations of homeotherms in colder climates have shorter appendages) and Gloger's rule (populations in more arid environments are paler in color). These and other clines are often discordant. For example, within 100 years of invading North America, house sparrows (*Passer domesticus*) evolved a north–south cline in body size (Bergmann's rule) and east–west cline in coloration (Gloger's rule).

Physiological traits also reveal clinal variation. For example, subpopulations of the vascular plant *Anthoxanthum odoratum* can grow on soil containing extremely high concentrations of zinc from mine waste. These plants are highly localized to an area less than 500 m across. When plants are tested in the laboratory, physiological tolerance for zinc of plants is positively related to the level of zinc in the soil. This pattern indicates selection for zinc-tolerance on contaminated soil and a cost to maintaining zinc-tolerance on normal soils. Other organisms reveal clinal variation in the physiological responses to temperature, salinity, and day length among other environmental factors. The best examples of clines in behavioral traits occur within hybrid zones between differentiated populations and species, where mating behavior for each of the parental types changes over space.

Clines at genetic loci (i.e., allozymes, microsatellites, protein-coding loci) are commonly under direct selection or tightly coupled to loci under selection. For example, the LdH of the killifish *Fundulus heteroclitus* shifts with latitude along the east coast of the United States. One allozyme is more efficient in warmer temperatures, while another is more efficient at cooler temperatures. This cline is also seen in humans across European and Middle Eastern populations. However, some clines may occur at loci that are neither under direct nor indirect selection. In theory, these neutral clines must be the consequence of secondary contact (i.e., historically separated populations are reconnected) that are not at equilibrium. At equilibrium, neutral clines should have collapsed because of the ongoing introgression of alleles due to gene flow.

Much of our understanding of single-species clines comes from hybrid zones between two different species because the theory of clines between and within species is broadly similar. One of the first applications of cline theory was by Szymura and Barton, who studied the hybrid zone between two *Bombina* toads in Poland (**Fig. 2**). There is striking concordance between morphological and allozyme clines across the same geographic space in this system. This pattern suggests that the species evolved in allopatry and their alleles are currently introgressing into the cline. The high level of linkage disequilibrium – the nonrandom gametic association of alleles between two or more loci – also suggests that strong selection helps to maintain these clines in the face of ongoing gene flow.

The Evolution of Clines at Equilibrium

There are at least five forces that affect the form of a cline: the genetics of the character, genetic drift, population density, the magnitude, direction and type of selection, and the magnitude and direction of gene flow. Arguably, the two most influential of

 doi:10.1016/B978-0-444-63768-0.00469-8

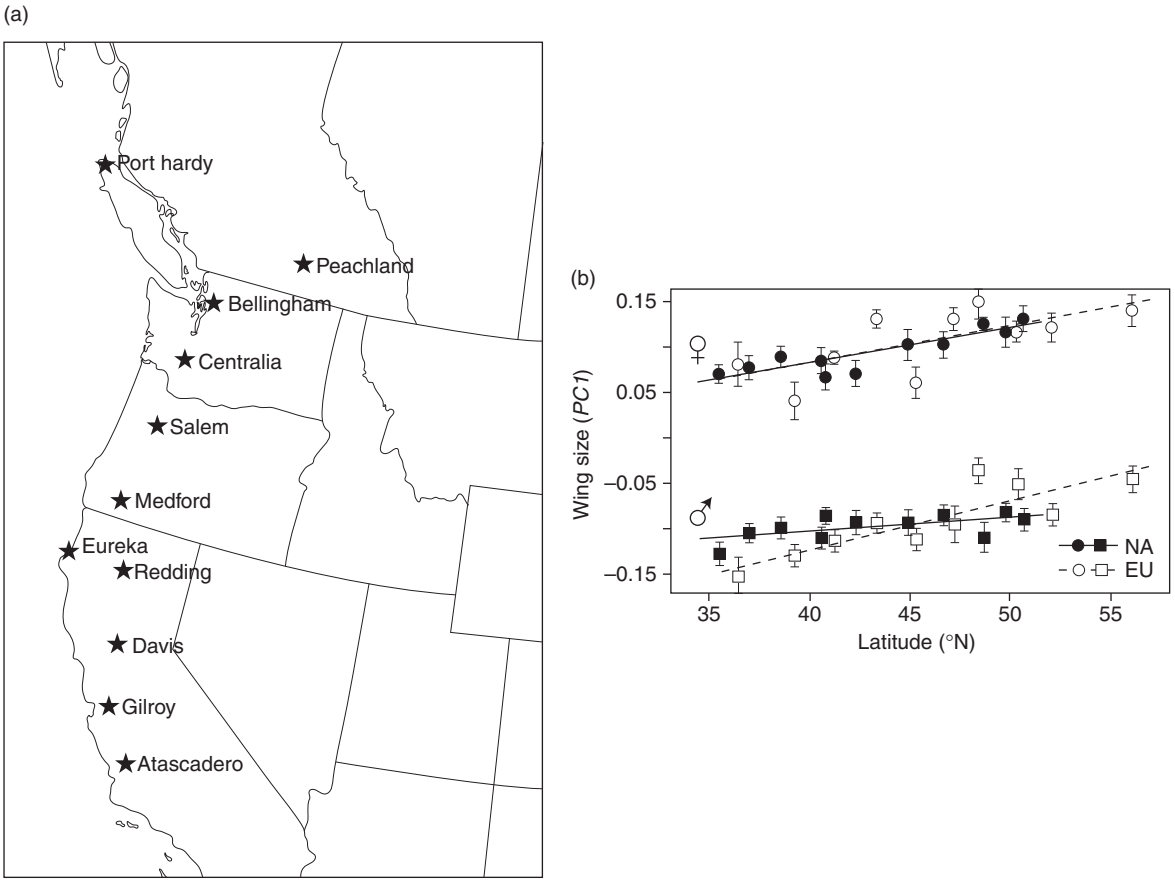

Fig. 1 *Drosophila* wing size cline in North America and Europe, as a proxy for insect body size. In less than 20 years, a wing size cline for North American females (see map) has evolved that is statistically indistinguishable from that in Europe (upper lines). Males, however, are different (lower lines). Whereas in Europe, the slope for males and females are similar, in North America, the slope of the male cline is very shallow. The error bars indicate ± 1 standard error. Figures taken from Gilchrist GW, Huey RB, and Serra L (2001) Rapid evolution of wing size clines in *Drosophila subobscura*. *Genetica* 112–113: 273–286.

these forces are selection and gene flow. At equilibrium, the width of a cline largely represents a balance between the diversifying effects of selection and the homogenizing effects of dispersal (**Fig. 3**). When selection (s) represents the difference in fitness between genotypes at the center of the cline, and σ is the standard deviation of the distance from parents to offspring along a linear gradient (which is broadly proportional to the width of the dispersal cloud around parents and is linearly related to the distance that an offspring moves on average), then the width of the cline at equilibrium is proportional to $\sigma s^{-1/2}$. Thus, narrow clines in highly dispersive organisms will be maintained only when there are high levels of selection, while narrow clines in poorly dispersed organisms can be maintained by weaker selection. The analytical power of clines is that if the magnitude of selection were known, this could be used along with the width of a cline to estimate dispersal. Conversely, if the magnitude of dispersal were estimated, this could be used to infer selection. The balance between selection and dispersal at the center of the cline is

$$w^2 = \frac{K\sigma^2}{s_e} \qquad [1]$$

where w is the cline width, s_e is the `effective' selection coefficient, and $K$ is a multiplier that depends on the type of selection. Strict application of this equation requires assumptions be met that might be rare in natural settings, including Gaussian dispersal, weak selection, and genetic equilibrium. The `effective' selection coefficient acting on the clinal locus includes direct selection on the locus that displays clinal variation in addition to the cumulative levels of indirect selection on linked loci. The multiplier K varies from about 3 in the case of exogenous selection across an ecotone to 4 in the case of heterozygote disadvantage at the center of a cline. Frequency-dependent selection against rare genotypes can increase K to 8–12, because frequency-dependent selection is effectively weaker than heterozygote disadvantage. Because cline width is proportional to the square root of K, different types of selection give cline widths that are similar to within about a factor of 2. In general, however, there are substantial deviations from the theoretical expectation when any type of selection is strong ($s > 0.2$).

Estimation of the clinal width is relatively straightforward. Traditionally, cline width has been defined as the geographic distance between populations that contain 10% or 20% and 80% or 90% of the parental gene frequencies, but in the theory of eqn

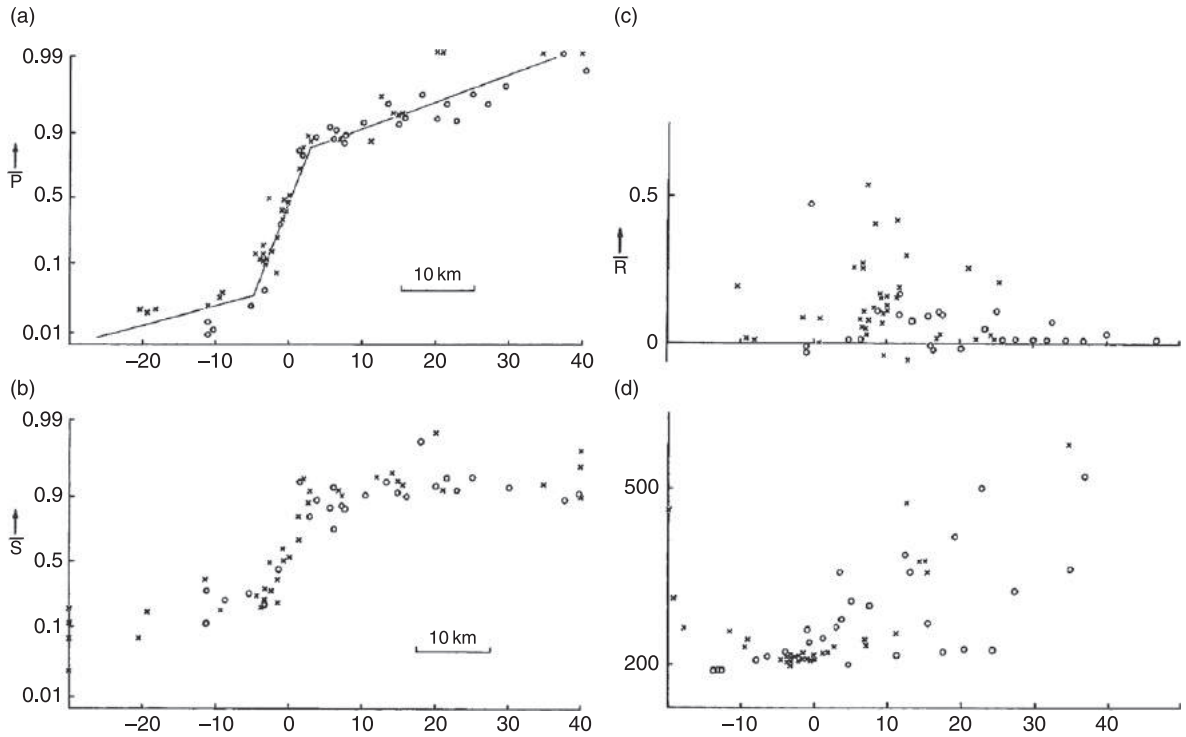

Fig. 2 The hybrid zone between two *Bombina* toad species in Poland across approximately 10 km. (a) Frequencies of *B. variegata* allozymes averaged across all loci. (b) Frequencies of seven morphological characters. (c) Standardized linkage disequilibrium, *R*, averaged across all pairs of loci. There is concordance of morphological and allozyme characters and the highest values of linkage disequilibrium within the hybrid zone. From Szymura JM and Barton NH (1991) The genetic structure of the hybrid zone between the Fire-bellied toads, *Bombina bombina* and *B. Variegata*: comparisons between transects and between loci. *Evolution* 42: 237–261.

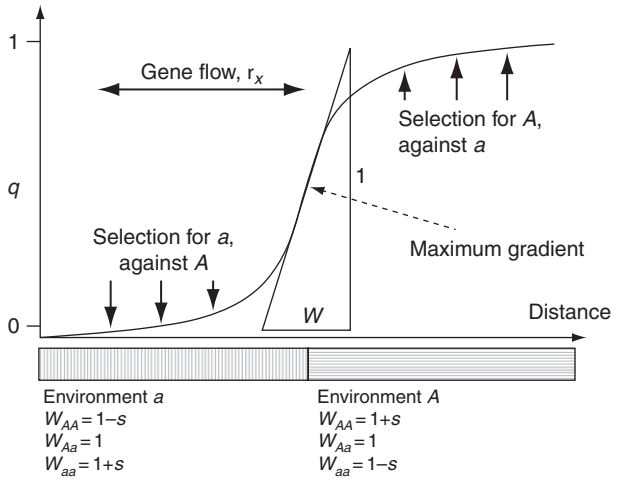

Fig. 3 Selection in continuous populations. Selection, *s*, in a continuous population may favor allele *a* on the left of the diagram, and allele *A* on the right. At equilibrium, the gene frequencies will form a sigmoid cline over the boundary between gene flow and selection (σ_x/s). The case of different environments is shown here; however, similar clines are formed in the case of intrinsic or frequency-dependent selection, for example, in contact zones between races differing in an underdominant chromosomal rearrangement, or in warning color pattern. From Mallet J (2001) Gene flow. In: Woiwood IP, Reynolds DR, and Thomas CD (eds.) *Insect Movement: Mechanisms and Consequences,* pp. 337–360. New York: CABI Publishing.

[1], cline width is the inverse of the maximum slope of the cline. An estimate of width may assume that allele frequencies vary between 0.0 and 1.0 along the cline, or alternatively, if the populations are not fixed on either side, cline width $w = \Delta p/\text{slope}$, where Δp is the change in gene frequencies among parental populations at the ends of the cline and slope is the slope at the center of the cline.

Using clines to estimate selection

The consequence of this equilibrial relationship between cline width, selection, and average dispersal distance is that evolutionary ecologists can utilize clinal theory to disentangle the relative strengths of selection and dispersal. For example, the strength of selection acting on loci within a cline of known width can be inferred using formula [1] when empirical estimates of dispersal are generated from direct censuses. However, selection estimates are probably far lower than the actual levels. This is largely because direct methods of measuring dispersal regularly underestimate the frequency of long-distance dispersal.

Selection operates either because hybrids of the parental lines are generally less fit, or alternatively, parents or hybrids may be less fit in non-native environments. Those different modes of selection have been called endogenous and exogenous selection, respectively, and they lead to similar consequences when clines occur between differentially adapted species or populations. Most commonly, clines are the result of some mix of both modes of selection. The scenario by which hybrid zones are maintained from selection favoring hybrids within a narrow zone of intermediate habitat (termed bounded hybrid superiority) is thought to be extremely rare, but when present, does not apply to the theoretical expectations.

The distinction between endogenous and exogenous selection is crucial for understanding the potential mobility of the hybrid zone. For example, if endogenous selection operates (selection against hybrids), then the transition zone tends to shift toward any region that had low population densities. Alternatively, hybrid zones maintained by exogenous selection tend to remain stationary at a particular place on an ecological gradient, or shift in geographic position when the environment changes.

Using clines to estimate dispersal

In a similar manner, evolutionary ecologists have begun to utilize clinal theory to estimate dispersal distances of organisms. This approach may become particularly useful to marine researchers, because most marine invertebrates produce hundreds to thousands of microscopic offspring per parent and as a consequence, there are few empirical estimates of larval dispersal of marine organisms to within several orders of magnitude. However, inferring mean dispersal distance requires a precise estimate of the selection coefficient (s_e), which is itself a logistically difficult task. Field-based experiments can sometimes detect rather strong selection coefficients, but weaker levels of selection are more difficult to measure. Laboratory-based experiments can be more sensitive, but in many cases, their results may not be generalizable to more natural conditions.

In response to the difficulty of estimating selection coefficients directly, researchers have instead focused on estimating linkage disequilibrium (LD) because LD correlates with the magnitude of selection. Positive values of LD along a cline generally reflect an excess of parental gametic haplotypes and a reduction of hybrid gametic haplotypes within the cline (see **Fig. 2** for example). LD is generated when either endogenous or exogenous selection acts within the clines and is weakened by recombination. The net effect is that hybrids are less readily generated or maintained, parental alleles do not readily recombine, and a greater than expected number of parental gametes or haplotypes are encountered within a hybrid zone. Consequently, the higher the rate of migration across the clines of a given width, the larger the number of parental genotypes found within the clines, and the higher the degree of LD (i.e., selection). Because LD is generated by selection after migration in each generation, it is largely equivalent to `effective' selection when $s_e < 0.10$. When greater levels of selection maintain the clines, LD is not strictly equivalent to s_e, but rather approximates selection within an order of magnitude. It is not strictly generated by epistatic interactions between loci.

For clines at equilibrium, the balance between selection and dispersal can be represented at the center of a cline by

$$w^2 \sim \frac{\sigma^2}{D_{AB} r} \qquad [2]$$

where r is the rate of recombination and D is the maximum level of LD between loci (A and B). The basic formulation of D is the two-locus deviation from random expectation, or

$$D_{AB} = p_{AB} - p_A p_B \qquad [3]$$

where p_A is the frequency of allele A at locus 1, p_B is the frequency of allele B at locus 2, and p_{AB} is the frequency of AB. If one assumes the loci are unlinked, then the rate of recombination is $r = 0.5$. Because changes in allele frequencies (p) affect the maximum potential genetic disequilibrium, eqn [2] can be replaced with one that uses the correlation coefficient between loci, R_{AB}:

$$R_{AB} = \frac{D_{AB}}{\sqrt{p_A p_B (1 - p_A)(1 - p_B)}} \qquad [4]$$

so that at the center of a perfect cline when $p_A = p_B = 0.5$,

$$w^2 \sim \frac{4\sigma^2}{R_{AB} r} \qquad [5]$$

The clinal theory outlined here is explained in much greater detail by its architects (see the section titled `Further reading' for more details), and includes a host of factors that complicate its applicability to particular data sets. For example, the equations largely assume an evolutionarily static balance between selection and dispersal. If the cline is new because a new population is invading a region after human introduction, the relationships between selection, width, and dispersal will be very different. For most clines, however, stabilization of clines occurs very rapidly. It has been estimated, for example, that if $s = 0.1$, then clines stabilize within on the order of 10 generations.

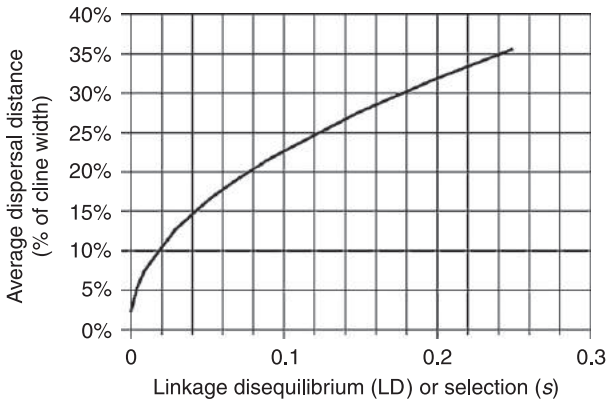

Fig. 4 The correlation between linkage disequilibrium (LD), selection (s), and dispersal distance within a stable cline. The curve is based on formulas [1] and [2]. Dispersal is given as the proportion of the clinal width (e.g., 20% of a 100 km clinal width is 20 km). Under reasonable levels of selection, the dispersal distance is a fraction of the clinal width. From Sotka EE and Palumbi SR (2006) The use of genetic clines to estimate dispersal distances of marine larvae. *Ecology* 87: 1094–1103.

A second complication is that clinal theory is directly relevant for loci under direct selection, such as some allozymes or morphological and physiological traits. However, many hybrid zones are detected using molecular markers (e.g., microsatellites) that are less likely to be under direct selection. If these neutral genes are not physically linked with loci under direct selection, then recombination quickly breaks up linkage disequilibria between loci, and the introgression of the neutral alleles across the cline will occur unimpeded. Thus, genetic differences among populations may be extremely strong immediately after secondary contact (i.e., after historically separated populations reconnect) and begin to weaken after hundreds or thousands of generations of gene flow. As a consequence, such neutral clines often look like a `staircase' of several steps of allele frequency across the hybrid zone (neutral markers are rarely fixed on both sides of the hybrid zone) and the introgression will eventually homogenize allele frequencies. The net effect of the flattening of the cline is a rather weak but artificial increase in estimated clinal width, and any given empirical estimate of selection in a snapshot of time will infer a rate of dispersal that is somewhat lower than the actual dispersal. In fact, a neutral cline will flatten at a rate proportional to a predictable product of dispersal and time; the width of a cline of neutral genes t generations after two differentiated populations come together is expected to be about $2.51\sigma\ (t)^{-1/2}$, assuming equal population sizes. On the other hand, clines at neutral genes can be stable if these genes are physically linked to genes under selection. Linkage of neutral markers to many genes under selection results in an effective selection (s_e) that helps sculpt neutral gene clines in a manner analogous to the action of non-neutral clines.

Third, these relationships are largely based on an underlying diffusion approximation and may be violated by rare long distance dispersal. Fourth, shifts in population densities, physical barriers to dispersal, and asymmetric gene flow can slightly alter the relationships between cline width, dispersal, and selection values.

The consequence of these and other complications is that estimates of dispersal based on selection or LD will be robust and of the right order, but may not be precise. Further, the dispersal estimates reflect the distances travelled within the clinal region only.

Still, in the absence of detailed information on linkage or selection, it is possible to produce a first approximation of larval dispersal distance using clinal theory. Even under high levels of selection (e.g., $s \sim 0.25$) and at equilibrium, the average geographic distance dispersed by offspring – as measured by the variance in distance between parent and offspring or neighborhood size – is less than about a third of the cline width ($s < 0.35\ w$; **Fig. 4**). Although this is a crude approximation; it suggests that in general, populations on the endpoints of clines do not typically disperse offspring across the entire cline width in one generation. Instead, typical propagules may requires 3–5 generations to traverse the cline. Only if selection were very large (e.g., hybrids were infertile) relative to rates of recombination would a cline be maintained by a dispersal distance that was as long as the cline was wide. In cases where selection was measurable but ecologically moderate ($s \sim 0.1$), then $s \sim 0.11\ w$. In other words, for selection that ranges from moderate to strong, clines are generally several times wider than average dispersal distance. For clines subject to weak selection, the subsequent clines can be an order of magnitude wider than dispersal, or more.

Clines and Parapatric Speciation

It is a general rule of thumb of evolutionary biology that it is far easier to describe the maintenance of genetic variation than to describe its generation. This is particularly true for understanding the evolution of clinal variation. On the one hand, clines may represent the consequence of a recent collision of formally separated populations that evolved in allopatry. These situations, termed secondary introgression are thought to dominate systems with steep clines (**Fig. 1b**) as when two species hybridize within a tension zone.

On the other hand, it is known that clines can be generated by spatially variable selection acting on a set of genetically identical subpopulations. One example of this comes from the *Drosophila* invader into North America (see **Fig. 1a**), in which a cline was

generated within two decades of the invasion. These situations reflect primary contact clines. The main problem for evolutionary ecologists is that it can be difficult to know whether a cline is the consequence of primary contact or secondary introgression. Recent authors indicate that cline theory can be utilized in either case, but these theoretical expectations provide little insight into the generation of the cline itself.

The mechanism of clinal generation is important to speciation, or the generation of species. Traditionally, natural historians believed that speciation across clines was commonplace, but today, there is far more skepticism largely because the evidence for such speciation is weak and elusive. The generation of `good' species within a cline is called parapatric speciation and will proceed through the following steps. First, the environment generates strong local genetic differences among subpopulations in multiple traits and is reflected in a series of a steep clines. If such differences persisted, then hybrids of subpopulations from the endpoints of the cline will become less fit, a situation called a tension zone. The exact mechanism by which hybrids are less fertile or viable can be intrinsic (e.g., genetic incompatibilities) or extrinsic (e.g., less competitive in the environment). As a consequence of the fitness cost of hybridization, there will be strong selection for prezygotic traits that minimize cross-breeding and thereby lead to the generation of `good' species, a process referred to as reinforcement.

However, to date, several of the predictions of parapatric speciation are poorly supported. There is growing evidence from molecular and other lines of evidence that most hybrid zones are not primary contact zones, but are instead the consequence of secondary introgression of formerly allopatric populations. Further, prezygotic isolation does not appear to be the primary force maintaining most hybrid zones.

Coevolution

RB Langerhans, Harvard University, Cambridge, MA, USA

Introduction

What Is Coevolution?

All organismal populations experience multiple selective pressures deriving from varied aspects of their environment. In addition to abiotic features (e.g., climate), this 'environment' is often comprised of many other organisms. Thus, most populations evolve in response to interactions with other species. While the abiotic components of the environment cannot evolve in response to organisms, the biotic components can – and this phenomenon has played an integral role in the evolution of phenotypic diversity. Coevolution is reciprocal evolutionary change between interacting species driven by natural selection. That is, each player in a coevolutionary relationship evolves adaptations in response to its interaction with the other player(s). Although this general concept has been around since Darwin, the term 'coevolution' was coined by Paul Ehrlich and Peter Raven in a classic article in 1964, "Butterflies and plants: A study in coevolution." Since then, the field of research examining coevolution has blossomed into a large-scale research program.

The Broad Importance of Coevolution

Coevolution is undisputed as one of the most important processes shaping biodiversity. The importance of coevolution goes far beyond the classic examples, such as predator–prey coevolutionary arms races, figs and fig wasps, yuccas and yucca moths, ants and acacias, and fungal farming by several taxa. Coevolution's influence spans all subdisciplines within ecology and evolutionary biology. Indeed, a large extent of the historical and ongoing patterns of phenotypic evolution and species diversification is the product of coevolution. Coevolution can stem from numerous types of species interactions that are commonplace on this planet, such as interspecific competition for resources, predator–prey interactions, host–parasite interactions, plant–herbivore interactions, and flower–pollinator interactions. Even the eukaryotic cell originated from a symbiotic relationship where one of the species evolved into the organelles we now call mitochondria. A similar scenario is responsible for the formation of chloroplasts, and thus the origin of plants. Most vertebrate and invertebrate species rely heavily on coevolved symbionts residing within their digestive system or other special organs to allow proper digestion and growth. Coral reefs, and the communities they support, depend largely on coevolved symbioses between corals and zooanthellae, as well as interactions with other corals and algae-feeding fish. The symbiotic organisms, lichens, are critically important during primary succession in terrestrial ecosystems. Even the colonization of land by plants was facilitated by mutualistic interactions with mycorrhizal fungi. Coevolution's influence is so far reaching that the history of life on Earth would be unrecognizable in the absence of it.

Empirical Evidence for Coevolution

Despite the widespread importance of coevolutionary interactions, empirical demonstration of coevolution is a difficult task. This derives from the inherent difficulties of demonstrating adaptation – much less reciprocal adaptation – that has plagued evolutionary biology for many decades. Nevertheless, a great deal of supportive evidence has been gathered for coevolution, coming from an assortment of tests for an array of hypotheses stemming from coevolutionary theory. As is discussed below, coevolution comes in many forms, and thus there are different manners in which researchers approach the question of coevolutionary association. As a general approach, researchers often examine phenotypic, ecological, and genetic evidence to test the hypothesis that organisms are evolving (or have evolved) in response to one another.

The Basics of Coevolution

Types of Coevolution

A few different categories of coevolution are often discussed by scientists in ecology and evolutionary biology: pairwise coevolution, diffuse coevolution, and gene-for-gene coevolution. Pairwise coevolution (or 'specific' coevolution) describes tight coevolutionary relationships between two species. Diffuse coevolution (or 'guild' coevolution) refers to reciprocal evolutionary responses between suites of species. This type of coevolution emphasizes that most species experience a complex suite of selective pressures derived from numerous other species, and their evolutionary responses change the selective environment for other species. Gene-for-gene coevolution (or 'matching gene' coevolution) describes the specific case where coevolution involves gene-for-gene correspondence among species, such as when hosts and parasites have complementary genes for resistance and virulence.

 doi:10.1016/B978-0-444-63768-0.00471-6

Symbiosis and the Nature of Coevolutionary Interactions

Some of the classic, and most obvious, examples of coevolutionary interactions involve two species that live in continuing, intimate associations, termed symbiosis. With such tight ecological associations, strong and repeated coevolutionary responses are easy to envision. Symbiosis is commonly used to refer to all relationships between different species, and thus an association need not be extremely close to qualify as symbiotic. There are five major types of interspecific relationships: antagonism, parasitism, amensalism, commensalism, and mutualism (**Table 1**). Antagonism describes the scenario where both members of the interaction are harmed, such as interspecific competition. In parasitic coevolution, one member benefits (parasite), while the other is harmed (host). Parasitism is an extremely common form of coevolution. Parasitic interactions do not only include associations where one organism lives in or on a second organism, but also encompass some other very common interactions such as herbivory and predation. Sometimes the benefiting member kills the harmed member (e.g., parasitoid–host, predator–prey), whereas other times the harmed member is merely injured (e.g., parasite–host, herbivore–plant). Amensalism is where one member is harmed, while the other member is neither positively nor negatively affected. A common example of amensalism is the production of a chemical compound by one member as part of its normal metabolism which is detrimental to another organism (e.g., allelopathy in plants, toxic skin secretions in animals). Commensalism describes a symbiotic relationship where one member benefits, while the other member is neither helped nor harmed. It is possible for some interactions to be parasitic under some circumstances (e.g., low host nutrition), but commensal during others (e.g., high host nutrition). Mutualism is a coevolutionary relationship where both members benefit. For instance, clownfish gain protection from sea anemones, and anemones gain food from clownfish. Many relationships may change in nature over time, space, or ecological context, and the distribution of these types of outcomes for a given interaction (e.g., percentage of outcomes that are antagonistic vs. mutualistic) can be important in determining the coevolutionary responses that will be elicited.

The Red Queen Hypothesis

The Red Queen hypothesis was first proposed by Leigh Van Valen in 1973, and is a coevolutionary hypothesis describing how reciprocal evolutionary effects among species can lead to some particularly interesting outcomes. While Van Valen specifically addressed macroevolutionary extinction probabilities, the hypothesis has since become much more general, providing an evolutionary explanation for numerous characters (e.g., sex, mating systems, pathogen virulence, maintenance of genetic diversity), and coevolutionary arms races in general. The conceptual basis of the Red Queen hypothesis is that species (or populations) must continually evolve new adaptations in response to evolutionary changes in other organisms to avoid extinction. The term is derived from Lewis Carroll's *Through the Looking Glass*, where the Red Queen informs Alice that "here, you see, it takes all the running you can do to keep in the same place." Thus, with organisms, it may require multitudes of evolutionary adjustments just to keep from going extinct.

The Red Queen hypothesis serves as a primary explanation for the evolution of sexual reproduction. As parasites (or other selective agents) become specialized on common host genotypes, frequency-dependent selection favors sexual reproduction (i.e., recombination) in host populations (which produces novel genotypes, increasing the rate of adaptation). The Red Queen hypothesis also describes how coevolution can produce extinction probabilities that are relatively constant over millions of years, which is consistent with much of the fossil record. Thus, extinction resistance of lineages does not improve over time, but rather remains fairly constant because the probability of evolutionary change in one species leading to extinction in another species should be independent of species age (they are constantly evolving with their changing environments, not constantly improving with respect to a static background environment).

The Geographic Mosaic Theory of Coevolution

Owing to relatively recent developments in ecological, evolutionary, genetic, mathematical, and phylogenetic studies, coevolution is viewed today as an ongoing, highly dynamic process where populations interact across geographical landscapes. This contrasts with the historical view dating back to Darwin where coevolution was largely visualized as a slow, directional molding of species' traits through long periods of evolutionary time. Recent and ongoing research in coevolution is revealing that ecological and

Table 1 The five types of relationships between species. Effects of interaction are negative (−), positive (+), or indifferent (0)

Type of interaction	*Effects of interaction on*	
	Species 1	*Species 2*
Antagonism	−	−
Parasitism	−	+
Amensalism	−	0
Commensalism	+	0
Mutualism	+	+

evolutionary timescales are often one and the same, where effects of selection can be very rapid (strong intragenerational shifts), and evolutionary responses and counter-responses can be observable in only a few generations. This conceptualization of coevolution places a strong emphasis on the geographic context of coevolution and the continual reshaping of species' traits across geographic landscapes.

John Thompson has championed this new framework for studying coevolution, the geographic mosaic theory of coevolution (Fig. 1). This theory posits that coevolutionary interactions have three components driving evolutionary change:

- *Geographic selection mosaics*. Natural selection arising from interspecific interactions varies among populations.
- *Coevolutionary hot spots*. Interactions are subject to reciprocal selection only within some local communities (coevolutionary hot spots), embedded within a broader matrix of communities where selection is nonreciprocal or where only one of the participants occurs (coevolutionary cold spots).
- *Trait remixing*. Spatial distributions of potentially coevolving genes and traits are continually being altered due to new mutations, gene flow, genetic drift, and extinction of local populations.

Thus, with this theory, populations are placed within a context of geographic selection mosaics, providing a more complicated, but more realistic view, than previous perspectives. A couple of examples from nature help illustrate how this framework facilitates the understanding of how coevolution shapes species traits and interactions across landscapes: (1) garter snakes and newts, and (2) conifers and crossbills. These examples demonstrate how coevolutionary hot spots can result in geographic patterns in coevolved traits. First, *Taricha granulosa* newts and *Thamnophis sirtalis* garter snakes inhabit western North America, and show strong evidence of coevolving traits across this region. The newts possess a potent neurotoxin, which paralyzes and often kills a predator that has ingested a newt. However, the garter snake has evolved varying amounts of resistance to the neurotoxin (this resistance is physiologically costly). Newt toxicity levels and snake resistance levels are tightly matched across the geographic landscape (i.e., where newts are more toxic, snakes have greater resistance). In addition, snake populations, where newts do not co-occur, exhibit very low levels of resistance. Research has revealed two coevolutionary hot spots, and a number of intermediate and cold spots. Second, both red crossbills (*Loxia* spp.) and red squirrels (*Tamiasciurus hudsonicus*) prey upon pine cones. Where squirrels are the primary seed predator, conifers have evolved heavier pine cones with fewer seeds and thinner scales, which defends against squirrels. Where crossbills are the major seed predator, pine cones are lighter with more seeds and thicker scales, which defends against crossbills. Crossbills in turn have evolved counter adaptations to consume the seeds, exhibiting deeper, less curved bills where pine cones have thick scales compared to areas where pine cones have thin scales. Thus, trees are evolving in response to crossbills and squirrels in different populations, and crossbills are evolving in response to these evolutionary changes in the trees.

Coevolution Drives Diversification

Cospeciation and Phylogenies

Farenholz's Rule (originally proposed in 1913) posits that parasites and their hosts speciate in synchrony. This process, the joint speciation of two or more lineages that are ecologically associated (coevolving), has since been termed cospeciation (or parallel cladogenesis). While most research to date has examined parasite–host interactions, other coevolutionary relationships may also exhibit cospeciation; however, we will focus on parasites and hosts for this discussion.

If the process of cospeciation were the only one operating, then phylogenetic trees of parasites and their hosts should be topologically identical (i.e., exact mirror images of each other; Fig. 2). However, virtually all such phylogenies are not perfectly concordant. This implies that other processes must also be at work, such as host switching, speciating independently of their host, members going extinct, failure to colonize all descendants of a speciating host lineage, or failure to speciate when its host does. Further, even when concordant, it is possible that one of the groups (often the parasite) has colonized the other (the host) – host

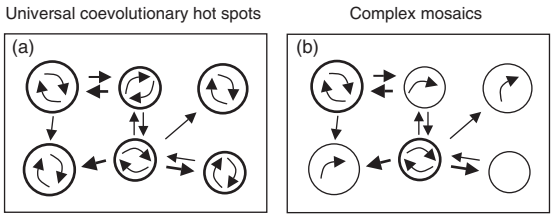

Fig. 1 Hypothetical illustration of the geographic mosaic of coevolution. The example depicts interactions between two species within local communities (arrows within circles). Interaction arrows represent different types of selection acting on different species. Arrows between communities reflect the magnitude of gene flow. Thick circles represent coevolutionary hot spots, while thin circles are cold spots. (a) Coevolution occurs in all communities, although the interaction coevolves in different ways among communities. (b) Coevolutionary hot spots occur within a matrix of cold spots. Adapted from *The Geographic Mosaic of Coevolution* by John Thompson (see Further Reading).

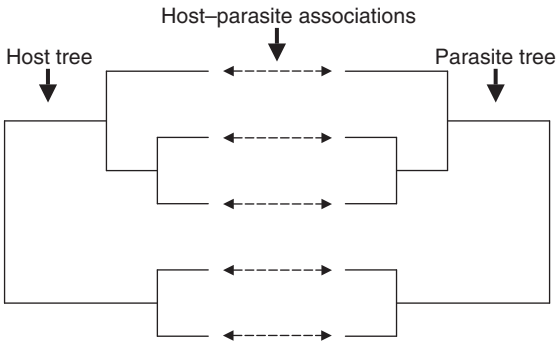

Fig. 2 Hypothetical phylogenies for host and parasite clades illustrating evidence for cospeciation.

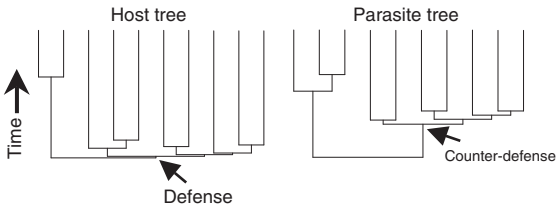

Fig. 3 Hypothetical illustration of escape-and-radiate coevolution. In this example, a host lineage has undergone an adaptive radiation after evolving an effective defense against the parasite clade. During this time, interaction with the parasites does not occur. Then, the parasite lineage evolved a counter-defense and also radiated. Because the parasite clade did not cospeciate or colonize each new host in a systematic manner, the parasite–host associations are not anticipated to exhibit one-for-one matching as in Fig. 2.

shifts might correspond to the host phylogeny because closely related hosts are more liable to colonization by closely related parasites. Comparisons of species' phylogenies can produce insight (with limitations) into the coevolutionary history of interacting organisms. Thus, as phylogenetic data, and more sophisticated tree-building methods, have become widely available, phylogenies have become very useful in the study of coevolution. A number of empirical studies now, at least partially, support the general notion of cospeciation occurring with some regularity in some parasite–host interactions.

Coevolution, Divergence, and Adaptive Radiation

Coevolutionary interactions can lead to phenotypic divergence among populations, speciation, and adaptive radiation. In addition to the process of cospeciation described earlier, diversifying coevolution across landscapes, which has now been demonstrated in several empirical systems, can (and apparently does) contribute to the formation of new species, as well as phenotypic differentiation within species. One hypothesis of coevolutionary diversification has its roots in the original article that first coined the term coevolution (Ehrlich and Raven article mentioned above), and proposes that reciprocal diversification among members of a coevolutionary association (often parasite–host) results from reciprocal adaptation, geographic differentiation, speciation, and periods of noninteraction in the diversifying lineages. This process is called escape-and-radiate coevolution (Fig. 3). In this process, one member evolves a defense (or some other innovation greatly reducing impact of interaction with other member), which enables a radiation due to the expansion of ecological opportunity. During the radiation, interaction among the members is minimal or nonexistent. Then, the other member evolves a counter-defense to overcome the innovation and radiates as well, producing reciprocal radiation events among the members. It is believed that diffuse coevolution among plants and herbivores may often follow such a coevolutionary diversification process.

Coevolutionary interactions may also often produce character displacement (exaggerated phenotypic divergence in sympatry) within local hot spots. This coevolutionary displacement is typically embedded within the broader geographic mosaic of coevolution among species, but may also result in fixation or speciation. A number of potential outcomes may result from coevolutionary displacement: character displacement among competitors in coevolutionary hot spots, displacement via apparent competition in hot spots, replicated community structure in hot spots, and trait overdispersion in competitive networks. Such displacement has been demonstrated in numerous systems in nature.

Coexistence☆

David J Booth and Bradley R Murray, University of Technology, Sydney, NSW, Australia

Introduction

One of the most perplexing issues in ecology is the coexistence of large numbers of species within communities across a range of spatial scales. The rainforests of South America and southeast Asia, for instance, are home to a high diversity of plant species, where over 200 species can be found in 1 ha of forest. On coral reefs, species richness is high at both large spatial scales (e.g., over 1500 species of fish and 400 corals on the Great Barrier Reef) and at the scale of small patches of reefs (e.g., over 200 species of fish on a reef only 50 m wide). The coexistence of large numbers of species is particularly puzzling given that many coexisting species seem to perform the same ecological roles within plant and animal assemblages. If so many species are doing the same thing, how can they all coexist in a world where resources are often limited and there is competition for these resources? To fully appreciate how such large numbers of species can coexist, we need to have a thorough understanding of the dynamics of their populations and, in particular, of how individuals within a species' population interact with each other, and with populations of other species, in the context of ambient environmental conditions. Indeed, the coexistence of individuals within a population is intriguing, given that interactions within species can in fact be stronger than interactions among the populations of different species. The ecologist George E. Hutchinson posed the *Paradox of the Plankton* in 1961, questioning how so many species of marine plankton could coexist in a relatively homogenous medium with limited food, seemingly in violation of Gause's rules of competitive exclusion. The research that Hutchinson stimulated over the next 45 years has given us a broad understanding of how organisms can coexist.

The Link Between Population Dynamics and Coexistence

The study of population dynamics involves investigating changes in features of populations such as numbers of individuals, individual weights and ages, and the biotic and abiotic conditions influencing those changes. The coexistence of the populations of different species simply refers to the persistence of two or more species' populations over time in a given area. Fluctuations in the dynamics of species' populations determine where, how, and when they will interact with individuals of the same species and individuals of other species. Those population interactions, and the ability to avoid interactions, are important properties determining the coexistence of large numbers of species. This article demonstrates the critical link between the dynamics of species' populations driving interactions among organisms and mechanisms promoting coexistence among species.

Competition and Coexistence

One of the most fundamental ways in which the populations of species interact is by competing with one another. In an environment with just a single species, the population of this species grows exponentially unless limited by crowding and a short supply of resources. Individuals of the same species have very similar requirements from the environment for growth and reproduction, and once individuals become crowded, individuals must compete with each other for limited resources. In this single-species system, the term "intraspecific competition" refers to the competitive interactions among individuals of the same species, where the growth, reproduction, and survival of some individuals are negatively affected. Grouping species (i.e., those species that aggregate for social or resource reasons) are particularly susceptible to crowding, and so may be expected to illustrate the most traits that enable coexistence. For instance, coral reef damselfishes can occupy small coral heads in groups of over 20 individuals, with a linear size-based dominance hierarchy (the largest fish is aggressively dominant over the next largest, and so forth; see **Fig. 1**). Larger groups suffer slower growth overall, due to increased competition for zooplankton food, and smaller (lower-status) fish within groups grow more slowly. However, survivorship and hence maturity are higher in larger groups due to greater vigilance for predators and predator swamping, so that coexistence is beneficial overall.

The situation becomes more complex when the dynamics of two or more species and their interactions in an environment need to be considered. A competitive interaction between the populations of different species is termed "interspecific competition," where growth, reproduction, and survival of one species is negatively affected either directly (e.g., interference competition) or indirectly (e.g., resource exploitation). For example, asymmetrical competition between two species can occur where one species has an advantage in resource exploitation or is able to interfere with another's ability to exploit resources. A great deal of effort has been invested in elucidating the role of interspecific competition in species coexistence.

☆*Change History:* March 2018, D.J. Booth made changes to the text, figures and references.

This is an update of D.J. Booth and B.R. Murray, Coexistence, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 664–668.

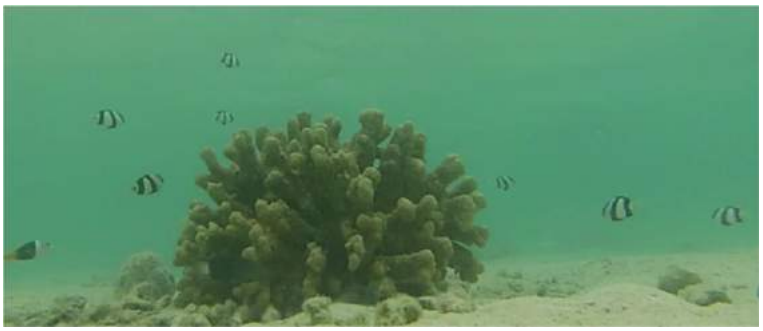

Fig. 1 Social group of the humbug damselfish (*Dascyllus aruanus*). Individuals coexist in dominance hierarchies. Photo by David Booth.

Interestingly, however, a paucity of opportunities for interspecific competition in some communities can result in the coexistence of large numbers of species. This situation may arise when the individuals of species are clumped (aggregated) in their spatial distribution. For example, populations of many shrubby plant species are spatially clumped in open-forest plant communities in southeastern Australia. Plant species that are better competitors for resources would normally out-compete and eliminate inferior competitors, but competitively inferior species are able to coexist with competitively superior species where there is clumping of individuals. This is because individuals of competitively superior species are mostly competing with each other when clumped, and not with populations of inferior competitors, thus reducing the chance of weaker competitors being eliminated.

Competitive networks can promote coexistence in crowded communities by allowing no one species to be competitively dominant in all situations. For example, if species A is dominant over species B (i.e., A > B), B > C, and C > A, a simple three-species network will result. On coral reefs, such networks in corals apparently promote coexistence in the face of overgrowth.

The Importance of Niche Differentiation for Coexistence

Competitive interactions among the populations of two species will lead to the exclusion of one of the species when the realized niche of the superior competitor encompasses the fundamental niche of the inferior competitor. This is known as the competitive exclusion principle. (Note that the fundamental niche of a species describes all possible combinations of resources and conditions under which species' populations can grow, survive, and reproduce; the realized niche describes the more limited set of resources and conditions necessary simply for the persistence of species' populations in the presence of competitors and predators.) The fact that so many species in a vast array of ecological communities are able to coexist means that species must differ in their realized niches. Such niche differentiation is critical to avoid competitive exclusion and allow coexistence.

Niche differentiation refers to differences among species in their physiology, morphology, and behavior, and concurrently in their use of resources and tolerance of conditions. Perhaps the simplest idea is that species partition available resources; that is, there is differential utilization of resources among species. Resources are often separated either spatially and/or temporally. For example, native mammals can often coexist in the same area because they forage and seek protection in different microhabitats provided by variation in native vegetation. In the Australian arid zone, for instance, the spinifex hopping-mouse *Notomys alexis* forages in the open while the sandy inland mouse *Pseudomys hermannsburgensis* is more commonly associated with hummocks of spinifex grass. The two species differ considerably in their morphology, related to their differential use of spatially segregated resources. The hopping-mouse has large hind legs for bipedal motion, which provides for rapid movement and quick changes in direction which are necessary for predator avoidance in the open habitats in which it forages. On the other hand, the sandy inland mouse is much more "mouse"-like in its limb structure, using all four limbs for quadrupedal motion, an efficient means of movement in tangled spinifex clumps.

The Roles of Predator–Prey Interactions and Density Dependence in Coexistence

Individuals in populations and communities of species can coexist provided shared resources are not in short supply. Predation is one process that precludes resource depletion and may thus facilitate coexistence. Predators may act as mediators of coexistence by harvesting all prey types equally, and so preventing resource depletion. Also, predators may switch to the most common of alternative prey types, which again will prevent competitive extinction. Lotka–Volterra predator–prey dynamics can explain coexistence of closely matched predators and prey, as seen in classic cycling of abundances of hares and lynx in Canada.

Tradeoffs and Species Coexistence

A "super-species" is the best at colonizing new patches of habitat, at outcompeting all neighbors and at avoiding predators. Such a species does not exist. The benefits obtained from performing one ecological function well come at the cost of performing a

different function. Such differences among species are referred to as tradeoffs. The population dynamics of different species are influenced by interspecific tradeoffs, which subsequently influence the possibilities for coexistence among species. It is important to note that in this context, tradeoffs represent niche differentiation among species (see above).

One way to consider a tradeoff is as a negative functional interaction between traits. In plants, for example, shrubs and trees must invest much of their resources into support structures to obtain height. This comes at the expense of investment in photosynthetic tissue. In contrast, vines must use host plants for structural support in order to reach any considerable height. The use of host plants for support results in a greater allocation of energy (which would otherwise be invested in stem tissue) toward photosynthetic tissue.

In spatially structured landscapes, the competition–colonization tradeoff is an important mechanism that can generate coexistence. Simply, while some species are good competitors, others are better colonizers. No one species can be good at both: there is a tradeoff, such that species with high fecundity and dispersal are poorer competitors, while species that are good competitors necessarily have lower fecundity and poorer dispersal. Under a fairly strict set of conditions, relating to the dynamics of competing populations, the competition–colonization tradeoff predicts the coexistence of a potentially infinite number of species. These conditions include the idea that there is a strict competitive hierarchy among species (i.e., competitive asymmetry), such that the superior competitor will always win competitive interactions with competitively inferior species. Being a good competitor comes at the cost of being a poorer colonizer, such that inferior competitors that are better colonizers can occupy sites that have not been colonized by the superior competitor.

For plants, the interspecific competition–colonization tradeoff has been linked to the life-history tradeoff relating seed size to seed number. From a finite pool of resources, a plant can make either many small seeds or few large seeds. There is fairly clear empirical evidence that seedlings from large seeds out-compete seedlings from small seeds during early seedling growth. The larger production of (smaller) seeds in other species leads to superior colonization. These differences in seed size and seed output neatly match the requirements of the competition–colonization tradeoff model for coexistence. Theoretical work, matched with neat empirical research, by Mark Rees and his research group reveals the complex nature of the competition–colonization tradeoff in annual plant communities. Importantly, the tradeoff appears to work as the sole mechanism of coexistence in the real world only when competitive asymmetries are extreme.

One form of coexistence (called density-dependent coexistence) requires that life-history strategies differ such that an advantage at one stage of the life cycle implies a disadvantage at another stage in the life cycle. With two species, each gains a relative advantage at some level of total density, and where densities fluctuate, both species may persist indefinitely. Such life-history tradeoffs appear in small-bodied fish assemblages in freshwater lakes, for instance, although density-dependent coexistence has not been demonstrated unequivocally in nature as yet.

Coexistence Through Variable Supply of Young

Several models of species coexistence have been developed through empirical studies of coral reef ecosystems, where species diversity at very small spatial scales can be considerably high. How do small (<100 m^2) patch reefs support over 300 species of fishes and many more invertebrates and algae? First, many reef species exhibit "functional versatility" whereby their use of resources (food, shelter) is flexible enough to allow many apparently overlapping species to coexist. The range of microhabitats present on coral reefs is large, also facilitating coexistence. However, the patchy and variable supply of young onto the reef (with parallels in other marine organisms and terrestrial insects) can also promote coexistence. The "lottery hypothesis" suggests that, should a reef resident be removed (e.g., through mortality) the replacement would be drawn at random from the larval species pool adjacent to the reef at that time. Therefore, even if certain species were competitively displaced from a habitat patch, it could be replenished through the larval pool. Hypothetical successional climaxes of reefs, forests, and many other ecosystems would never be reached, so resulting coexistence would not be stable. One consequence would be enhancement of biodiversity in these situations, through invasion of larvae, seeds, and other propagules or migrants. Such invasion could be facilitated by mortalities or displacement of residents through a disturbance (see the next section).

Coexistence Mediated by Disturbance

Physical disturbance of habitat can also facilitate coexistence of individuals and species. Gap formation in rainforests through storms and fire is a major mechanism promoting coexistence and by which many species are maintained. Cyclones and smaller-scale storms on coral reefs may shift coral assemblages from domination by massive, slow-growing forms to faster-growing branching taxa. Crown-of-thorns seastar invasions can decimate reefs at small scales, leaving a mosaic of habitats in their wake. By preventing reefs reaching successional climaxes, disturbances such as these may enhance coexistence of the species that live there.

Neutral Models of Coexistence

Recently, there has been a surge of interest in ecology for neutral models of coexistence. In neutral models of coexistence, niche differentiation among species is removed from consideration and species are considered to be equivalent. However, fundamental

Table 1 Some models and explanations of processes that promote coexistence among species and individuals within habitats

Model	*Explanation*	*Example*
Lottery	Available space occupied at random from larval/propagule species pool	Species with dispersive larvae/propagules (e.g., coral reef fishes) occupying space at random
Recruitment limitation	As above, but habitat occupation limited by patchy supply of larvae/propagules	Marine benthic organisms esp., at edge of their range
Niche diversification		Many available microhabitats promote coexistence
Different plant parts used by invertebrates as a resource		
Tradeoffs	High performance in one life-history feature at the expense of reduced performance in another	Plants either produce many small seeds (good colonizing ability) or few large seeds (good competitive ability)
Competitive networks	No species is dominant over all others	Overgrowing corals
Predation limitation	High predation (esp. on common prey-switching) promotes coexistence	Predation on lower rocky intertidal marine environments
Abiotic disturbance	Physical factor(s) that create space for colonization/replenishment	Storm gaps in rainforest canopies
Intraspecific aggregation	Species undergo higher intraspecific than interspecific competition	Patchily distributed and aggregated plant populations of different species
Asynchronous life histories	Seasonal resource use asynchronous among species, promoting coexistence (e.g., reproductive cycling, population irruptions)	Cicadas
Neutral theory	No niche diversification among species, probabilities of birth, death, and immigration and interspecific competition determine coexistence	High diversity of plant species in rainforests

properties of population dynamics (e.g., probabilities of birth, death, and immigration) and interspecific competition play an important role in determining coexistence. Many of the patterns of coexistence and diversity, species–area relationships, and the distribution of abundances among species in the real world can be explained through neutral models that do not include niche differentiation among species. Frequency-dependent natural selection can also generate coexistence between species that are apparently neutral (i.e., there is no niche differentiation between the species). In this situation, when species are rare (in low-abundance), they adapt to a high frequency of interspecific competitive interactions, thus providing for their persistence. When species are common (in high-abundance), they adapt to a high frequency of intraspecific competitive interactions, as they are more likely to encounter conspecifics in the habitat in which they are abundant. Under these conditions, the species are said to have evolved "pseudo-neutrality." Nevertheless, the problem is that a community theory that accounts neither for species differences nor for patterns of species distribution across real physical geography must be incomplete.

Conclusion

A wide range of ecological interactions separately or in concert, facilitate coexistence within populations and between species (for a summary see **Table 1**). Coexistence mechanisms can explain both the enormous species richness in some habitats and the dominance of a few taxa in others. Close coexistence of individuals within a species, or very similar species, is possible through a combination of biotic interactions and physical disturbances which may prevent "equilibrium" conditions ever being reached.

Colonization

MJ Donahue, Humboldt State University, Arcata, CA, USA
CT Lee, Stanford University, Stanford, CA, USA

Introduction

Colonization is the arrival of individuals to areas of suitable habitat that are currently uninhabited by individuals of the same species. Populations are established (or re-established) in uninhabited areas by the successful colonizers that survive and reproduce. Colonization, or recolonization, is a spatial process central to several fundamental concepts in ecology, including the spatial structure of populations, species coexistence, succession, disturbance and recovery, invasive species, and speciation.

Colonization is one possible consequence of dispersal. Dispersal is the permanent movement of an individual from one location to another (commonly, a seed, larva, or juvenile stage moving from its natal area to the area it will inhabit as an adult). If the individual disperses to an area uninhabited by conspecifics, then dispersal has resulted in colonization. If that colonizer survives to reproduce, then a new population has been established.

Colonization occurs at a range of spatial scales. For sessile organisms in which space is a primary resource (e.g., plants, sessile marine invertebrates), the death of an individual may open space for recolonization by another individual. At this smallest scale, the balance between extinction (individual mortality) and colonization (settlement of another individual in that location) determines the persistence of a population. Small disturbances, such as gopher mounds in grasslands or tear-outs in intertidal mussel beds, create small habitat patches that allow good colonizers to coexist with dominant competitors, enhancing local biodiversity through competition–colonization tradeoff. Larger-scale disturbances, due to fire, logging, or sedimentation–erosion dynamics, may result in a successional mosaic, a landscape in which different areas were disturbed at different times in the past, resulting in a range of successional stages and, therefore, higher regional biodiversity. Colonization is also essential for range expansion and spatial spread. Anthropogenic effects have increased the rates of spread of many species by enhancing colonization. Over a longer timescale, colonization of new niche space may lead to niche expansion or speciation.

We first consider characteristics which enhance species' colonization ability. Then, we use the central ecological concept of colonization–extinction balance to consider the implications of colonization from the smallest scale of an individual to the largest scale of species ranges. In doing so, we consider the implications of colonization for population growth, species coexistence, disturbance, succession, species invasions, and speciation.

Factors Enhancing Colonization Ability

Organisms vary considerably in their ability to colonize new habitat. **Figs. 1a** and **1b** illustrate the variation between taxa of freshwater zooplankton in the time needed to colonize experimental mesocosms, and in the total number of mesocosms colonized over the course of 2 years. In general, whether or not a particular organism colonizes a given new habitat depends on life-history characteristics, behavior, and environmental factors. Classically, the *r*-selected life-history strategy is associated with strong colonization ability through the production of many, low-quality propagules, often adapted to long-distance dispersal via wind or water. This strategy increases the probability that propagules will arrive in a patch because of the vast number of propagules released. However, strategies that increase the probability of establishment, rather than simply the probability of arrival, also enhance colonization success, including habitat selection and competitive ability. Many animals use habitat selection to detect appropriate habitat, thereby increasing the probability of arrival and subsequent establishment. This is particularly true for specialist organisms with highly specific habitat requirements or organisms that utilize short-lived resources (e.g., rotting fruit or hydrothermal vents). Good competitors, especially those with clonal growth, often make good colonizers; few propagules may arrive, but those that do are likely to be successful.

Among herbaceous plants, an annual life-history strategy, rapid growth, and the production of many, small seeds are characteristic of the `ruderal' strategy (*sensu* Grime; see section titled **`Further reading'**). Ruderals rapidly colonize habitat opened by disturbance, allowing them to coexist with stronger competitors that colonize more slowly but ultimately exclude the ruderal species. Ruderals are *r*-strategists that increase colonization ability by increasing the probability of arrival at a new patch. Other life-history characteristics may enhance the probability of establishment after arrival, such as phenotypic plasticity and the ability to reproduce asexually. Phenotypic plasticity allows an organism to use the morphology or behavior that is appropriate to its new environment. The ability to reproduce asexually, whether by clonal growth or selfing, is clearly advantageous to establishment because only a single individual is necessary to produce a viable population. In their experimental mesocosms, however, Caceres and Soluk (2002) found that the colonization ability of freshwater zooplankton was not necessarily predicted well by mode of reproduction (see the section titled **`Further reading'**).

 doi:10.1016/B978-0-444-63768-0.00472-8

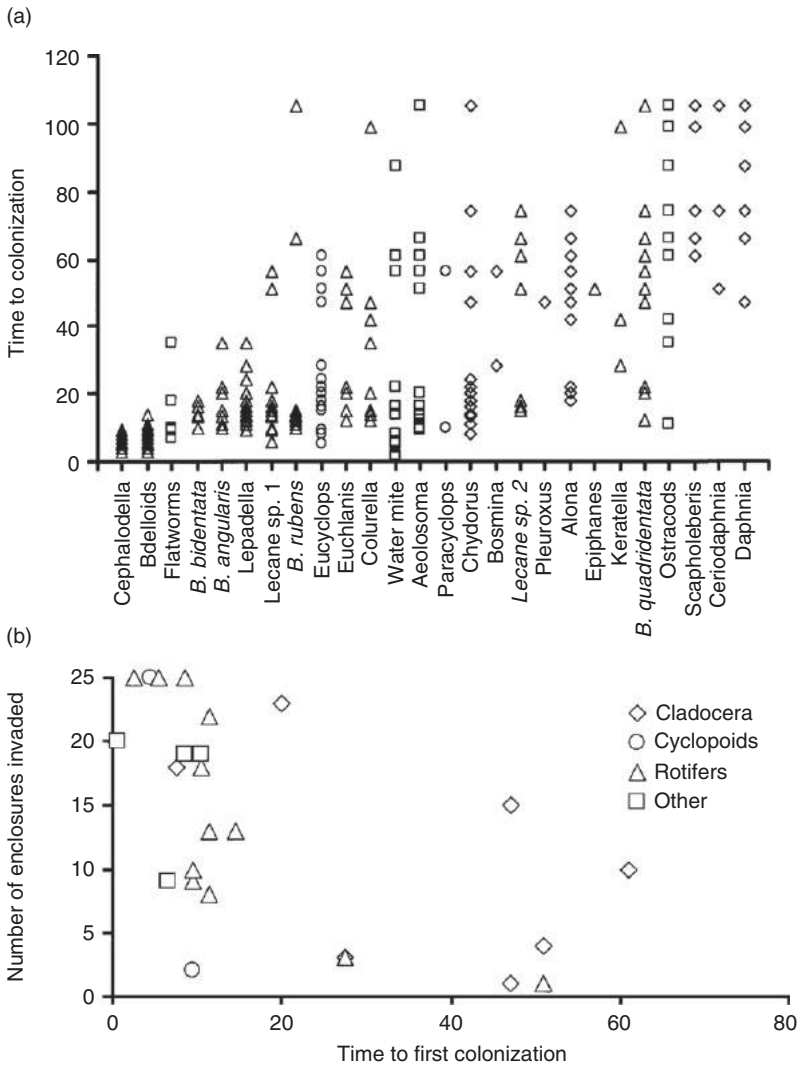

Fig. 1 (a) Time to colonization (weeks) into each mesocosm for each of 26 zooplankton taxa. Taxa are listed in order of average time to colonization. Diamonds indicate cladocera; circles indicate copepods; triangles indicate rotifers; squares indicate all other taxa. Because colonization by individuals is difficult to observe, `colonization' here also includes establishment of reproducing populations large enough to be detected in samples. (b) Negative correlation between the week each taxon was first found in the array, and the number of mesocosms that were invaded over the 2 years. The other category includes annelids, flatworms, water mites, and ostracods. Reprinted from Caceres, C.E., Soluk, D.A., 2002. Blowing in the wind: A field test of overland dispersal and colonization by aquatic invertebrates. Oecologia 131, 402–408.

Among sessile marine invertebrates, there are two contrasting life-history strategies that may enhance colonization ability. Some taxa produce many, small larvae that feed during an extended larval period (weeks to months) in the plankton and are, therefore, transported over long distances. This long larval period results in long-distance transport far from their natal areas, enhancing the probability of arrival in uninhabited areas. Other taxa produce fewer, larger, larvae with enough yolk to survive a shorter (hours to days), nonfeeding planktonic period or, more extreme, larvae that crawl away and have no planktonic transport at all. While these taxa are less likely to be transported far from their natal areas, when they do arrive they are more likely to colonize successfully and establish a new population. This increased colonization success is due to the increased survival of colonizing individuals but also to more rapid local population growth since subsequent reproduction is retained locally. These examples make it clear that there are two strategies for colonization success: produce many propagules to ensure arrival at new habitat or produce well-supplied or highly competitive propagules that are likely to succeed if they arrive.

Competition–Colonization Tradeoff

Ecologists contrast *r*- and *K*-strategy life histories to identify the broad pattern of life-history tradeoffs between short-lived organisms with fast maturation, good dispersal ability, and many, small propagules and long-lived organisms with slow

maturation, strong competitive ability, and few, well-supplied propagules, respectively. Because resources are finite, selection has forced a tradeoff between colonization ability and competitive ability. This tradeoff also produces a mechanism of species coexistence, called competition–colonization tradeoff.

In systems where disturbance creates colonization opportunities, competition–colonization tradeoffs can lead to coexistence between multiple competitors that share a single, limiting resource. This tradeoff is most easily imagined when the limiting resource is space; the dominant species is a better competitor and will overgrow the fugitive species, which is a better colonizer. Disturbance results in mortality of both species and opens space on the landscape. If the fugitive species can colonize and exploit this new space fast enough, then the dominant and fugitive species can coexist.

We can see competition–colonization tradeoff as one case of colonization–extinction balance. Species coexistence is determined by the relative colonization rates of each species, the mortality rate of both species due to disturbance, and the mortality rate of the fugitive species by competitive exclusion. For coexistence to occur, the fugitive species and dominant species must each solve the problem of colonization–extinction balance; the dominant species must have a high-enough colonization rate to avoid extinction by disturbance alone, while the fugitive species must have a higher colonization rate to withstand extinction from both disturbance and competitive exclusion. It acts at the scale of an individual or small group of individuals and determines whether one or both species will persist.

This pattern of coexistence has been best documented between organisms that compete for space. One classic example of competition–colonization tradeoff is the interaction between the annual sea palm, *Postelsia palmaeformis*, and the long-lived mussel, *Mytilus californianus*, in the rocky intertidal of the northeast Pacific. *M. californianus* is the competitive dominant, which will exclude *P. palmaeformis* over time. However, in areas of high wave energy, patches of M. *californianus* are ripped from the rocky substrate and *P. palmaeformis* colonizes these open patches more quickly than *M. californianus*. Transplant experiments demonstrate that *P. palmaeformis* can survive and reproduce in areas of low wave energy; however, in the absence of wave disturbance, it is overgrown by *M. californianus*. Therefore, when wave energy is high enough, *M. californianus* mortality due to disturbance and the faster colonization rate of *P. palmaeformis* allow these two species to coexist. For more on this examples, see section entitled **Further Reading**.

In Laikipia district of Kenya, fire-prone bushland savannah is dominated by a single species of swollen-thorn acacia tree, *Acacia drepanolobium*, which is host to four acacia-ant species that are obligate mutualists with *A. drepanolobium*. The ants nest within the swollen thorns and feed on nectaries of *A. drepanolobium*; the presence of ants deters herbivores from browsing on *A. drepanolobium*. Any one acacia tree hosts a single colony of ants. The four species of ants coexist on a single limiting resource of host trees; the species form a strict competitive hierarchy, in which more dominant species displace subordinate species from neighboring host trees. Unoccupied trees arise due to fire and elephant disturbance, which destroys colonies but not trees, and by small trees growing into a habitable size. A tree may be colonized by a colony from a neighboring tree or by a foundress queen. The two subordinate ant species both have higher colonization rates; the most subordinate species produces many more foundress queens to colonize newly available mature trees while the second most subordinate species has a higher than expected rate of colonizing empty neighboring trees by colony expansion. This tradeoff between competitive dominance and colonization ability is one mechanism of coexistence for these four species sharing a single limiting resource. For more on this examples, see the section titled **`Further reading'**.

Competition–Colonization Tradeoff and the Successional Mosaic

In systems where disturbances act on larger spatial and temporal scales, competition–colonization tradeoffs can maintain regional species diversity. Large-scale disturbances, such as fire, logging, or sedimentation–erosion dynamics, open up tracts of unoccupied habitat. These newly opened areas are colonized by a predictable sequence of species in a process called ecological succession. Newly disturbed areas are first colonized by ruderal pioneer species. These species may be outcompeted or overgrown by larger or longer-lived organisms. Over time, competitively superior species will dominate. When different areas in a landscape are disturbed at different times, the landscape becomes a patchwork of communities in different stages of succession, called a `successional mosaic'. When disturbance is moderate, this successional mosaic is thought to result in high diversity at the regional scale because communities in all successional stages are represented. This is called the `intermediate disturbance hypothesis' and is discussed in detail in another article in this volume.

The intermediate disturbance hypothesis has been proposed as an explanation for patterns of macroinvertebrate diversity in lotic streams in the Taieri River catchment in New Zealand. In this system, the intensity and frequency of disturbance are determined by the flow rate and frequency, respectively, of periodic high-discharge events. Disturbance varies from reach to reach in the catchment due to stream slope, distance from headwaters, and local topography, among other factors. Macroinvertebrate diversity is a unimodal function of disturbance intensity. At high disturbance intensity, some stream macroinvertebrates cannot survive a disturbance or colonize fast enough after a disturbance to persist in high-disturbance reaches. At low disturbance intensity, macroinvertebrates are distributed evenly, indicating competition among the species that remain long after a disturbance. For more on this examples, see section entitled **`Further reading'**.

A critical piece of this `successional mosaic' is the availability of colonists from other populations on the landscape. In streams, these colonists can come from several sources: upstream habitat, flying adults from another reach, or refuge habitat that organisms use to escape the effects of disturbance. If disturbance is too frequent (or to rare) across the entire landscape, then there will be no

areas in the later (or earlier) stages of succession to provide colonists to areas in other stages of succession. At this scale, colonization–extinction balance can influence the diversity of local communities (e.g., stream reaches) with different disturbance regimes and whole regions (e.g., river catchment) through the successional mosaic.

Metapopulation Biology

On larger spatial scales still, extinction of entire populations can provide the requisite unoccupied suitable habitat for colonization to occur. If recolonization from extant local populations occurs quickly enough to balance local extinction, persistence of a species on a regional scale can occur. Such a regional population, called a metapopulation is an important concept for understanding population dynamics in patchy habitats.

A classic metapopulation is a regional population composed of many local populations, each of which may be extant or extinct at any one point in time. This situation occurs when patches of suitable habitat are separated by uninhabitable areas. If habitat patches are essentially equal, and the dynamics of individual populations are fast relative to interpatch dynamics, then the important characteristic of a given patch is whether or not it is occupied. Thus, the primary variable in classic metapopulation theory is the proportion of patches that is occupied (or the proportion of populations that is extant), and the determinants of this proportion are the rate of local population extinction and the colonization rate. Extinction occurs because of demographic stochasticity; no finite population can persist indefinitely. Colonization occurs via movement of individuals from extant populations to empty patches, and all patches are assumed to be equally accessible to all others. The theory, first set out in 1970 by Richard Levins, describes the dynamics of patch occupancy by the equation

$$\mathrm{d}p/\mathrm{d}t = cp(1-p) - ep$$

Here, p is the proportion of occupied patches, e is the extinction rate per occupied patch, and c is the rate of colonization per occupied patch per unoccupied patch. Alternatively, if p is the probability that a given patch is occupied, e is the probability that a given extant population goes extinct, and c is the probability that an individual from a given extant population colonizes a given empty patch. The equilibrium proportion of extant populations is $P = 1 - e/c$. Thus, the colonization rate must exceed the extinction rate to ensure persistence of the regional ensemble, and the magnitude of the excess determines the species' regional abundance. Factors such as the number of potential colonists leaving occupied patches, their dispersal ability, and their ability to establish new populations in unoccupied habitat patches are all included in the overall rate of colonization, c, in this model framework.

The classic metapopulation model involves several assumptions. While few natural populations may strictly meet these assumptions, the model provides a powerful conceptual framework for patchy populations, with important implications for conservation and evolution as well as population biology. It also serves as a starting point for introducing complications such as spatially restricted dispersal, spatial aggregation of and/or correlation between local populations, differential size or quality of habitat patches, etc. Such modifications may allow the model to describe the dynamics of the many natural populations that meet a looser definition of a metapopulation as a regional population comprised of local populations that are interconnected by dispersal.

The metapopulation approach is perhaps most useful for modeling disease dynamics, since many of the classic model's assumptions are best met by populations of microorganisms. From the point of view of the disease, occupied patches are infected hosts and empty ones are susceptible hosts. The disease spreads if colonization via infection of susceptible hosts exceeds extinction via host immune response. The Kermack–McKendrick model, proposed to describe the dynamics of bubonic plague and cholera, is one of the simplest examples of this approach. The model consists of three differential equations describing the dynamics of susceptible hosts (suitable, unoccupied patches, $|S|$), infected hosts (suitable, occupied patches, $|I|$), and recovered hosts who have developed immunity from disease (unsuitable patches, $|R|$):

$$\frac{\mathrm{d}S}{\mathrm{d}t} = -\beta SI$$

$$\frac{\mathrm{d}I}{\mathrm{d}t} = \beta SI - \gamma I$$

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \gamma I$$

where β is the infection rate per infected host per susceptible host, and γ is the recovery rate per infected host. The infection rate in this epidemic model is thus analogous to the colonization rate in the classic metapopulation model. The major difference in this case is that with extinction of disease populations due to host immune response, habitat patches are also rendered unsuitable. Therefore, the question of most interest is not how many patches are infected at equilibrium, but whether or not the disease ever spreads. In this model, spread occurs if $R_0 > 1$, where

$$R_0 = \frac{\beta S}{\gamma}$$

Thus, although models of disease dynamics and the questions they ask and answer may differ in important ways from basic metapopulation models, the role of colonization and its balance with extinction is clear in both cases. More sophisticated metapopulation models for disease allow host population dynamics and host mobility, as well as any of the refinements to the metapopulation model mentioned above.

Island Biogeography

We turn now to considering the balance between colonization and extinction on the spatial scale of continents, oceanic islands, and the distances between them. In doing so, we move from a single species occupying many patches to many species in a single large patch. The influential theory for this situation is `island biogeography theory', and covers it in detail. In brief, the theory predicts that the number of species on an island depends on a dynamic balance between colonization of the island by species from the mainland and extinction of species already on the island. The mainland serves as a permanent pool of a fixed number of colonist species, and the island is permanently suitable for all of them, but each species colonizes the island only when not currently present there. As a result, as the number of species occupying the island increases, the rate of colonization per unit time decreases. If all species were equal in their colonization ability, then the colonization rate would decrease linearly with the number of species on the island. Since species usually differ in colonization ability, however, as we discussed above, the poorer colonizers take longer to arrive, and the better colonizers are likely already present when they do. Thus, we expect the decrease in the colonization rate to be more gradual at higher island species richness, and the rate should be a convex decreasing function of species richness on the island. The exact value of the colonization rate function at any richness depends on the specifics of a given situation, including the identities of the species in the colonist pool and the isolation of the island from the mainland. The intersection of the colonization function with the extinction function (an increasing function of island richness) determines the richness at which colonization and extinction balance. This is the island's equilibrial or long-term species richness.

Empirical tests of the general theory have upheld its essential points. The classic model, however, does not detail interaction between colonizing species (such as facilitation of colonization by earlier colonists, for example and also excludes any effects on species richness of evolution on either the mainland or the island. Despite these omissions, the model provides a valuable conceptual framework for understanding the role of colonization in determining diversity and community composition over large spatial scales, and also provides a starting point for understanding spatial systems other than oceanic islands. For instance, the theory can apply to habitat islands such as mountaintops or lakes, as long as a permanent `mainland' habitat exists to provide colonists. `Island biogeography theory', where colonization occurs between pairs of very unequal habitat patches, and metapopulation theory, where colonization takes place between many equal patches, are two special cases of colonization–extinction interactions in patchy habitats. These two classical theories are thus useful tools for understanding the dynamics of the many patchy natural systems on regional to continental spatial scales. Metacommunity theory is a contemporary synthesis of these and other conceptual approaches to spatially structured communities.

Availability of New, Suitable Habitat on a Large Scale

Biological invasion is a prominent example of colonization of new areas of suitable habitat. Invasive species often have life-history characteristics that make them good colonizers. In cases where invasive spread occurs most quickly, many secondary colonization events follow the initial introduction, so that rapid spread occurs by the establishment, increase, and eventual coalescence of many small and widely dispersed populations descended from the initial colonizers of the new habitat. Species that exhibit such rapid, patchy spread include cheatgrass, *Bromus tectorum*, in western North America; smooth cordgrass, *Spartina alterniflora*, in Willapa Bay, Washington State; and the Argentine ant, *Linepithema humile*, which disperses poorly on its own but covers long distances when assisted by humans. Because many conspicuous invasive species disperse widely, invaders often fall into the `ruderal' or `fugitive' life-history categories; but many (such as yellow starthistle, *Centaurea solstitialis*, and the Argentine ant, *L. humile*) are very strong competitors, while others (such as saltcedar, *Tamarix ramosissina*) tolerate extreme environments very well. Whether they are good colonizers because they disperse often, survive well during dispersal, and/or find many types of habitat acceptable for vigorous growth (sometimes despite the presence of a prior resident), invasive species increasingly take advantage of new dispersal pathways opened by the global human economy to reach previously unavailable areas of suitable habitat. These issues are of primary importance in attempts to slow, stop, or prevent biological invasions that are potentially devastating to native communities.

Changes in habitat suitability can provide new opportunities for colonization on large spatial scales. One way to be a good colonizer is to enhance the suitability of a new habitat, and some species can facilitate their own spread into new areas by changing the properties of the surrounding ecosystem. For instance, colonization by alien grasses can increase the fuel available to fire and thereby increase fire frequency, area, and intensity. The grasses recover quickly from fire and colonize burned areas, generating a positive feedback loop that favors the grasses' spread. Alternatively, one colonist can open large areas of suitable habitat for another; when the European green crab, *Carcinus maenas*, arrived in San Francisco Bay, its predation upon two species of native clams reduced their densities dramatically and allowed the rapid spread of the eastern gem clam, *Gemma gemma*. Finally, climatic change can also drive changes in habitat suitability, with colonization of the newly suitable areas resulting in geographic shifts in

species' ranges. Northward plant colonization of newly uncovered habitat after withdrawal of glaciers at the end of the last ice age is well documented in the pollen record. In recent decades, changes in intertidal community composition in the northeastern Pacific reveal northward shifts of several southern species into waters that previously were too cold for them. Climate change can also lead to colonization by facilitating dispersal. Low sea levels may have facilitated the spread of humans from Eurasia to the Americas by revealing the Bering land bridge. Understanding interactions between climate change and colonization is an urgent priority for conserving biodiversity and anticipating likely novel community assemblages, given rapid predicted natural and anthropogenic habitat changes in the future.

One of the most dramatic instances of colonization of new habitat occurs not in physical space but in niche space. Organisms can increase the area of suitable habitat by evolving to use new areas. The global influenza pandemic of 1918, recently shown to be derived from avian influenza, is a spectacular example of a virus' evolution to take advantage of an entirely new host, and other deadly human diseases throughout history (including recent times) may have their origin in niche shifts of animal disease. Colonization of a completely new habitat type frequently occurs after colonization in physical space, as evidenced most clearly by adaptive radiation on species-poor islands. The lag between the initial colonization of a new area by an invasive species and the onset of rapid spatial spread is sometimes also attributed to genetic adaptation to the new environment. Genetic founder effects may also play a role in this adaptation process. In any case, niche shifts precipitated by physical colonization can be an important process in allopatric speciation.

Dominance and Its Evolution☆

Reinhard Bürger, University of Vienna, Vienna, Austria
Homayoun C Bagheri, University of Zurich, Zurich, Switzerland

Introduction

As Gregor Mendel noted in his seminal paper of 1865, it had been known for some time that hybrids are usually not exactly intermediate between the parental species. Mendel introduced the term "dominant" to refer to characters that are transmitted almost unchanged to the hybrids, and "recessive" to those that become latent. In the meantime, more than a century of genetics has shown that dominance is a ubiquitous phenomenon with most deleterious mutations being recessive. Deleterious mutations are constantly created anew, while selection continually eliminates such mutations from populations. However, mutations can more easily persist and spread through a population, when heterozygote individuals do not (fully) experience the deleterious effects, that is, the mutation is recessive. Dominance is not only ubiquitous, but clearly of great evolutionary importance because it masks the effects of deleterious mutations as long as they are rare and are found predominantly in heterozygous individuals. Mutations are rarely completely dominant or recessive, but usually intermediate, also called codominant. Complete absence of dominance is uncommon, however. The degree of dominance plays an important role in the explanation of several evolutionary phenomena. These include the evolution of sexual reproduction and recombination, the evolution of selfing, Haldane's rule on inviable species hybrids, and the maintenance of genetic variation of metric traits. It is also well established now that dominance is a property of the phenotype and not the gene because genes that affect several traits can be dominant for one trait and recessive for another.

In 1928, R. A. Fisher raised the question why most deleterious mutations are recessive and proposed a model for the evolutionary modification of dominance relations. This was motivated by early experiments by W. Bateson and others which had demonstrated that dominance relations can be modified by changing the genetic background or, later, by selection. Fisher's theory was criticized by Sewall Wright for reasons discussed below. As an alternative, he suggested that the explanation of dominance has a strong physiological component. In agreement with Wright, J. B. S. Haldane held that dominance provides a factor of safety, in that a single dose of the most active allele would, suitably regulated, provide enough of the gene product for normal viability. Fisher's hypothesis led to fierce controversies between proponents of "physiological" and "evolutionary" explanations. In 1981, Kacser and Burns developed a molecular explanation using metabolic control theory which, by many, was taken as evidence that an evolutionary explanation of dominance is obsolete. Still, there are many demonstrated cases of evolution of dominance in natural systems. However, the demonstrated cases of evolution of dominance in natural systems, some of them discussed below, require an explanation. In the meantime, alternative molecular theories, also based on biochemical principles, have been proposed. Some of them provide the potential for evolutionary modification of dominance. Despite its central importance and a huge body of empirical and theoretical work, no generally valid explanation for dominance has been provided until today. In fact, disagreement among scientists about several issues related to its explanation abound.

We shall start with a brief summary of empirical and experimental facts. Then we shall highlight and evaluate the various explanations of dominance (molecular basis of dominance), the theories that have been proposed for the evolution of dominance, as well as some of the main controversies. Finally, we will suggest a possible reconciliation.

Empirical Facts

It has been known for long, and is a generally accepted fact now, that mutations with major (deleterious) fitness effects are almost always recessive. In the simplest case of two alleles, A and a, at a locus, the fitness of the three possible genotypes, AA, Aa, and aa, are usually denoted by 1, $1 - hs$, $1 - s$. Here, s is the selection coefficient and h the dominance coefficient. A mutant is neutral if $s = 0$ and lethal if $s = 1$. If $h = 0$, then A is dominant and a is recessive; if $h = 1$, then a is dominant and A recessive; if $h = {}^1/_2$, one says there is no dominance; if $0 < h < 1$, one speaks of intermediate dominance or codominance; if $h < 0$, then there is overdominance, whereas underdominance prevails if $h > 1$.

Estimates of Dominance

Measuring the coefficient of dominance, h, in particular, for mutations of small effect (s), which constitute the vast majority of all mutations, is difficult. Direct estimates can be obtained from spontaneous mutations in mutation–accumulation experiments of highly inbred lines. Such assays are very laborious. By assuming mutation–selection balance, indirect estimates can be obtained

 doi:10.1016/B978-0-12-409548-9.11201-1

from the structure of segregating populations. These estimates, however, are based on additional assumptions that often cannot be checked and also face statistical challenges. Therefore, they are not very reliable, and the development of methods for measuring dominance coefficients is an active field of research.

All known data demonstrate widespread correlations between dominance and fitness effects of mutations; that is, mutations with a large deleterious effect tend to be more recessive than those with a small effect. This is true for coding genes and, more recently, has also been shown for noncoding genes. Because fitness and dominance effects vary across loci, and the locus at which a mutation occurs can often not be determined, in general, only average coefficients of dominance ($\bar{h}$) and selection ($\bar{s}$) can be inferred. Available data suggest that $\bar{h}$ is about 0.1–0.2 and decays approximately exponentially with increasing s.

Mutations affect fitness through phenotypic traits. In fact, the fitness effect is a consequence of a mutation's effect on one or several traits. If these are closely correlated with fitness, then the fitness effect may be large. Many traits, however, for instance morphological traits, influence fitness only weakly. Dominance effects have been estimated with respect to traits that can be measured on a metric scale. For such metric traits (e.g., body size, oil content in maize, or abdominal bristle number in Drosophila, the latter being extremely well studied genetically), average dominance coefficients appear to be close to 0.5 and depend only weakly on the size of the mutational effect. In particular, no significant skew has been observed.

Compared with intermediate dominance, over- and underdominance are rare. The probably best-known example for overdominance is sickle-cell anemia, which provides immunity against malaria in heterozygous state. Over- and underdominance often seem to be the consequence of frequency-dependent selection or spatially heterogeneous selection. The first occurs if the heterozygotes have an overall advantage, for instance because they are generalists and can use most or all available resources. Underdominance can easily occur by migration–selection balance if each of the two homozygotes is optimally adapted to a different ecological niche and heterozygotes are maladapted because they do not have their own niche.

Modification of Dominance

Numerous experiments have shown that dominance relations can be changed experimentally by substitution of the genetic background or by selection. Therefore, certain genes have the ability to modify the character expression, and such genes seem to be abundant.

Most empirical evidence for evolutionary modification of dominance concerns wing patterns in lepidopteran species, mimicry in butterflies, and pesticide resistance. A classical example is provided by industrial melanism in the peppered moth *Biston betularia*, a lepidopteran species. During the second half of the 19th century, dark forms of this usually light-colored insect became more common in industrial areas and within about 50 years nearly replaced the pale form. One of the reasons why the melanic form gained a selective advantage was that the tree trunks on which these butterflies rested became blackened due to pollution which killed light lichen, and the pale form, originally cryptically colored, became better visible to their predators. Interestingly, the dark form became dominant during this process. Extensive experiments by H. B. D. Kettlewell in the 1950s and 1960s suggest that selection for an unlinked modifier occurred during the spread of the favorable mutant. Later, similar experiments were performed in related species with slightly different outcomes, which may be explainable by linked modifiers that, initially, had a different frequency as in *B. betularia*. Since the ecological setting is complex, other selective forces as well as migration–selection balance may also have played an important role. In all of these cases it seems that an originally recessive or intermediate allele became more or less dominant.

A quite different situation was observed in some cases of mimicry by P. M. Shepard, C. A. Clarke, and others in the 1950s and 1960s. There, frequency-dependent selection maintains overdominance, and one of the homozygous phenotypes is modified to resemble the heteroyzgotes.

Another well-studied class of examples for dominance evolution concerns insecticide-resistance genes. Often the genes causing resistance, and sometimes even those causing dominance, are known. Since pesticide applications are heterogeneous in space, and alleles conferring an advantage in treated areas tend to be disadvantageous in untreated areas, underdominance is often maintained by migration–selection balance.

Explanations of Dominance and Its Evolution

Basic Scenarios for the Evolution of Dominance

Almost all population-genetic explanations for the evolution of dominance are based on scenarios involving selection. Distilled down to its simplest form, the common idea in these models is the notion that, given a set of homozygous and heterozygous genotypic variants, one or more of the less-fit variants evolve to resemble the fitter variant at the phenotypic level. Consider a starting condition in which the phenotypes associated with a pair of allele variants are codominant. The original scenario proposed by Fisher was one in which the fitness landscape associated with the three possible genotypes mimics the qualitative shape of the phenotypic landscape. Hence one of the homozygous variants is fitter than its alternate, and the heterozygote is intermediate in fitness. **Fig. 1**A depicts such a scenario. In the latter case, dominance could evolve if the phenotype of the heterozygote is modified (via selection) to resemble the fitter homozygote. This would lead to dominance of the fitter phenotype, and a form of robustness with respect to mutations, since now the effects of the less-desirable allele are masked in the heterozygotes.

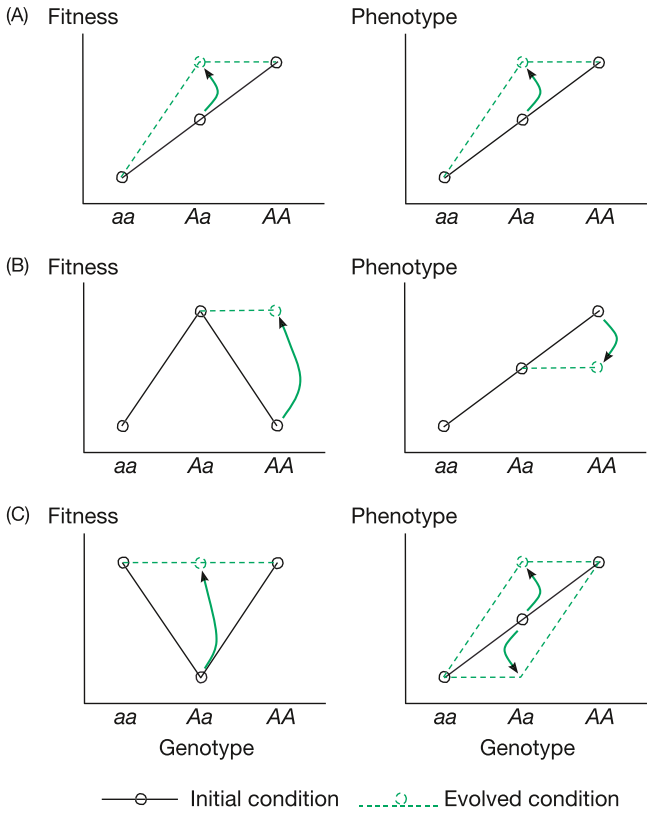

Fig. 1 Idealized representation of some situations under which dominance could evolve. (A) Superior homozygote as initial condition, (B) heterozygote superiority as initial condition, (C) heterozygote inferiority as initial condition.

The noteworthy concept here is that a "phenotypic" landscape that is described as function of the genotype at a single locus is not necessarily fixed. Consequently, fitness in relation to a single-locus genotype is also not necessarily fixed. In this scheme, the question that remains is what are the causes by which the relation between genotype and phenotype can change. One possibility is a change in the environment. A second is a change in the genetic background. The latter case is usually the main protagonist in models of dominance evolution. In the simplest case, changes in the genetic background can be represented as changes in alleles at a "modifier locus,", which in turn modify dominance relations with respect to alleles at a "primary locus." All such modifier models and their more complicated derivatives inherently assume that the relation between genes at separate loci and the phenotype are nonadditive (i.e., nonindependent) and that the latter relation can be modified by gene interactions. Nonadditivity, whereby allele substitutions at one locus can alter the phenotypic effects of substitutions at another locus, is referred to as "epistasis." Models of dominance evolution via changes in the genetic background inherently assume the existence of epistasis.

If mutational effects at one locus can be modified by substitutions at another, then the general scheme presented in Fig. 1A is not the only scenario by which dominance could evolve. Two commonly considered scenarios are presented in Fig. 1B and C. Both rely on balanced polymorphisms as the starting condition. One possible scenario is when the heterozygote is superior in fitness to the homozygotes (Fig. 1B). Dominance would evolve under such a condition if the phenotype of one of the homozygotes were modified to resemble the fitter heterozygote. The reverse starting condition can be also considered, whereupon either homozygote is superior to the heterozygote (Fig. 1C). In the latter case, dominance would evolve if the heterozygote were modified to resemble either one of the homozygotes. The latter starting condition is more complicated from the population-genetic perspective, since the maintenance of a balanced polymorphism involving two fit genotypes depends on frequency-dependent selection.

The situations presented in Fig. 1 deal with the possibility of dominance modification due to selection—provided that a physiological trait of interest can be modified, and that it can be subject to selection. In the next section, we consider some of the physiological grounds for the manifestation of dominance modification. Whether population conditions allow for selection to be an effective force is itself a decisive matter. This will be discussed in a subsequent section.

Mechanistic Explanations for Dominance: The Case of Metabolism

During the early years of the 20th century, one of the more prominent explanations for dominance, advocated by W. Bateson, R. C. Punnett, and others, was the "presence-and-absence" hypothesis. Consider a situation in which a phenotype or trait comes about as a result of the action of a set of gene products. One can conceive of a situation in which each gene i plays a role X_i for the

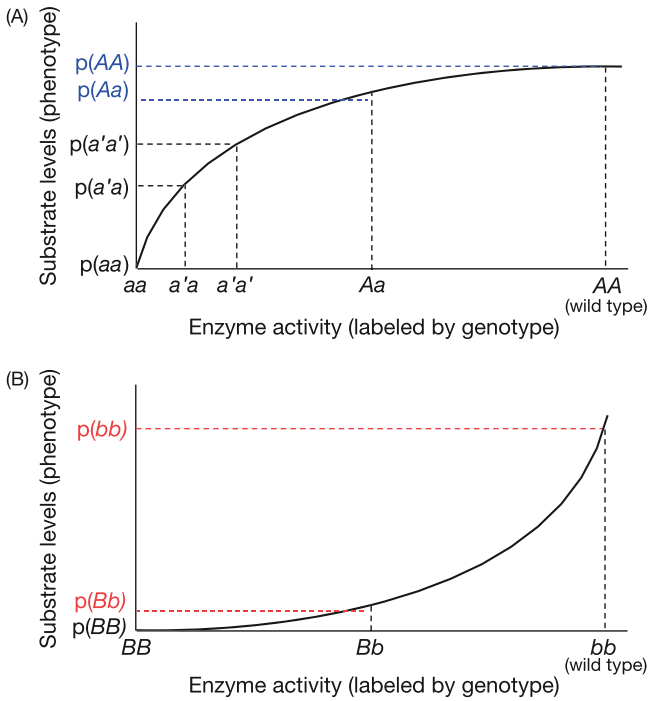

Fig. 2 Physiological model for dominance based on enzyme activity and substrate accumulation. (A) Dominant wild type (Wright's physiological model), (B) recessive wild type (hypothetical model).

formation of a given phenotype *P*. The presence–absence hypothesis assumes that as long as there is one functional copy of gene *i*, then the role X_i is satisfied, and hence *P* remains at wild-type levels. With advances in physiological genetics, and subsequent advances in molecular biology, the presence–absence hypothesis has been abandoned. Nonetheless, we should note that the prime weakness in the presence–absence hypothesis was not necessarily its incomplete representation of the underlying mechanisms; all mechanistic representations of genotype–phenotype relations are at some level incomplete. By the standards of today, the presence–absence hypothesis is more a logical argument than a detailed exposition on mechanism. However, its major failure was that as a phenomenological description, it failed to fit much of the mounting experimental evidence; it was not general enough to encompass many exceptions.

Given present knowledge of the variety of molecular processes occurring in the cell, such as gene regulation, signal transduction, and metabolism, it would now seem unreasonable to use any specific mechanistic model as a general model for dominance modification. Depending on the underlying causes of a given phenotypic trait, the proximal causes for dominance modification and the constraints placed upon it can be very different from one case to the next. Hence, any given molecular explanation may serve as an instantiation of general concepts pertaining to dominance modification, but it is unlikely to serve as the grand model for modification. Nonetheless, if any given modification model is sufficiently well-developed, it can be used to test some general evolutionary questions.

The case study that has been most central to addressing dominance evolution revolves around phenotypes that are directly dependent on the functioning of metabolic enzymes. Shortly after Fisher proposed his hypothesis, both Wright and Haldane argued that the proximal causes for the manifestation of dominance would have to depend on the underlying physiology. At the time, enzymes and their biochemistry were at the forefront of mechanistic explanations for the inner workings of organisms. Accordingly, they also had a central role in Wright and Haldane's explanations. With the assumption that most genes code for enzymes, and the use of a simplified nonlinear model of enzyme pathways, Wright tried to address dominance from a physiological perspective. Based on his model, he hypothesized that the rate of substrate formation throughout a pathway will have a diminishing returns relation to enzyme concentrations (**Fig. 2**A). Under such circumstances, when enzyme concentrations are in the flat region of the curve, then reductions in enzyme concentration will have relatively small effects on substrate levels. Accordingly, let us assume that a wild-type homozygote *AA* has two copies of a gene coding for an enzyme *E*, while the mutant heterozygote *Aa* has one functional copy. Furthermore, let us assume that enzyme concentrations are proportional to copy numbers, and hence that the concentration of functional enzyme *E*, and consequently enzyme activity, is halved in *Aa* genotypes in comparison to *AA*. If the *AA* genotype lies deep in the plateau region of the curve in **Fig. 2**A, then the reduction of enzyme concentrations in *Aa* genotypes to half of *AA* would not have an appreciable effect on phenotype, and the wild-type phenotype associated with *AA* would be considered dominant. In Wright's model, dominance of the wild type results from the convex shape of the relation between enzyme activity and phenotype. On the other hand, a concave curve such as the one in **Fig. 2**B would lead to the wild type being recessive. In the context of **Fig. 2**A, dominance of the wild type would evolve when wild-type enzyme

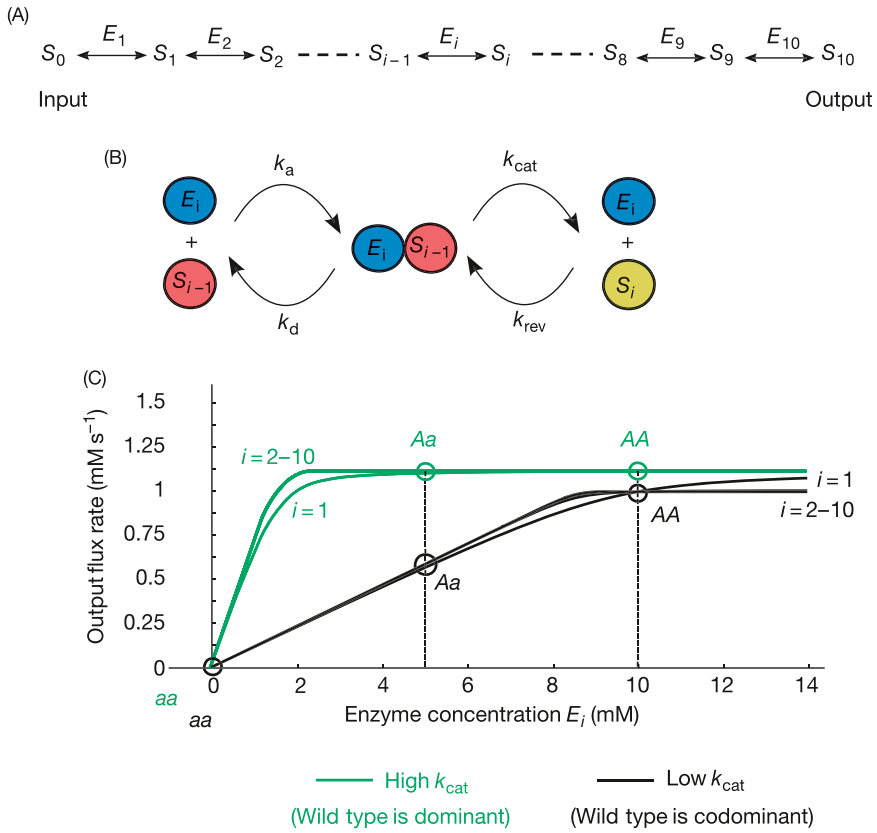

Fig. 3 Model of dominance modification for the flux phenotype of a 10-enzyme pathway. (A) Ten-enzyme sequential pathway, (B) details of each enzyme-catalyzed reaction, (C) flux phenotype of pathway as a function of enzyme concentrations.

activity is pushed to the flat end of the curve. Conversely, as exemplified by the $a'a'$ homozygote in Fig. 2A, a phenotype that is associated with the steeper part of the curve will tend toward codominance with respect to the null *aa* homozygote.

The physiological model discussed above ignores compensatory effects such as gene regulation, feedback, redundancy, and nonsequential pathway topologies. Nonetheless, as a model, it is a plausible starting point for addressing questions related to dominance and its evolutionary origins; in fact, it has been central to research on this topic. An important question that arises within this model, is the reason whereby wild-type enzyme activities should be at the high end of the curve. Haldane's suggestion was that organisms could evolve a "factor of safety" against perturbations. Such perturbations could in principle be either environmental or genetic. Another explanation could be that high enzyme activities are simply required for individual fitness, and because of the convex shape of the curve, dominance evolves as a side effect of selection for high enzyme activity.

As an alternative explanation for dominance, Kacser and Burns suggested that in metabolic systems, one could explain dominance without making recourse to evolutionary explanations. Their argument is based on models that are at first sight similar to Wright's model. However, there is a fundamental difference. In Wright's model, levels of dominance can be modified by changing the enzyme activity associated with the "wild-type" homozygote. The Kacser and Burns model (from here on abbreviated as the KB model) places a crucial constraint on this modification. In the latter case, dominance can be modified at any given locus in the same sense as in Wright's model. However, the KB model also suggests that modifications that result in increased phenotypic sensitivity to any enzyme are compensated by decreased sensitivity to other enzymes. Furthermore, the model also implies that the more enzymes are involved in a pathway, the smaller the average effect of each enzyme on the phenotype. Based on these premises, Kacser and Burns concluded that dominance—which depends on insensitivity of the phenotype to enzyme concentration changes—is a de facto property of metabolic pathways and that evolutionary explanations based on dominance modification are not necessary.

Many of the mechanistic details of Wright's model do not reflect what is known of enzyme kinetics today. However, his model does preserve some of the nonlinear aspects of chemical transformations. On the other hand, the KB model is more akin to modern conceptions of enzyme kinetics. However, the model contains some approximations that eliminate important nonlinearities in enzyme kinetics—namely, enzyme saturation. The consequence is that the scope of the KB model is much more limited than originally intended and, in hindsight, not a good candidate for investigating the evolutionary origin of dominance. For example, Bagheri and Wagner have suggested that if one considers simple models of enzyme kinetics, with the possibility of enzyme saturation, one finds that system robustness or dominance is not a de facto property of enzyme systems. In particular, the compensatory constraints on dominance modification that are postulated in the KB model are eliminated when the system allows

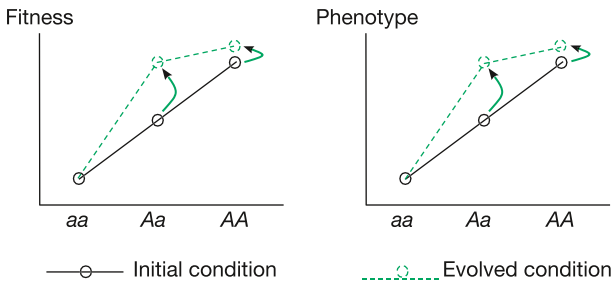

Fig. 4 Example of dominance evolution due to a modifier with multiple effects.

for saturation. In fact, the modulation of enzyme saturation levels allows for dominance modification, and hence, dominance evolution. **Fig. 3** shows an example of a 10-enzyme pathway, which contrary to the KB model is modeled with the possibility of enzyme saturation. The pathway consists of a constant input S_0 and an output substrate S_{10}, whose rate of production (flux, dS_{10}/dt) is the phenotype of interest (**Fig. 3**A). As indicated by **Fig. 3**B, each enzyme-catalyzed reaction can be conceptualized as a process by which a substrate and an enzyme join to form an enzyme–substrate complex, which subsequently dissociates into a product and the unaltered enzyme. Saturation levels can be altered by mutations that either change concentration levels or the dissociation constant k_{cat}. Flux for such a model can be obtained by numerical integration of the resulting system of differential equations. **Fig. 3**C shows the flux function for two realizations of a 10-enzyme pathway. The green lines trace a pathway whose enzymes possess relatively high k_{cat} values. The black lines trace a pathway with low k_{cat} values. Within each case, flux responses to changes in enzymes 2–10 are very similar, and the corresponding curves are almost indistinguishable. Responses to enzyme 1 are slightly more sensitive. What is important to note in this figure is that we are observing two different endpoints of possible evolutionary trajectories. In the low k_{cat} case, the wild-type phenotype is codominant with respect to mutations that halve the concentration of "any" enzyme. In contrast, in the high k_{cat} case, the wild-type phenotype is dominant with respect to mutations that halve the concentration of any enzyme. Hence, one can conceptualize dominance evolution as an evolutionary process whereby k_{cat} levels have been gradually modified from low to high values. High k_{cat} values result in low enzyme saturation levels, and consequently, higher dominance levels for the wild type.

A further consequence of the model in **Fig. 3**C is the important observation that there is a slight difference between the wild-type *AA* phenotypes of the high and low k_{cat} pathways. This means that if one is selecting for the high-flux phenotype, one can select modifiers due to their direct fitness effects rather than their dominance modification effects. Direct effects can be relatively small, but they are not dependent on the frequency of *a* alleles. Meanwhile, modifying effects can be larger, but nonetheless they occur less frequently due to their dependence on the frequency of *a* alleles. Hence, selection for modifiers with multiple effects would circumvent some of the frequency sensitivity problems associated with modifier evolution. A schematic drawing of such a scenario is shown in **Fig. 4**, which corresponds to the enzyme kinetic model in **Fig. 3**. Dominance evolution in such a scenario is more likely to be successful than in cases where modifiers only have a dominance modification effect (e.g., **Fig. 1**A). Interestingly, despite the lack of an explicit enzyme kinetic representation, the mathematical properties of Wright's model are similar to the enzyme kinetic model presented here; namely, Wright's model allows for the possibility of dominance evolution through multiple effects, while the KB model does not.

Evolutionary Explanations for Dominance

As discussed above, dominance relations are not necessarily fixed but can be modified and may even evolve. Fisher's basic argument was the following. At mutation–selection balance, deleterious alleles are kept at low frequency in a population but, nevertheless, reduce its mean fitness. Therefore, genes that protect the population from the effects of recurrent deleterious mutations should be selectively favored and increase in frequency. Since most rare alleles occur in heterozygotes, modification of the heterozygous phenotype would increase mean fitness. Wright introduced a model that formalized Fisher's proposition and has become the archetype for the evolutionary modification of dominance. It assumes a primary locus at which a wild-type allele, *A*, and a deleterious mutant allele, *a*, occur. In addition, it assumes a so-called modifier locus, with alleles *M* and *m*, where *M* modifies the fitness effects of heterozygous genotypes as follows:

$$\begin{array}{cccc} & AA & Aa & aa \\ MM & 1 & 1 & 1-s \\ Mm & 1 & 1-ks & 1-s \\ mm & 1 & 1-hs & 1-s \end{array} \qquad (1)$$

Here, the intensity of selection against *a* is $s > 0$, and the dominance coefficients satisfy $0 \le k \le h \le 1$ and $h \neq 0$. Mutation is assumed to occur from allele *A* to allele *a* at rate *u*, and recombination between the two loci occurs with frequency *r*, with $0 \le r \le {}^1/_2$. Fisher, and in order to refute him, also Wright, assumed that evolution commences at mutation–selection balance between *A* and *a* when a new allele *M* is introduced at the modifier locus at low frequency. At this initial state, with fitnesses given by the last line of (1), the mean fitness of the population is approximately $1 - 2u$. If *M* became fixed, which was not proved by Fisher or Wright but only much later, the

first line in (1) applies, and the mean fitness increased to about $1 - u$. This model is in line with the graphical representation in Fig. 1A. Several more elaborate analyses in the 1960s and 1970s corroborated and extended Wright's analysis. Given that per-locus mutation rates are very small, typically of the order of 10^{-6} to 10^{-5}, this is a very small fitness increase. Whereas Fisher considered this to be sufficient, Wright argued for the contrary because, in his opinion, genetic drift could easily overcome this tiny fitness advantage and probably cause the loss of the modifier. In addition, the slightest disadvantage of the modifier would nullify its favorable effect. However, Fisher adhered to his proposition because he considered population sizes to be very large, of the order of 10^9 or higher. Hence, in contrast to Wright, genetic drift was only of minor relevance to him. Today, we know that so-called effective population sizes (this is what matters for the effects of genetic drift) are much lower than actual population size, and for most higher organisms (even species of Drosophila) less than 10^6. For these and other reasons, Fisher's proposition is now generally considered to be untenable.

Several other hypotheses, usually also formalized in terms of modifier models, and mostly in line with one of the mechanisms depicted in Fig. 1B or C, have been advanced to explain various cases of dominance evolution. If, for instance, as in Fig. 1B, a homozygous phenotype is changed to resemble the advantageous heterozygote, then the potential fitness increase is substantial and there are no theoretical obstacles to such an occurrence. Several cases of mimicry fall into this category. Similarly, if, as in several cases of pesticide resistance, underdominance is maintained by spatially heterogeneous selection, heterozygotes are frequent and their fitness disadvantage can be reduced by modifiers. In general, whenever there is a balanced polymorphism, as in Fig. 1B or C, there are many heterozygotes present and evolution of dominance can readily occur.

An interesting hypothesis, in line with the formal model (1), was considered by Haldane in 1956. He suggested that when a gene was sweeping through a population as a result of natural selection, heterozygotes would be very frequent, and this would provide an opportunity for intense selection for modification of the heterozygote. A case in point seems to be industrial melanism in moths and butterflies. Apparently, selection of the modifier has occurred during the spread of a favorable mutant. This requires that, when the favorable mutant arises, or a rare mutant becomes favorable through a change in the environment, modifiers are already present in the population. During such a process, heterozygotes become very frequent, and a modifier can rise to high frequency and become fixed. It was proved by Bürger and Wagner in the early 1980s that this mechanism indeed works. It also helps to explain several obstacles raised by backcrossing experiments in various cases of industrial melanism. Another interpretation of this process, put forward by G. S. Mani in 1980, maintains that heterozygotes have been kept at high frequency by migration–selection balance, a scenario studied in more detail by S. Otto and D. Bourguet in 1998.

Despite many well-established cases of evolution of dominance and despite several mathematical analyses that have demonstrated that dominance evolution can occur under a number of scenarios (but not under Fisher's original one), evolutionary explanations have been largely dismissed and are ignored by most textbooks.

There are several reasons why evolutionary explanations of dominance are considered to be irrelevant or even wrong. One is that Fisher's original proposition is untenable and many seem to believe that this applies to any evolutionary explanation of dominance without realizing how different they can be. A second and related reason is, as first pointed out by Charlesworth, the strong inverse correlation between the deleteriousness of a mutant and its degree of dominance. Such a correlation cannot, and was not, predicted from Fisher's theory. If, however, evolution occurs as in Haldane's model and the population is finite, the situation changes. A third, very important reason, is that Kacser and Burns' metabolic theory has been widely accepted, and thus an evolutionary explanation of dominance had seemed unnecessary. Finally, Orr showed that in "artificial" diploids of the normally haploid alga Chlamydomonas, wild types are about as often dominant as in diploid species. He claimed that this finding falsifies Fisher's theory. It, however, only shows that dominance can occur without evolution. Moreover, as discussed by Saved and Mayo, a similar observation has already been made in 1947 by D. Lewis.

What is clear by now is that, even if the theory of Kacser and Burns is eventually replaced by a more general or different theory, molecular pathways can often generate dominance. Therefore, a priori, dominance does not necessarily require an evolutionary explanation. However, it should also be noted that molecular pathways can allow for dominance modification, and hence dominance evolution. Furthermore, and this must not be ignored, many instances of evolution of dominance have been demonstrated, noteworthily in well-understood ecological settings, and these require an evolutionary explanation.

We close this discussion by pointing out that evolution of dominance, by whatever mechanism, is a special case of evolution of robustness, and modifier models are conceptually the simplest, and oldest, models to study it. More generally, epistatic interactions among loci can lead to the evolution of robustness and of genetic architecture, for instance, because new mutants can change the effects of current as well as future (mutant) alleles at other loci. In recent times, this has become an active field of research, and due to the complexity of the problems involved, is likely to remain so in the coming years.

Eco-Evolutionary Dynamics

Gabriel Pigeon and Fanie Pelletier, Université de Sherbrooke, Sherbrooke, QC, Canada

Glossary

Animal model A mixed effect model (i.e., a form of linear regression in which the explanatory terms are a mixture of both "fixed" and "random" effects) where one of the random effects of interest is the additive genetic value of individual animals. It is used to partition plastic from genetic part of traits.

Co-evolution Evolution of two or more species having a close ecological relationship, where both species adapt to the evolutionary changes occurring in the other species, thereby affecting each other's evolution.

Contemporary evolution Evolutionary changes observable over less than a few hundred years. The concept is also sometimes referred to as microevolution or rapid evolution or evolution on short time-scale.

Eco-evolutionary feedbacks The reciprocal interactions between the ecology of populations, communities, and ecosystems.

Evolution Change in allele frequencies in a population over time.

Evolvability The ability to respond to selection.

Extended phenotype All the effects a gene has on the outside world that may influence its chances of being replicated. These can include effects on the organism in which the gene resides, the environment, or other organisms.

Functional traits Any morpho-physio-phenological traits which impact fitness indirectly via its effects on performance traits.

Phenotypic plasticity Change in the average phenotype expressed by a genotype in different environments.

Standing genetic variation Allelic variation that is currently segregating within a population, as opposed to alleles that appear by new mutation events.

The classic view is that natural selection determines which phenotypes persist or go extinct, over a long time-scale while population growth, community, and ecosystem processes are mostly driven by ecological factors such as density-dependent competition and stochastic factors on a shorter time-scale. Thus, micro-evolutionary changes are assumed to occur on an evolutionary time-scale and scientists have typically ignored the potential feedback of evolution on ecological processes. However, the realization that selection can be strong and that evolutionary changes can occur over ecological time-scale (also termed contemporary time-scale) has led researchers to ask a very important question: can evolutionary changes feedback on ecological dynamics? Several studies have shown that evolutionary processes can have quantifiable effects on ecological dynamics. Under some circumstances, evolution can occur within a few generations, and it is therefore necessary to consider the possibility that evolutionary changes may feedback on ecological processes and vice versa. Eco-evolutionary dynamics studies explore both the unidirectional effects of ecological changes on evolutionary processes (often referred to as the ECO to EVO links) and evolutionary changes on ecological processes (often referred to as the EVO to ECO link), and, even more importantly, they document the bidirectional eco-evolutionary feedbacks on contemporary time-scale. Considering that the ECO to EVO links have been recognized for decades and deeply investigated in evolutionary ecology, the main contribution of eco-evolutionary dynamics is to bring insights on the less explored EVO to ECO links and to document feedbacks between these processes over a contemporary time-scale.

Natural Selection

All ecological and evolutionary changes ultimately occur as a result of alterations to the birth and death patterns of individuals. As the changes in birth and death are often associated with specific phenotypes (selection) and because those phenotypes generally have a genetic basis, evolutionary responses are expected. Assuming no other changes, it is expected that an evolutionary response should improve reproduction and survival of the next generation. Changes in phenotypes, however, are not always synonymous with evolutionary changes. Indeed, phenotypic plasticity may result in trait changes even in the absence of any evolutionary changes. Furthermore, plasticity itself can evolve and most studies to date have not been able to partition the ecological effects of trait changes into their plastic and evolutionary components. While the distinction between genetic variation and phenotypic plasticity is important to understand phenotypic variation and to identify whether the phenomena of interest is an ECO to ECO link or an EVO to ECO one, the effect of the changes in traits on the ecological processes of interest will be due to changes in the mean phenotype. Because it is the phenotype of individuals that will influence interactions between individuals or the effect of trait changes on the environment, eco-evolutionary dynamics studies often take a phenotypic perspective and assume that part of the trait changes has a heritable component.

 doi:10.1016/B978-0-12-409548-9.10548-2

The main drivers of natural selection are environmental. Those drivers are very diverse and include changes in predation pressure, density, sex ratio, weather, etc. One of the classical examples that have documented natural selection in the wild is the study on the effects of drought on the beak size of Darwin's finches (*Geospiza fortis*). Another classical example comes from the peppered moth (*Biston betularia*), where the incidence of the dark form increased due to industrialization during the 19th century. Lichen cover had decreased due to industrialization, making the dark form more cryptic and less predated on than the normal form. This selective advantage led to a change in frequency of the dark form, a change that was later shown to be genetic. This change in frequency of the dark form compared to the light one is thus one of the clearest and most intuitive examples of evolution under natural selection. A dynamic vision of the impact of ecology on evolution is therefore necessary, and all studies investigating the ecological drivers of natural selection on short time-scale document the ECO to EVO links of eco-evolutionary dynamics.

Contemporary Evolution

As previously mentioned, evolution was traditionally considered to be very slow, occurring over millions of years. For example, Darwin believed that evolution by natural selection could not allow for rapid changes, since it operated only by taking advantage from slight small successive variations. Experiments from animal breeding, however, have taught us that if selection is strong, evolutionary responses can occur over only a few generations. For instance, evolutionary changes in the resistance of certain breeds of cattle (Belmont Adaptaur; *Bos taurus*) to ectoparasite resistance (tick and worm) have been produced in as little as 15 years of selection by breeders.

Another important step in documenting the ECO to EVO links of eco-evolutionary dynamics is to evaluate whether evolutionary responses to natural selection occur and to identify the circumstances under which these responses are likely to occur on a contemporary time-scale. Several empirical studies have indeed revealed that even in a natural context, traits can also evolve over a relatively short time period in response to changing environments. Cases of contemporary evolution were also observed in humans. A study of a pre-industrial human population reported evolutionary changes in the age at first reproduction in less than two centuries. These evolutionary changes in phenotype occurred on similar time-scale as ecological processes. Thus, interactions between evolutionary changes and ecological processes are possible. Beyond that realization, however, a critical question is not whether such reciprocal interactions are possible but whether they are strong enough to matter in our understanding of ecological processes. For example, are these changes large enough to change the fate of a population, alter the composition of a community, or to a larger extent, even slow down the nutrient cycles?

From Evolution to Ecology (The EVO to ECO Link)

As just exemplified in previous sections, the clear and rapid effect of ecological change on evolution of different phenotypes is well established. The consequence of these phenotypes changes on various levels of biological organizations, however, is still under investigation. The phenotype of an individual can shape its interactions with its biotic and abiotic environment: its competitiveness, its ability to acquire resources, its ability to survive, grow and reproduce. By extension, the phenotypes present in a population will determine the possible interactions this population can have with its environment: its growth or decline, its coexistence with competing species or with predators, its geographical range. These changes in the community can further cascade and cause changes in the properties of the ecosystem. In response to ecological changes, evolutionary changes in traits can hence have a profound impact on the ecological landscape. The ecological processes affected can be on several levels of organization, ranging from the population to the ecosystem level (**Fig. 1**). The expectation is that effects should decrease with higher hierarchical levels as the effects of the evolutionary changes are buffered at each level. However, direct links and interactions between levels may also magnify the effects. Research on the impact of evolutionary changes on each of these organizational levels is starting to emerge, with studies at the population and community levels being most abundant.

Population Level Eco-Evolutionary Dynamics

One aspect of evolutionary dynamics is aiming to document the links between changes in the distribution of phenotypic traits generated by selection and population dynamics (**Fig. 1**; yellow box). As previously mentioned, natural selection and population dynamics are linked by birth and death. It is therefore necessary to consider the possibility of an eco-evolutionary feedback for traits linked to demography. When the trait change also causes changes in the fitness landscape, feedback loops can occur. The best example would be in the case of a trait under density-dependent selection. Density-dependent selection may favor the evolution of traits more closely linked to competitive ability at high densities than at low densities. These competitive traits, however, are often costly, yielding increased mortality, or reduced growth and fecundity. Consider a hypothetical example where the level of aggressiveness was selected differently according to density. When density is high, competition for resources increases and so does the optimal level of aggressiveness. In this case, the fitness landscape may resemble **Fig. 2A**, with an optimal fitness with high aggressiveness at high density, but low aggressiveness being favored at low densities. When density is high, directional selection,

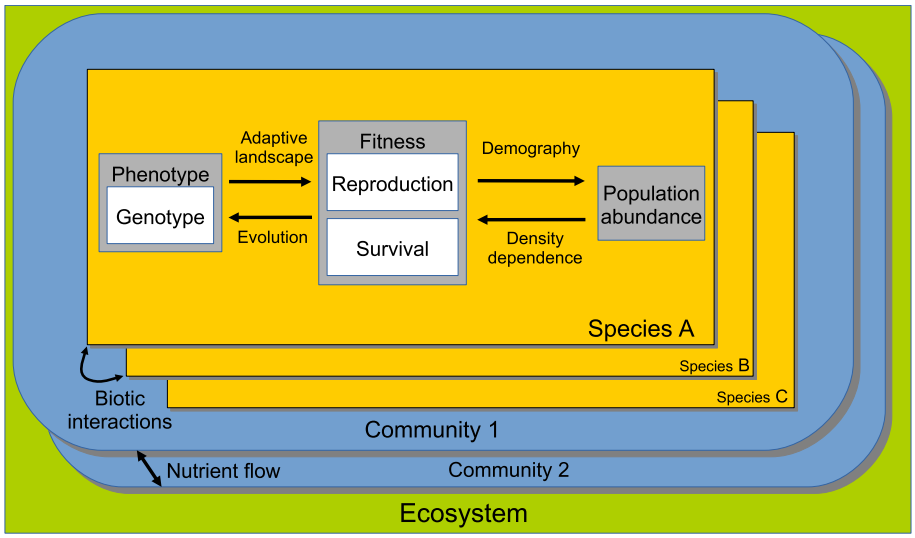

Fig. 1 Conceptual model of eco-evolutionary dynamics, demonstrating the potential effects of changes in genotype on higher levels of ecological process going from population, community to ecosystem levels of organization. *Yellow* boxes represent processes within the species level, where phenotype is based on genotype, which affects fitness through the fitness landscape. Fitness is determined by reproduction and survival which influence population abundance. Population abundance can feedback to genotype via density abundance, which changes the selective pressure, and leads to evolution. Different species interact within a community (*Blue box*). These interactions can also be based on the genotype of species (not shown on the figure). Communities are linked within the ecosystem (*green box*) via subsidies and nutrient flow.

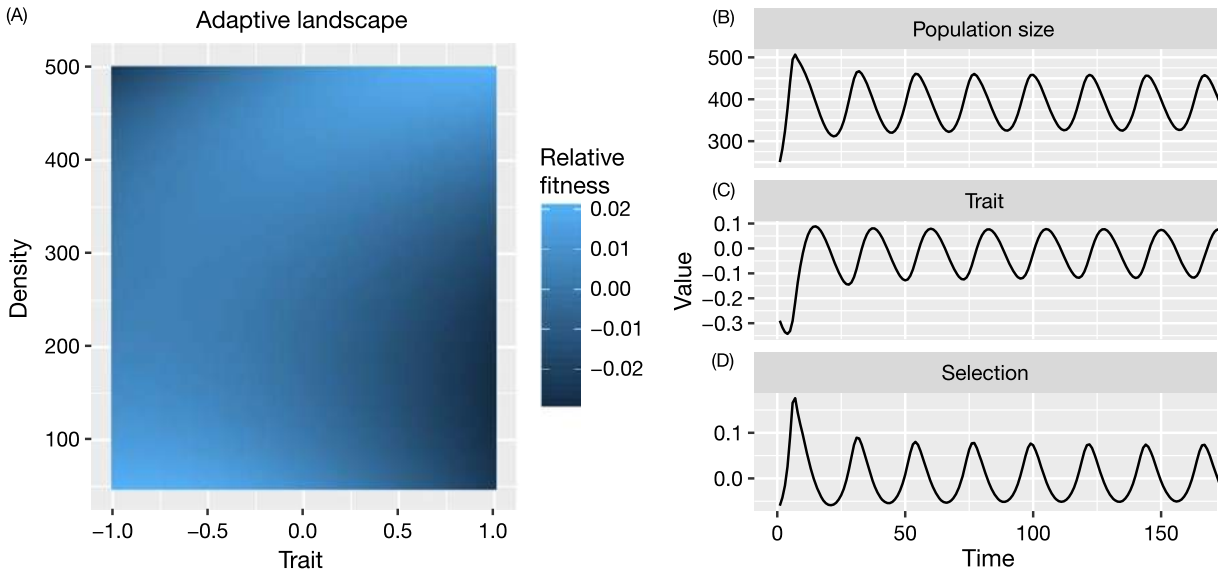

Fig. 2 Simulated example of eco-evolutionary feedback loops at the population level. (A) Fitness landscape where relative fitness of the trait of interest depends on density. The *right panel* shows the resulting cyclic fluctuations in (B) abundance, (C) mean trait value within the population, and (D) selection differential.

combined with phenotypic variability and heritability, may lead to evolutionary changes toward more and more aggressive individuals. If aggressiveness is negatively correlated with population growth rate (e.g., because more aggressive individuals have a lower life expectancy or ability to raise offspring), changes in this trait could lead to a decrease in population growth important enough to lower density. This population level change will, in turn, generate a change in the selective pressures (**Fig. 2D**) and will favor a return to less aggressive phenotypes with lower mortality. If the demographic effects of trait changes are faster than the genotypic changes, which is likely, the evolutionary lag can induce cycles in the population dynamics with the density and mean phenotype alternating between states of high density and aggressiveness and low density and aggressiveness (**Fig. 2B** and **C**). Evidence of such dynamics has been found in nature in the side-blotched lizards (*Uta stansburiana*), where reproductive strategies

whose fitness consequences were density-dependent effects induced cycles alternating between morphs with few competitive offspring and morphs with numerous less competitive offspring (Sinervo *et al.*, 2000).

Additional evidence that traits tightly linked to fitness may lead to EVO to ECO effects come from evolutionary changes in life-history traits. For example, size-selective harvesting, targeting large and older individuals, has led to a reduction in the age at maturity of some heavily fished species. Such evolutionary responses favor r-like life-history strategies which, in turn, can result in increased population growth rate as a larger proportion of the population produces recruits. Similarly, selection favoring higher reproductive output can increase the production of recruits, leading to increased population growth rate. However, evolution of earlier maturity is not a guarantee of an increased population growth rate given that trade-offs between different life-history traits are common. The increase in population growth rate caused by earlier maturation could be counteracted by a reduction in survival. Similarly, larger recruitment could reduce the quality and survival prospects of the offspring produced. All of these considerations need to be taken into account when trying to predict the ecological response to evolutionary changes in life-history traits. Given this complexity, empirical studies are often necessary to obtain realistic and thorough understanding of the complete ecological response to these changes. As populations become adapted, population growth rates may increase until the population approaches carrying capacity, where density-dependence becomes a constraint. Carrying capacity, however, is also partly determined by the ability of individuals to acquire resources, which is also a phenotypic trait under selection. As such, evolutionary changes in traits may also cause changes in the carrying capacity and in density dependence in natural populations. Apart from a few exceptions, however, eco-evolutionary theory has seldom been challenged with empirical data outside the lab.

It is worth mentioning that evolution does not necessarily lead to an increase in population growth rate. Frequency-dependent selection may result in the evolution of a phenotype conferring a lower mean fitness. Additionally, it is important to remember that natural selection acts primarily on traits at the individual level, and not to improve the performance of the population as a whole. For example, in carnivores, sexually selected infanticide will favor male fitness of the perpetrator but will have a negative effect on offspring survival and ultimately reduce population growth. Further, the effects of evolutionary changes on population growth rate may be relatively weak if the population is regulated by other intrinsic or extrinsic factors which are independent of the evolving trait. The real challenge in eco-evolutionary dynamics is therefore not only to show the existence of interactions between trait changes and population parameters, but also to quantify their biological importance at the population level and evaluate whether those effects can cascade at higher level of biological organization such as the community.

Community-Level Eco-Evolutionary Dynamics

Through changes in population growth, eco-evolutionary dynamics will alter the abundance of the evolving species with potential cascading effects on the community. For example, the abundance of predators will undoubtedly influence the abundance of its prey, as often exemplified by the Canada lynx (*Lynx canadensis*) and snowshoe hare cycles (*Lepus americanus*) in most ecology textbook. However, community processes are not solely determined by the abundance of its constituent species. Trait changes in a species could also have direct effect on community-level dynamics because phenotypic traits will affect how species interacts with their abiotic and biotic environments. As a consequence, evolutionary changes in those traits could impact species niche and hence community assemblages. The increased focus on functional traits to study community ecology is a testament of the ecological importance that traits play in structuring communities. Thus, it has been suggested that the impact of evolutionary changes in traits of a species could be as important as those of changes in functional traits in a community assemblage.

Functional traits, in combination with environment filtering, have been found to be key drivers of community assemblage. Evolutionary changes in traits may therefore shift the ecological niche of a species and therefore its distribution, leading to new community compositions as one species range expands or contracts. For example, a plant may adapt to the local climatic conditions at its range margin allowing it to expand its niche toward colder and formerly unsuitable climates. Evolutionary changes in traits can also impact interspecific competition, trophic interactions, mutualism, parasitism, etc. These new biotic interactions can have several ecological consequences. One of the possible community-level outcomes of eco-evolutionary dynamics is a switch to an alternative stable state, which is often in response to a strongly altered selective regime. This can lead to changes in community assemblage. A second possible outcome of changes in biotic interactions is co-evolution. Indeed, co-evolution can be considered a special case of eco-evolutionary dynamic. Selection and evolution of one of the co-evolving species induces changes in the selective pressure on the second co-evolving species which in turn evolves in response to these changes, creating a feedback loop centered on the interaction between the two co-evolving species. Another possible outcome of eco-evolutionary dynamics at the community level is the emergence of cyclic evolutionary dynamics.

A great example of altered cyclic dynamics was shown in an experiment tracking the predator–prey dynamics of rotifer and green algae (**Fig. 3**) in the presence or absence of evolution in the prey. The ability of the prey to evolve (or not) in response to a high predation pressure was controlled by setting up the experiment either using clonal populations (i.e., no genetic diversity) or using populations composed of several genotypes. This experiment showed that the population abundance of algae fluctuates with the abundance of rotifers, the main predator, leading short population cycles in the absence of evolution by the prey (**Fig. 3A**). In prey populations that have the opportunity to evolve, the algae populations develop effective defense mechanisms that allow the populations to increase in size. As those defense mechanisms are costly, they are traded off with competitive abilities and the populations are doomed to crash at high densities. The evolution by the prey increased the duration of cycle and changed the

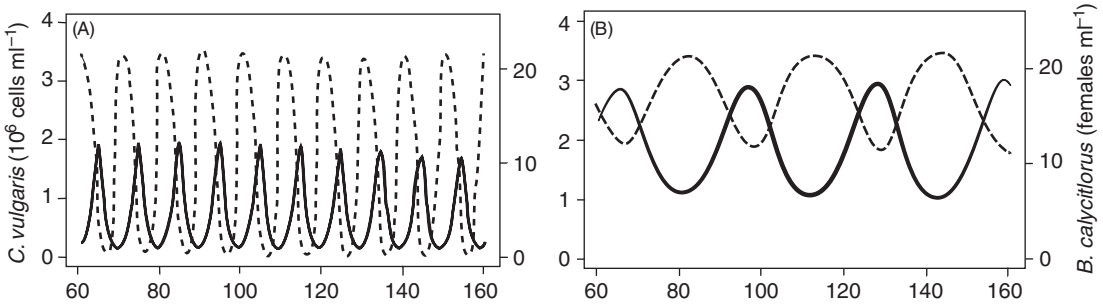

Fig. 3 Cycles predicted by the model for the *Brachionus* predator (*solid line*) and *Chlorella* prey (*dashed line*) in a single-clone system (A) and a multiple-clone system (B). Adapted from Yoshida, T., Jones, L. E., Ellner, S. P., Fussmann, G. F. and Hairston, N. G. (2003). Rapid evolution drives ecological dynamics in a predator-prey system. *Nature* **424**, 303–306.

predator–prey dynamics (Fig. 3B). This experiment provides support for the eco-evolutionary effects on predator–prey interactions.

The impact of evolutionary changes on communities will likely vary depending on which species and traits evolve. For example, the evolution of keystone species, such as an apex predator, is likely to have profound impacts on the community assemblage. For example, a reduction in size for a top predator will affect its ability to consume large prey. Alternative prey (smaller species) can then be exploited shifting the size distribution of the prey community. However, the ability of a species to influence its community probably also increases with its prevalence, suggesting that community effects are not limited to the evolution of top predators or traits with large ecological effects. Eco-evolutionary dynamics may also play a major role in the dynamics of invasive species. Indeed, invasive species with a high potential for adaptation to new environments will be more likely to be successful invaders. Similarly, the arrival of an invasive species will modify the selection pressures on endogenous species, making potential evolutionary changes in the endogenous species with unknown evolutionary consequences. Researchers working on invasive species (e.g., Pimentel) were among the first to underline the potential importance of the EVO to ECO links.

An alternative way to study the EVO to ECO links on community processes that complement the approach used in the studies presented above is the "focal-species composite-response" approach. The community composition, structure, and properties can be considered as an extended phenotype. As such, the focal species is able to evolve and as it does, it can have indirect genetic effects on its community. An example of a study using such an approach was conducted on North American cottonwoods (*Populus* sp.) and their arthropod communities. This study revealed that arthropod communities were highly heritable. Their results suggested that cottonwoods possessed an unknown trait that was heritable and which imposed selection upon arthropods. This trait generated indirect genetic effects on the fitness of the arthropod community members and produced distinct arthropod communities with distinguishable phenotypes potentially affecting other processes at the ecosystem level.

Ecosystem Level Eco-Evolutionary Dynamics

Eco-evolutionary dynamics at the ecosystem level has proven particularly challenging to study because of the logistic difficulties associated with working at large spatial scales while maintaining the resolution needed to measure evolutionary changes. Quantifying ecosystem-level effects of evolutionary changes may be further hindered because many ecosystem processes may require a long time to respond or for the effects to be measurable. Thus, studies focusing on this aspect of eco-evolutionary dynamics have initially relied on contrasting the effect of standing genetic variation on ecosystem processes compared to other ecological variables. One of the best examples of such an approach was conducted on Populus hybrids that differ in their polyphenol production of a genetically based trait. The study revealed that the concentration of condensed tannins was the best predictor of decomposition and nitrogen cycling, suggesting that intraspecific variation in that trait was an important driver of ecosystem functions.

An alternative approach to overcome the logistic difficulties of monitoring ecosystem level eco-evolutionary dynamics has been to use mathematical models. Recently, ecosystem modeling has been used to evaluate the ecological feedback of evolutionary changes in demography and life-history traits in response to size-selective fisheries. These models suggest that by selecting against large and more fecund fish, biomass of heavily harvested fish is greatly reduced. Some key studies have now provided strong evidence that those changes are likely to be, at last partially, genetically based. Given the critical importance of fish body size in the dynamics of consumer-resource aquatic networks, allometric trophic network model has revealed that heavily fished ecosystems are more likely to further decrease fish abundance and increase temporal variability in their food resources.

Theory suggests that the consequences of evolutionary changes in dispersal may also play an important role in ecosystem level eco-evolutionary dynamics. For example, the transition of species from an anadromous to freshwater resident life history can be important because anadromous fishes provide important subsidies of marine-derived nutrients to rivers, lakes, and streams. Additionally, studies on experimental metacommunities have suggested that dispersal rates may influence ecosystem properties, with productivity peaking at intermediate dispersal rates. Thus, evolutionary changes in migration propensity could be strong drivers of ecosystem processes.

Studies in mesocosms suggested that evolution could be a strong driver of ecosystem functions. For example, one study using guppies (*Poecilia reticulata*) and rivulus (*Rivulus hartii*) as model species compared the relative importance of evolution, coevolution, and species invasion on algal dynamics, invertebrate biomass, and decomposition rates. The evolution of guppies in response to alternative predation regimes significantly influenced algal biomass and accrual rates. More importantly, the effects of evolution and coevolution were larger than the effects of species invasion for some ecosystem responses, suggesting that under some circumstances within species changes in color and life-history traits may be as important a driver of ecosystem processes as changes in species composition.

Eco-Evolutionary Feedback

Most studies focus on the ECO to EVO link or the EVO to ECO link independently. Eco-evolutionary feedbacks have seldom been studied and can be pictured as the *Holy Grail* of eco-evolutionary dynamics studies. The occurrence of those two-ways feedbacks over long ecological time-scales are evident but are generally ignored over contemporary time-scales. It has been proposed that two main requirements need to be met in order to expect eco-evolutionary feedbacks: first, there must be a strong effect of the phenotype on the environment (e.g., organisms may structure or construct their environment) and second, the new environment must cause the subsequent evolution of the phenotype of the organisms inhabiting it. Those requirements have been suggested because for feedbacks to occur on an ecological time-scale, the evolving phenotype needs to have enough effects on the environment for new selective pressures to emerge, affecting in return the phenotype of the evolving species. Models of eco-evolutionary dynamics, such as the one presented in "From Evolution to Ecology (The EVO to ECO Link)" section on ecosystem consequences of size selective fisheries, are looking at those two-way interactions but empirical studies documenting both links are still scarce.

Cryptic Eco-Evolutionary Dynamics

More recently some researchers have argued that eco-evolutionary dynamics interactions may be most important when they are the least obvious. This phenomenon has been referred to as cryptic eco-evolutionary dynamics. Cryptic dynamics arise in a system when processes interact in a way that effectively conceals the action of one, or more, of those component processes. Thus, eco-evolutionary feedbacks, as described in previous sections, could occur but may not have measurable consequences on ecological processes because several processes can obscure their effects. First, evolution can be cryptic for example, when several genotypes may be favored in a varying environment because they produce the same outward phenotype. Such counter-gradient variation may be common and result in cryptic eco-evolutionary dynamics. Similarly, evolution of tolerance or resistance may result in no obvious change in the phenotype unless one is careful and controls for the relevant challenging environmental conditions. These types of cryptic eco-evolutionary dynamics may be of great ecological importance because they contribute to ecological stability. Another process leading to ecological stability with the potential for cryptic dynamics is environmental tracking, which would reduce the fluctuation in population size even as the evolving trait changes to accommodate some environmental changes. While the ecological consequences of cryptic eco-evolutionary dynamics are null or quasi-null, their importance becomes apparent only when compared, in practice or in theory, to an equivalent case in the absence of evolution. Eco-evolutionary biologists should therefore keep in mind that the most parsimonious explanation (no effect of evolution) may not always be the best answer if we are more interested in explanatory theory than mere predictions.

Approaches to Studying Eco-Evolutionary Dynamics

To date, a lot of our knowledge on eco-evolutionary dynamics comes from laboratory systems where the importance of interactions between ecology and evolution might have been amplified due to their quantification in controlled environments. Thus, to evaluate the importance EVO to ECO links over a short time-scale in natural environments, researchers have used various approaches to assess under which conditions feedbacks between ecology and evolution are expected and to quantify their importance in the wild.

Modeling

Modeling is probably the approach to the study of eco-evolutionary dynamics where most progresses have been made thanks to the theoretical study of processes such as co-evolution and host–parasite interactions. These theoretical models come in a variety of forms and reviewing them all is outside the scope of this review. Models of adaptive dynamics have also been very informative to understand eco-evolutionary dynamics. In this mathematical framework, an environment generated by genotypes is modeled and mutants are introduced to this fictive initial environment. Mutants with higher fitness are able to invade the environment while mutants with lower fitness are not. The presence of these successful mutants in turn changes the subsequent environment. The

ensuing dynamics can be simulated until a steady state is reached. The elaboration of such models has led to a better understanding of how previously stable coexistence dynamics can be perturbed when evolutionary changes occur much more quickly than ecological changes. Individual-based models, where every individual is modeled specifically from its genotype and phenotype to its reproduction and survival, have also been insightful. Such models have been used, for example, to predict evolutionary consequences of commercial fishing on population dynamics as well as the indirect consequences on aquatic communities.

A drawback of a theoretical modeling approach is that while it provides convincing evidence that eco-evolutionary dynamics can happen and could have significant impacts on ecological processes, it does not provide evidence of their presence in nature or information on their strength and prevalence. Mathematical models do provide insight into the condition under which eco-evolutionary dynamics are more likely to be present. Those models also provide hypotheses and predictions, which can then be verified in nature. Combining modeling to experimental or observational studies is a powerful approach, having the generalizability and precision of modeling while gaining the realism of the real world. The mechanisms that are supposed to be behind the observed effect can be modeled to verify the interpretation of the observed results. Alternatively, an eco-evolutionary process can be modeled and the result of the modeled is compared to the results of a similar experimental setup.

Observational Studies

Most observational studies are based on some sort of comparative approaches contrasting situations with and without evolution. This comparison can be made using two different populations (one that went through an evolutionary response and the other that did not), or by monitoring one single population that showed an evolutionary response in time. The researchers can then measure the effects that those evolutionary changes had on population dynamics as well as community and ecosystem processes. The changes in ecological processes due to evolution can be measured directly by correlating them to variation in genotypes. For example, such an approach was used in our previous example on cottonwood tree and arthropods revealing that the genotype of trees explained around 60% of the variation in arthropod communities (see "Community Level Eco-Evolutionary Dynamics" section). In this way, the community effect of individuals could be considered as an extended phenotype and standard quantitative method could be used.

Mathematical methods, such as the Geber method, strengthen the conclusion that can be made from observational studies by decomposing changes in ecological processes due to evolution from other processes. The Geber method consists in comparing the relative importance of different factors in generating the change in some ecological variables. Using the Geber method, one first measures the temporal changes in various factors, including evolutionary and environmental variables, as well as their effects on an ecological variable of interest. These resulting effects are then used to estimate the relative contribution of the change in each factor to the observed change in the ecological variable of interest allowing the quantification of the influence of trait changes on population growth. This method was used to partition the effects of traits and environmental conditions on population growth in five populations of wild ungulates and revealed that variation in birth mass in those species explained just as much of the variance in population growth rate as variation in weather conditions.

As previously mentioned, a key distinction to make when studying eco-evolutionary dynamics is that of evolutionary changes and phenotypic plasticity. A useful tool to achieve this in nature is the animal model, provided that pedigree information is available. First developed in the animal breeding and statistical genetic fields, the animal model is a form of mixed effects model which uses relatedness information from a pedigree to decompose phenotypic variance into its different genetic and environmental components. Using this information, the animal model allows estimating key parameters such as the heritability of a trait or the genetic correlations between traits. The animal model is now widely used in the field of quantitative genetics. The major advantage of the animal model over more traditional methods for estimating heritability, such as parent-offspring regressions or half-sib designs, is that it makes use of all the information from all types of relationship within the pedigrees. Further, other factors having potential effects on the phenotype can also be easily incorporated into the animal model.

Another framework in the study of eco-evolutionary dynamics, which has received increasing attention, is the integral projection matrix, or IPM. IPMs are an extension of matrix models where the distribution of continuous trait is tracked over time. IPMs are based on four basic functions: survival, development, recruitment, and inheritance. The survival function determines the survival of individuals according to their trait; the development function determines the change in traits such as size among survivors (growth); the recruitment function determines the recruitment from individuals according to their trait; and the inheritance function describes the relationship between the offspring and parent traits. Extensions of the IPMs which track changes in genotypes through time in addition to the trait are being developed. Given that the model tracks the distribution of the trait over time, its resulting survival, recruitment, and population growth, this tool could be well suited to the study of eco-evolutionary dynamic, although careful consideration of the genetic interpretation must be made. For instance, the inheritance function used to parametrize IPMs determines the trait distribution of the offspring at the next model iteration but it is not the heritability of the trait as defined in quantitative genetics.

Experimental Manipulation

Experimental manipulation provides the most convincing demonstration of the effects of eco-evolutionary dynamics. Experimental manipulation allows careful decomposition of the plastic, genetic, and other environmental effects on population and

community dynamics. Experiments with chemostats (i.e., aquatic microcosm system used for the culture of microorganisms in which the chemical composition is kept at a controlled level) have provided very convincing evidence of the importance of eco-evolutionary dynamics. This type of experiment was used to study predator–prey cycles of communities (algae-rotifer) with or without genetic diversity as previously explain in this article ("Community Level Eco-Evolutionary Dynamics" section and **Fig. 3**). In a later experiment using a similar experimental setup, it was shown that rapid evolution of rotifers (lower investment in sexual reproduction) caused an important shift in the nutrient balance of the ecosystem.

The major advantage of experimental manipulations, such as chemostats, and the reason why they have been so successful in demonstrating effects of evolution on ecology is that environmental conditions can be carefully altered to cause rapid and important evolutionary changes. Changes in genotype, phenotype, and their "ecological" consequences can be precisely measured. However, this strength is also their most criticized weakness because such study may amplify the effect size due the controlled environment in which they are conducted. Moreover, whether results obtained in a "bottle" can be extrapolated to natural populations or not is often questioned. The recent realization that natural conditions can also influence genetic variation, and hence evolvability, also cast doubts on the generalizability of laboratory experiments. Steps have been taken to remedy this issue by using mesocosms, which consist of large experimental set-ups, which aim at being closer to natural systems while still permitting replication and experimentation.

Conclusion

The fact that ecology and evolution interact has been known since Darwin. Evolutionary biologists have studied the ECO to EVO links for decades and have shown how natural and artificial changes in ecological conditions can drive evolution. The main novelty of eco-evolutionary dynamics is to emphasize the EVO to ECO links. The potential for evolution to feedback on ecological processes over long time-scales has been recognized for decades, but it is only recently that researchers have realized that interactions between these processes might also be important over short time-scales. Eco-evolutionary studies try to identify the circumstances where the EVO to ECO links may matter and more importantly quantify the importance of evolutionary changes relative to all other factors known to affect the ecology of wild species.

Eco-Immunology: Past, Present, and Future

Meredith Kernbach, Chloe Ramsay, Jason R Rohr, and Lynn B Martin, University of South Florida, Tampa, FL, United States

A Brief History of Immunology

Immunology and especially ecoimmunology are young fields. Although Thucydides speculated as long ago as 400 BC about immunity after noticing that survivors of the plague became protected from second infections, the first true immunological study was by Ilya Methchnikoff who observed cellular defensive responses in starfish to wood splinters (Newell-McGloughlin and Re, 2006). By the 18th century in Europe (Riedel, 2005), immune processes were exploited in the interest of human health even though the mechanistic bases of protection were unknown. In ensuing years, Robert Koch, Louis Pasteur, and others improved such vaccination and other hygienic measures, although explicitly immunological insight, such as the distinction between humoral and cellular immunity, was not gained until the early 20th century (Tauber, 2003; Kaufmann, 2008).

By the mid 20th century, coincident with the molecular revolution, immunology grew rapidly including discoveries about tumor regulation, allergies, anaphylaxis, and the structure and synthesis of immunoglobulins. As many of these discoveries were made possible through the emergence of cellular and later molecular tools, immunology thrived as an almost exclusively reductionist discipline. Since its inception, the field focused predominantly on how host cells and tissues engaged various "dangerous" (Matzinger, 1994) and nonself (Burnet, 1961) threats, but recently, the emphasis has been made that such directives have shortcomings that might have affected the accumulation of knowledge (Tauber, 2017). For instance, important discoveries in other fields, such as the ability to classically condition immune responses (Ader and Cohen, 1982) and predict the size of disease epidemics using mathematics (Anderson and May, 1985), developed separately. Indeed, the field of epidemiology, which eventually instigated the discipline now recognized as disease ecology, has only recently and partly begun to merge with immunology (Brock et al., 2014). Some immunology, namely vaccinology, is well integrated with epidemiology, but mostly intellectual pursuits about infectious disease biology have developed and operated independently of immunology (Tauber, 2017). The most striking distinction among infectious disease-related disciplines is how they deal with variation. Almost all immunologists have tried to control or eliminate it, going to extremes of breeding hosts in sterile conditions, standardizing genetic backgrounds, and/or attempting to ensure that temperature, diet, photoperiod, and other factors are identical among study groups. Most other disease biologists, and especially ecoimmunologists, instead strive to explain existing variation among or within hosts (Martin et al., 2010). Ecoimmunologists (and "wild immunologists" sensu Pedersen and Babayan, 2011) study the defenses of thousands of different host species, oftentimes in their natural environments (Plowright et al., 2008). For these immunologists, variation is the topic of interest.

Ecoimmunology Past

Ecoimmunology emerged from the work of behavioral ecologists interested in understanding elaborate sexual traits such as songs, ornaments, and mate-directed behaviors (e.g., courtship dances). Zahavi (1975) argued that these traits acted as handicaps, allowing females to use them as honest signals of male quality. The argument was that only mates of genuine high quality would be able to produce and keep such costly traits and achieve reproductive success too. Around the same time, Hamilton and Zuk (1982) extended the handicap hypothesis, proposing that male ornaments are good indicators of mate quality because the costs of elaborate traits should compromise the ability of males to combat infections (Hamilton and Zuk, 1982). If a male could maintain a large tail, produce an elaborate song, and/or execute a complicated display while infected, he would be a truly good male. Females should choose such males, especially if male traits had a genetic basis, which they often do. These ideas were later extended in the form of the immunocompetence handicap hypothesis (ICHH), which proposed a physiological mechanism for trade-offs between ornaments and immunity (Folstad and Karter, 1992). Observing that high levels of androgen hormones positively affected male ornamentation but negatively affected many immune functions, they proposed the first ecoimmunological

hypothesis. They suggested that the benefits of testosterone for attracting mates were traded off against the adverse effects of testosterone on immunity, providing a mechanistic basis for handicaps. Although this hypothesis has since been tested extensively (Hunt et al., 1997; Enstrom et al., 1997) and in some sense launched the field of ecoimmunology, androgen effects on immune defenses are not as consistent as they originally conveyed (Arredouani et al., 2014; Roberts et al., 2004). Alternate versions of the ICHH have since been proposed and supported in organisms that do not use androgens (Nunn et al., 2009), and these propositions, which are also based on eco-evolutionary principles (i.e., Bateman's hypothesis) explain intra- and interspecific immune variation reasonably well.

The term, ecological immunology, was first introduced in 1996 by Sheldon and Verhulst, and was proposed then as a valuable research area because most hosts remained susceptible to infections in spite of a strong history of selection by parasites. At the time, Sheldon, Verhulst, and others (Lochmiller and Deerenberg, 2000; Schmid-Hempel and Ebert, 2003) parroted a central proposition of evolutionary biology to justify ecoimmunology research: in most environments, resources are limited, so trade-offs should affect whether and how hosts defend themselves against infections. From that simple conjecture, the field developed rapidly (Martin et al., 2011). Growth increased especially rapidly as the costs of immune defense became clear. It was long known that immune defenses required a supply of amino acids and calories (Beisel, 1977), but the eco-evolutionary ramifications of such costs were never before considered. In the livestock industry especially, the costs of immunity were well studied because of the economic consequences of breeding the largest and fastest growing, yet immunologically well-protected, animals. For these reasons, diet effects on immune functions were extensively studied in domesticated species (Klurfeld, 1993; Klasing, 2013). Not too long after Sheldon and Verhulst's call to action, data corroborating the costliness of immune defenses started to emerge from ecologists (Demas et al., 1997; Martin et al., 2003, 2007; Lochmiller and Deerenberg, 2000). The next steps were to probe whether such immune costs were large enough to lead to consequential trade-offs in nature (Norris et al., 1994; Richner et al., 1995).

In the ensuing 20 years, an enormous number of studies provided both correlative and experimental evidence revealing important costs of immunity for many vertebrates and invertebrates (Saino et al., 1997; Festa-Bianchet, 1989; Graham et al., 2010; Moret and Schmid-Hempel, 2000). Just this year, a metaanalysis involving many of these studies revealed significant costs of immunity for almost every taxon ever studied (Brace et al., 2017). Songbirds and a few insects (i.e., bumblebees, *Drosophila* sp.) were the organisms of choice for much of the early work in this field. Several avian brood size experiments concluded that many measures of immune defense decreased with increasing reproductive output (Gustafsson et al., 1994; Norris et al., 1994; Norris and Evans, 2000). Trade-offs between immune function and other costly life processes, such as feather regrowth, were observed in domesticated chickens (Alodan and Mashaly, 1999), wild house sparrows (Martin, 2005), and other species. Even migratory disposition was found to impact immunity (Møller and Erritzøe, 1998), although results were mixed depending on several factors (Owen and Moore, 2006; van Gils et al., 2007). Growth too was found to affect and be affected by immunity (Rivera et al., 1998). Today, the costs of immunity and defenses generally are so ensconced in ecology (Connors and Nickol, 1991; Lochmiller et al., 1993) that we no longer question their relevance. Now, we seek to understand whether and how their effects can percolate through communities (Beldomenico and Begon, 2010; Paull et al., 2012).

Immunocompetence: The Ecoimmunologist's Red Herring

Coincident with the rise of ecoimmunology were frustration and healthy skepticism about the immunological tools of ecologists. What ecologists and organismal biologists wanted to measure was immunocompetence, or "how hosts prevent or control infections." What they used to describe such a complex trait were coarse measures at best (Adamo, 2004). This approach was understandably a frustration to traditional immunologists who spent years developing precise tools to characterize the responses of (mostly) murine immune systems to diverse viral, microbial, and metazoan threats. Most prominent among those first ecological tools was the phytohemagglutin (PHA) skin test. This assay was thought to quantify cell-mediated immunity and by extension serve as a measure of T-cell sensitive parasite control (Duffy and Ball, 2002; Faivre et al., 2003; etc.). In practice, one injected a small amount of PHA (in solution) under the skin and measured resultant swelling using pressure-sensitive calipers. Although this technique revealed several surprising things about the immune systems of wild animals (e.g., seasonal variability in strength (Martin et al., 2004) and nonlinear scaling with body mass (Tella et al., 2002)), rarely were PHA measures related to control of a given infection, so its relevance as a metric of immunocompetence remained unclear. For these reasons, the PHA and related tests (i.e., leukocyte counts, quantification of total immunoglobulins) began to fall out of favor.

At that time, ecoimmunologists started to rely less on easy-to-use tools, instead favoring functional readouts of host protection or tools used in the labs of modern immunologists (Fassbinder-Orth, 2014; Boughton et al., 2011). One assay involving agglutination of foreign red blood cells became quite popular (Deerenberg et al., 1997); another involving the killing of various microbes by blood plasma and serum quickly grew in popularity (Millet et al., 2007; Liebl and Martin, 2009). As ecoimmunologists started to accept that measuring single measures could never capture something as nebulous as immunocompetence (Martin et al., 2006; Viney et al., 2005), progress in the field grew. Not too long after, ecologists would propose new frameworks and concepts that would eventually spill into traditional immunology (Schmid-Hempel and Ebert, 2003; Viney et al., 2005). Foremost among these was the concept of parasite tolerance (Råberg et al., 2007).

Parasite tolerance emphasizes that hosts can cope with infection in a different manner than usually emphasized in immunology. Historically, immunology focused on mechanisms to regulate the numbers of parasites (i.e., resistance), just as a few behavioral ecologists had emphasized avoidance and other behaviors as a way to escape infection. The additional possibility, that hosts could

mitigate parasite damage instead of controlling parasite burden (Medzhitov et al., 2012), had never really been embraced, perhaps because as a predominantly biomedical field the thought of permitting enduring infections was too distasteful to pursue (Acevedo-Whitehouse and Cunningham, 2006; Hill, 2001; Schroder and Bowie, 2005). In the mid-20th century, though, plant biologists demonstrated quite clearly that hosts can cope feeding insects, fungi and other enemies better than trying to prevent exposure to these organisms altogether. Animal biologists eventually co-opted this concept, defining parasite tolerance mathematically as the relationship between host fitness or performance and parasite burden (Roy and Kirchner, 2000; Råberg et al., 2009). Today, research on parasite tolerance abounds and includes studies that attempt to refine its measurement (Louie et al., 2016), resolve its mechanistic basis (Sears et al., 2011; Ayres and Schneider, 2012; Soares et al., 2017; Medzhitov et al., 2012), and elucidate its eco-evolutionary effects at levels of biological organization above individuals (Gervasi et al., 2017; Johnson and Levin, 2013).

Ecoimmunology Present

From Immunocompetence to Host Competence

Ecoimmunology continues to be a popular field, as evidenced by the many reviews (Little et al., 2012; Demas and Nelson, 2011; Demas et al., 2011; Adamo, 2004; Raffel et al., 2008; Martin, 2009; Martin et al., 2006, 2010; Adelman and Martin, 2009; Ezenwa et al., 2016) of its history, purview, and implications. Of the many concepts that currently captivate researchers, one, host competence (i.e., the propensity of an individual to generate infections in another individual) is facilitating integration with other disease research at multiple levels of biological organization (Gervasi et al., 2015, 2017; Barron et al., 2015; Martin et al., 2016; Keesing et al., 2012; Luis et al., 2013). Competence is underlain by many physiological and behavioral characteristics that affect exposure, elimination, and subsequent transmission of a parasite (Ferrari et al., 2004). Variability in host competence within and among individuals and species can contribute to spatiotemporal heterogeneity in disease at the community level (Barron et al., 2015; Gervasi et al., 2015; Martin et al., 2017). To date, there have been two prime ecological areas of study with regards to competence: the dilution effect and superspreading.

The first, the dilution effect, represents the recurrent observation that host diversity often reduces disease risk (Civitello et al., 2015; Ostfeld and Keesing, 2000). Although the scale of study and other factors can eliminate or even reverse the effects of biodiversity on disease risk (Wood et al., 2014), dilution effects are common enough (LoGiudice et al., 2003; Keesing et al., 2010; Ezenwa et al., 2006) that many have been motivated to investigate their mechanistic bases. Prime among them is heterogeneity in host competence. Potential hosts in an environment differ dramatically in their ability to replicate parasites (Schmidt and Ostfeld, 2001). To date, the Lyme disease system has been best-studied with regards to the role of competence in dilution effects. Lyme disease is caused by infections with the bacterium, *Borrelia burgdorferi* (Bb), with is transmitted by ixodid ticks. A few mammalian hosts are much more competent than others and play important roles in the local dynamics of Lyme disease. The white-footed mouse (*Peromyscus leucopus*) is especially competent for Bb, and its immune system and particularly its antimicrobial responses are quite distinct from other mammals (Previtali et al., 2012), even other *Peromyscus* (Martin et al., 2007, 2008). What is also particularly compelling and somewhat concerning about this and similar species is that it is competent for multiple tick-borne, disease-causing microbes (Ostfeld et al., 2014). Intriguingly, variation in competence can be predicted by the life history and behavioral traits of hosts, phenomena that provide opportunities for the mitigation of human disease risk and perhaps even predictions about under- or unstudied species in new ecosystems or novel parasites (Han et al., 2015). Evidence is gathering in other systems, such as vertebrate-trematode, snail-trematode, vertebrate-fungal, and plant-fungal systems, that the most abundant and widespread hosts, with life-history traits that favor reproduction and dispersal, are often the most competent (Johnson et al., 2012; Sears et al., 2015; Venesky et al., 2014; Lively and Dyndahl, 2000; Parker et al., 2015).

A second reason ecologists are now interested in host competence is embodied in the hallmark superspreader, Mary Mallon, better known as Typhoid Mary (Soper, 1939). Typhoid Mary was said to be responsible for the infections of 22 people, which proved fatal for three of those individuals. As an asymptomatic typhoid fever carrier, Mary came into contact with many others while working as a cook. Typhoid Mary is not an aberration it seems. Superspreaders appear to be important for other diseases, such as acute respiratory syndrome, or SARS, which first emerged in late 2002 and rapidly spread via air travel through May 2003. There were nearly 8000 reported cases of SARS (Riley et al., 2003), but transmission events varied quite extensively across patients. Patient A, the first known infected patient, reportedly transmitted the SARS pathogen to 33 other individuals (Shen et al., 2004). Scientists concluded that SARS was likely transmitted to three other individuals, all of whom infected more than eight additional people (Shen et al., 2004).

Although only recently emphasized, superspreaders might be common in many host-parasite systems (Lloyd-Smith et al., 2005; Kilpatrick et al., 2006) including tuberculosis and measles outbreaks (Stein, 2011). Indeed, the 20:80 rule in epidemiology highlights that 20% of infected individuals tend to be responsible for 80% of new infections (Woolhouse et al., 1997). Methods for identifying these keystone individuals are only just being developed (Modlmeier et al., 2014; Paull et al., 2012), and often identification is quite hard to do because hard-to-quantify behavioral differences are what distinguishes hosts. Mechanistically, though, there are several promising avenues to consider as biomarkers, and there is a large need for such work, as competence can be quite labile in some species (Gervasi et al., 2016). In other words, whereas host species vary quite a bit in their competence, individual hosts within species too could be quite different too. Various natural and anthropogenic stressors, resource depletion, habitat quality, and other factors could alter the traits that hosts use to cope with infections (Gervasi et al., 2015; Martin et al., 2010).

For instance, glucocorticoids, which have profound and diverse effects on immune function (Martin, 2009), dramatically altered the ability of avian hosts to serve as competent reservoirs for West Nile virus. Birds with chronically (surgically) elevated stress hormones were 2× more attractive (Gervasi et al., 2016) and enduringly more infectious (Gervasi et al., 2017) to biting vectors than controls. Some of these effects were related to the expression of cytokines (e.g., interferon gamma), molecules expressed by leukocytes and other cells that directly antagonize parasites or coordinate cellular defenses (Martin et al., 2016).

Causes and Consequences of Co-Infection

Another growing area of interest in ecoimmunology and a prime example of the ongoing merger between ecoimmunology and disease ecology (Hawley and Altizer, 2011; Brock et al., 2014) involves co-infections. In the wild, it is probably much more common to be infected by many versus a single pathogen, which makes the common practice in immunology to study one parasite alone naturally unrepresentative. When a host is co-infected, interactions between pathogens can alter the outcome of infections (Corbett et al., 2003; Bromenshenk et al., 2010; Johnson and Hoverman, 2012). Pathogens can interact directly, competing for resources or space (Kuris and Lafferty, 1994), but they can also interact indirectly, through the immune system (Sousa, 1992). The best known and most extreme example of co-infection in hosts and how the immune system can play a role in the outcome of disease entails the human immunodeficiency virus, HIV (Shankar et al., 2014; Moreno et al., 2000; Abu-Raddad et al., 2006). HIV reduces the functionality of the host immune system, leaving the host open to secondary infections. For instance, co-infection with HIV and tuberculosis (TB) accelerates the deterioration of the host immune system and increases the negative effects of both pathogens (Shankar et al., 2014). Patients with leishmaniasis and HIV experienced more relapses in leishmaniasis symptoms after treatment with pentavalent antimony than individuals who were not co-infected (Moreno et al., 2000). Co-infected individuals had significantly lower levels of serum transforming growth factor-beta (TGF-β1; Moreno et al., 2000). The authors postulated that the lower levels of TGF-β1 and the host's inability to mount a leishmaniasis-specific immune response could be the reason for more common relapses (Moreno et al., 2000). Co-infection with HIV and malaria has been shown to increase transmission of both of these pathogens. HIV facilitates malaria transmission and infection with malaria strongly activates CD4 cells, which then facilitates HIV transmission because HIV can replicate rapidly in the CD4 cells (Alemu et al., 2013).

Outcomes of co-infection can be dependent on the host's immune resource allocation and, as described above, the type of immune response necessary to combat the infections in question (Alemu et al., 2013; Graham, 2008; Sousa, 1992). In situations where resources allocated to the host's immune response are limited, mounting a sufficient immune response can be challenging. This is particularly true in cases where the immune system mounts differing responses to the pathogens from different taxa. Given limited resources or a lack of coevolutionary history between host and pathogen (Graham, 2002; Graham et al., 2005), activating and maintaining two distinct immune pathways might be impossible. Subsequently, co-infection could have greater impacts on hosts or even host populations than single infections. For instance, in African buffalo (*Syncerus caffer*), co-infection with bovine tuberculosis (BTB) and gastrointestinal helminths decreased mortality risk in individual buffalo. Individuals infected with BTB alone had higher levels of interferon gamma (IFN-y) than individuals that were coinfected with worms. Altogether, interactions between these two infections led to higher prevalence of helminth infections in the population because of the effect of BTB on host immune systems (Ezenwa and Jolles, 2015).

Co-infection with similar pathogens can also increase disease burden. Co-infection of murine hosts with *B. burgdorferi* and *Ehrlichia bacteria*, the causative agent of Granulocytic Ehrlichiosis, increased pathogen loads and Lyme arthritis severity relative to hosts infected with *B. burgdorferi* alone. Co-infected hosts also had lower levels of interleukin-12 (IL-12), interferon-y (IFN-y), and fewer INF-y receptors on macrophages. These Th1-type cytokines are typically upregulated to combat bacterial infections. Conversely, they saw an increase in interleukin-6 (IL-6) levels with co-infection (Thomas et al., 2001). Increases in IL-6 levels can decrease the effects of Lyme arthritis in C57BL/6 mice (Anguita et al., 1996), which means that despite increased burden, this immune response might decrease symptoms. Indeed, co-infections with similar pathogens need not always increase disease burden. Co-infections with similar pathogens could foster cross immunity in hosts. In these cases, parasites are so similar that host responses to one infection will be protective against subsequent infections. For example, when mice were infected with genetically distinct clones of rodent malaria, the primary infecting clone established. However, if the secondary infecting clone was added after the primary infection had established, the secondary clone did not reach as high a burden (de Roode et al., 2005). Moreover, exposure to like pathogens at similar times can cause a more rapid or larger magnitude systemic response. This scenario could lead to more rapid and effective protection against both pathogens. Co-infections are known alter host immunity (Thomas et al., 2001; Moreno et al., 2000), which in turn, can change the outcome of infection and increase pathogen transmission between hosts (Alemu et al., 2013; Ezenwa and Jolles, 2015). Ecoimmunologists are working to better understand how pathogen interactions are immune-mediated and how co-infections alter transmission dynamics and population disease dynamics.

Ecoimmunology Future

The above text about dilution effects, superspreading, and coinfections highlights the need to understand the effects of anthropogenic change on disease in natural systems. Since the inception of the field, scientists have probed how global changes will affect immune responses of individuals and the impacts of these effects on populations and communities (Martin et al., 2010; Martin and Boruta, 2014). For years now we have known that reproduction, molt, migration, and development all induce context-dependent

costs on an individual, and these costs affect their ability to respond to infections (Brace et al., 2017). Ongoing, escalating global changes are apt to alter or sometimes even exacerbate immune-related trade-offs. For example, amphibian species that reside in human-impacted forest exhibit reduced bactericidal killing ability (Hopkins and DuRant, 2011). Poor habitat quality and resource scarcity also correlate with land development (Klurfeld, 1993; Moret and Schmid-Hempel, 2000; Cropper and Griffiths, 1994), and these factors are known from other fields to affect immune responses (Glick et al., 1981). Habitat destruction is not the sole consequence of human disturbance in several circumstances. There is evidence that chemical toxins affect susceptibility to pathogens (Ross et al., 2000). In a metaanalysis, pesticide exposure at environmentally relevant levels was shown to decrease immune function and increase pathogen load in fish and amphibians (Rohr and McCoy, 2010). Pesticides have been shown to decrease a variety of immune functions in these taxa including decreases in proliferative activity of B and T lymphocytes (Rymuszka et al., 2007), lower levels of melano-macrophages in the liver, eosinophils in the blood (Rohr et al., 2008), and total white blood cell counts (Christin et al., 2004).

In its short lifespan, ecoimmunology has made many important contributions and begun to merge with disease ecology to produce one of the most integrated biological research fields (Brock et al., 2014; Ezenwa et al., 2016). Going forward, an integrated disease ecology promises to have more positive impacts on our understanding of immune variation among and within species, which could be helpful in medicine, mitigation of global climate change effects, and management and prevention of zoonotic and other disease outbreaks (Tauber, 2017).

Ecological Niche☆

Jitka Polechová, University of Tennessee, Knoxville, TN, United States; BioSS, Edinburgh, United Kingdom; University of Vienna, Vienna, Austria
David Storch, Charles University, Prague, Czech Republic

Introduction

Ecological niche is a term for the position of a species within an ecosystem, describing both the range of conditions necessary for persistence of the species, and its ecological role in the ecosystem. Ecological niche subsumes all of the interactions between a species and the biotic and abiotic environment, and thus represents a very basic and fundamental ecological concept. The tentative definition presented above indicates that the concept of niche has two sides which are not so tightly related: one concerns the effects environment has on a species, the other the effects a species has on the environment. In most of ecological thinking, however, both meanings are implicitly or explicitly mixed. The reason is that ecology is about interactions between organisms, and if persistence of a species is determined by the presence of other species (food sources, competitors, predators, etc.), all species are naturally both affected by environment, and at the same time affect the environment for other species.

If we want to treat both of these aspects of ecological niche within one framework, we can define it more formally as the part of ecological space (defined by all combinations of biotic and abiotic environmental conditions) where the species population can persist and thus utilize resources and impact its environment. It is useful, however, to distinguish three main approaches to the niche. The first approach emphasizes environmental conditions necessary for a species presence and maintenance of its population, the second approach stresses the functional role of species within ecosystems, and the third one a dynamic position of species within a local community, shaped by species' biotic and abiotic requirements and by coexistence with other species.

Concepts of Niche

Niche as the Description of a Species' Habitat Requirements

The first formulations of the concept of an ecological niche were close to the general meaning of the term: the ecological niche was defined by a place a species can take in nature, determined by its abiotic requirements, food preferences, microhabitat characteristics (e.g., a foliage layer), diurnal and seasonal specialization, or predation avoidance. This concept is associated mostly with Joseph Grinnell, who first introduced the term. He was especially interested in factors determining where we can find a given species and how niches, generated by the environment, are filled. The knowledge of a species niche determined by its habitat requirements is essential for understanding and even predicting its geographic distribution; this concept of the niche is thus more relevant in biogeography and macroecology than in community or ecosystem ecology.

Niche as Ecological Function of the Species

In this concept of a niche, each species has a particular role in an ecosystem and its dynamics, and one such role can be fulfilled by different species in different places. The observation of distant species adapted to equivalent ecological roles (the resemblance

☆*Change History:* February 2018. Polechová updated Figure 1, minor changes throughout (ambiguities, English - suggestions by Swati Patel), second paragraph in Evolution of Niche Width ("swamping" by gene flow) and checked by Polechová and Storch.

between jerboa and kangaroo rat, between many eutherian and marsupial species, or the Galapagos finches diversifying to highly specialized roles including those normally taken by woodpeckers) was clearly influential to Charles Elton, who emphasized the functional roles of species. According to Elton, there is the niche of burrowing detritivores, the niche of animals specializing in cleaning ticks or other parasites, or the pollination niche. Elton's niche can apply to several species, for example, "the niche filled by birds of prey which eat small mammals". This *functional niche* therefore refers to a species position in trophic chains and food webs, and the concept is thus especially relevant for ecosystem ecology.

Niche as a Species Position in a Community: Formalization of Ecological Niche Concept

The emphasis on the diversity of ecological communities and interspecific competition within them in the second half of 20th century has lead to the formalization of niche concept, and an emphasis on the properties of the niches which enable species coexistence within a habitat. George Evelyn Hutchinson postulated that niche is a "hypervolume" in multidimensional ecological space, determined by a species requirements to reproduce and survive. Each dimension in the niche space represents an environmental variable potentially or actually important for a species' persistence. These variables are both abiotic and biotic, and can be represented by simple physical attributes as temperature, light intensity or humidity, but also more sophisticated attributes such as soil texture, ruggedness of the terrain, vegetation complexity or various measures of resource characteristics. This could be viewed simply as a formalization of original Grinnellian niche, that is, the exact descriptions of a species habitat requirements. However, in the Hutchinsonian view ecological niches are dynamic, as the presence of one species constrains the presence of another species by interspecific competition, modifying the position of species' niches within the multidimensional space. This concept therefore combines the ecological requirements of the species with its functional role in the local community.

Fundamental and Realized Niche

Hutchinson recognizes a species' *fundamental niche*, a multidimensional 'cloud' of favorable conditions determined by all environmental (abiotic and biotic) variables where the species can reproduce and survive, and the *realized niche*, which is a subset of the abstract fundamental niche, where the species can persist given the presence of other species competing for the same resources. Thus, a realized niche always has a narrower extent along respective dimensions; a species which could potentially live in a broad range of humidity conditions, for instance, may occupy a much narrower range of these conditions in an environment with competing species, since its population growth rate decreases to negative values in some conditions. To a good approximation, if we ignore stochastic sampling from a heterogeneous species' population, species does fill its realized niche.

According to Hutchinson's formalization, niches of different species can be separated along any of these dimensions or by a combination of them (i.e., their interaction) (Fig. 1). Although this formal model of the niche has quite straightforward theoretical

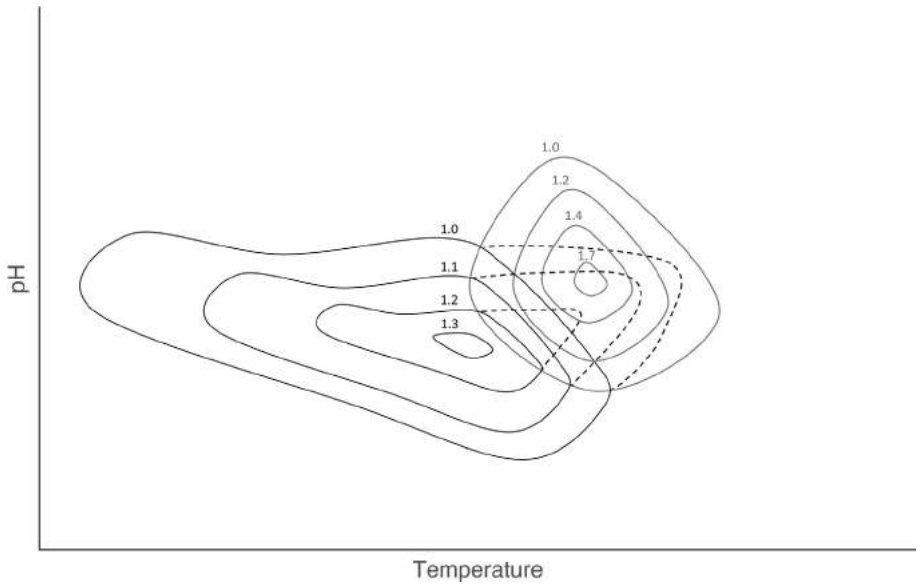

Fig. 1 A hypothetical example of species niches and their interaction. Two niche axes are shown, pH and temperature. The two species of hypothetical protists have different optima, and one (left) is adapted to wider range of conditions and has overall lower growth rate (measured at a given low density). When the niches of the two species overlap, the growth rates are expected to decrease, potentially to the point where the population cannot be sustained. Here, one of the species if fully dominant in its niche. Therefore, the other species can sustain its population only on a part of its fundamental niche, as its growth rate decreases at the overlapping areas. The growth rate isoclines are shown, with the dashed lines depicting the growth rate isoclines of the fundamental niche (i.e., had the other species been absent).

consequences, in practice it can be quite difficult to describe properly the ecological niches of real species, because the number of niche dimensions is potentially infinite, and the significant niche axes (and appropriate measurements) may be rather hard to find; a niche overlap among species may mean we did not succeed in determining the crucial niche axes of separation. However, often a few variables are sufficient to separate species' realized niches, and they or their correlates can be inferred assuming we understand the species' biology reasonably well. For example, five species of warblers, analyzed by Robert MacArthur, showed significant (though incomplete) separation along only three niche axes (feeding behavior, feeding height and nesting time).

The difficulties in determining appropriate niche axes, however, still considerably limit the usefulness of the concept in empirical research. Even if we know the important resources, it is still problematic to decide which characteristics to measure. A further problem, albeit rather technical, is posed by including discrete categories: the width of the cloud in the respective dimension would be reduced to zero, and its position can be arbitrary. More importantly, although species can often potentially live in a much broader range of environmental conditions than where they do actually live, the distinction between the "fundamental" and "realized" niche is slightly arbitrary, driven purely by the interest in coexistence of species sharing resources. As the dimensions of the fundamental niche are both abiotic and biotic, there is no a priori reason to exclude presence of competitors from the dimensions characterizing fundamental niche. The distinction between the fundamental and realized niche may also be blurred, as species' interactions need not fit to our discrete categories—for example, competitors may act also as predators.

Due to the difficulties with the concept, and for tractability, a considerable part of the theory actually dealing with species coexistence works with a one-dimensional approximation of the *trophic niche, a resource utilization function*—given by the frequency distribution of an important characteristic of utilized resource (e.g., a prey size).

Competitive Exclusion

Historical development of the niche theory is very closely related to one of the most important topics of ecology, that is, the problem of species competition and coexistence. Since the beginning of the ecological niche concept, it has been assumed that no two species sharing a single niche could locally coexist. Originally, the later *Volterra–Gause principle* states that "under constant conditions, no two species utilizing, and limited by, a single resource can coexist in a limited system" and was formulated and proved by Vito Volterra, whilst Alfred Gause showed experimental evidence of competitive exclusion in an undiversified environment. The explanation of the competitive exclusion lies in the fact that utilization of a limited resource leads to its depletion, and the population growth, therefore, necessarily leads to a moment when the resource level is insufficient for further growth. If only one population utilizes the resource, this situation leads to simple negative feedback, causing the decrease of population growth rate and thus a release of resource consumption, stabilizing the population size. However, in the case of two species sharing the resource, there will likely exist a resource level when the first species can still grow up even if the second cannot, leading to further decrease of population growth rate of the second species, and eventually to its extinction. Even if two species sharing several resources have exactly the same requirements and ability to utilize them, the coexistence of such species is not stable due to environmental or demographic stochasticity: over time, one of the species would ultimately become extinct by chance.

The "competitive exclusion principle" is the core principle in community ecology, and much of this field has been devoted to study how species with similar ecological requirements can coexist. This question has transformed into the problem of "limiting similarity": how similar can ecological niches be to still ensure local coexistence.

Limiting Similarity, Species Packing: How Close Can Species Be to Each Other?

Hutchinson states that a species' realized niche is exclusive, that is, no two species can share a single niche and no overlap in the realized niches is possible in a stable environment. In other words, were there to be an overlap in, say, the trophic "dimension" of the niche, species would differ in other dimensions—for example, in their tolerance to abiotic factors, or avoidance of predators. Now, the (rather vague) consensus is that a little overlap between niches is consistent with coexistence, whereas somewhat larger overlap is not. The theory of *limiting similarity*, formalized by Robert MacArthur and Richard Levins, predicts the minimum permissible degree of overlap in the resource utilization curve. They showed that coexistence between species utilizing a continuous resource is possible when the ratio between the niche width (see Box 1) and the distance between species' optima is approximately unity or smaller. (This has been derived using the Lotka–Volterra equations describing the growth rates and hence stability of populations of competing species, where the competition coefficients were determined by the proximity of species' bell-shaped utilization curves.) However, the result is sensitive to the assumptions about the form of the resource utilization function and population growth rate; notably, highly peaked resource utilization functions show actually almost no limits to coexistence (as their overlap is always minute) and niches can overlap broadly when fitness increases as the frequency of individuals carrying the respective trait decreases—under negative frequency-dependence. Also, coexistence between species can be facilitated by nonlinear responses of the competitors to common fluctuations in the environment. Note that the predictions of the theory of limiting similarity cannot be directly corroborated by observation: by definition, the population density of one of the species is close to zero if the species pair is close to limiting similarity, and thus the utilization functions are not observable in such a situation. On the other hand, finding a similarity higher than predicted would clearly indicate that some of the assumptions of the model are violated.

The spacing between species in niche space, resulting from partitioning the available resources (*species packing*), differs considerably between sexually and asexually reproducing species. In sexually reproducing populations, recombination generates

Box 1 Niche width

Niche width describes the dispersion of population resource use along a niche dimension. As such, it is very laborious to measure: more often, we get estimates of niche width from the morphological traits related to the resource use: for example, beak dimensions, jaws or teeth size. However, this measure delivers only a part of the information: both phenotypic variation in the traits important for food gathering and the ability of an individual to exploit a range of resources generally contribute to the niche width. For example, the niche breadth of *Anolis* lizards, studied by Joan Roughgarden, is mostly determined by variation in jaw size within species, but any individual still contributes to the total niche width, having its own range of prey sizes. Importantly, Rougharden shows that a measure of the total niche width can be calculated as a sum of a *within-phenotype component*, the average variance of the individual's utilization function, and a *between-phenotype component*, the variance in population resource utilization function. Often, the range of two standard deviations (twice the square root of the sum), comprising about 95% of resource used, is denoted as the niche width.

The related term *niche breadth* is originally due to Richard Levins. Levin's measures of niche breadth reflect the diversity of species' use of available resources: niche breadth is determined by the Shannon index (i.e., information entropy), or Simpson's index (i.e., the inverse of the sum of squared frequencies of the focal species over all resources). Although niche breadth intuitively captures differences between generalists and specialists, the measure is very sensitive to the categorization of resources and their frequency distribution.

all possible combinations from the common gene pool, although some of these may be maladaptive. Trade-offs in utilizing the resource spectrum may—or may not—generate disruptive selection strong enough to drive evolution of reproductive isolation and evolution of distinct species, thus eliminating maladapted recombinant genotypes. In contrast, in asexual species, clones bearing favorable combinations do not recombine, and therefore those adapted to the various resource combinations can be arbitrarily spaced in the niche space. Due to the necessity of finding a mating partner, population growth rate of sexual populations can sharply decrease at low densities (*Allee effect*), limiting both adaptation to marginal conditions and invasion to a new area. Both these effects contribute to discontinuities in distribution of resource use of sexually reproducing species.

Modes of Species Coexistence

Species coexistence is often ensured by niche separation. The *niche shift* can follow from the competitive exclusion of one species from the part of ecological space where the niches overlap, or from coevolution of competing species, favoring in each species phenotypes differing from the phenotype of the competitor. Current niche segregation can be due to the processes that took place in distant evolutionary past—sometimes emphasized by the term "the *ghost of competition past*". When phenotypic differences arose due to divergent evolution of sympatric competitors, we speak of *character displacement*. Typically, sympatric populations of competing species evolve towards more different sizes of characters associated with food consumption (beaks, teeth) than allopatric populations – if there is an island with only one species of Galapagos finches, it has an intermediate beak size enabling it to utilize a wide spectrum of seed sizes, whereas if there is an island with two species, one has a bigger and the other a smaller beak than the species occurring without competitors. If there are more than two locally coexisting species, we often observe regularly spaced sizes of morphological characters, again indicating past competition leading to maximum niche separation.

Simple separation of niche optima is not, however, the only way that stable local coexistence of species is attained. Many species pairs, for instance, consist of one species which is competitively dominant, and the other species which is less specialized and can thrive in a broader range of ecological conditions. An example is the pair of two closely related species of redstarts, where the black redstart *Phoenicurus ochruros* is bigger and more aggressive, but the common redstart *Phoenicurus phoenicurus* can utilize a wider spectrum of habitats, such that it always has an option to thrive outside of the range of conditions preferred by the black redstart. Such niche division between dominant aggressive specialist and subordinate generalist has also been observed in many mammal species, and is apparently stable. In plants, competitively inferior species are often those with higher rates of spreading and growth, which enable them to quickly occupy empty places before arrival and eventual overgrowth of competitively superior species. In this case, we speak about the *regenerative niche*, representing a time window for the success of competitively inferior, but fast spreading and fast growing species, thus ensuring long-term coexistence of competitors in the same habitat.

If species are very similar to each other, such that they do not differ substantially in their utilization of resources, the competitive exclusion can take a very long time. If the replacement of old individuals by young ones is basically a random process, that is, all individuals regardless of species identity have equal chances to give birth to their descendants within an environment, populations of all involved species will fluctuate randomly and the prevalence of a particular species is just a matter of chance. However, due to these stochastic fluctuations and due to the fact that the species which incidentally prevails in a time step will have higher probability to further increase its abundance, this process will finally lead to apparent competitive exclusion. This process, called *community drift*, can be relatively slow and may be further slowed down by dispersal limitations (leading to random prevalence of different species in different local communities isolated by migration barriers) and balanced by the emergence of new species (i.e., speciation or migration from elsewhere).

Communities where dispersal limitation and community drift play a major role are called *dispersal-assembled communities*, in contrast to *niche-assembled communities* where niche differences play a major role in determining species distributions and abundances. Trees in tropical forests represent a very good candidate for dispersal-assembled communities. Most tropical tree

species are very similar in terms of their ecology and growth characteristics, and it has been documented that for their recruitment the proportion of parent individuals in a given locality (i.e., dispersal limitation of more distant individuals) is much more important than any habitat characteristics. Still, an incredible number of species can coexist locally. It is hardly believable that there are several hundreds of different narrow ecological niches (i.e., combinations of environmental characteristics) on a hectare of tropical forest to enable coexistence of several hundreds tree species on the basis of their niche differences—the dispersal assembly and coexistence without significant niche differentiation seems more likely. However, an unusual aspect of niche differences can still be involved in this classical case of species coexistence. It has been demonstrated that coexistence of tropical trees is facilitated by frequency-dependence, where relatively rare species have an advantage of not being so severely attacked by natural enemies which strongly limit recruitment of more common species on which they specialize. In a sense, all species compete for "enemy-free space", and this "niche" for a given species is open only if the species is not too abundant to allow population growth of specialized natural enemies. Separation of "niches" of tropical trees seems thus to be determined by the community of species-specific pathogens.

In conclusion, coexistence among species can be certainly maintained both by niche differences and—at least in a none-quilibrium world—by niche similarity. Coexistence of species with similar niches maintained by dispersal-assembly processes could be a reason why we often observe that species are not regularly distributed in a niche space, but form clumps of species whose niches are closer to each other than to other species.

How Many Ecological Niches Are There?

The notion that ecological niches cannot be infinitely similar to each other, and the knowledge that ecological space is heterogeneous and that the distribution of resources available to a community is always limited, has led to an idea that for a given environment there is a limited number of available niches which could be potentially occupied. An environment then could be seen as a set of empty niches, which could—but may not—be filled with species. Consequently, we might ask whether in a particular case the niche space is or is not saturated with species.

There are two facets of the problem, which are sometimes confused. First, there is no doubt that the limited amount of resources in an ecosystem can sustain only limited total number of individuals (assuming a given body size distribution). Therefore, there is always a limited potential for the whole community size determined by total amount of resources, and thus also for a limited number of species (given that each species needs some viable population size). If this potential is fully utilized, we speak about biotic saturation of the community. However, biotic saturation does not imply that the number of ecological niches is fixed and that all possible niches are occupied. Such a statement would be much stronger and would require at least some level of discreteness of ecological niches, that is, that ecological space cannot be divided into an infinite number of subtly different niches with arbitrary positions. Is there any reason to believe that niches are discrete and their number within an environment is limited?

Apparently, there is a considerable level of environmental heterogeneity in resource distribution and abundance; resources are more abundant for some combinations of parameters than for other. Environmental heterogeneity would not be, however, a sufficient condition for discreteness of ecological niches if species could utilize equally easily several different resources. The discreteness of ecological niches comes out from the existence of *trade-offs* in resource utilization: resources can always potentially be utilized in many ways, but a species which utilizes many resources typically does so with a lower efficiency compared to a specialist. A Galapagos finch from the genus *Geospiza* can have either a big beak appropriate for cracking big seeds, but then it can crack small seeds with much more difficulty—and vice versa. Some strategies in resource utilization are mutually exclusive: a plant can either invest to its rapid growth and so quickly utilize resources, or it can invest into woody trunk which enables it to grow higher and sustain longer—but at a cost associated with slower growth. Whilst natural selection supports phenotypes that are better at utilizing available resources, it can only explore the vicinity of the current strategy, selecting from the available phenotypes. Consequently, evolution leads to utilization of only a restricted spectrum of resources.

In the presence of trade-offs, there is only a limited number of mutually exclusive ways to utilize resources, and thus a limited number of available niches. However, as the discreteness of niches follows from the trade-offs between adaptations, and since all the trade-offs are determined by unique properties and constraints of given organisms, it makes sense to speak about available niches only in relation to organisms which already inhabit the environment. A habitat without its inhabitants can provide a potentially infinite number of opportunities for existence, and this landscape of opportunities changes with each new inhabitant. For the organism in an environment, the number of possible niches is determined by the number of possible ways to utilize the resource—with all constraints and trade-offs of the given organism. Therefore, it is likely that there are always more niches than the current number of species, because each species has several mutually exclusive possibilities of future adaptive evolution arising from the trade-offs—unless all niche changes require a corresponding niche change in other species.

In some cases, the number of available niches can be predicted from the knowledge of resource heterogeneity and the possibilities of resource utilization for given taxon. The number of Galapagos finches occurring on each island is reasonably well predicted by the number of peaks of the "landscape" constructed using the knowledge of frequency distribution of seed size, the general relation between finch and seed biomass, and the relation between preferred seed size and beak depth (Fig. 2). Similarly, using the knowledge of the relationship between beak shape of crossbills (*Loxia curvirostra*) and their foraging efficiency in obtaining cone seeds from cones of various coniferous tree species, it is possible to construct a resource utilization function related to different morphologies, and find out how many optimal shapes do exist. And again, it has been found that there are several ecomorphs of crossbills, each of them occupying one adaptive peak (optimum) in the morphological space.

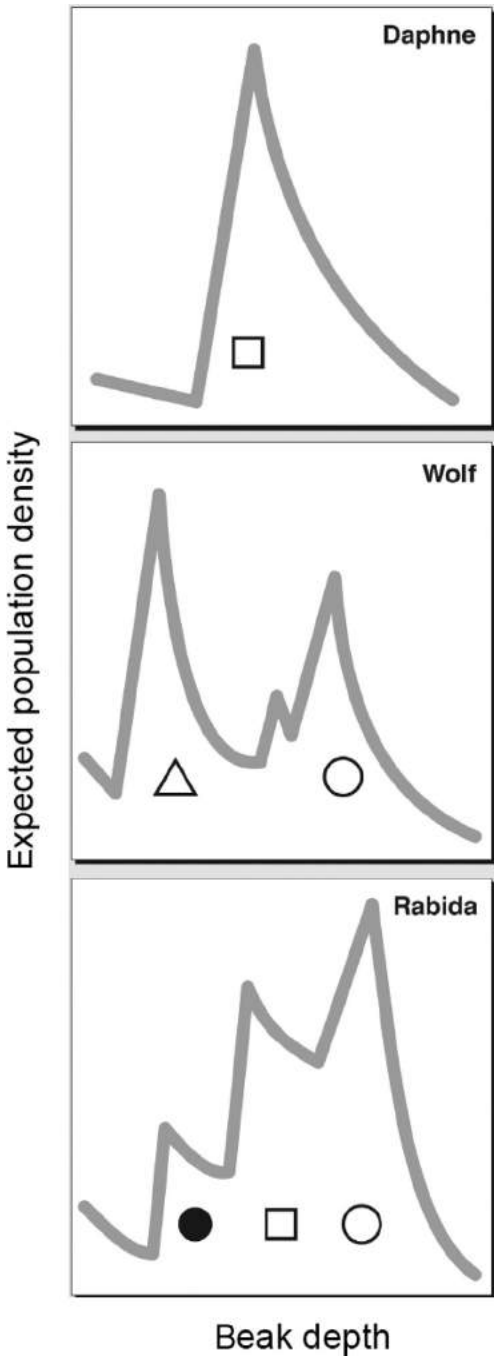

Fig. 2 In this example of Galapagos finches on three different islands, the number of niches can be predicted from the peaks in the expected finch density. The expected finch density is calculated from distribution of seed biomass converted to finch numbers, using preferred seed size estimated from the mean size of the beak. The beak depth of the finches occurring on each islands corresponds well to the maxima of the curve. Position of the symbols marks mean beak depth of male ground finch on each of the three islands: *Geospiza fortis* (□), *G. difficilis* (△), *G. magnirostris* (○) and *G. fuliginosa* (●). The beak depth scale is kept the same for the three pictures; the population density is scaled to the maximum. Modified from Schluter, D. and Grant, P. R. (1984). Determinants of morphological patterns in communities of Darwin's finches. *American Naturalist* **123**, 175–196.

There is other evidence that ecological niches are partially predictable—the phenomenon of community convergence. Animal or plant communities occurring on different continents or biotic provinces often comprise similar morphological types utilizing similar types of resources. *Anolis* lizards, for instance, have evolved independently into several well-recognizable ecomorphs on each Caribbean island, with known sequence of this evolution, repeated on every island. However, there can be more than one species within each ecomorph, and thus this convergence does not imply that the number of species-specific niches is predictable. This is quite typical for most cases of community convergences: they provide a clue to our understanding of how many possibilities are

there for utilizing resources within a given habitat and for a given taxon, but not to the prediction of how many species can actually coexist there. The total potential number of species within an environment is given by the total amount of resources determining the total number of all individuals, regardless the level of discreteness of ecological niches.

Ecological Niches and Patterns in Species Abundance and Distribution

Species spatial distributions as well as their abundances are often attributed to the breadth and position of their niches. A species occurs in places where its requirements are fulfilled, that is, where it finds its niche. However, the "presence of the niche" is not a sufficient condition for the presence of a species, and in special cases it may not be even the necessary condition. Spatial population dynamics driven by dispersal and spatial distribution of available habitat patches is equally important. Consequently, species may be absent even in sites containing habitat that fulfills its niche requirements if the site is far away from other occupied sites and the dispersal distance of the organism in concern is relatively small, hindering immigration into the site. On the other hand, a species may be present even in a site where its niche requirements are not fulfilled and population growth is negative if the population is maintained by a continuous supply of individuals from neighboring sites with positive population growth (so-called source-sink population dynamics). Therefore, species spatial distributions are determined by species niches and available habitat distributions, as well as by spatial population dynamics and dispersal limitation.

In a similar line, it has been argued that a significant proportion of the variation of species' abundances can be explained by the breadth of species' niches (Box 1). It is reasonable to assume that species which are able to utilize wider spectrum of resources can attain higher population abundances and also can occupy more sites. Local population densities are mostly positively correlated with species range sizes, which can be taken as evidence of such niche differences. However, patterns in species abundances can be often well explained by spatial population dynamics—for instance species which were incidentally able to spread to more sites have higher chance to colonize further sites and to further increase local population densities by immigration (this is the nonlinearity of the dynamics of metapopulations). Moreover, the statistical relationship between niche breadth and abundance can actually have a reversed causality, as abundant species are forced to utilize a wider range of resources due to intraspecific competition. More abundant species can also be those that do not utilize a broader range of resources, but are specialized on resources which are relatively more abundant, or may simply have higher population growth and/or dispersal rate (although these features can be understood as niche properties).

One of the most prominent ecological patterns is the frequency distribution of abundance of individual species within local communities or regional species assemblages—the so called species-abundance distribution. It is always highly unequal, the majority of species having low abundance and only a few being common (the frequency distribution is often close to lognormal, though other models may fit the observed species-abundance distribution better in particular situations). This distribution has been modeled as a stepwise division of niche space, where each newly arriving species obtains some (random) proportion of niche space previously utilized by other species. One of these models, based on sequential resource partitioning, predicts observed species-abundance distribution quite well (Box 2). However, models based on spatial dynamics and dispersal limitations—especially those involving "community drift"; see above—can provide equally good predictions of species-abundance distribution. This again indicates the complementarity between niche-based and dispersal-based explanation of ecological patterns, and supports our consideration of both niche differences and spatial population dynamics as essential drivers of species distribution and abundance.

Niche Divergence and Resource Specialization

The diversity of ecological niches even among closely related species is enormous and demands explanation. What is the reason for such diversity? We have already mentioned one of the most important factors—interspecific competition, which pushes ecological niches of species far away, to avoid niche overlap. More specifically, natural selection prefers such phenotypes of competing species which utilize different resources than those which share them. Competition thus leads to the increase of the resource range utilized by a given taxon, and this process is faster when other taxa do not constrain this diversification. Indeed, the increase of the breadth of utilized resources in the course of evolution is fastest in such situations where other taxa with similar requirements are absent. For example, ecomorphological diversification of Galapagos finches and Hawaiian honeycreepers has been much faster than the

Box 2 Sequential resource partitioning

It appears that relative species abundances within taxa can be reasonably well explained by a simple null model of resource partitioning between species, proposed by Mutsunori Tokeshi. A common resource, represented by a "stick", is divided once at a random location chosen uniformly along its length, and for further partitioning one part is chosen with a probability proportional to its length raised to a power of K, where K is a parameter between 0 and 1 (e.g., 0.05), and the division and selection process continues to distribute the "niche" among all the species within the taxon. The model seems to describe well relative abundances of species within taxa, across a large range of their species richness.

diversification of related taxa on the mainland, where the utilization of new resources was constrained by other taxa already utilizing them.

Interspecific competition is not, however, the only force driving niche diversification. Each species has its own evolutionary history, and thus can adapt to different resources by an independent process of evolutionary optimization, as phenotypes which are more efficient in transforming obtained energy into offspring are favored by natural selection. If there are several mutually exclusive ways to achieve this, it is likely that each species will go by a different route due to evolutionary contingency, and niche diversification will follow without competition. Notably, optimization does not lead to an advantage of the whole species in terms of the resource utilization but only to an individual advantage regardless of the evolutionary fate of the whole species: when the niche becomes narrower, the species' range and hence total population size decreases. As evolution is opportunistic, species can evolve to extremely specialized forms in terms of either habitat utilization or food preference, which is apparently disadvantageous for future species persistence in ever changing world.

Evolution of Niche Width

Progressive specialization, that is, narrowing of niche width in the course of evolution, is forced by interspecific competition (when the niches overlap) and intraspecific optimization, and thus represents an expected evolutionary trend. The opposite process, that is, an extension of niche width, is observed mostly after entering a new environment without competitors, allowing utilization of a wider spectrum of resources. This process is called *ecological release* and may be underlined both by the extension in within- and between-phenotype component of species ecological variation (importance of the two contributing modes vary widely among species). Species niches can widen also because of *phenotypic plasticity* (heritable genotype–environment interactions directing the trait in the early ontogenesis), and can vary even purely behaviorally, as an immediate response to an altered resource or species structure.

Although sometimes there is an obvious constraint on expanding a species' niche—for example, physiological constraints like freezing of body fluids or presence of a competing species—we often see no apparent reason why species niches stay restricted to a fraction of a resource which continuously varies in space. However, even a gradual change in the environment can lead to a sharp range margin, as "swamping" by gene flow from central to marginal areas can create a positive feedback between the reduction in fitness, where population size decreases due to maladaptation, and the erosion of genetic variance by genetic drift. When local genetic variance is too low, continuous adaptation to a spatially variable environment fails. Moreover, when there is a large asymmetry in the carrying capacity across the habitats, even alleles which neutral or nearly neutral in the main population and deleterious in the marginal populations, can sweep through the small marginal population, thus preventing the adaptation.

Asexual reproduction or self-fertilization can hence provide an advantage in adapting to marginal conditions—both because small populations are still viable (as there is no need to find a mating partner) and because gene flow does not restrict adaptation to marginal conditions. Indeed, it is found in many plants and animals adapting to extreme, marginal habitats (classic animal examples are *Daphnia pulex* or freshwater snail *Campeloma*). However, although lack of recombination in asexuals means that locally favorable gene combinations are maintained, adaptive evolution in asexual species is significantly slowed down as beneficial combinations have to arise in each strain independently. It appears that high levels of, but not obligatory, self-fertilization or asexual reproduction (parthenogenesis and vegetative reproduction) are commonly advantageous for adaptation to marginal habitats.

In some cases, we observe an apparent regularity in the evolution of niche width and position. The classical example represents cycles of species dispersal, specialization and local adaptation (and eventual extinction) observed on various archipelagoes, called *taxon cycles*. They were originally described by Edward O. Wilson on Melanesian ants, but were best documented by Robert Ricklefs and his coworkers on Caribbean birds. In the first stage, an immigrant, which is mostly a species with a high dispersal ability, colonizes coastal or disturbed areas. Then the species spreads across the island, adapting to the new resources and expanding its niche (quite likely as a consequence of a release from competitors, predators and parasites). In the next step the species becomes more specialized, and its distribution becomes spottier. The narrowing of its niche may be driven by an immediate advantage of an adaptation to a local resource or immigration of new generalist competitor. Finally, species distribution becomes very fragmented, ending in local endemism, and ultimately extinction.

Changing the Niche Space, Niche Construction and Coevolution

Both environment and species change in the course of time, and thus ecological niches are not stable and given forever. Species not only respond to environmental changes, but also actively change their biotic and abiotic environment, affecting both their own niche and the niches of other organisms. The importance of competition, predation or mutualism has been already stressed. Moreover, organisms often make niche space for other organisms available in the environment—think of the resource space generated by an emerging tree or of successive colonization of an island, where first colonizers modify the environment for their successors. Some organisms strongly directly affect abiotic environment, determining possible niches for a whole community of species. Beavers building dams, earthworms altering soil structure or, on a larger scale, plants providing oxygen are classical examples. Organisms substantially affecting abiotic environment are often called *ecosystem engineers* and the process in which an

organism systematically modifies its own niche (both biotic and abiotic components), is called *niche construction*. Obviously, this process is most pronounced in *Homo sapiens*, which is currently the most conspicuous ecosystem engineer.

If a species can change its environment as well as to adapt to it, coevolution between a species and its niche can follow, based on the continuous feedback between a species' *niche construction* and its adaptation. Since species continuously change the environment for themselves as well as for other species, species' niches can be very dynamic. Often, however, species' ecological requirements are quite stable over evolutionary time, so that it is even possible to reliably reconstruct an ancient environment on the basis of presence of particular species in the fossil record and the knowledge of their contemporary ecological niches. This can be attributed to the fact that it is often easier to search for appropriate habitat elsewhere if an environment within a locality is changing than to adapt to it. All species have some dispersal abilities, and are thus able to track spatiotemporally changing habitat availability by migration rather than adapt to different conditions by mutation-selection process. The other reason for the apparent niche conservatism is the existence of evolutionary constraints and consequent trade-offs: species often cannot easily change their traits in a particular direction if these traits are associated with other traits whose change is not advantageous.

As species undertake evolutionary changes, their functional niches can change, leading to changes in the overall "ecological space" in an ecosystem, and promoting further changes in species traits. On the other hand, some functional niches, that is, particular ecological roles, can be rather stable even if species evolve, go extinct and new species emerge—similar functional role can be progressively fulfilled by different species. Community evolution can be therefore viewed as a coevolution of ecological niches rather than of species themselves.

Endemism

JJ Morrone, UNAM, Mexico City, Mexico

Introduction

The term 'endemism' refers to a taxon restricted to a particular geographical area of the world. Such taxon is said to be 'endemic' to that area. Areas where distributional areas of two or more taxa overlap are called 'areas of endemism'. The concept of endemism dates back to Augustin Pyramus de Candolle's *Geographie Botanique*, in the early nineteenth century. The biogeographical, evolutionary, and conservation perspectives of endemism are explored herein.

What Is Endemism?

Endemism describes taxa that are distributed on particular areas. It represents a basic feature of geographic distributions: species are rarely cosmopolitan and most species and even supraspecific taxa are confined to restricted regions. Endemism occurs on a variety of spatial scales, from areas as large as continents to small areas as islands or mountain tops. The puma (*Puma concolor*) is endemic to the Americas, occurring from Canada to Patagonia. Several plant families are endemic to the Neotropics. The volcano rabbit or teporingo (*Romerolagus diazi*) is endemic to some volcano tops (2800–4250 m) from the central part of the Transmexican Volcanic Belt (Mexico). Many researchers in the past focused on species endemic to small areas and thus endemism has been incorrectly associated with 'rarity'.

Organisms can be endemic on different taxonomic levels; usually the size of the area depends on the category of the taxon, with genera having larger areas than species, and families having larger areas than genera. This situation, however, is not comparable between different taxa: the distribution of a plant species may correspond to the distribution of an insect family. Conventionally, some authors have used the term 'endemic' for taxa restricted to a single biogeographical region, 'characteristic' for those taxa shared by two regions, 'semicosmopolitan' for taxa inhabiting three or four regions, and 'cosmopolitan' for taxa inhabiting five or more regions.

The restriction of taxa to particular areas is a consequence of both historical and ecological factors. Historical events are invoked to explain how a taxon became confined to its present range. Vicariant events caused by drifting continents, long-distance dispersal, and extinction are some of these events. On the other hand, ecological explanations are invoked to explain the present limits of endemic taxa. Abiotic (temperature, altitude, soil) and biotic factors are commonly considered.

Classification of Endemism

Endemic taxa can be classified into some categories, based on their distribution, origin, age, and taxonomy.

Autochtonous endemics. Taxa that evolved in the areas where they are currently found.

Allochtonous endemics. Taxa that evolved in a different area from where they are found today.

Taxonomic relicts. Taxa that are the sole survivors of a once diverse group.

Biogeographic relicts. Taxa that are the narrowly endemic descendants of a once widespread taxon. They are also known as living fossils or narrow endemics. Tuataras (*Sphenodon punctatus* and *S. guntheri*), endemic to New Zealand, are a good example of biogeographic relicts.

Neoendemics. Taxa that have evolved relatively recently and may be restricted in their distribution because they have not had yet time to disperse further. The plant species *Aquilegia barbaricina* (Ranunculaceae), which grows only along water courses at 1300–1400 m in Sardinia, is an example of a neoendemic taxon.

Paleoendemics. Taxa that have a long evolutionary history and usually are restricted by barriers to dispersal or by extensive extinction in the remaining areas where they were distributed in the past. *Bupleurum dianthifolium* (Apiaceae), which today grows only in the small island of Marettimo, west of Sicily, but was widespread in mountains of the Mediterranean area when there were more tropical conditions, represents a paleoendemic species.

Areas of Endemism

Areas where the distributional areas of two or more taxa overlap are called areas of endemism. The congruence of the distributional areas of different taxa gives identity to areas of endemism. It is interpreted as primary biogeographical homology, which means a conjecture on a common biogeographic history, namely, they belonged to the same ancestral biotic component.

If we map the distributional ranges of relatively well-known taxa, the substantial overlapping in their ranges determines an area of endemism. When dealing with few taxa, this represents an easy task, but when having a high number of taxa to analyze, difficulties may arise. In order to provide ways to choose objectively which taxa to map and maximize the number of taxa

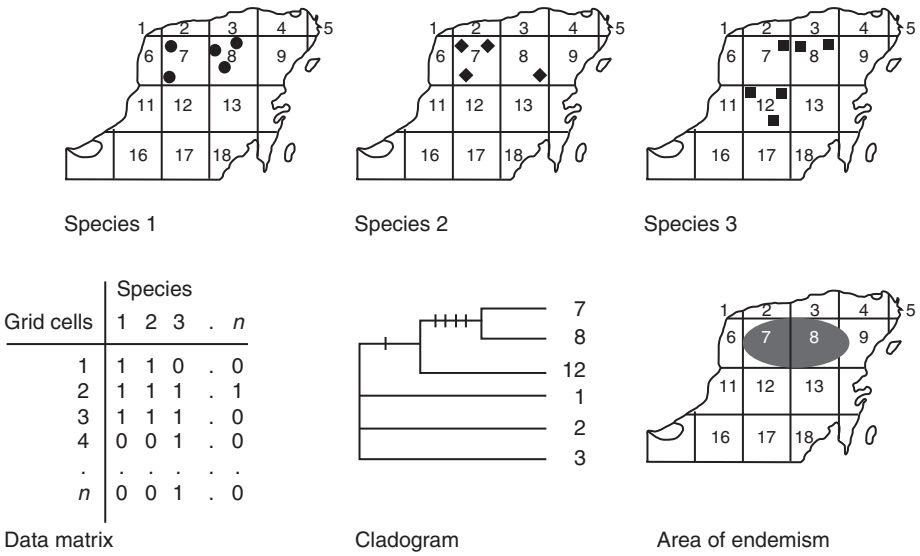

Fig. 1 Steps of a PAE, procedure that allows to identify areas of endemism.

contributing to the areas of endemism recognized, several procedures have been developed during the last decades. The most popular is PAE, formulated originally by the paleontologist Brian Rosen. It comprises the following steps (Fig. 1):

1. Draw grid cells on a map of the region to be analyzed, considering grid cells only where at least one locality of one taxon exists.
2. Construct an $r \times c$ data matrix, where r (rows) represent the grid cells and c (columns) the taxa. Entries are 1 if a taxon is present and 0 if it is absent. A hypothetical area coded 0 for all columns is added to root of the tree.
3. Perform a parsimony analysis of the data matrix; if several cladograms result, obtain a strict consensus cladogram.
4. Delimit in the cladogram obtained the groups of grid cells defined by at least two species.
5. Superimpose the groups onto the grid cells and map the species endemic to each group of grid cells, in order to delineate the boundaries of each area.

Although the extension of the grid cells to be considered in step 1 is difficult to assess *a priori*, an additional step could be added when the five steps have been completed. In this step, the original grid cells involved in conflictive relationships with more than one of the delimited areas, could be further subdivided in smaller units, and then the procedure restarted. When dealing with distributions of widespread species, they could overlap and generate many equally parsimonious cladograms. The strict consensus cladogram, however, preserves the most robust groupings of grid-cells, thus minimizing the influence of widespread species.

Areas of endemism are successively nested, which means that within larger areas of endemism smaller ones are recognized, and within the latter there are even smaller ones. This allows proposing a hierarchic biogeographical classification that parallels the taxonomic Linnaean hierarchy, employing the following subdivisions (in decreasing size): realms (or kingdoms), regions, dominions, provinces, and districts (Fig. 2).

Biogeographical Classification of the World

Modern biogeographical classification began with De Candolle, Sclater, and Wallace in the nineteenth century. Based on recent studies, Morrone proposed the following biogeographical system for the world:

1. *Holarctic realm*. It comprises Europe, Asia north of the Himalayan mountains, northern Africa, North America (excluding southern Florida), and Greenland. From a paleogeographic viewpoint, it corresponds to the paleocontinent of Laurasia.
   1.1. *Nearctic region*. It corresponds to the New World, in Canada, most of the USA, and northern Mexico.
   1.2. *Palearctic region*. It corresponds to the Old World, in Eurasia and Africa north of the Sahara.
2. *Holotropical realm*. Basically the tropical areas of the world, between 30° south latitude and 30° north latitude. The Holotropical region has been previously recognized by Rapoport and would correspond to the eastern portion of the Gondwanaland paleocontinent.
   2.1. *Neotropical region*. Tropical South America, Central America, south-central Mexico, the West Indies, and southern Florida.
   2.2. *Afrotropical region*. Central Africa, the Arabian Peninsula, Madagascar, and the West Indian Ocean islands.

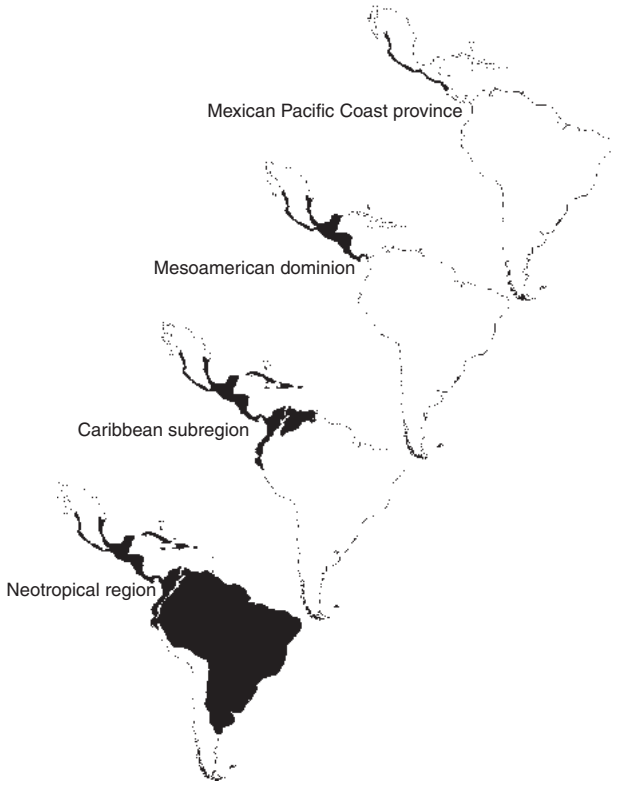

Fig. 2 Nestedness of the areas of endemism, which is the basis for biogeographical classification.

2.3. *Oriental region*. India, Himalaya, Burma, Malaysia, Indonesia, the Philippines, and the Pacific islands. In spite of the obvious tropical biotic elements of this region, it has been placed in earlier paleogeographic reconstructions as part of Laurasia. Recent authors have postulated that this area was part of Gondwanaland.
2.4. *Australian Tropical region*. Northwestern Australia.

3. *Austral realm*. It comprises the southern temperate areas in South America, South Africa, Australasia, and Antarctica. This region has been recognized previously by Kuschel and Rapoport and would correspond to the western portion of the paleocontinent of Gondwanaland.
   3.1. *Andean region*. Southern South America below 30° south latitude, extending through the Andean highlands north of this latitude, to the Puna and North Andean Paramo.
   3.2. *Antarctic region*. Antarctica.
   3.3. *Cape or Afrotemperate region*. South Africa.
   3.4. *Neoguinean region*. New Guinea plus New Caledonia.
   3.5. *Australian Temperate region*. Southeastern Australia.
   3.6. *Neozelandic region*. New Zealand.

Evolution

In order to reconstruct the historical relationships of areas of endemism, Donn Rosen, Gareth Nelson, Norman Platnick, and Ed Wiley developed cladistic or vicariance biogeography. It assumes that the correspondence between taxonomic relationships and area relationships is biogeographically informative. It is based on an analogy between biogeography and systematics, where taxa are treated as characters.

A cladistic biogeographic analysis is comprised of three basic steps (**Fig. 3**):

1. Construction of taxon-area cladograms from taxon cladograms, by replacing the terminal taxa by the area(s) of endemism inhabited where they are found.
2. Conversion of taxon-area cladograms into resolved area cladograms, by resolving problems due to widespread taxa, redundant distributions, and missing areas.
3. Derivation of general area cladogram(s), that represent(s) the most logical solution for all the taxa analyzed.

Patterns of area relationship derived from a cladistic biogeographic analysis are interpreted as secondary biogeographical homology. This is the cladistic test of the primary biogeographical homology formerly recognized.

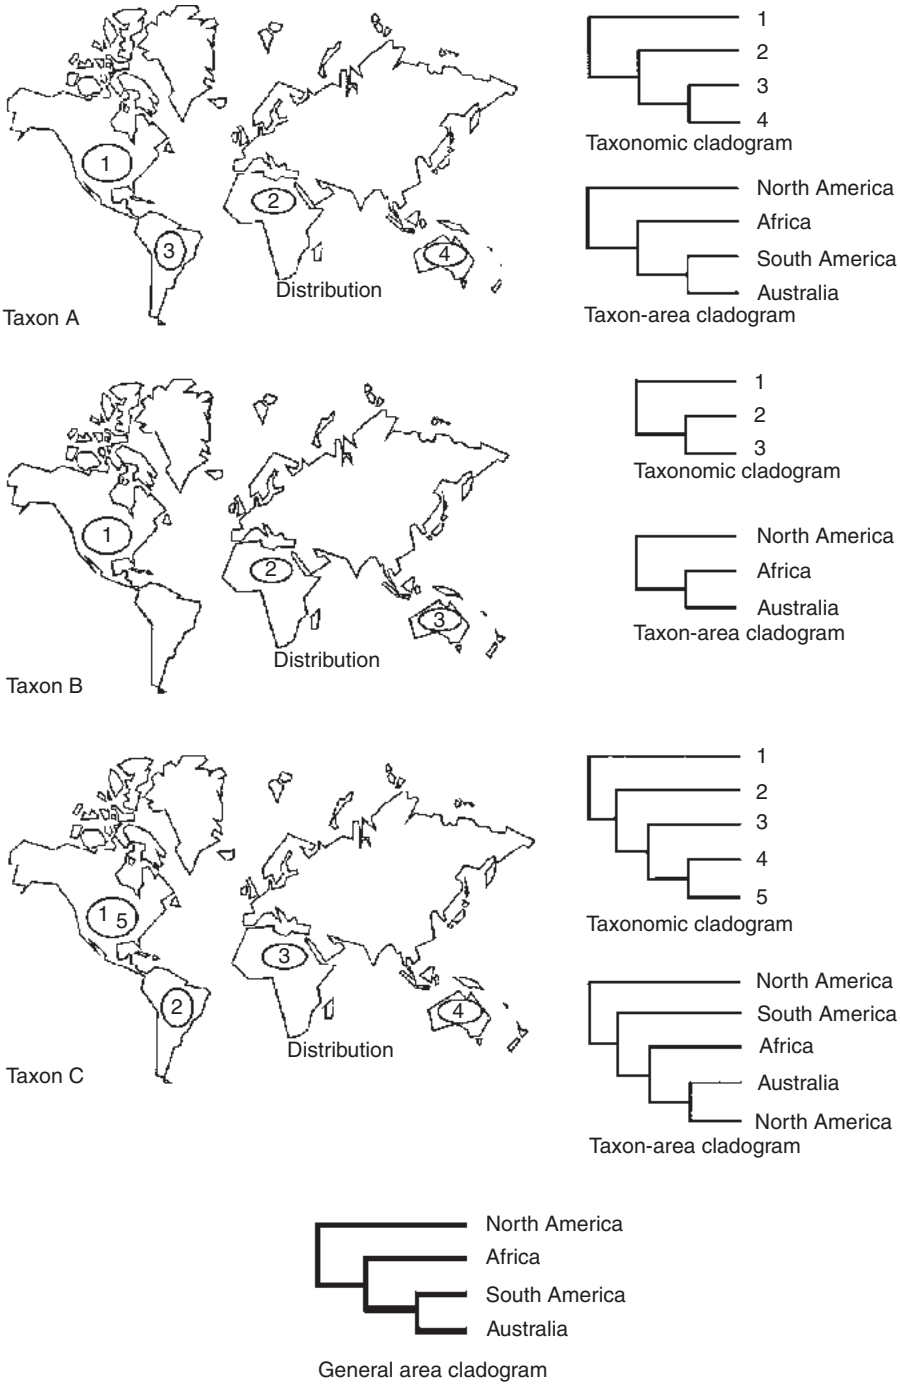

Fig. 3 Steps of a cladistic biogeographic analysis, where distributional and phylogenetic data of three different taxa allow to obtain a general area cladogram.

Conservation

Biodiversity is in global crisis. One of the major goals of conservation is the maintenance of as much as possible of the diversity of life. Thus we have to measure and compare priorities regarding areas to be protected, and we need to measure and compare local biodiversity, taking into account not only the number of species, but also the degree of difference among them.

One criterion for measuring biodiversity is species richness, exemplified by the 'megadiversity countries' concept; however, many important components of biodiversity are not represented in countries with highest values of diversity, and some areas could harbor a large number of widespread species, with no great conservation concern. Ecologists have developed diversity measures that combine species richness with information about abundance among species, and information on the vulnerability

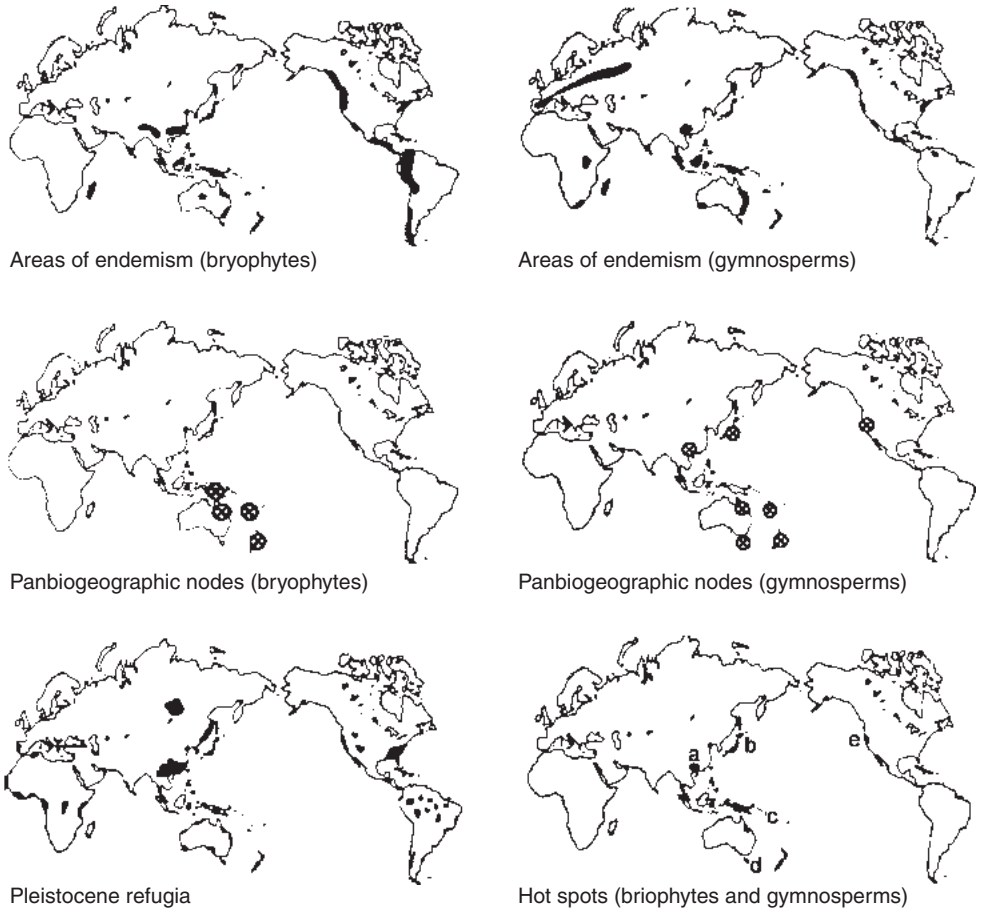

Fig. 4 Biogeographic analysis of gymnosperms of the world, with the hot spots that resulted from overlap among areas of endemism, panbiogeographic nodes, and Pleistocene refugia. a, Southeastern China; b, Japan; c, New Caledonia; d, Tasmania; e, western North America.

of those species, including the 'hot spots' analysis. Some authors have suggested that endemicity may help determine priorities for biodiversity conservation, whereas others have argued that it is not an appropriate measure of diversity, and is an ineffective mean for selecting areas for conservation.

A recent analysis of the distributional patterns of bryophyte and gymnosperm taxa of the world has found a remarkable congruence among areas of endemism, panbiogeographic nodes, and refugia in western North America, Japan, southeastern China, Tasmania, and New Caledonia (**Fig. 4**). It was concluded that these areas deserve special status for conservation, being significant candidates for designation as 'hot spots'.

Evolutionary Ecology

Bregje Wertheim, University of Groningen, Groningen, The Netherlands

Glossary

Genome The complete genetic information of an individual, including all its genes and noncoding DNA.
Genotype The combination of alleles of an individual at one or more positions in the genome.
Habitat The natural environment in which an organism lives.
Life history The age-, size-, or stage-specific resource allocation of organisms to development, growth, maturation, maintenance, survival and reproduction.
Meta-community Local communities that are linked by dispersal.
Phenotype The set of traits that an individual exhibits.
Taxa Taxonomic categories or groups, such as phyla, orders or species.

Introduction

Evolutionary ecology is the field of science that studies biological diversity as the outcome of evolution and ecology. Diversity is used here in its broadest sense of the word, encompassing species diversity as the product of evolutionary processes (including diversification, speciation and extinctions) and ecological interactions in the habitat or (meta-)community, trait diversity (including life history strategies, morphology, behavior and physiology) that evolved through natural selection, and genetic diversity that can be studied to infer the occurrence and influence of evolutionary and ecological processes. Evolutionary ecology aims to explain the distributions, abundance and characteristics of organisms from ecological and evolutionary processes, both at historical and contemporary timescales. It seeks to explain the ecology of organisms in the context of evolution, as well as the patterns of evolution as explained by ecological processes.

Among the evolutionary processes, natural selection is what causes organisms to adapt to their environment. Natural selection is the difference in reproduction and survival (fitness) among individuals with different traits or phenotypes. When these trait or phenotypic differences are (partly) heritable and not all individuals are equally successful in reproducing, then natural selection over successive generations leads to an increased frequency of individuals with advantageous traits or phenotypes in the population. Natural selection thus accounts for the traits and adaptations that equip organisms to survive and reproduce in a particular habitat. It also has lead to the present-day biodiversity that arose from a single common ancestor, with many different organisms now inhabiting every environment on Earth. However, not all evolution is adaptive, and also nonadaptive evolutionary processes, such as genetic drift, mutation and migration can largely contribute to trait diversity and species distributions. The combined adaptive and nonadaptive processes can eventually lead to the formation of new species (speciation), new traits (evolutionary innovations) or trait optimizations, as well as the loss of species (extinctions) or trait loss.

The ecological processes that affect diversity include the match of individuals with their environment, the interactions of individuals with members of their own populations, the interactions between populations of different species, and the exchange among communities at both local and regional scales. The match with the environment comprises the ability of an organism to cope with both the prevailing abiotic conditions (e.g., temperature, salinity and humidity) and biotic conditions (i.e., all the other organisms that exist in the environment). Whether a species can persist in an environment is determined by its own ability to survive and reproduce under the particular conditions of that environment, the abundance and characteristics of food, competitors, mutualists and natural enemies, its ability to disperse to/from other populations, as well as historic and regional events that shaped the species diversity in the meta-community.

The premise that diversity is the outcome of both ecology and evolution makes for a vast, nearly all-encompassing, research field. To allow for more tractable research domains, many subdisciplines developed where evolutionary phenomena are investigated in the context of ecology, or vice versa. For example, research that focuses on natural selection and fitness optimization to explain trait diversity include, among others, behavioral ecology, life history theory and ecophysiology. Research domains that focus on species abundance or diversity in (meta-)communities include, for example, population dynamics, predator–prey interactions, facilitation, coevolution, community ecology and biogeography. Research domains that primarily focus at causes and consequences of genetic diversity within species include, for example, molecular ecology, population genetics, conservation biology and ecological genetics. To address the rich variety of research questions in evolutionary ecology, many different research approaches are applied. These comprise observational, descriptive and comparative research, laboratory and field experiments, molecular and genomics analysis, as well as mathematical simulation and theoretical modeling. The subdisciplines share the overarching aim to explain the origin and maintenance of biological diversity, but they tend to focus on different subsets of processes or spatio-temporal scales. By integrating knowledge from the different subdisciplines and approaches, evolutionary

ecology has contributed largely to the development of a strong synthesis of the many factors that can shape biological diversity. This has lead to conceptual theories (e.g., optimality theory, evolutionary game theory, life history theory, foraging theory, adaptive dynamics) that have been adopted throughout biology, and some have also permeated in economics, psychology and medical sciences.

There is large consensus on the interdependence of ecology and evolution—without ecology we cannot understand adaptive and diversifying evolution, and without evolution we cannot explain the properties of organisms for their interaction with the environment. However, ecologists and evolutionary biologists have had different perspectives on the timescale at which some of the processes occur, the extent to which evolution can affect short-term ecological dynamics, and the extent to which (localized) ecological processes and complexity are influential for the long-term outcome of evolutionary processes. Many ecologists considered evolution as a process that is too slow to have a direct impact on contemporary population dynamics or species interactions. Implicitly, species traits were considered to be "static" at ecological timescales. This applies indeed for the origins of new species or new traits, but it does not take into account the ample (heritable) trait variation that natural selection acts upon. When we use the population genetics definition of evolution, that is, the change in the genetic composition of a population over time, then evolutionary and ecological processes can operate at similar spatial and temporal scales. The appreciation for the potential of evolution to act rapidly and reciprocally between interacting species, and its impact on ecological dynamics, has substituted the static perception of species traits in the field of eco-evolutionary dynamics. Conversely, many evolutionary biologists have disregarded the patchiness and local variation that is paramount in the environment. They typically acknowledge this as potentially relevant for processes such as local adaptation, but tend to limit ecological complexity in reductionist experiments to dissect how a single ecological factor leads to evolutionary change. Ecological complexity, however, can lead to very different ecological and evolutionary dynamics, that may not be captured in reductionist experiments. While this may not be easily resolved in experimental laboratory settings, it can be addressed in carefully designed field experiments. Additionally, the development of genomics technology provides new opportunities to investigate the interface between ecological and evolutionary processes, both at ecological and evolutionary timescales.

History of Evolutionary Ecology

In essence, the field of evolutionary ecology came into existence the moment that scientists started to realize that life is not static, that is, the end product created by God, but that life in all its forms changes in response to the interaction with its natural environment. Since the Middle Ages, the Western scientific society had developed a strong theological and teleological worldview, also based on the manuscripts of Plato and Aristotle. These manuscripts, in combination with the belief in a Creator of the universe and all species, fuelled the notion that God had created perfect forms that remained forever unchanged, in the same (perfect) form as when they were created. For many centuries, natural scientists worked toward describing and cataloguing the grand diversity as a homage to this great design by God, with naturalists characterizing the striking biodiversity, astronomers and physicists describing the stars and the universe, and geologists describing the composition of the Earth. This worldview came under debate toward the end of the 17th century during the Scientific Revolution, when geologists started to report evidence that Earth had undergone profound changes through time, astronomers that the universe was not perfectly shaped around the Earth, and naturalists that life was not static but changeable. These scientists included Erasmus Darwin, the grandfather of Charles Darwin, who propositioned that "all warm-blooded animals have arisen from one living filament […] with the power of acquiring new parts, attended with new propensities" (Darwin, 1794, http://www.gutenberg.org/files/15707/15707-h/15707-h.htm). It also included Chevalier de Lamarck, who was a clear advocate for the nonstatic worldview, and proposed that new species could arise (from nonliving matter), and that traits could change due to the needs that a species had. It culminated with the seminal book of Charles Darwin on the "Origin of Species by Means of Natural Selection" (1859), in which he sets out two major theories, (i) the theory of descent with modification of all living species from common ancestors by incremental and small changes, and (ii) the theory of natural selection as cause for the evolutionary changes that leads to adaptations of organisms to their environment. The theory of natural selection was simultaneously and independently conceived by Alfred Russel Wallace.

Ernst Haeckel became inspired by the work of Darwin on the theory of descent with modification through natural selection, and how this may alter the systematic study and classification of the morphology of organisms. In his book, "*Generelle Morphologie der Organismen. Allgemeine Grundzüge der Organischen Formen-Wissenschaft, mechanisch begründet durch die von Charles Darwin reformirte Descendenz-Theorie*" (1866) he was the first to introduce the term "*ecology,*" and he did so explicitly in the context of evolution. He defined ecology as "the whole science of the relations of the organism to the environment including, in the broad sense, all the conditions of existence. These are partly organic, partly inorganic in nature; both, as we have shown, are of the greatest significance for the form of organisms, for they force them to become adapted. […] Thus the theory of evolution explains the housekeeping relations of organisms mechanistically as the necessary consequences of effectual causes and so forms the monistic groundwork of ecology" (Haeckel, 1866; translated by Stauffer, 1957).

Darwin's theories inspired many, but they were also received with skepticism by scientists and the general public, both because it conflicted with the reigning worldview, and because of serious discrepancies with the then prevailing incorrect ideas on "blending" inheritance of traits. These ideas were incompatible with the proposed action of natural selection on individual variation, and the maintenance of individual variation. The incorrect view on inheritance were resolved by the discoveries of Gregor Mendel, a contemporary of Charles Darwin, who developed the fundamental laws of inheritance: (1) the law of

segregation, (2) the law of independent assortment and (3) the law of dominance. However, Darwin was unaware of the important work by Mendel on "particulate" inheritance. It took until the 1930–1940s when Mendel's laws were rediscovered by the mathematicians Ronald Fisher, John Haldane and Sewell Wright, who reconciled it with Darwin's theory of natural selection. Theodosius Dobzhansky then wrote the book "Genetics and the Origin of Species" (1937), where the population genetics models of Fisher, Haldane and Wright were applied to the study of natural populations, making it more accessible to other biologists. This "Modern Synthesis" provided a solid genetic mechanism for natural selection, and now forms the foundation for modern evolutionary theory.

The Study of Biological Diversity

Species Diversity

The species diversity in a large area can be partitioned into the local diversity and the regional diversity, where the latter allows for exchange, or turnover, of species between localities. Local diversity is constraint by the local characteristics of the habitat (e.g., productivity, habitat heterogeneity, climate and other abiotic conditions), species interactions (e.g., competition, predators and parasites) and chance events (e.g., habitat disturbance or destruction). Saturation of the local species diversity is considered to be largely due to antagonistic species interactions, primarily competition but also parasite–host interactions. However, species interactions can also facilitate coexistence of species through facilitation or mutualisms. Evolutionary processes can contribute to species coexistence at local scales when the populations becomes better at coping with the species interactions and/or the environmental challenges that they encounter in their habitat. For example, species can develop behavioral preferences or character divergence to reduce competition (resource partitioning, ecological specialization), or evolve a higher resistance against the local parasites that they are exposed to. Additionally, spatial and temporal heterogeneity can facilitate coexistence of species, because it diversifies the direction and strength of fitness effects caused by species interactions. Similarly, adaptations to a particular condition in the habitat may trade-off with other traits that influence the performance under different conditions, such that species perform better under some, but not all, environmental conditions. Although adaptive processes were originally considered to be too slow to matter for local diversity, nowadays it is recognized that even at ecological timescales, such evolutionary dynamics can occur and can indeed affect ecological dynamics.

Local diversity can increase by immigration from the regional species pool. Regional species diversity is also to some extent governed by the ephemeral processes and species interactions that affect local communities. At intermediate time scales, the generation and maintenance of species diversity is due to processes that operate within the regional landscape, such as dispersal, colonization, diversification, speciation and extinction. At very long timescales, historical processes (e.g., glaciation) and geographic events (e.g., plate tectonics) are important drivers for the accumulation or loss of species over time. It can be informative to retrace the historical development of regional species diversity, for example, to explain the adaptive evolution of traits in the context of species interactions, or to relate patterns of adaptive radiation to nutrient availability or release from predators or parasites. This requires a reconstruction, for example, of the composition of the historic (meta-)communities, including the associations and coevolution within these communities or the historic patterns of resource use, or on the phylogenetic origin of species and the rates of clade diversification.

One major question in evolutionary community ecology is what caused and maintained the differences in species composition and species diversity of local communities. This has become of a matter of intense debate. One extreme position is that these differences are largely driven by local species interactions, primarily competition, which results in ecological diversity and niche differentiation through adaptive evolution. The other extreme position is that it is largely determined by random sampling from the regional species pool (i.e., ecological drift), essentially assuming that species are ecologically identical and the assembly of species is a purely stochastic process relying on random death, dispersal and speciation events. The latter has been formalized in the neutral theory of species diversity. While the neutral theory initially received much criticism as too much a simplification of reality, it is now considered a useful null-model to contrast different ecological and evolutionary scenarios that may explain species diversity. The vast number of processes that can govern community composition and contribute to the uniqueness of each study system, was synthesized into four general classes by Mark Vellend: (i) speciation and (ii) dispersal add species to communities and (iii) drift and (iv) selection shape the relative abundances of these species, while ongoing dispersal drives the community dynamics (Vellend, 2010).

Trait Diversity

The living world exhibits a rich diversity in forms, functions, strategies and behaviors. This phenotypic variation is prominent both among and within species. Trait diversity describes the alternatives in behavior, personality, physiology, morphology and life history strategies. In evolutionary ecology, trait diversity is studied both within and among species, mostly in the context of adaptive evolution in response to biotic and abiotic conditions of the current or past environment. It addresses how natural selection and/or sexual selection have lead to a optimization of a trait, or maintained trait variation, to maximize reproduction and survival in the context of limited resources, within-species interactions, between-species interactions, the abiotic conditions of the environment and the spatio-temporal variability that may exist in any or all of these factors. When the trait is a new

characteristic that enhances the survival or reproduction of an organism relative to ancestral character states, it is called an adaptation. Natural selection is the only mechanism known to cause the evolution of adaptations.

Optimization of a trait in response to an environmental challenge can take very different forms, depending on the nature of the selection pressure, as well as trade-offs and constraints. Under directional selection, for example, for larger body size, the average trait value will shift upward within the population until ecological and physiological constraints restrict further increases. Under negative frequency dependent selection, however, rare alleles have a selective advantage, and the optimal trait value thus depends on the allele frequency in the rest of the population. This will lead to ongoing evolutionary dynamics, but in constantly changing directions. This may occur, for example, in host-parasite coevolution, with continual adaptations and counter-adaptations that alter resistance and virulence. Organisms have to optimize a variety of traits to maximize their fitness, and may thus need to economize in the allocation of resources to some traits to increase the investments in others (trade-offs). Moreover, the expression of many traits, for example, body size, is also strongly influenced by environmental conditions, such as the quantity and quality of nutrients, and the density of competitors. Finally, natural selection and sexual selection may form opposing selection pressures on a single trait; for example, increased coloration may enhance mating success but simultaneously increase the risk of predation.

Genetic Diversity

Genetic diversity describes the number of DNA sequence variations between individuals. The variations arise through random mutation and recombination. Most mutations do not result in detectable effects on phenotypic traits or fitness and are effectively neutral. Neutral and nearly-neutral mutations accumulate over time at a rate that depends mostly on the mutation rate and genome size. The mutation rate and genome sizes vary considerably among taxa, differing by several orders of magnitude. In general, however, the genetic diversity among individuals is huge, in the order of 1 sequence variation in every 50–1000 nucleotides in the genome. Any two unrelated individuals therefore differ in their DNA sequence in up to hundreds of thousands of nucleotides. Moreover, these neutral sequence variations evolve mostly under genetic drift, which is a random process that is not affected by environmental conditions and operates independently in separate populations. The factors that do affect genetic drift are population size and migration. Some of the genetic diversity, however, is not neutral. When a mutation results in a phenotypic effect, this is most often deleterious and only rarely beneficial for fitness. Natural selection against or for individuals with these DNA sequence variations then leads, over time, to a change in the frequency of these alleles in the population.

Genetic diversity may be investigated to study the ecological and evolutionary factors that drive a species' distribution. Species are usually subdivided into separate or partially overlapping populations across the geographic areas that they inhabit. The genotype of individuals for various sequence variations can easily be measured from field-collected samples. The patterns in genetic diversity of the neutral sequence variations reveal information on, for example, the connectivity of populations and their genealogical structure, the mating structure of the species, recent and historic changes in population size (constrictions and expansions), and the frequency of migration or gene flow among populations. Population genetics analysis is widely used to infer these patterns. When these patterns are combined with knowledge on concurrent ecological or historical events, this can reveal which processes have likely contributed to the current distribution and abundance of species. It can also be used in conservation management of threatened species, or to help identify populations that have become isolated from other populations.

Genetic diversity can also be used to study adaptive evolution by comparing the genetic diversity among species and/or within species. In these comparisons, low genetic diversity in particular regions of the genome may indicate evolutionary conservation or negative selection, indicating that sequence variation cannot be tolerated without negative consequences for fitness. High genetic divergence is a signature of positive selection and can indicate adaptation to a habitat. Populations or species that occupy multiple habitats with different selection pressures can evolve along different trajectories due to the local combinations of selection pressures. This is associated with genetic divergence for the genes that are associated with traits that affect fitness. When comparing unrelated taxa across long phylogenetic distances, these comparisons can also provide indications of convergent evolution, where multiple species have evolved the same solution to a common ecological problem.

Ecological and Evolutionary Genomics

A major transition in evolutionary ecological research was initiated by the development of genomics technology at the start of this century. Whereas we previously were restricted to study fragments of DNA and the expression of a small subset of genes or protein variants, we now have access to whole genome sequences, genome-wide gene expression profiles (transcriptome) and the total protein composition of a cell, tissue or organism (proteome). Importantly, we can now generate these data for many species and for many individuals of each species, which allows us to characterize both the similarities and differences among individuals, populations and species. These technologies, when combined with experiments on ecological interactions or information on the natural history of individuals, populations and species, has added a new dimension to evolutionary ecological research. It enables us to investigate long-standing fundamental questions on diversity, diversification and the evolutionary and ecological processes that shape variation. It also enables us to formulate new research questions and hypotheses on the molecular mechanisms of evolutionary processes and ecological interactions.

All of life stems from a single ancestor, and every trait and every species is the outcome of ecology and evolution. This diversity and diversification can be partially retraced or studied by investigating the genome sequences. Information from DNA enables us

to connect changes in individual genomes to population level processes to the generation of biodiversity. Extracting this information from the DNA allows us to reach back in time to infer past evolution, but also to directly observe the dynamics of evolution at ecological timescales. We can map the changes in the DNA in populations that occur during evolutionary adaptation, for example, in experimental populations that are exposed to a specific environmental condition for a number of successive generations (experimental evolution), or by monitoring natural populations over time to measure their evolutionary response to environmental change. We can also align and compare genomes from populations (population genomics) or from different species (comparative genomics) to identify genes and genomics regions that experienced positive and negative selection, to study speciation events, to trace ancestry and to determine genealogical or phylogenetic relations. With genomics technology, we can test hypotheses on individuals, traits, populations and species, both from existing theories as well as to construct new theories.

Genomics technology is also applied to measure species diversity in metacommunities by studying the genetic material from entire metacommunities or environmental samples (meta-genomics, environmental genomics or ecogenomics). This approach has had an enormous impact on microbial ecology, as it revealed the hidden diversity of microscopic life. Previously, the characterization of microbes had been restricted to those that could be cultured in the laboratory. Genomics technology uncovered the astronomical diversity and complexity of microbiota. As a consequence, the tree of life had to be largely redrawn (Hug *et al.*, 2016). What makes this particularly relevant in the context of evolutionary ecology is that microbes are essential for all life on Earth. They are key to the geochemical and nutrient cycles that convert carbon, nitrogen, oxygen and sulfur into biologically accessible forms, and form close and necessary associations with every species on Earth. Among the ecological and evolutionary processes that have been shaping biological diversity, the direct and indirect interactions with microbes have been enormously important.

Also studies on trait diversity have profited from genomics technology. The earlier overview on trait diversity was mostly restricted to the functions of traits and why they evolved, for example, which ecological processes resulted in natural selection for new adaptations or trait optimization. Another important question is how traits evolve, that is, how natural selection on individual phenotypes results in a change in the genetic composition of the population. This requires bridging the gap between the phenotype and the genotype of an individual. For most traits that are relevant in the ecology of an organism, it turns out that complex gene interaction networks underlie those traits, with many genes and gene interactions that contribute to the trait variation (the genotype–phenotype map). To identify the genes that matter for a trait, transcriptomics has been widely used to measure which genes change in expression in response to an environmental challenge or ecological stimulus (e.g., cold or heat stress, desiccation or drought, salinity, feeding by herbivorous insects, infection by a pathogen). Another approach relies on measuring individual variations in both the phenotypic trait and the genotype for many individuals, and then statistically associating phenotypic or trait variations with the genetic variation among those individuals (GWAS, or genome-wide association studies). These studies have provided much insight on the complex molecular and genetic mechanisms of trait diversity, for example, by showing that evolution of gene expression regulation (regulatory evolution) is a major contributor to trait and species diversity. Nonetheless, the genotype–phenotype map remains largely elusive for most traits. The complexity of the genetic architectures of trait can to some extent impede our ability to predict how traits will evolve in response to ecological changes and challenges. Yet, these complex genetic networks also provide a mechanism for robustness to produce a functional phenotype under a range of ecological conditions. Additionally, genetic variation anywhere in the network may contribute to phenotypic variation, which provides the adaptability of organisms to changing conditions.

Concluding Remarks

Evolutionary ecology is a field of science that addresses research questions on diversity across all levels of biological organization—from genetics to metacommunities—and on all levels of spatial and temporal resolution. The range of phenomena that is being investigated spans all aspects of life. Evolutionary ecologists typically specialize their research toward a subset of subdisciplines, based on personal preferences but also by necessity. Mastering the expertise required for each subdiscipline is simply impossible. Nonetheless, the integration of knowledge from the full breadth of the field is important, as evolutionary ecology is effectively "the theory of everything." Genomics technology is providing a new stimulus for further integration of studies on ecological processes (including their complexity) and evolutionary processes (including the direct observation of evolution in real-time) that shape the diversity of life.

Research in evolutionary ecology addresses fundamental scientific questions and is driven by curiosity on the processes that have contributed to and shaped the bewildering diversity in all of life around us. The knowledge, insight and theories that are being developed within the field of evolutionary ecology also have broad societal relevance. This knowledge-base provides important bearings for facing some of the grand challenges of our time, including the development of realistic plans for coping with the implications of global change, for stopping the alarming biodiversity loss, for designing evolutionary stable strategies to set-up a sustainable society with food security for an expanding human population, and for developing evolution-informed medical treatment.

Fecundity

CJA Bradshaw, Charles Darwin University, Darwin, NT, Australia
CR McMahon, University of Wales Swansea, Swansea, UK

Introduction

Organisms exist to reproduce and fecundity is the measure of an individual's (or population's) reproductive performance. As such, fecundity (in combination with its sister concepts – see below) can be viewed as one of the two cornerstones of population biology, the other being the ability of an individual to survive in order to reproduce. Mortality (proportion of surviving individuals) expresses the proportion of a population that dies within a defined period of time and fecundity quantifies the new individuals added to the population. A population remains stable when the number of individuals dying is equivalent to the number of new individuals added, and it decreases when mortality exceeds replacement (births and immigration). Although these themes may appear straightforward, the relationships between reproduction, age, population density, and environmental stochasticity (random variation due to environmental changes) are complex and not fully understood. Furthermore, these relationships must be contextualized within the major reproductive strategies that have evolved as a result of different selective pressures, and they must be examined while taking into account the multitude of tradeoffs that occur between reproduction and individual survival.

In ecology, 'fecundity' can be described simply as the physiological maximum potential reproductive output of an individual over its lifetime, and it is usually applied to the female's (rather than a male's) output, although there is no inherent reason why fecundity should be restricted to females. Regardless, ecologists have defaulted to using the gender-general term of 'reproductive success' to describe the reproductive output of both males and females. We adhere to these traditions and restrict our definition of fecundity to apply to females only. However, reproductive success is not equivalent to fecundity because the former is a measure of an individual's genetic contribution to subsequent generations. As such, reproductive success can vary among individuals due to the effects of maternal age, fitness of progeny from clutches of different size, and other life-history characteristics. Fecundity is therefore a genetical and developmental trait that evolves within a particular selective framework. The term 'fertility' differs from fecundity in that it describes the actual (or current) reproductive performance of (typically) a female, and it is a generalization of the terms 'maternity', 'birth rate' and 'natality' which refer to the average number of offspring produced by an individual female of a particular age per unit time. 'Net reproductive rate' is defined as the average number of daughters produced by mothers over a lifetime. Fertility varies primarily as a function of environmental stochasticity and demography, and generally fluctuates temporally and spatially among individuals and populations.

In this article we have chosen to discuss both fecundity and fertility given their obvious connection and importance to the discipline of ecology. Henceforth the usage of each term relates specifically to the developmental and evolutionary (fecundity) or environmental (fertility) contexts shaping these fundamental parameters of population biology.

Sexual and Asexual Reproduction

The concept of fecundity should, in practice, be applied equally to the two major modes of reproduction – sexual and asexual. Discussions centered on the evolution of sexual reproduction must reconcile the theoretical advantage asexual reproduction presents to an individual – the possibility of a twofold fitness (fecundity) advantage over their sexual counterparts. The relatively higher cost of sexual reproduction arises from anisogamy (gamete dimorphism), but sexual selection can reduce or even eliminate this cost. Although there is no difference in the fecundity of sexual females and asexuals of the same genotype, the equilibrium frequency of deleterious mutations is lower in sexual populations, usually giving rise to higher fitness in sexual females.

Despite the advantages of sexual reproduction, the prevalence of clonal or asexual reproduction in the life histories of many plant and animal species suggests that this strategy does indeed provide advantages at least in some circumstances. For example, clonal reproduction may allow the clone to survive many reproductive events by reducing a potentially catastrophic local extinction associated with a restricted distribution. A large number of clone-mates may also increase the number of bodies producing gametes and improve the probability of them finding mates once sexual reproduction is invoked. Thus, variation in the costs and benefits of clones should depend on an individual's sexual neighborhood (relative abundance of potential mates) and the degree of competitive stress induced by the environment.

Inclusive Fitness

The concept of inclusive fitness has become the foundation of modern biology and may be one of the most important advances in evolutionary biology since Darwin introduced the theory of natural selection. If natural selection occurs at the individual level

(i.e., individuals with higher reproductive success have the greatest genetic representation in future generations), how do cooperative breeding systems evolve? The apparent paradox of some individuals within a population foregoing the opportunity to breed can be explained if some individuals help their close relatives reproduce. By assisting close relatives, altruists still manage to pass on their genes indirectly. This behavior can arise when the genetic relatedness between an altruist and beneficiary (r) multiplied by the fitness gain to the beneficiary (b) minus the fitness cost to the altruist (c) is greater than zero; that is, $(rb - c) > 0$.

Consequently, the degree of relatedness between the altruist and the beneficiary determines the probability that they share a particular gene, and therefore, the probability that the altruistic gene will be passed on to the next generation. Sterile castes in social insects are an extreme case of quasi-altruism (worker females give up reproduction and raise their mother's offspring). This occurs most commonly in the Hymenoptera (bees, wasps, ants), and is probably the result of their haplodiploid chromosomal organization where males have single chromosome copies and develop parthenogenetically from unfertilized eggs and females have two copies of each chromosome. Because males are haploid, there is no meiosis and all daughters of a particular male have identical paternal genes. Nonreproductive females have a greater chance of passing on their own alleles via their reproductive sisters than they do by reproducing themselves, so zero direct fecundity for these individuals results in the highest indirect lifetime reproductive success.

Eusocial Systems

Eusocial systems are an evolutionarily advanced level of colonial existence in which adult colonial members (1) belong to two or more overlapping generations, (2) care cooperatively for the offspring, and (3) are divided into either reproductive and nonreproductive (or less-reproductive) castes. The presence of castes is an integral requirement of eusociality, and it is most commonly found in social insects, especially ants, bees, wasps, and termites. As a reproductive strategy it is rarely observed in nature, but it appears to be an important mode of reproduction nonetheless. Although eusocial ants comprise only 2% of the *c.* 900 000 insect species known globally, this taxon comprises more than half of the global insect biomass. The strategy is obviously successful in evolutionary terms, so why then, despite this apparent success, has eusociality rarely evolved? It is generally thought that eusociality is the result of some extraordinary environmental circumstances that existed in the evolutionary past when a particular genome coding for group breeding and subordinate reproductive suppression was selected. Selection of this genome consequently led to a cooperative breeding system and was maintained not by the inability of individuals to breed, but because individuals are outcompeted by breeding conspecifics in well-integrated communal colonies.

Implicit in understanding fecundity patterns in eusocial systems is recognizing the factors that regulate body size and growth. The eusocial female that does all or most of the breeding is usually the biggest and most dominant. As such, in species of cooperative insects living in large groups, selection for increased fecundity has repeatedly resulted in the evolution of an increased body size for females. Whether this is also true of cooperative vertebrates is currently debatable; however, increased size of dominant breeding females has been documented in naked mole rats (*Heterocephalus glaber*) and meerkats (*Suricata suricatta*). Eusociality and the resultant reduction or eradication of fecundity in some individuals among diploid animals is rare and appears to occur only when (1) species live in burrows, (2) food is abundant, (3) parents care for offspring, and (4) mechanisms exist for mothers to manipulate other females, such as pheromones that inhibit their breeding.

Fecundity Patterns

The term 'parity' is used to describe a breeding event, and species can assume various modes of reproductive timing and frequency depending on their evolutionary past and the constraints of their current environment. There are too many variants of life-history strategies to describe succinctly given the large number of possible combinations of longevity, breeding frequency, and offspring number, but there are some major groups of strategies that have evolved. The two major fecundity patterns are semelparous and iteroparous reproduction.

Semelparity

Semelparous organisms reproduce only once during their lifetime. This may occur at the age of only 20 min in certain bacteria, a few hours in many protozoa, or up to a few weeks or months in some insects and mammals. Many semelparous species are annuals (live only one year), but some reproduce only after several years of maturation. Early work predicted that greater temporal variation in adult survival relative to juvenile survival favored the evolution of semelparity, although more recently it has been demonstrated that this also depends on the age structure of the population under selection. Semelparity may also provide other advantages over iteroparity in terms of offspring body size, leading possibly to increased juvenile growth rates and survival.

Semelparity in mammals is restricted to two marsupial families (Didelphidae and Dasyuridae), where all species demonstrate high post-reproductive senescence, but not all are semelparous. In some of the semelparous species, only the males die after the short, highly synchronous mating season, whereas in others, male die-offs are facultative. Some have argued that because the interval between conception and weaning is short and that these marsupials tend to live in highly predictable seasonal environments, there should be selection for a monoestrous reproductive pattern, high estrus synchrony, and a short mating season. These factors should therefore

induce intense male–male competition and a low probability of multiseason male survival giving rise to the evolution of male semelparity. Additionally, the high rate of female mortality resulting from long lactation periods in some species also demonstrating female semelparity selects for a bet-hedging strategy by males and the evolution of male semelparity.

Iteroparity

Species that reproduce more than once during their lifetime are iteroparous. The time of maturation preceding first reproduction may vary from a few days in small crustaceans to greater than 100 years in some trees. The frequency of reproduction can also vary markedly – daily (e.g., some tapeworms), semiannually, annually, biennially, or irregularly (e.g., humans). Some have argued that iteroparity is favored over semelparity when high environmental variability induces large variation in offspring production and offspring survival. However, it has been demonstrated more recently that the evolution of either strategy does not depend on environmental variability alone, but also on the strength of intrinsic regulation (a tradeoff between fertility and survival – see below) operating on a population and the demographic rates most affected by extrinsic variation.

In many iteroparous species there are a certain proportion of individuals that reproduce only in alternate seasons (or less often), thereby foregoing a proportion of their potential lifetime reproductive success. Known formally as 'low frequency of reproduction', this phenomenon is most common among vertebrate ectotherms, but it has also been documented in endotherms (e.g., willow tits (*Parus montanus*); kittiwakes (*Rissa tridactyla*); fat dormice (*Myoxus glis*)). There is also considerable phenotypic variation within a species, with some individuals opting for lower-frequency reproduction than others. Ectothermic species employing this strategy appear to have accessory activity associated with reproduction (but independent of fecundity) such as breeding migrations, egg brooding through incubation, and live bearing. With its apparent ubiquity, low-frequency reproduction appears to offer some selective advantage in certain systems. It has been suggested that the strategy could evolve only under two scenarios: (1) when reproduction does occur, it confers a much higher fecundity benefit than would a regular-frequency breeding event; or (2) the probability of surviving the interval between reproduction is much higher than it would be during the same interval of regular-frequency breeding. Thus, lower-frequency reproduction may actually result in higher average fecundity over the individual's lifetime when at least one of the two previous conditions is met. There also appears to be a relationship between the occurrence of low-frequency breeding with habitat quality. Here, regular reproduction may become less favorable as the habitat becomes less suitable because resource availability declines and accessory activity cannot decrease to the same extent.

Age Specificity

In iteroparous organisms, fecundity often increases with age following reproductive maturity and then can decline at older ages. As such, age specificity of reproduction is an essential element for understanding the evolution of life-history strategies. Reproductive rate may increase with age when an individual devotes relatively more resources to reproduction with increasing age. For example, growth rate often declines after reproductive maturity is achieved, so more resources can thereafter be directed to reproduction, thereby increasing age-specific fecundity. This introduces the concept of 'primiparity', which is generally defined as the age of first reproduction. In some species, this age is rather constant suggesting genetic control. However, in other species (especially ectothermic organisms), it is environmentally mediated and may demonstrate high phenotypic plasticity. The extent to which primiparity is delayed (i.e., the length of the pre-reproductive period) also depends on type of niche exploited by a species and the particular demographic configuration of a population.

Increasing fecundity is also observed in many organisms that do not grow following maturity, giving rise to three hypotheses to explain the pattern: (1) less-fit individuals are constantly eliminated from a population so that the average fecundity of surviving individuals increases; (2) increasing fecundity is a reflection of the gradual improvement in the competence of older, more experienced, and often higher-ranking individuals; and (3) as life expectancy decreases with age, individuals allocate more and more resources to reproduction at the expense of survival. The decline in fecundity with age is often referred to as 'reproductive senescence'. One hypothesis to explain this pattern is as an individual ages its resource acquisition rate deteriorates due to physiological ageing.

Recent work has attempted to combine the various hypotheses for age specificity in fecundity into a single conceptual model that incorporates the other key life-history parameter – age-specific survival. When extrinsic mortality is high, early maturity is favored allowing for high reproductive investment and fecundity early in life (**Fig. 1**). Under this scenario, allocating resources to repair cumulative somatic damage is not beneficial when life expectancy is already low, and fecundity will still diminish with time due to physiological ageing. When extrinsic mortality is low, investing in somatic repair at the cost of reduced fecundity is beneficial because it increases life expectancy. Thus, reproductive rate is low early in life, but gradually increases toward a late-life maximum, and then inevitably declines again due to physiological deterioration late in life (**Fig. 1**).

Allometric Scaling

Allometry is the relation between the size of an organism and aspects of its physiology, morphology, and life history. Typically, variation in body mass among individuals or species can be used to predict traits such as metabolic rate, dispersal capacity, survival

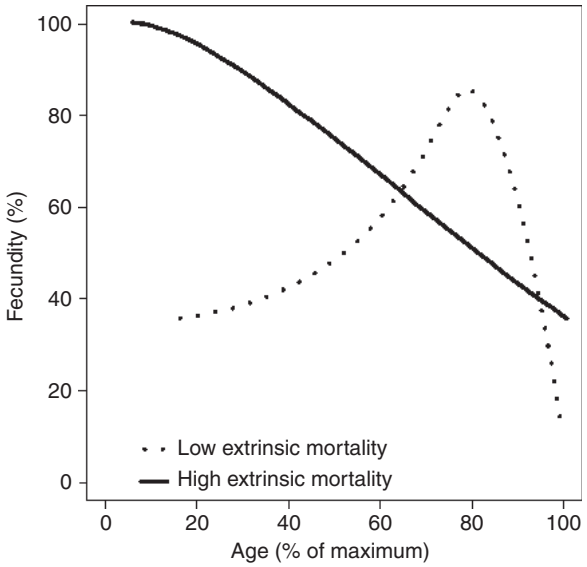

Fig. 1 Patterns of age-specific fertility fecundity expressed as a percentage of maximum age under two different rates of extrinsic mortality. Reproduced from Cichoń M (2001) Diversity of age-specific reproductive rates may result from ageing and optimal resource allocation. *Journal of Evolutionary Biology* 14: 180–185.

probability, and fecundity. The ratio of combined offspring mass to maternal mass tends to remain approximately constant over a broad range of maternal sizes within a species. As such the ratio of offspring mass at independence to average adult body mass remains stable within major taxonomic groups. In other words, larger females tend to have more or larger offspring, especially among invertebrates and ectothermic vertebrates. An increase in fecundity with increasing female body size may constitute a selective advantage toward large female body size (the so-called 'fecundity advantage' model) in some taxa, especially in those for which energy is not limiting. However, this does not necessarily mean that larger females will always have higher reproductive success because of the increased risks due to predation, limited resources, and environmental uncertainty.

Density Dependence

It is in every individual's interest to maximize its reproductive output without compromising its own survival prospects; however, the production of too many individuals can lead to overcrowding and a reduction in per capita resources such as food availability, breeding sites, and territories. Under such circumstances, it is clearly unprofitable for individuals to engage in potentially wasteful energy expenditure associated with fertility if the probability of their progeny surviving to breeding age is low. This observation is supported by the ample evidence that population density affects fertility negatively. In general, as population size increases, either the average number of offspring produced per female decreases (in litter or clutch sizes greater than one), or average offspring size decreases. However, the relationship between density and fertility is not necessarily linear. For example, for many long-lived, iteroparous species, the negative effects of population density are not expressed in average fertility until the population approaches its environmentally mediated carrying capacity. In many semelparous species with short life expectancies the opposite is true – fertility declines rapidly as soon as the population begins to grow. **Fig. 2** shows examples of fertility patterns relative to population density in different species.

Increasing density does not always result in depressed fertility. In many species, fertility is relatively invariant over the range of population densities experienced so that intrinsic regulation operates almost exclusively through the modification of age-specific survival rates. Some species do not appear to respond to density by adjusting fertility *per se*; rather, the age of first reproduction (primiparity) may change according to the per capita resources available. In other species, high-density living can actually stimulate production of offspring (known as inverse density dependence; e.g., **Fig. 2c**). For example, many plant species require high population densities to attract grazers or pollinators that assist in cross-pollination and propagule dispersal. This Allee effect (a term used to describe a reduction in reproductive output with decreasing population density, thus affecting population growth rate) is another example of inverse density dependence that occurs when populations existing at low densities suffer from stochastic demographic events that, for example, skew the tertiary sex ratio (the ratio of the rarer sex to the total number of breeding adults). In these cases, the availability of potential mates for the more common sex is reduced so that not all reproductively capable individuals succeed in fertilization and the production of offspring. The type and strength of density dependence operating on a population also have implications for the patterns of age-specific fecundity. A reduction in extrinsic mortality favoring the evolution of reduced reproductive senescence is predicted only when density dependence acts principally on fertility and without differentially decreasing late-age fecundity. Alternatively, a reduction in extrinsic mortality can favor the evolution of faster senescence if density dependence acts mainly on the survival of older age classes.

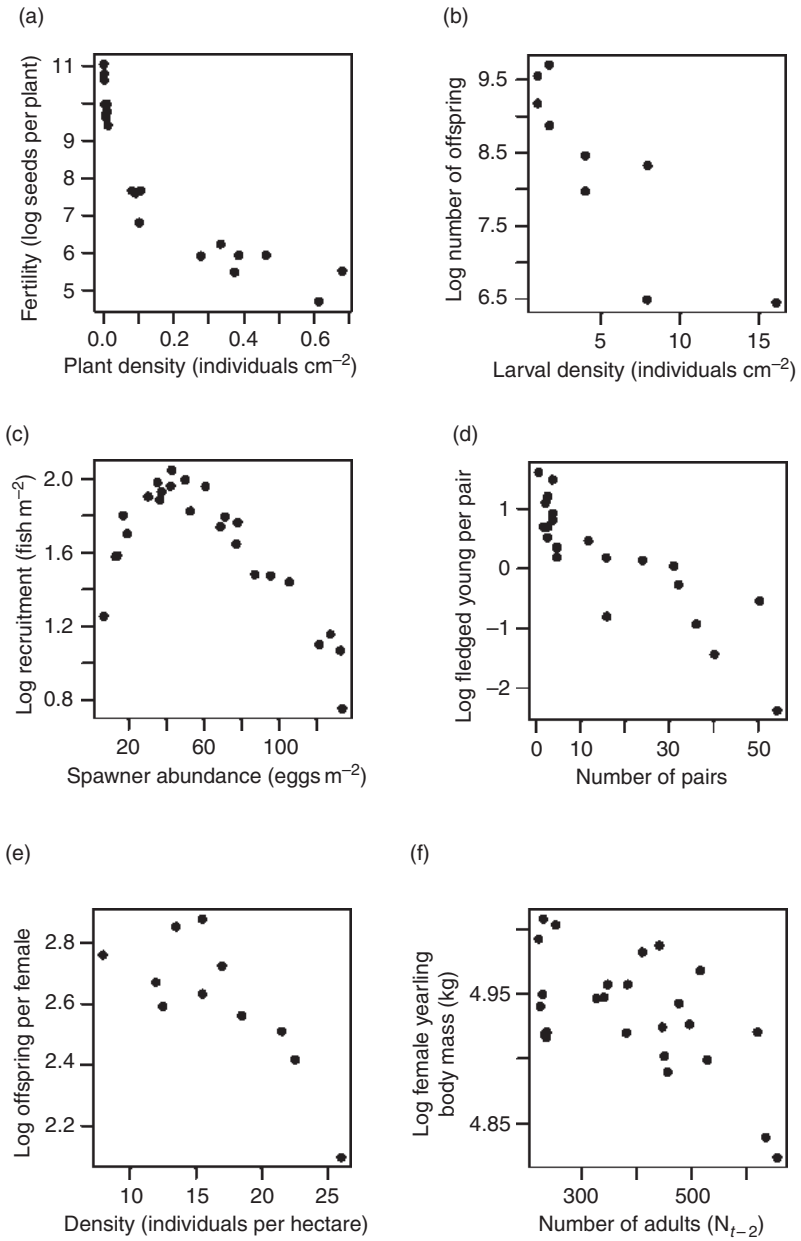

Fig. 2 Example patterns of fecundity fertility with changes in population density for (a) scentless chamomile (*Tripleurospermum perforatum*); (b) midge (*Chironomus riparius*); (c) brown trout (*Salmo trutta*); (d) muted swan (*Cygnus olor*); (e) European rabbit (*Oryctolagus cuniculus*); and (f) moose (*Alces alces*). Tradeoffs

A particular fecundity pattern evolves as an adaptation to the specific constraints imposed by the niche exploited by a species. For example, the high fecundity of parasites and many marine organisms is thought to have evolved because the probability that any particular individual will establish itself and reproduce successfully is low. As such, life-history theory predicts that the degree to

which parents place themselves or their offspring at risk of mortality when threatened with predation depends on the offspring number and survival probability of parents. This type of tradeoff will also vary between the sexes in relation to the degree of investment in the offspring. A species with low adult survival and high fecundity should tolerate greater risk from predation given the low probability of surviving to reproduce in the future. In contrast, species with high adult survival and lower fecundity should tolerate less risk even at a cost to their offspring. This fundamental tradeoff essentially expresses an organism's capacity to maximize its potential lifetime reproductive success by assessing the best strategy to achieve the highest potential fecundity. Thus, tradeoffs are the benefits accrued from one life-history process that are purchased at the expense of another. For example, pre-breeding migrations requiring the use of stored resources can result in less energy available for the production of offspring. Other processes that present an individual with additional energy costs can also affect reproductive output, including exposure to antigens or parasites that increase the costs associated with mounting an immune reaction.

This introduces the concept of 'reproductive allocation' (or 'reproductive effort') which is the proportion of an individual's acquired resources that is allocated to reproduction over a defined interval of time. Because resources are finite, reproduction itself can incur a cost in that it can reduce the survival probability or growth rate of the individual. As such, the rules governing reproductive allocation are viewed in a benefit–cost framework. Dimensionless ratios of the benefits and costs of reproduction, such as the ratio of the life span spent in reproduction (E) to the length of the pre-reproductive period (α), and the ratio of the fraction of adult mass (m) devoted to reproduction (R/m) to the inverse of the life span spent in reproduction (E^{-1}), provide useful indices to classify life histories because they tend to be invariant within major taxonomic groups.

Environmental Stochasticity

Climate change is perhaps the most pressing and urgent environmental issue facing the world today. Despite the limitations in our ability to predict and quantify the consequences of this change, there is ample evidence that changes in climate have profound effects on the bios. Indeed, given that fertility is one of the key life-history parameters determining population abundance and persistence, it is important to understand how it responds to environmental stochasticity. Prevailing environmental conditions can affect fertility in four principal ways by altering (1) maternal body condition, (2) maternal survival, (3) offspring body condition, and (4) offspring survival. However, quantifying these effects can be challenging. The usual way of collecting such information on vital rate variability is to census a population in different age classes or stages over time and to compare measured vital rates (e.g., fertility) against some environmental variable (see **Fig. 3** for examples). Although repeated measures provide estimates of temporal variance in vital rates, this total variance also includes two other sources: demographic stochasticity and measurement/sampling error. The true variance due to environmental stochasticity must be isolated from other sources of variability or risks of decline and extinction may be biased. Several methods exist for partitioning these variances for fertility to examine the role of environmental stochasticity on this life-history parameter within population models (see also the section titled 'Fecundity and fertility in population dynamical models').

Sex-Allocation Theory

Although sex ratios are discussed elsewhere in this encyclopedia, it is important to understand the basics of sex-allocation theory with respect to fecundity. The discussions centered on the allocation of resources toward reproduction have thus far ignored the notion that the long-term value of producing offspring of one sex versus another depends on the complex relationship between current and future reproduction. Just as various life-history strategies have evolved with respect to the timing, frequency, and magnitude of reproductive effort, there are various optimality models that exist to explain sex ratio variation. Early theoretical work argued that equal sex ratios are evolutionarily stable because parental investment in sons and daughters should be identical under stable environmental conditions and population-wide random mating. However, skewed sex ratios are commonly observed due to factors such as nutritional stress, age, condition, and social rank of mothers, litter size, population density, and changes in resource availability. Optimality models focus on the idea that parents should adjust the sex ratio of their offspring in response to factors affecting their own and their offspring's future reproductive success. For example, one highly cited model used to explain sex ratio variation in mammals predicts that in polygynous species with marked sexual dimorphism, good-condition mothers should invest in the sex showing the highest variation in reproductive success because investment in that sex can potentially provide a better lifetime return on maternal investment. The apparent contradiction to the evolutionary stability of equal sex ratios invoked by adaptive sex ratio manipulation models may be explained by the existence of negative temporal autocorrelation in sex ratios between breeding events over the lifetime of the individual. In other words, equal investment in the sexes may only operate when taking total lifetime reproductive output into consideration.

Mate Choice

In the case of sexual reproduction, the optimal allocation of resources to reproduction actually begins prior to fertilization itself. The theory of mate selection by females is usually described in the context of sexual selection so that the evolution of female mating preferences centers on the genetic consequences of gamete union. Hypotheses to explain the patterns range from females

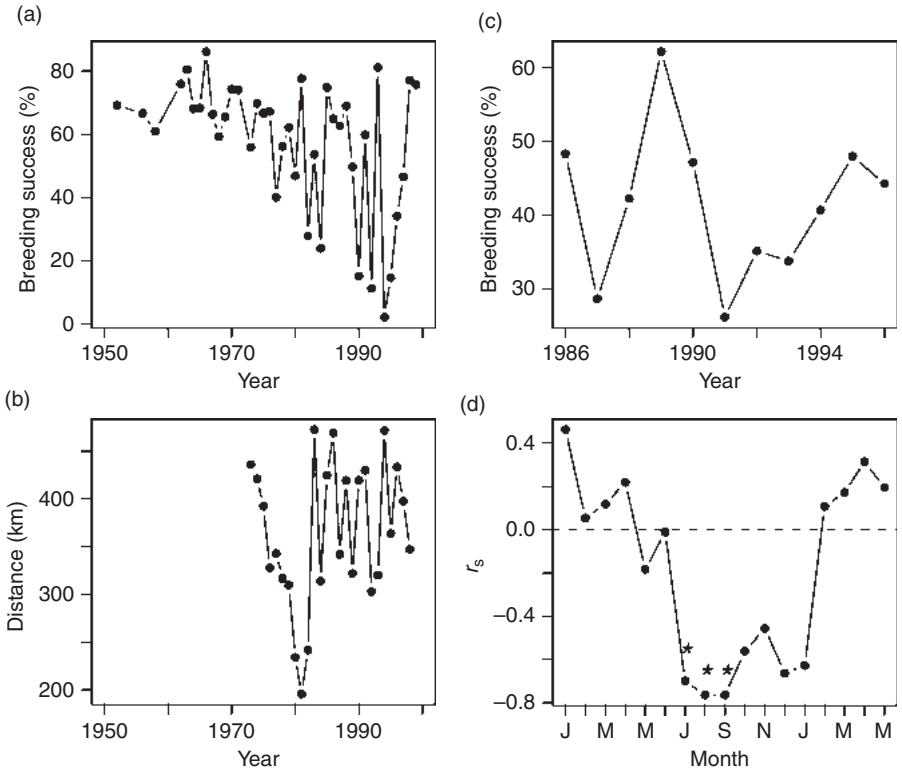

Fig. 3 Examples of fecundity fertility measures fluctuating with environmental stochasticity. (a) Breeding success (% chicks fledged of eggs laid) of emperor penguin (*Aptenodytes forsteri*) pairs from 1952 to 1999. Variation in breeding success increased progressively since the 1970s resulting from complete or extensive breeding failures in some years due to early breakout of the sea ice (b) or from prolonged blizzards during the early chick-rearing period. (c) Breeding success (% chicks fledged of eggs laid) of blue petrel (*Halobaena caerulea*) pairs from 1985 to 1996. (d) Spearman's rank correlation coefficients between sea surface temperature (SST) anomalies and blue petrel breeding success for the period ranging from February preceding the reproductive period until May the following year. Months where the correlation was nonzero are indicated by an asterisk (*). (a) Reproduced from Barbraud C and Weimerskirch H (2001) Emperor penguins and climate change. *Nature* 411: 183–186. (c) From Inchausti P, Guinet C, Koudil M, Durbec J-P, *et al.* (2003) Inter-annual variability in the breeding performance of seabirds in relation to oceanographic anomalies that affect the Crozet and the Kerguelen sectors of the Southern Ocean. *Journal of Avian Biology* 34(2): 170–176.

seeking to improve the genetic quality of their offspring by choosing genetically superior male mates to the existence of genetic correlations between female preference and male traits. Indeed, the direct benefits of female choice can be expressed in terms of increased fertility during a breeding season, or the evolution toward selecting particular mate characteristics to increase fecundity. Mate choice is therefore seen as an important component in the evolution of particular life-history strategies.

Models constructed to investigate mate choice can be complicated by the existence of multiple mating. In many species (e.g., the majority of insects), females permit or actively seek multiple mating with different males, even though several female fitness costs of excess mating are known (e.g., additional time and energy devoted to mating, increased predation risk, higher chance of injury, higher probability of disease or parasite transmission, male-originating chemicals reducing female longevity or female fecundity). Nonetheless, the ubiquity and magnitude of this trait suggest large positive effects on female fitness. For example, a fresh supply of sperm can maintain egg fertility, accessory substances can increase egg production rate, and the mating act itself can stimulate egg production.

However, the most studied component of multiple mating concerns sperm competition. This widespread phenomenon occurs when sperm from two or more males compete for a female's ova. Relative sperm numbers are important for sperm competitive success, so that species experiencing higher rates of sperm competition have males with larger testes that produce more sperm. Sperm competition is therefore a selective force shaping optimal ejaculate structure, although spermatogenesis is not unlimited. While males usually possess a greater reproductive potential than females, males have evolved mechanisms for the optimal allocation of finite sperm among females to maximize lifetime reproductive success.

Fecundity and Fertility in Population Dynamical Models

Being a cornerstone of population biology, quantifying fecundity and fertility patterns is a central component of models that attempt to describe complex population dynamics and structure. Many models exist exclusively to provide direction in the

understanding of the evolution of life-history strategies, while others have a more utilitarian function such as the estimation of a population's future status for conservation purposes. One of the most common methods used to summarize population behavior mathematically is the stage-structured matrix population model that provides a link between the individual (and its selective pressures) and the population using stage-specific estimates of vital rates (rates of birth, growth, maturation, fertility, and mortality). A more detailed description of matrix models is provided in this encyclopedia; however, there are some important aspects of these models that deal with fecundity and fertility specifically.

Stage-structured models provide an estimate of the stable stage distribution, which is the theoretical proportional allocation of individuals within the population to the defined stages (e.g., age groups, size classes, developmental stages) resulting from constant demographic rates. The stable stage distribution is a useful metric because it provides the theoretical composition of a population exhibiting a fixed birth rate, so factors such as environmental variation or intrinsic regulation that alter this theoretical distribution can be ranked for their effects on the future composition of a population. This introduces the concept of 'reproductive value' – a measure of the combined effects of fecundity, fertility, and survival that takes an individual's proportional contribution to the future status of its population into account. It is formally expressed as the sum of the current and future reproductive values, and is considered the currency used by natural selection to produce a particular life-history strategy.

Because life histories evolve to maximize reproductive success, fecundity is linked formally to population models by using the measure of reproductive value. In matrix models the relative effects of proportional changes in fertility (and survival) to population growth provide a sensitivity analysis for stage-specific terms. Here, the reproductive value for a particular stage is calculated as the product of the sensitivity of all matrix elements that contain that stage and the stable stage proportion. For example, short-lived species tend to demonstrate a relatively higher sensitivity for fertility than survival, while the reverse is often true for long-lived organisms. Thus, sensitivity analysis can be used in combination with observed variation in demographic rates to determine which factors have the largest impact on population growth and thus, the future composition of the population. Lifetime reproduction patterns expressed as reproductive allocation and ranked relative to other demographic rates therefore provide a means to compare the evolution of life-history strategies.

Genetic Considerations

An important consideration for population studies is the effect of inbreeding on reproductive fitness (the combination of fecundity, fertility, and survival). There is strong evidence to demonstrate that inbreeding reduces reproduction and survival in naturally outbreeding species and to a lesser extent in self-fertilization species, whereas increasing the incidence of outbreeding can reverse these deleterious effects. Not only does inbreeding reduce individual reproductive fitness, a population of inbred individuals often results in a declining population and an increased rate of inbreeding. As such, inbreeding is also expected to increase the risk of population extinction. This process begs the question: how much inbreeding can be tolerated without inbreeding depression? All finite closed populations will eventually become inbred without outbreeding, and even a low frequency of inbreeding is expected to result in some inbreeding depression. Effective population sizes of 50 or greater have been suggested as sufficient to avoid inbreeding depression, although it is generally unknown how large populations must be to avoid inbreeding depression in the long term. This number will also be highly variable among populations as a result of local dynamical processes and extrinsic forces.

Fitness☆

Xia Hua and Lindell Bromham, Australian National University, Canberra, ACT, Australia

Nomenclature

W	Absolute fitness of a class of variant
w	Relative fitness of a class of variant
s	Selection coefficient of a class of variant
$\overline{w}$	Mean fitness of a population
ϕ	Value of a continuous trait or the presence of a class of variants
$\overline{\phi}$	Mean value of a continuous trait or the relative frequency of a class of variant in the population
δ	Change in ϕ during a time period that is due to factors other than directional selection
N	A vector of the number of individuals with each state in a class of variants
A	A matrix of the probability of a transition from each state to each of the other states in a class of variants
B	A matrix of the per capita rate of a transition from each state to each of the other states in a class of variants
C and D	Matrices of the probability of a transition from one class to another class in a population
$s_x(y)$	Invasive fitness of a new class x under the environment of a resident population y
$H(x)$	Shannon's entropy of the uncertain system x
$I(x;y)$	Mutual information of y on uncertain system x
x_t	Environmental state at time t
π_t	Representation of different classes of variants in a population at time t
π	The value that π_t averaged over time approaches as time goes on
G_{max}	The highest conceivable growth rate of a population in the uncertain environment
G_{min}	Long-term growth rate of a population with no information on the uncertain environment
$H'(x)$	Fitness cost of uncertainty on the environment x
$I'(x;y)$	Fitness value of information y on environment x
$D(\hat{\pi}\|\pi)$	Kullback-Leibler divergence from π to $\hat{\pi}$.
c	Cost of the behavior to the actor in kin selection
b	Benefit to recipient of the behavior in kin selection
r	Genetic relatedness between the actor and the recipient in kin selection

Glossary

Allele One of two or more alternative versions of a heritable trait, often corresponding to a DNA sequence difference at a particular locus (place) in the genome.

Class General term for an identifiable variant of a heritable trait, which may be present in multiple copies in the population. For example, a given allele is a class representing a variant DNA sequence for a particular locus (place) in the genome. There may be many copies of the allele in many individuals, but they all belong to the same class.

Evolutionarily stable strategy (ESS) A class (typically representing some form of strategy) or a particular mix of classes that cannot be replaced by any other classes because no other class or combination of classes will have a fitness advantage over it (relative to an environment).

Genotype While this term has several possible meanings, here we use it to mean the particular genetic variants carried by an individual: that is which allele or alleles it has in its genome.

Kin selection Selection based on inclusive fitness, which includes the fitness advantage due to helping relatives to reproduce so that they increase the representation of shared alleles in the population.

Malthusian parameter Per capita growth rate of the number of copies in a class (e.g., individuals with a particular heritable trait, or number of copies of a given allele in a population).

Polymorphism Occurrence of more than one class of variants (e.g., multiple alleles of a gene, or different strategies for a behavioral response) in a population.

Background

The term "fitness" can have a range of meanings in biology, sometimes referring to a relatively general concept, at other times as a label for a specific parameter. This variation in meaning can lead to some confusion, partly due to the changing roles the term fitness has played in evolutionary biology over time (Dawkins, 1982). Fitness had long been used to describe the way that organisms are evidently suited to their particular mode of life, or the way that parts of an organism work together (Paley, 1809). Herbert Spencer introduced the phrase "survival of the fittest" as equivalent to "natural selection" (Spencer, 1896). Alfred Russel

☆*Change History*: February 2018. X. Hua made minor changes to the text, figures, and references.

This is an update of J.A.J Metz, Fitness, In Reference Module in Earth Systems and Environmental Sciences, Elsevier, 2014.

 doi:10.1016/B978-0-12-409548-9.09361-1

Wallace adopted the phrase, equating it to Darwin's description "preservation of favoured races in the struggle for life" (Wallace, 1867), and he recommended Darwin do the same, in order to avoid some of the misunderstandings associated with the phrase natural selection, which some readers took to imply a conscious choice (akin to artificial selection). Darwin concurred, and used the phrase survival of the fittest in some of his later works, though he preferred the term natural selection (Darwin, 1868). So, at its most basic, fitness is the capacity of organisms to survive and reproduce in the environment in which they find themselves.

Under this broad concept, the fitness of an individual is considered to be reflected in the number of its descendants. But it is not clear how this broad concept of fitness should be measured in practise, because there is no obvious point in time at which descendants should be tallied. In a finite population every allele in the genome can be traced to a single ancestor at some point in the past, leaving little obvious leverage for comparing fitness between individuals or genetic variants. An alternative and more practical measure would be to measure fitness differences by comparing differences in lifetime production of offspring. However, the actual reproductive output of an individual is dependent not only on its own characteristics but also chance events, therefore fitness should be expressed as the probability distribution of the number of offspring. Classical models in population genetics suggest that natural selection maximizes the expected number of offspring as long as the relative expected number of offspring of different genetic variants stay constant over time and space, which usually requires constant (or infinitely large) population size and a stable environment (Fisher, 1930). When these assumptions are relaxed, natural selection no longer maximizes the expected number of offspring, but maximizes some more complicated form of fitness. For instance, under fluctuating environment, natural selection maximizes the geometric mean of the expected number of offspring over generations (Orr, 2009).

In most usages in evolutionary theory, fitness does not describe a property of a unique individual, but the property for a class of variants. Here we mean "class" in the sense of a group that all share the same feature, so our focus might on a specific allele, or a haplotype consisting of several base changes inherited as a unit (e.g., a mitochondrial variant), or individuals with the same trait of interest, or a phenotype consisting of several traits, or a life history strategy. For example, the use of antimalarial drugs places selective pressure on *Plasmodium* (malaria) parasites: any allele that confers resistance will be favored by selection, so individuals carrying this allele have a fitness advantage over susceptible individuals. Under these conditions, we expect the allele with the fitness advantage to steadily increase in the population (Roper *et al.*, 2004). Note that this is a statement about expected outcomes. We cannot predict the reproductive success of a particular *Plasmodium* individual based on whether or not it has the resistant allele —a susceptible individual may thrive if it is lucky enough to avoid being exposed to pyrimethamine, and a resistant individual may fail to reproduce when the mosquito it is carried in gets squashed by an irate human before it can achieve infection. But we can say that on balance, when considered across the whole population, over the period of observation, the favored allele had a higher rate of inclusion in subsequent generations that would be expected under random sample (Nair *et al.*, 2003).

Influence of Environment on Fitness

Fitness is always considered relative to a given environment. We would rarely consider an allele to have an absolute advantage under all sets of environmental conditions. For example, the fitness advantage of the resistance allele in populations of *Plasmodium* would disappear if pyrimethamine were not present in the environment (and may even be reversed if there is a cost to resistance). The "environment" of a class of variants can be considered to have many different levels.

On the genomic level, when a class is a specific allele, the "environment" of the class includes the other alleles in the genome in which it resides. No gene acts in isolation, but in combination with other genes, so the selective advantage of an allele depends on the presence of other alleles. Selection on one allele can carry linked neutral or nearly neutral alleles to fixation (hitchhiking: Maynard Smith and Haigh, 1974). Similarly, selection against a deleterious allele will removed linked alleles from the population (background selection: Charlesworth *et al.*, 1993). Both hitchhiking and background selection will result in a reduction in observed variation around a site under selection, thus one way of detecting alleles under selection is to detect chromosomal regions of reduced variability, which is interpreted as sign of a "selective sweep" that has driven linked alleles to fixation. For example, selection on the pyrimethamine resistant allele has led to reduced variation for 100 kb of linked sequence (Nair *et al.*, 2003).

The fitness of an allele can also depend on unlinked alleles in the same genome, or between nuclear and organelle genomes in the same cell, due to interactions between gene products. For example, some mitochondrial genes will be advantageous in combination with particular nuclear alleles, but have fitness costs when combined with other nuclear alleles, which can lead to cytonuclear conflict (Rand *et al.*, 2004). There may even be sex-specific differences in fitness costs and benefits of alleles. For example, some mitochondrial alleles lead to poor sperm performance, but because mitochondria are passed through the female line, alleles deleterious in males can persist for many generations (Gemmell *et al.*, 2004).

Because interactions with other alleles can have positive or negative effects on an allele's fitness, the "environment" of an allele against which fitness is tested will also include other alleles segregating in the population. In a sexual population, each generation is formed by sampling the alleles from one generation and reassorting them into individuals in the next generation. But alleles are not simply filtered through a "substitutional sieve" that preferentially lets those of higher fitness through to the next generation (Dobzhansky, 1937). The passage of an allele to the next generation will depend on whether it tends to have a fitness advantage when combined with other common alleles in the population, such that particular combinations of alleles will tend to result in higher rates of reproduction. This means that alleles that do not work well with other common alleles will tend to have reduced representation in subsequent generations. As a consequence, co-adapted alleles tend to accumulate in populations. Alleles within a

population are selected to work well with each other, but if lack of gene flow prevents those alleles being tested against variants in a neighboring population, then alleles that have high fitness in one population may have low fitness when combined with alleles in another population. This leads to hybrid individuals, who have a parent from each population, to have lower fitness than the offspring of parents from the same population, potentially generating selection for isolating mechanisms that prevent interbreeding, thus leading to the formation of genetically isolated species (see Hua and Bromham, 2017).

The fitness of some alleles may depend on characteristics of the population in which they are found. Some alleles may be beneficial under high population density, but lose this fitness advantage under low densities. Furthermore, when considering the fitness of particular behavioral strategies, the "environment" includes the frequency of other strategies in the same population. For example, the fitness of alleles influencing foraging behaviour in *Drosophila melanogaster* can be frequency dependent: in low nutrient environments, alternative alleles of the same gene that promote "roving" (moving around) or "sitting" (remaining) are both advantageous when rare, as rare strategies allow access to resources with less competition from others following the same strategy (Fitzpatrick *et al.*, 2007).

Three Alternative Ways of Defining Fitness

We have discussed general conceptions of fitness, and the way that fitness is influenced by the complicated web of interactions with other alleles, other individuals in the population and many aspects of the environment. Formal concepts of fitness are mostly mathematical and statistical, and there is a range of different parameters that have been labeled as fitness. These mathematical definitions of different fitness parameters differ from the conceptual definition of fitness that we have just discussed (Otsuka, 2016). Below, we describe some bases of the most popular theories: the Price equation, Evolutionarily Stable Strategy (ESS) theory, and information theory. To make this discussion general to any population that can undergo evolution by natural selection, we are going to refer to the variants under selection as a "class." The "class" might refer to alleles, strategies, lineages, groups, or any other unit where we can compare the relative reproductive success of one class of heritable variants against others.

The Price Equation

The Price equation was derived by Price (1970), originally for the purpose of re-deriving W.D. Hamilton's work on kin selection (Hamilton, 1964), but it is now considered as a fundamental theorem that summarizes all the equations and theorems in population genetics. In population genetics, fitness, or more specifically, the absolute fitness (W) of a class of variants typically refers to the class's expected number of progeny multiplied by its chance of survival (Orr, 2009). Often, population geneticists normalize this fitness by the absolute fitness of the fittest class and call this relative fitness (w), so that the fittest class has a relative fitness of 1. Now the relative fitness of all the other classes can be written in a form of $1 - s$, where s is called the selection coefficient. The mean fitness of a population ($\overline{w}$) is then the weighted sum of the relative fitness of each class in the population and the weight is the frequency of each class. For example, if a class is a genotype and a population contains two different genotypes, then the mean fitness of the population is $\overline{w} = p_1 w_1 + p_2 w_2$, where p_1 and w_1 are the frequency and the relative fitness of one genotype and p_2 and w_2 are the frequency and the relative fitness of the other genotype. Similarly, if a class is a given value of a continuous trait (z), then the relative fitness is described as a function of trait value, $w(z)$, and the mean fitness of a population integrates the fitness over the total range of values that the trait could take $\overline{w} = \int p(z)w(z)dz$.

The Price equation describes the average change in the representation of a class ϕ in a population during a time period ($\Delta\overline{\phi}$). The class can be a given value of a continuous trait, such as body size or some measure of fitness itself, and $\overline{\phi}$ is the mean value of the trait or the mean fitness of the population. The class can also be a categorical type, such as the allele of interest, and $\overline{\phi}$ is the relative frequency of the category in the population. According to the Price's equation, $\Delta\overline{\phi}$ is the sum of two parts (Queller, 2017):

$$\Delta\overline{\phi} = \frac{1}{\overline{w}}[\mathrm{Cov}(w_i, , \phi_i) + E(w_i\delta_i)]$$

where i denotes a class of variants. The first part, $\frac{1}{\overline{w}}\mathrm{Cov}(w_i, , \phi_i)$, represents change in $\overline{\phi}$ due to directional natural selection. When ϕ is the relative fitness itself: $w_i = \phi_i$, the covariance between fitness and the class $\mathrm{Cov}(w_i, \phi_i)$ becomes the variance for fitness, and so the first part of the Price equation captures Fisher's fundamental theorem of natural selection that states natural selection increases the mean fitness of a population at a rate equal to the additive genetic variance for fitness (Fisher, 1930). The second part, $\frac{1}{\overline{w}}E(w_i\delta_i)$, where δ_i is the change in the value of ϕ_i during the time period, describes the expected change in $\overline{\phi}$ due to factors other than directional selection, such as mutation, migration, a change in the environment, and so on. Classical models in population genetics show that natural selection maximizes the expected number of offspring of a population $\overline{w}$, because these models assume constant relative fitness, that is, $\delta_i = 0$; in other words, the second part of the Price's equation is ignored.

In principle, the Price equation can predict changes in the representation of any kind of class in a population under natural selection as long as the class has heritability (Queller, 2017). For example, a class can be a suit of co-adapted alleles or traits, so that fitness depends on multiple alleles or traits. Then $\mathrm{Cov}(w_i, \phi_i)$ in the first part not only accounts for the covariance between fitness and each trait, but also the association among traits. The second part of the Price equation can be modified to account for changes in $\overline{\phi}$ due to various factors other than directional natural selection. For example, consider frequency-dependent selection on sex ratio. Class ϕ is a given value of the number of male offpsring relative to female offspring. Starting with an initial condition

where there are more females than males in the population, females who have more male offspring should have higher fitness in a random, multiple mating population, because their offspring will have higher reproductive success in total. However, when more males are produced, environment for these males changes because there is stronger competition for mates; in other words, δ_i becomes negative because some male offspring will not reproduce. As a result, there may be a point where the two parts of Price's equation cancels out, that is, $\Delta\overline{\phi} = 0$. Under this condition, natural selection keeps ϕ at an optimal point.

Evolutionarily Stable Strategy (ESS) Theory

The concept of the evolutionarily stable strategy was first formulated by John Maynard Smith, who applied game theory to study the evolution of animal behaviors (Maynard Smith, 1974). Game theory essentially looks for the existence of strategy equilibria given the expected payoff of each strategy. Here, the payoff is the fitness of the strategy, often estimated by the Malthusian parameter that was proposed by Ronald Fisher to describe the rate of increase in the number of individuals as an aggregate of individual fecundity and mortality (Fisher, 1930). This is also a measure on the logarithm scale of the absolute fitness used in population genetics. In principle, ESS theory can be generalized to any class of variants, such as a new mutation, a new trait value, or a new strategy, so hereafter we use "class" instead of "strategy."

We can write changes in the number of individuals for discrete time as:

$$\mathbf{N}(t+1) = \mathbf{A}\mathbf{N}(t)$$

or for continuous time as:

$$\frac{d}{dt}\mathbf{N}(t) = \mathbf{B}\mathbf{N}(t)$$

For a class of variants where each variant has multiple states, for example, age state often matters for a reproductive strategy because only mature individuals can reproduce, $\mathbf{N}(t)$ records the number of individuals at each state, and components of matrix **A** are demographic parameters, with the i, j-th components of matrix **A** describing the probability of a transition from state j to state i. For age state, matrix **A** is the classic Leslie matrix, in which the first row is the average number of female offspring born from mother of each age state and diagonal of the rest of the matrix is the fraction of individuals that survive from an age state to the next age state. Matrix **B** is similar to matrix **A**, except that its components are per capita rates. The Malthusian parameter for a given class is then the natural log of the dominant eigenvalue of matrix **A** or the dominant eigenvalue of matrix **B** (Metz *et al.*, 1992).

We can also calculate the Malthusian parameter of a population that consists of multiple classes. This is analogous to the mean fitness of a population used in population genetics. To do this, we combine the matrix **A** or **B** of each class into a larger matrix. For example, if there are two classes in the population, class 1 has matrix **A1** and class 2 has matrix **A2**, they are combined into one matrix as:

$$\begin{bmatrix} \mathbf{A1} & \mathbf{D} \\ \mathbf{C} & \mathbf{A2} \end{bmatrix}$$

where matrix **C** describes the probability of a transition from class 1 to class 2, and matrix **D** describes the probability of a transition from class 2 to class 1. These transition probabilities can have various forms, depending on the genetic bases of the two classes. For example, in a haploid population, the transition probabilities may reflect the mutation rate between classes. When the population can grow exponentially, natural selection will maximize the Malthusian parameter of the population; otherwise the population size will eventually reach equilibrium where the Malthusian parameter equals 0.

ESS theory is often used to ask two questions related to the relative fitness of classes in a population. First, can a new class invade an existing population? Second, if it can, will the new class replace or be replaced by any existing classes in the resident population, or will it coexist with the resident? To study the first problem, the theory introduces a new parameter $s_x(y)$, the invasive fitness of a new class x under the environment of a resident population y. Assuming that mutations are rare so that the resident population is always at its strategy equilibrium, when a new mutation enters the population, $s_x(y)$ equals the Malthusian parameter of the population that consists of both the new and the existing classes. If $s_x(y) > 0$, the new class has a positive probability to invade the resident population. If $s_x(y) < 0$, the new class is doomed to extinction (Metz, 2008).

As the new class forms a greater proportion of the population, its influence to the environment of the population gets larger. So to predict the fate of the new class in long run, we not only account for the influence of the resident classes to the environment, but also the influence of the new class on the environment. Organism's influence on the environment can be modeled by expressing the demographic parameters in the matrix **A** as a function of "feedback variables" that describe the source of the influence (Rueffler *et al.*, 2013). For example, under density dependence, the fraction of individuals that survives from an age state to the next age state may depend on the total number of individuals in the population due to competition. Here, the total number of individuals in the population is the feedback variable. At the strategy equilibria, the Malthusian parameter of the population equals 0, so one way to look for the existence of strategy equilibria is to prove that there are finite number of conditions under which the Malthusian parameter of the population equals 0 (Diekmann, 2004).

An ESS view of fitness is particularly helpful in cases where the fitness effects of classes have complicated interactions. For example, a non-transitive set of behaviors can form a loop, in which each class has higher fitness that one alternative class but lower fitness than another alternative class. This is like a "rock-scissors-paper" game (rock beats scissors, scissors beats paper, paper beats rock). In other words, if $s_x(y) > 0$ and $s_y(z) > 0$, no one class can replace the others when $s_x(z) < 0$ (Gyllenberg and Service,

2011). For example, *Escherichia coli* that can produce the antibacterial compound colicin (C) can have a fitness advantage over colicin-sensitive strains (S), but colicin-resistant strains (R) have a reproductive advantage over C by avoiding the cost of producing colicin. But the resistant strains (R) have a slower growth rate than sensitive strains (S). This is a non-transitive fitness loop because C beats S, S beats R and R beats C, leading to the potential for stable co-existence of the three strategies (Kerr *et al.*, 2002).

Another condition under which no one class can replace the others is when there are more than one "feedback variable" (Diekmann, 2004). For example, to study the evolution of annual versus biannual strategies in a population, we may express the Malthusian parameter of the population as a function of the relative frequency of the annual strategy in the population. If the survivability over the first winter is affected by the number of newborns and the survivability over the second winter is affected by the number of one-year-old individuals, then there are two feedback variables: the number of newborns and the number of one-year-old individuals. It has been shown that under this condition, populations with different frequencies of the annual strategy perform equally well (Diekmann, 2004). In contrast to the wide interest in finding a good proxy for fitness, the ESS theory suggests that the conditions under which natural selection will maximize the fitness of a population are actually limited.

Information Theory

The fundamental question in the information theory is how to reduce the error rate of data communication over noisy channels, or more abstractly, how to increase the amount of information on uncertain systems. To answer this question, we first need a measure of uncertainty: Shannon's entropy (Shannon, 1948). Given a variable x that could take N states, each with a probability p_i, the entropy of the variable is:

$$H(x) = -\sum_{i=1}^{N} p_i \log\ p_i$$

which counts the expected number of bits needed to code the variable x. Now we have a piece of information y on x. The value to attain the information is measured by how much uncertainty it reduces or how many bits it saves to code variable x, which we called mutual information (Cover and Thomas, 1991):

$$I(x;y) = H(x) - H(x|y)$$

If we treat environment as the uncertain system x and measure the value of information y on the environment in terms of the amount of increase in fitness, then it is more straightforward to account for uncertainty in the environment using information theory than the Price equation or ESS theory. With environmental uncertainty, long-term growth rate of a population becomes a more relevant proxy of fitness than the instantaneous Malthusian parameter because maximizing the growth rate at one time does not guarantee positive growth rate at another time. The long-term growth rate of a population can be intuitively defined as the arithmetic mean of the Malthusian parameter during each time step that is small enough that the environment during a time step is assumed constant (Donaldson-Matasci *et al.*, 2010). Mathematically, the long-term growth rate is the dominant Lyapunov exponent that describes the asymptotic rate of increase in population size (Metz, 2008).

Early work by Haldane (1957) and Kimura (1961) and recent studies on evolution under fluctuating environments (Donaldson-Matasci *et al.*, 2010; Rivoire and Leibler, 2011) suggest a tight link between fitness as formulated by information theory and the long-term growth rate of a population. To illustrate the link, we denote the environmental state at time t as x_t. The population will increase the representation of the class of variants that has the highest absolute fitness at time t in the population based on the information y_t they attain on x_t. The representation of different classes of variants at time t is denoted as π_t. The information can be directly acquired from the current environment, if π_t are mediated by phenotypic plasticity as a response to the current environmental cues, such that π_t does not depend on π_{t-1}. But more often, the information is inherited. The information on the current environment comes through the selective transmission of alleles or traits that are better suited to the previous environments than others, such that π_t depends on both π_{t-1} and the current environment. As time goes on, π_t averaged over time will approach a real number π. Our goal is to find the π that maximize the fitness or the long-term growth rate of the population.

It is intuitive that the maximum conceivable growth rate for a population occurs when the class of variants with the highest absolute fitness has 100% representation in the population at any point in time, so that the population is tuned perfectly to x_t. The worst situation is when traits associated with high fitness in past generations provide no information on likely success in the current environment. Under this situation, a population is most likely to survive over time if the relative frequency of different classes in the population is proportional to the relative frequency of different environmental states over time. Now, we denote the maximum conceivable growth rate as G_{max} and the long-term growth rate in the absence of information as G_{min}. The relationship between G_{max} and G_{min} follows (Rivoire and Leibler, 2011):

$$G_{min} = G_{max} - H'(x)$$

where $H'(x)$ is the fitness cost of uncertainty on the environment. When the information on the environment is imperfect, that is a population with π_{t-1} does not behave optimally under x_t, the maximum long-term growth rate of the population with $\hat{\pi}$, the optimal value of π is (Rivoire and Leibler, 2011):

$$G(\hat{\pi}) = G_{max} - H'(x) + I'(x;y)$$

where y is the imperfect information on the environment x and $I'(x;y)$ is the fitness value of information y on x. The selective

disadvantage of a population with an arbitrary value of π is related to $D(\hat{\pi}\|\pi)$ (Frank, 2012), the Kullback-Leibler divergence from π to $\hat{\pi}$, which is used in the information theory to measure the number of extra bits required to code variable π using a code optimized for $\hat{\pi}$ rather than the code optimized for π.

It has been shown that when π_t does not depend on π_{t-1}, and when the absolute fitness of the population in x_t is nonzero for only one class of variants, $H'(x)$ equals $H(x)$, the Shannon's entropy of the environment, $I'(x;y)$ equals $I(x;y)$, the mutual information on the environment, and the selective disadvantage of π equals $D(\hat{\pi}\|\pi)$ (Donaldson-Matasci *et al.*, 2010; Rivoire and Leibler, 2011). Under other conditions, the forms of $H'(x)$ and $I'(x;y)$ are more complicated, but $H(x)$ and $I(x;y)$ still defines the upper bounds of these values (Donaldson-Matasci *et al.*, 2010; Rivoire and Leibler, 2011).

Individual Fitness

The three different formulations we have discussed are related, in that each can be derived from each of the others (Demetrius and Ziehe, 2007; Frank, 2012). But these different formulations may be suited to answering different empirical questions. For example, the Price equation is a convenient way to investigate which features of organisms are correlated with fitness. ESS theory is well-suited to examining why populations may contain one or more alternative strategies. Information theory allows us to consider how environmental uncertainty affects fitness in the long run. These are all questions that biologists may wish to ask of real populations. In order to do so, we need to be able to measure the fitness relevant parameters, such as the Malthusian parameter, in real populations, in the lab or the field.

Field ecologists often measure fecundity and survivability by tracking marked individuals through their life span. So the major problem of estimating the Malthusian parameter of a class of variant or of a population in the field is how to translate discrete individual events—the birth, death, and reproduction of an individual—into the growth rate of the class or the population. For example, while any given individual will have a specific value for age at death that reflects both fitness and chance events, the survivability measures the proportion of individuals that survive to a given age in the population, so reflects the fitness of a given class of individuals.

Fisher (1930) showed that, without demographic and environmental stochasticity, the sum of the reproductive value of all individuals in the population increases at the population's asymptotic growth rate, regardless of whether the population is in stable age distribution. This suggests that if there is a measure of the reproductive contribution of each individual to the class or the population (Fisher, 1930), sometimes called the individual fitness (Sæther and Engen, 2015), then we can estimate the fitness of the class or the population by tracking some individuals of the class or the population through their life span. Using individual fitness is also a logic way to accounting for demographic and environmental stochasticity, because these sources of stochasticity must be reflected in the variation of individual fitness (Engen *et al.*, 2009).

Traditionally, individual fitness is measured by the number of offspring produced by an individual during its lifetime. However, using this individual fitness to estimate the fitness of the class or the population that the individual belongs to require additional assumptions, including constant population size and stable age distribution (Sæther and Engen, 2015). To avoid these assumptions, at least two new measures of individual fitness have been proposed. One measure defines individual fitness as the sum of the number of offspring an individual produced during a given time step (divided by 2 if sexual reproduction) and a dummy variable describing whether the individual is alive or not during the time step (Sæther and Engen, 2015). This measure is readily applicable to the Price equation by replacing w_i with the individual fitness and ϕ_i with the feature value of the individual. Another measure calculates individual fitness as the dominant eigenvalue of a matrix that is similar to the Leslie matrix, where the first row is the number of offspring produced at each age of the individual (divided by 2 if sexual reproduction) and the diagonal of the rest of the matrix is 1 if the individual is alive at the age and 0 if not alive (McGraw and Caswell, 1996). The geometric mean of individual fitness converges to a value as the number of individual increases, but the value is a biased estimate of the Malthusian population growth rate (McGraw and Caswell, 1996).

There are other measures of individual fitness, but they require estimating population growth rate or some demographic parameters of the population first. For example, one measure calculates individual contributions to population growth by comparing population growth rate estimated from datasets before and after removing the individual and its offspring that are produced during a given time step (Coulson *et al.*, 2006). These measures are still useful to remove demographic and environmental uncertainties because they can capture the variation in individual fitness either due to chance events that happen to different individuals during their lifespan or variation in the environment around an individual, such that some individuals happen to live in a good year and others in bad years.

Fitness Beyond the Individual

The fitness of a class of heritable variants, whether defined at the level of the genotype or the phenotype, is due to it having properties that increase its representation in the next generation. But, given that fitness concerns the expected outcomes for a class of heritable variants, not the fates of any given individual carrying the trait, an individual does not have to reproduce to increase the fitness of the class of variants. If an allele causes its carrier to help others with the same allele, even at personal cost, then it may result in a net fitness advantage if more copies of the allele are included in the next generation than would have been without the

altruistic action (Haldane, 1955). The more closely individuals are related, the more alleles they will share in common, hence the famous quote attributed to J.B.S. Haldane that he would risk his life to save two brothers from drowning, or eight cousins (Maynard Smith, 1975). This idea is captured in Hamilton's (1964) inclusive fitness, which writes the fitness effect of having a particular co-operative behaviour as

$$w = 1 - c + br$$

where c is cost of the behavior to the actor, b is the benefit to recipient, r is the genetic relatedness between the actor and the recipient. "1" is the baseline fitness as used in population genetics. In the ESS theory, this is the fitness of the resident population, but on the logarithm scale $\log(1) = 0$. The ESS theory predicts that a new variant can invade the resident population if its fitness is greater than the fitness of the resident population. So natural selection favors a particular co-operative behaviour when $1 - c + br > 1$, that is $br > c$ (Hamilton, 1964).

But individuals do not have to be close kin to share an allele whose fitness is increased by co-operation. If an allele within a population leads carriers of the same allele to co-operate to raise their net reproductive output, it will have a selective advantage. Such a situation is referred to as a "green beard" phenomenon: an allele that causes both green beards and propensity to help others with green beards could lead to evolution of altruism by providing a heritable basis for the fitness benefits of co-operation (Dawkins, 1979). For example, in the highly invasive fire ant *Solenopsis invicta*, a gene that codes for an odor-binding protein acts as a green beard: workers carrying the b allele help queens with the b allele to reproduce, and tend to kill queens that lack b (Keller and Ross, 1998). This is not strictly a case of kin selection, because it is irrelevant in this case whether the queens with the b allele are related to the workers or not, it is the presence or absence of the "green beard" olfactory cue allele that determines co-operation.

Individuals often inherit more than just genes from their parents. For example, if offspring tend to be located closer to their parental home than other members of the population are, then they inherit their environment as well as their genes. Since organisms also influence their own environment, natural selection can create feedback between the environment and the organism through niche construction. Organisms may change the physical structure of the world (e.g., termite mounds or birds nests), the physical form of other organisms (e.g., galls induced by wasps infecting trees), or the behaviour of other organisms (e.g., parasite manipulation of host behaviour). Influences on the environment may be neutral with respect to fitness or even deleterious (e.g., exhaustion of resources). But if there are heritable influences on environment that increase the fitness of a class of heritable variants by increasing its relative representation in subsequent generations, then we expect this "extended phenotype" to be under natural selection (Dawkins, 1982).

Because the fitness effect may extend beyond the physical boundaries of an individual organism, the fitness of a class of heritable variants depends not only on features of other classes of variants in the conspecific population, but also on the heritable features found in other species. These tangled fitness relationships blur the line of demarcation between individuals, and even between species. It is not always obvious when a mutually beneficial relationship between endosymbiont and host (e.g., termites and the bacteria that allow them to digest cellulose) becomes a dual genetic inheritance system (e.g., nuclear and mitochondrial genes). For example, braconid wasps reproduce by parasitizing caterpillars, but cannot do so without genes encoded in a virus that is amplified and transmitted in the wasps' eggs. The fitness of any alleles in the wasp genome depends on their co-transmission with viral genes, and vice versa (Louis *et al.*, 2013).

The consideration of combined fitness effects of alleles in different organisms leads us to the question of whether the concept of fitness can be applied to communities or ecosystems. In the informal sense, we might consider communities to have features that aid survival and propagation, such as robustness or resilience, and these features could be ultimately due to the net genetic information in the system (Van Valen, 1989). However, the formal theoretical sense of fitness concerns relative reproduction rate, and it is not clear what we might be comparing the fitness of an ecosystem to. To apply the theoretical framework of fitness to multi-species groups we would need to be able to define a system where communities compete for some key resource, that they have the capacity for reproduction (not just persistence) and that they have heritable traits that influence their chances of representation in subsequent generations.

Gause's Competitive Exclusion Principle☆

Jamie M Kneitel, California State University, Sacramento, CA, United States

Introduction

The "competitive exclusion principle" (CEP), usually attributed to Gause (1934), states: "Two species with identical niches (and compete for a single resource) cannot coexist together indefinitely." This statement, in its simplicity, represents one of the most influential, compelling, and controversial concepts in ecology. Indeed, it pervades almost all theoretical and empirical approaches to species coexistence and diversity. Further, it is a conceptually centralizing paradox in ecology: if similar competing species cannot coexist, then how do we explain the great patterns of diversity that we observe in nature? If species living together cannot occupy the same niche indefinitely, then how do competitors coexist? Community ecology strives to reconcile this paradox and explain the mechanisms of species coexistence: niche differences among species have been the primary explanation for the maintenance of species coexistence.

Conceptual Beginnings

Since the beginning of ecology in the 19th century, research has centered on resource competition as the primary interaction regulating and structuring populations and communities. As far back as Darwin, ecologists have acknowledged that species occupied roles in their environment and that ecologically similar species, especially closely related species, will compete strongly and result in the extinction of poor competitors. Alternatively, species may ecologically or evolutionarily diverge in their resource use, or niche, resulting in reduced niche overlap. These interactions represented the perceived driving mechanisms for speciation and much of the diversity of life on this planet. Early in the 20th century, Grinnell (1917) had coined the term "niche" to refer to species' requirements and their use of habitat. At that time, he had been expressing for over a decade that no two species can occupy the same niche. A decade later, Elton elaborated on the term to also mean a species' role and effects in its habitat.

"The Struggle of Existence"

The concept of "struggle for existence" has been around for millennia, but it was coined by Darwin (1859). Darwin used it in regard to individuals of a species or different species interacting strongly for limited resources; however, we observe species persistence in communities with the plethora of these strong interactions. This leads to numerous questions regarding community level patterns, including the nature of species dominance, persistence, and extinction; the structure and assembly of communities; the patterns of biodiversity; and ultimately the mechanisms leading to observed community patterns. Early in the 20th century, Lotka and Volterra separately developed mathematical equations that addressed the population dynamics of competing species and the conditions when extinction or coexistence will occur in these populations. For example, on a single resource, only one species can persist (Fig. 1), but if intraspecific competition is greater than interspecific competition in the two competing populations, then similar species may stably coexist. In 1934, Gause published *The Struggle for Existence*, which consisted of the first experimental tests of Lotka–Volterra equations. Specifically, Gause used unicellular organisms (protozoa and yeast) in a series of laboratory experiments to quantify species interactions in competition to determine the conditions necessary for coexistence. One of Gause's competition experiments showed that two *Paramecium* species exhibited logistic growth when grown alone, but when grown together, one was always driven to extinction (Fig. 1). Naturalists and theoreticians had previously mentioned this pattern of competitive exclusion; Gause united the niche and competitive interactions conceptually and empirically.

☆*Change History*: March 2018. Jamie Kneitel made minor changes to the references and text.

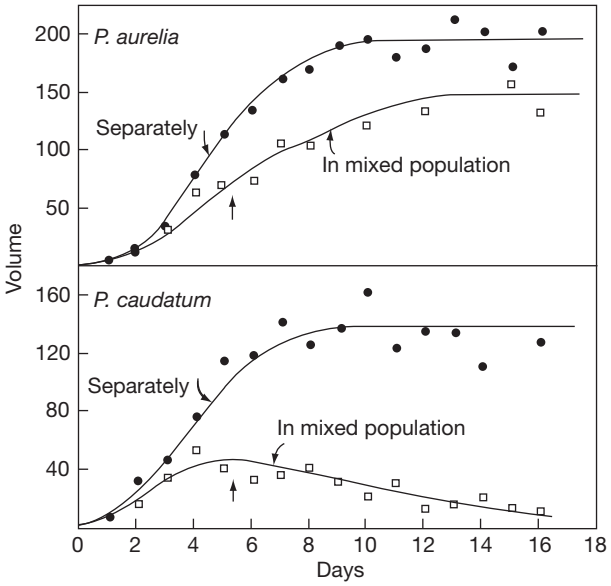

Fig. 1 Population growth for *Paramecium aurelia* and *Paramecium caudatum* when grown alone ("separately") and in competition ("in mixed population"). This is an example of competitive exclusion between two similar species. From Gause, G.F. (1934). *The Struggle for Existence.* Baltimore: Williams and Wilkins.

Gause's Contributions

Gause's book was influential on future studies in the areas of competition, the niche, and species coexistence. His approach of experimentally testing mathematical models has become a standard for ecologists, and his experimental results have become common textbook examples of competition and predator–prey interactions. In the years following publication of his book, various authors referred to the "competitive exclusion principle" as Gause's hypothesis, axiom, law, postulate, contention, or thesis. However, it was not until Hardin (1960) that the term "competitive exclusion principle" was coined. The article summarized the historical development of the principle and its various uses in ecology. Hardin also provided a critique of the principle and ecologists' ability to test it. For example, the CEP is not falsifiable: extinction between competitors provides support for it, but if species coexist, then the conclusion is that the species must somehow be ecologically different (i.e., different niches). This naturally leads to the question of "how different is different?" (see also excellent discussion in Palmer (1994)). Nonetheless, competition experiments dominate the ecological literature to this day, and the approaches have become more quantitative and rigorous in experimental designs.

Species Coexistence

The study of biodiversity is the study of how competitive exclusion is foiled—through the exploitation of heterogeneity and pattern in the environment, and through the evolutionary displacement of the ways species see and utilize the environment (Levin, 2000).

Ecologists have long sought to determine the factors that allow competing species to coexist in nature. Competitive exclusion (extinction) is one possible outcome of competitive interactions, and ecologists have determined several potential outcomes and mechanisms for species coexistence, typically associated with trait differences among species as implied by CEP. As mentioned previously, these differences result in intraspecific interactions being stronger than interspecific interactions. For the past several decades, Lotka–Volterra equations have been further developed and elaborated to identify conditions in which coexistence is possible. One conclusion from several theoretical studies in the 1960s pointed out that n species can coexist only when the number of resources or limiting factors is greater than the number of species, $k > n$. Other work has pointed to nonlinear functional response relationships with resources, varying densities, and temporal variation in resources as other conditions facilitating coexistence.

Early studies by Tansley and later by Park showed that the nature of competitive interactions may differ, in fact may be reversed, under different environmental conditions. In Tansley, conspecifics of the plant genus *Galium* differentially dominated in different soil types, and Park found *Tribolium* beetle species to differentially dominate under different temperature and humidity conditions. Recent examples of this common pattern highlight that the strength of competitive interactions can vary with habitat conditions in space or time, and coexistence may be occurring because of habitat heterogeneity along spatial and/or temporal scales. Therefore, species coexistence and exclusion are contingent on habitat conditions and spatiotemporal scale.

Resource competition can also lead to character displacement, whereby competitors evolutionarily diverge in their resource use, reduce niche overlap, and thereby coexist. This competition-driven process assumes that individuals of species who overlap in their niche (and this being directly related to the degree of competition) will have lowered fitness, causing directional selection. Species will then evolve decreased niche overlap and competition, which may also be reflected in morphological differences. The evidence

required to support the presence of character displacement should include (1) nonrandom size differences, (2) genetic basis for trait differences, (3) differences resulting from evolutionary shifts, (4) morphological differences resulting in differential resource use, and (5) competitive interactions must be established.

The ecologist G. E. Hutchinson contributed immeasurably to the development of the niche concept. Hutchinson's "Homage to Santa Rosalia" article addressed why so many species were able to coexist and was a pivotal landmark in bridging the relationship between the niche and competition. He pointed out that species that were too similar morphologically (e.g., body size) and ecologically will result in competitive exclusion of one species. However, coexistence between closely related species will occur when the species are sufficiently different in body size and therefore their resource use. This minimum difference in body size was estimated to be 130% or a factor of 1.3, which came to be known as the Hutchinsonian ratio; the measuring of size ratios as an estimate of prior character displacement became the focus of much research for a generation of ecologists trying to understand community structure and species coexistence. Ultimately, this approach faced an array of criticisms based on statistical and inferential grounds. For example, in many communities, the size differences were not different than randomly selected sets of species, the patterns were not different than random distributions of size differences. Further, species that differ in body size may not always compete less than similarly sized species.

For several decades, there was a decline in the use of the term "niche," but the tide has turned. In recent years, there has been a resurgence and renewed interest in the niche as a central concept and explanation for species coexistence. This has also resulted in the conceptual development of how the niche is measured by using traits. Further, the "niche" has been enhanced (e.g., species traits) and promoted as a central theme for the future of ecology, reflecting previous work on fundamental and realized niche. Another update on the view of the niche has been the concept of niche tradeoffs as a mechanism for species coexistence (Fig. 2).

One criticism of the niche explanations for coexistence is that they have difficulty explaining high levels of species diversity. In recent years, the metacommunity concept has emerged to address community dynamics at different spatial scales, local and regional. Processes at the local community scale are the smaller-scale factors affecting communities, including species interactions with each other (e.g., competition, predation) and their environment. At the regional community scale, processes among local communities dominate, including dispersal and habitat heterogeneity. The processes at local and regional scales contribute to community dynamics and patterns of abundance and diversity. A number of perspectives have emerged within this framework for explaining diversity and abundance patterns. One explanation for diversity patterns has been the neutral theory of species diversity. In these models, species are assumed to be identical ecologically and demographically, and diversity and relative abundance is driven by metacommunity size, and random (stochastic) variation in demographic (births and deaths), dispersal, and speciation rates. Empirical support has been variable for neutral theory, but it has proven to be an influential alternative to the niche perspective. It appears that both niche (deterministic) and neutral (stochastic) processes act in community dynamics. While most approaches to the niche viewed differentiation on a single dimension (except for Hutchinson's *n*-dimensional hypervolume), niche tradeoffs view two or more niche axes where species traits have a negative functional relationship (Fig. 2). For example, a species' ability to compete may come at the cost of defending against predators (Fig. 2), which has been documented in numerous aquatic and terrestrial communities. Further, ecologists are increasingly becoming aware of the importance of spatial dynamics that can contribute to species coexistence. The competitive–colonization ability tradeoff has been hypothesized as a mechanism for species coexistence in space, with some empirical support. Consequently, species niche differences can be exhibited along numerous niche axes along on spatial and temporal planes, potentially explaining higher levels of diversity.

In *The Origin of Species*, Darwin suggested that closely related species should compete strongly since they are more likely to be similar in their resource use (i.e., niche). Empirical (experimental and observational) support for this observation has been rather weak, but new molecular and computational approaches have facilitated hypotheses on the relative importance of evolutionary history and ecological traits for species coexistence. Two alternative hypotheses, overdispersion or clustering, are proposed for relationships among species occupying local communities. Phylogenetic overdispersion is found when coexisting species are less related than expected by chance, a pattern that assumes competitive exclusion and consistent with Darwin's observation. In contrast, phylogenetic clustering is found when coexisting species are more related than expected by chance, which implies environmental

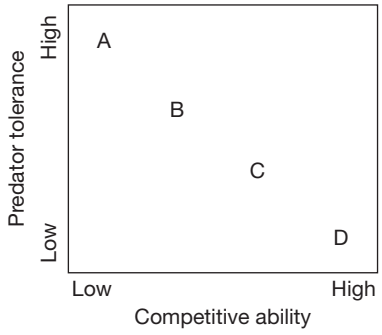

Fig. 2 An example of tradeoffs among species A–D along two niche axes, competitive ability and predator tolerance, which will hypothetically facilitate coexistence.

filtering is more important than competition in determining community patterns. Empirical studies have found support for both hypotheses. Additionally, factors other than competition (e.g., herbivore effects) are often found to influence these patterns.

The Competitive Exclusion Principle is one of ecology's most influential concepts. Empirical evaluations have been diverse and support has been varied for the importance of competitive exclusion in structuring communities. In addition, other explanations for coexistence patterns include stochastic processes, dispersal limitation, apparent competition, and abiotic conditions. Nonetheless, CEP and its modern descendants will continue to inspire ecological research and develop with technological, empirical, and theoretical advances.

Genetic Drift

Olivier Honnay, University of Leuven, Heverlee, Belgium

Glossary

Allele One form of a gene or a specific chromosome region (locus). For one diploid organism, two forms are possible.

Effective population size The number of individuals in an ideal population that has the same properties with respect to genetic drift as the actual population does. The effective population size is usually smaller than the census population size because not all individuals contribute to the offspring to the same degree.

Genetic differentiation The amount of the genetic variation in an organism that is present among different spatially separated populations. Genetic differentiation may vary between 0.00 (all populations possess exactly the same alleles) and 1.00 (all populations have no alleles in common).

Heterozygote An organism possessing two (in the case of a diploid organism) different forms of a particular gene or specific chromosome region (locus), one inherited from each parent.

Introduction

Genetic drift, also known as the 'Sewall Wright effect', is one of four factors (next to mutation, gene flow, and natural selection) causing a gene pool to change over time. Genetic drift is the random variation in allele frequencies between generations due to sampling error in finite populations. As an example consider a single locus with two alleles, A and a, with equal frequencies $p=0.5$ and $q=0.5$, in a population of 10 diploid parents that interbreed and produce 10 offspring. Although the probability of drawing either allele a or A is 0.5, it is likely that a random sampling of 20 alleles from the available allele pool will yield a slightly different allele frequency in the offspring. For example, allele frequencies in the second generation might have shifted to $p=0.4$ and $q=0.6$, purely due to chance effects. Continuing with these second-generation allele frequencies, and after a second random sampling of 20 alleles, in the third generation deviations from the initial 0.5 frequencies will become even more likely. Note that this process of genetic drift shows that the Hardy–Weinberg equilibrium, predicting constant allele frequencies over time, does not hold in finite populations. Genetic drift is also nondirectional and as likely to decrease as to increase the frequency of one particular allele. Although genetic drift is an evolutionary process (because allele frequencies are changing), it does not directly change the degree of adaptation of an individual or a population.

Example

In a classic experiment with 107 small ($N=16$) populations of the fruit fly *Drosophila melanogaster*, each consisting of eight males and eight females, Peter Buri in 1956 has empirically shown how initial allele frequencies ($p=q=0.5$) of a gene coding for eye color can dramatically change after relatively few generations. The evolution of the frequency distribution of the alleles, over all experimental populations, can be seen in **Fig. 1**. Each population can be considered as a random sampling of 32 alleles from the available pool. After 19 generations, one of the alleles has reached a frequency of 1.0 in almost half of the 107 experimental populations (it is said that the allele has become 'fixed' in that population), implying that the other allele was lost from the population. This illustrates a first very important consequence of genetic drift: The loss of genetic diversity. The proportion of populations where fixation for a certain allele is expected to occur is equal to the initial frequency of that allele. **Fig. 1** also shows a second important consequence of genetic drift. Because allele frequencies are changing in different directions in each population (one allele becomes more frequent in one population, whereas it decreases in frequency in another population), the populations start to differentiate from each other. It is said that genetic differentiation among populations is increasing. A third consequence of genetic drift is that as the population becomes fixed for one allele, the heterozygosity (H_t) in the population (the frequency of heterozygotes) in generation t is expected to decline each generation. Starting from an initial heterozygosity (H_0), this happens according to the rule: $H_t=(1-1/2N_e)^tH_0$. This means that heterozygosity will decrease much faster in populations with small effective population size (N_e).

Genetic Drift and Population Size

Drift is much more important in small populations because the sampling error effect causing changes in allele frequencies is relatively small in large populations. In the absence of dominance or epistatic variance, genetic variance will be lost at the same

 doi:10.1016/B978-0-444-63768-0.00616-8

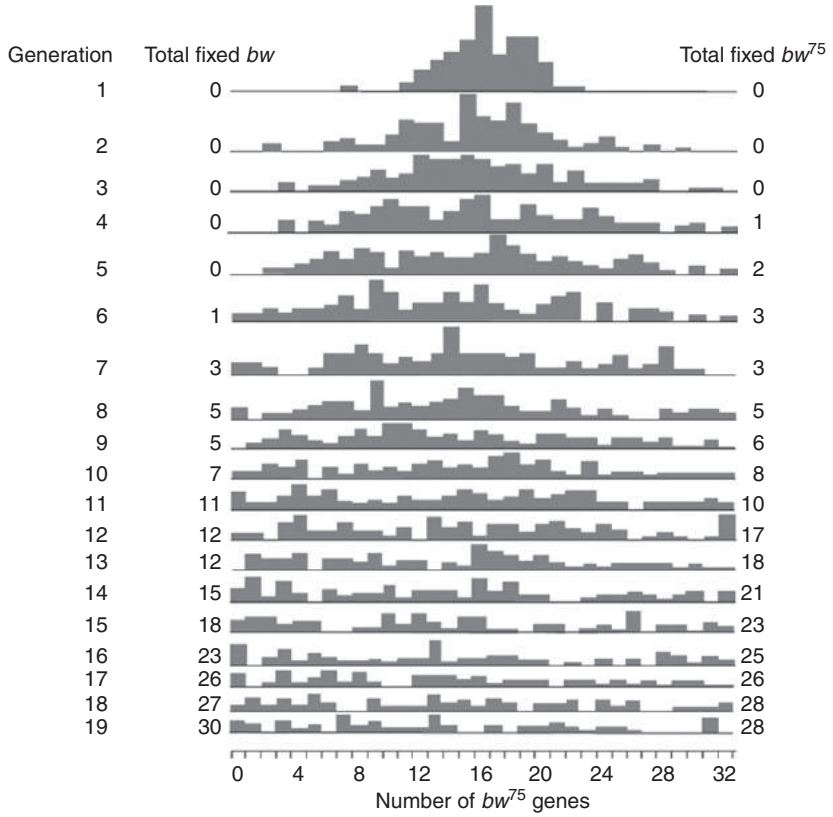

Fig. 1 Empirical histogram of allele frequencies of two alleles in 107 experimental populations of the fruit fly *D. melanogaster* over 19 generations. All populations started with an allele frequency of $p=0.5$. Redrawn from Buri, P., 1956. Gene frequency in small populations of mutant *Drosophila*. Evolution 10, 367–402.

rate as heterozygosity, that is, at a rate of $1/2N_e$ per generation. **Fig. 2** shows simulations of the random change in the frequency distribution of a single hypothetical allele over 20 generations for two different-sized populations. In the smallest population, alleles are driven to fixation in a very short time, while in the larger population allele frequencies remain more constant. Note that on average, the frequencies of the alleles remain constant across all populations, but that the frequencies start to diverge among populations. Kimura and Ohta in 1971 have presented an expression for the mean time until fixation (T) of an allele with an initial frequency of q: $T=(-4N_e(1-q)\ln(1-q))/q$. It can be seen that the time until fixation (and hence until the loss of genetic variation) is a linear function of the effective population size (N_e).

Bottleneck and Founder Effects

Even populations that are currently large may be genetically impoverished because genetic drift has been important in the past. This may be the case when the population went through a bottleneck (the bottleneck effect), or when it is derived from a small number of founding parents (the founder effect). Genetic bottlenecks occur when populations show a drastic reduction in population size, for example, due to temporally deteriorating environmental conditions, followed by population growth when the environmental conditions improve again. Bottleneck effects and founder effects imply that also the genetic properties of currently large populations can be shaped by genetic drift.

Minimal Viable Population Size

Genetic drift is an important concept in conservation biology where often small and spatially isolated populations of threatened plant and animal species are studied. Often crucial is the estimation of the minimum viable population size. The minimum viable population size is an estimate of the number of individuals required for a high probability of survival of a population over a given period of time. A commonly used definition is a higher than 95% probability of persistence over 100 years. One important requirement to prevent extinction of a population is to maintain sufficient population genetic diversity to allow for adaptation to changing environmental conditions. Genetic drift should then be minimized, and at most equal the mutation rate within the

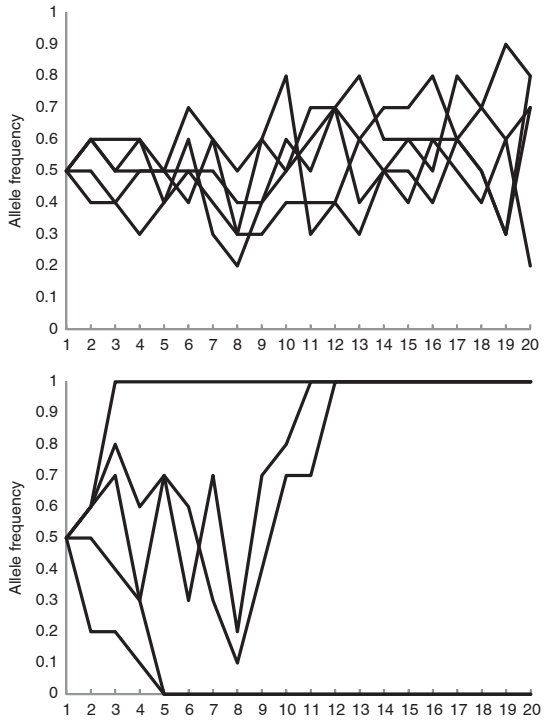

Fig. 2 Hypothetical frequency of an allele A for a number of replicate small (10 individuals, below) and large (100 individuals, above) populations across 20 generations.

population. In 1980, Ian Franklin has proposed that there is an equilibrium between loss of genetic diversity through drift and gain of genetic diversity through mutation, when $1/2N_e = 0.001$, this is when $N_e = 500$ individuals. This rule of thumb for minimum viable population size has become widespread among conservation biologists, although recent meta-analyses have put forward minimum viable population sizes of at least a few thousand individuals. Note that the census population size should usually be much larger than the effective population size, because not all individuals in a population are contributing to the genetic diversity of the offspring. Many factors can increase the difference between the effective population size and the census population size: An unequal numbers of males and females, variance between individuals in likelihood to produce offspring, high variance in the number of offspring between individuals, nonrandom mating, and fluctuations in the number of breeding individuals from one generation to the next. Populations where N_e equals the census size are said to be ideal.

Genetic Drift and Gene Flow

The loss of alleles through drift from a population, and the concomitantly increasing population genetic differentiation, can be counteracted if there is sufficient gene flow among populations. Gene flow can occur through the active migration of individuals or through the passive dispersal of seeds and pollen. It can be shown that for a large number of ideal populations: $F_{ST} = 1/(4N_e m + 1)$, where F_{ST} is a measure of the genetic differentiation between populations, m is the proportion of individuals that migrate between populations per generation, and N_e is the effective population size of the populations. This implies that one incoming migrant per generation in each population ($N_e m = 1$) results in a population genetic differentiation of 0.20. This is considered as still acceptable and has been coined the 'one-migrant-per-generation-rule', which states that receiving one migrant per generation is sufficient to prevent genetic drift from reducing the population genetic variation and increasing the genetic differentiation. It should be noted that a genetic differentiation of 0.20 is a relatively arbitrary threshold, and that in the case of nonideal populations, much more migrants are required to counteract the effects of genetic drift.

Genetic Drift and Evolutionary Theory

Genetic drift is at the core of the shifting-balance theory of evolution coined by Sewall Wright where it is part of a two-phase process of adaptation of a subdivided population. In the first phase, genetic drift causes each subdivision to undergo a random walk in allele frequencies to explore new combinations of genes. In the second phase, a new favorable combination of alleles is fixed in the subpopulation by natural selection and is exported to other demes by factors like migration between populations.

Much of the basic theory of genetic drift was developed in the context of understanding the shifting-balance theory of evolution. Genetic drift has also a fundamental role in the neutral theory of molecular evolution proposed by the population geneticist Motoo Kimura. In this theory, most of the genetic variation in DNA and protein sequences is explained by a balance between mutation and genetic drift. Mutation slowly creates new allelic variation in DNA and proteins, and genetic drift slowly eliminates this variability, thereby achieving a steady state. A fundamental prediction of genetic drift theory is that the substitution rate in genes is constant, and equal to the mutation rate.

Hardy–Weinberg Equilibrium

Patrick G Meirmans, University of Amsterdam, Amsterdam, Netherlands

Glossary

Allele A variant form of a gene or genetic marker; a gene or genetic marker is only regarded to be variable when there are multiple alleles present in a species or population.

Genetic drift Change in the frequency of an allele resulting from random sampling of parents and random sampling of gametes to produce offspring. The strength of genetic drift is inversely related to population size.

Inbreeding coefficient Summary statistic that quantifies the level of inbreeding in a population or, more generally, the degree of deviation from Hardy–Weinberg equilibrium. Also called F_{IS} F, f, or the fixation index.

Locus The location of a gene or genetic marker on a chromosome.

Type I error In statistical significance testing this is the probability of rejecting the null hypothesis when it is actually true.

Type II error In statistical significance testing this is the probability of not rejecting the null hypothesis when it is actually false.

Introduction

The Hardy–Weinberg (HW) principle is one of the cornerstones of evolutionary theory. Arguably, the whole field of population genetics started with the first description of the HW principle (Crow, 1988). After all, this was the first time that Mendelian genetics was scaled up from describing the inheritance of alleles in pedigrees to a quantitative description of genotype frequencies in populations. The fundamental points of the HW principle can be neatly summarized in two postulates (following Waples, 2015):

1. After a single generation of random mating, the frequencies of the different genotypes at a locus can be expressed as a simple function of the allele frequencies.
2. In the absence of genetic drift, selection, mutation and migration, the allele and genotype frequencies remain stable over time.

Even though, historically, the HW principle arose from a discussion about the stability of allele frequencies under Mendelian inheritance (postulate 2), current applications of the HW principle almost exclusively concern the calculation of the expected genotype frequencies (postulate 1).

For a single biallelic locus with alleles A and a, there are three possible genotypes: AA, Aa, and aa. When the frequency of allele A in a population is p and that of allele a is q (where $q = 1 - p$), the expected frequencies of these genotypes are p^2, $2pq$, and q^2, respectively, where $p^2 + 2pq + q^2 = 1$ (see **Fig. 1**). A similar expansion can be made for multi-allelic loci, though the number of terms in the equation gets rather cumbersome for loci with many alleles. When the observed genotype frequencies in a population match the expected frequencies, the population is said to be in Hardy–Weinberg equilibrium (HWE). Note, however, that this is a special kind of "equilibrium" as for diploids it is reached within a single episode of random mating. This sets it apart from other equilibria in genetics, such as linkage equilibrium and migration-drift equilibrium, which are approached asymptotically over time.

Testing for deviation of observed genotype frequencies from the HWE expectations is often the first step in the analysis of genetic data. This is because many subsequent analyses rely on an assumption of HWE in order to work correctly. Testing for HWE deviation is furthermore often employed to check for the possible presence of genotyping errors that can be removed before proceeding with the further analyses.

Quantifying the degree of deviation from HWE is often done using the summary statistic F_{IS} (also called F, f, the fixation index, or the inbreeding coefficient; Wright, 1922). F_{IS} compares the observed frequency of heterozygotes (H_O) with the expected frequency under HWE (H_E, also frequently indicated as H_S): $F_{IS} = 1 - H_O/H_E$. When a population is in HWE, the observed and expected heterozygosity are equal and F_{IS} has a value of zero. However, the range of the statistic goes from -1 to 1, with negative values indicating an excess of heterozygotes and positive values a shortage of heterozygotes. Note that a value of -1 can only be reached when there are only heterozygotes; for a biallelic locus this is only possible when $p = q = 0.5$. Comparing F_{IS} values among populations or species can be highly informative on how differences in mating system or demography can influence the distribution of genetic variation.

History

Mendelians Versus Biometricians

After the rediscovery of Mendel's laws in 1900, evolutionary biologists in England were engaged in a fierce debate that dominated the field for over a decade. On the one side were the "Mendelians," headed by William Bateson. The mendelians thought that only discontinuous

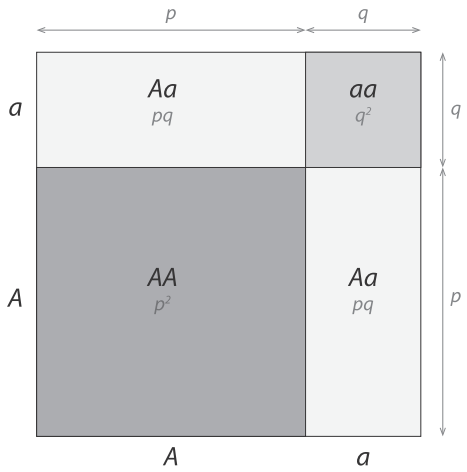

Fig. 1 "Punnet square" diagram illustrating how the frequencies of the three genotypes of a biallelic loci relate to the allele frequencies. The length of the sections labeled "*A*" and "*a*" on the *X* and *Y*-axes correspond to their frequencies ($p = 0.7$ and $q = 0.3$). The area of the rectangles in the plot thus corresponds to the genotype frequencies.

characters could lead to evolution and saw an important role for Mendel's laws of inheritance for this. On the other side were the "biometricians," headed by Karl Pearson. The biometricians put most emphasis on continuous, quantitative, traits. Though they did recognize the validity of Mendel's experiments, they thought that his results were only of moderate interest as they did not see how they could explain the quantitative variation seen in nature. This argument was only fully resolved in 1918 when Fisher published his landmark paper (Fisher, 1918) on combining quantitative and mendelians genetics. In any case, both camps were studying Mendel's laws. The Mendelians did so in order to show how it could explain evolutionary significant variation; the biometricians did so to show that it could not explain what they thought were the most important evolutionary processes.

Among the biometricians was G. Udny Yule, who had joined the group around Pearson in 1893. In 1902, Yule published a long-winded paper (Yule, 1902) that he started with a diatribe against Bateson and his writing style, before explaining his "law of ancestral heredity." In the second half of the paper he discusses Mendel's laws and in doing so actually reveals the HW genotype ratios for $p = q = 0.5$. In a later paper, Pearson (1904) does the same, though without acknowledging the prior work of his co-worker. Surprisingly, both scientists failed to see how these genotype ratios could be generalized beyond allele frequencies of exact one half.

In February 1908, Yule attended a lecture by the mendelian R.C. Punnett (who lent his name to the Punnett square, see **Fig. 1**) titled "Mendelism in relation to disease." In this lecture, Punnett gave an extensive explanation of Mendel's laws and Bateson's work on it, adapted for a medical audience. In the subsequent discussion, Yule led the argument against the mendelian school. Yule argued that for a dominant trait, such as brachydactyly, one would expect, over the course of time and assuming random mating, to have three brachydactylous persons for every normal person. Yule pointed out that this was obviously not the case in the human population. Punnet was taken aback by this question and could not readily provide a satisfactory answer (Edwards, 2008).

Geoffrey H. Hardy

G.H. Hardy was the leading mathematician of his time. In a way he can be regarded as the prototypical English gentleman scholar; a staunch bachelor, he devoted his time between mathematics, cricket, and conversation at Cambridge University's "High Table". Punnet and Hardy played cricket together, so naturally Punnett posed Yule's problem to Hardy. Hardy quickly grasped the concept and provided Punnett with a satisfactory answer. He then proceeded to write a short letter to the editor of Science (Hardy, 1908), which was published in July 1908. In it, he expressed both his reluctance "to intrude in a discussion concerning matters of which I have no expert knowledge" and his exasperation about the apparent lack of ability of biologists to perform "mathematics of the multiplication-table type." He then pointed out the stability of both allele and genotype frequencies, which afterwards became known as "Hardy's law."

Wilhelm Weinberg

Meanwhile in Stuttgart, Germany, a physician was persistently working on a large volume of papers on a wide range of subjects, but mostly focusing on genetics. Wilhelm Weinberg spent all his working life as both a private physician and a volunteer physician to the poor. His specialism being obstetrics, he is said to have delivered no <3500 babies (Crow, 1999). Among these must have been a good number of twins and children with hereditary defects, which may have triggered an interest in these subjects. In his spare time Weinberg wrote around 160 scientific papers.

In January 1908—3 months before Hardy wrote his letter to the editor—Weinberg gave a lecture titled "Über den Nachweis der Vererbung beim Menschen," to the society for natural sciences of the state of Württemberg. A corresponding paper was published in the yearbook of the society in the fall of the same year (Weinberg, 1908). In this paper Weinberg discusses several subjects

regarding human genetics, most notably the heredity and genetics of twinning. At the end of the paper, Weinberg explained the expected genotype frequencies under random mating and their stability, doing so in a much clearer and more extensive fashion than Hardy in his short letter. Similar to Mendel's paper 40 years earlier, Weinberg's paper was written in German and published in an obscure journal and consequently completely ignored by the scientific establishment. After all, the field of genetics was largely dominated by English speakers. It was not until 1943—6 years after Weinberg's death—that Curt Stern, a German geneticist working in the U.S. called attention to Weinberg's paper (Stern, 1943) and declared that the rule regarding the genotype frequencies should be known as the "Hardy–Weinberg law."

Assumptions

The HW principle as posited above is only valid in a highly idealized population where there are no perturbations affecting the genotype and allele frequencies (Waples, 2015). Therefore, the principle as a whole makes a number of assumptions: random mating, infinite population size, no mutation, no selection, a single population, no migration, non-overlapping generations, and diploid inheritance. However, each has different effects on the two postulates of the HW principle. Most importantly, factors that affect the stability of allele frequencies (postulate 2) do not necessarily have an effect on the expected genotype frequencies (postulate 1). Here, I discuss violations of these assumptions one by one and for each explain whether and how it affects the two postulates. Note that all these assumptions regard biological processes; in many cases, deviation from HWE is caused by genotyping errors, a topic that is discussed later.

Non-Random Mating

In an infinitely large population, non-random mating has no effect on the allele frequencies and so does not invalidate postulate 2. On the other hand, the genotype frequencies (postulate 1) are more strongly affected by the violation of the assumption of random mating than by the violation of any of the other assumptions. Truly random mating is rare, and there are many reasons why organisms may not mate randomly. In animals, there may be polygyny, where one male has multiple females, or polyandry, where one female has multiple males, which causes the dominant adults to have a disproportionate number of offspring. A similar type of non-random mating occurs when the sex-ratio is biased. Another type of non-random mating is assortative mating: preferentially mating among individuals with a similar phenotype. If the phenotype is determined by a simple Mendelian gene, with the two homozygotes having two contrasting phenotypes, assortative mating results in increased homozygosity at that gene, relative to HW expectations. Much rarer than assortative mating is its opposite, disassortative mating (or negative assortative mating), the preferential mating among dissimilar genotypes. Disassortative mating results in an excess of heterozygotes at the corresponding locus; when there are overall differences in allele frequencies between the phenotypes (e.g., as a result of genetic drift), the excess of heterozygotes may also be visible at unlinked loci. There is also non-random mating when dispersal is limited so individuals that are geographically close are more likely to mate with each other even though these are also more likely to be genetically related. In plants this happens as pollinators tend to subsequently visit flowers that are in close proximity. The most extreme form of inbreeding is self-fertilization, which occurs in many hermaphroditic species. All these forms of inbreeding lead to an excess of homozygotes in a population ($F_{IS} > 0$) that increases over generations until it asymptotically reaches an equilibrium. In the case of complete self-fertilization, there are no longer any heterozygotes left when this equilibrium is reached, and consequently $F_{IS} = 1$. However, one generation of random mating is enough to restore the genotype frequencies to the HW proportions.

Finite Population Size

Finite population sizes lead to genetic drift, which is widely recognized as a major evolutionary force by itself. The presence of genetic drift invalidates the stability of the allele frequencies (postulate 2). On the other hand, genetic drift only affects allele frequencies from one generation to the next and is therefore not visible when looking at a single generation. As a result, genetic drift does not affect the expected genotype frequencies (postulate 1). However, population size does have an actual effect on the genotype proportions that is unrelated to drift. Rather, population size affects HWE because of the non-random mating occurring in finite populations. Truly random mating is unlikely in small populations, especially in species with two separate sexes or when self-fertilization is not possible. Such non-random mating leads to an excess of heterozygotes and therefore to negative values of F_{IS}. The expected effect on F_{IS} is proportional to the inverse of the effective population size (Balloux, 2004; Waples, 2015):

$$E(F_{IS}) = -1/(2N_e + 1)$$

For most values of the effective population size, this effect is negligibly small. Even when N_e equals 100 individuals—small enough to make genetic drift very strong—the expected value of F_{IS} is only about -0.005; this means that in practice the effect of population size will be virtually undetectable in tests of HWE.

Mutation

Mutation induces a change in allele frequencies and thus presents a violation of postulate 2. However, since mutation rates are typically very low, the effect of mutation itself is very slight; mutation only leads to appreciable allele frequency changes when

paired with genetic drift or selection. When testing for deviation of genotype data to HW expectations (postulate 1), mutation actually has no effect. This is because mutation most importantly takes place during gametogenesis and therefore does not affect the genotype frequencies after random union of the produced gametes. So even when a sample would contain one or multiple mutants, the newly introduced alleles still result in genotype frequencies that are in HWE.

Selection

Selection is the most potent evolutionary force, and as such can affect both the allele frequencies and the genotype frequencies, so both postulates 1 and 2. However, not all types of selection are equal. For example, balancing selection does not change the allele frequencies (postulate 2), and even makes them impervious to genetic drift. Similarly, even strong selection does not necessarily lead to genotype frequencies that deviate from HW expectations (postulate 1). This is the case when there are differences in fertility among genotypes. Assume that genotype *aa* produces only half the number of gametes compared to genotypes *AA* and *Aa*, resulting in a drastic reduction in the frequency of allele *a* from one generation to the next. Nevertheless, when the produced gametes all unite at random, the resulting genotype frequencies conform perfectly to HW proportions, despite the strong selection. The effects of selection will also go unnoticed when sampling takes place before selection can act. For example, when selection at a locus for mimicry affects butterfly survival, the genotypes of the caterpillars will conform to HW expectations (provided other relevant assumptions are met). Finally, there are some very specific combinations of values for the genotype fitnesses that, for mathematical reasons, will not lead to deviation from HW expectations even though selection is strong (Lewontin and Cockerham, 1959). This is the case when $W_1{*}W_3 = W_2^2$, where W_1, W_2, and W_3 are the fitness of genotypes *AA*, *Aa*, and *aa* respectively. So even if we have independent proof that a locus is under selection, this does not necessarily mean that the locus is not in HWE.

Multiple Populations

The HW principle concerns only a single population, so any case where there are multiple interconnected populations may lead to a violation of both postulate 1 and 2. Unknowingly sampling individuals from more than one population may occur because of several reasons. For example, individuals may be philopatric with respect to breeding grounds, but still share feeding grounds. Taking a sample from the feeding grounds then yields a mixture of multiple genetic clusters. In other cases, it may simply not be clear how a species is distributed into populations as the main dispersal barriers may not be discernible. In such situations, it may be prudent to perform a clustering analysis to detect any possible population structure, before drawing any conclusions about HW conformity (De Meeûs, 2017). Taking samples from multiple populations will lead to an excess of homozygotes relative to HW expectation ($H_E > H_O$, and consequently $F_{IS} > 0$). The strength of this so-called "Wahlund effect" depends on the proportions at which the populations are mixed and on the differences in the allele frequencies between the populations (population differentiation). The most extreme case for two populations is when they are each fixed for a different allele at a locus. In this case, there are no heterozygotes at all though the mixed sample is expected to harbor 50% heterozygotes when the populations are mixed evenly.

Migration

Migration can be seen as a special case of sampling from multiple populations, though it merits discussion on its own. Migration into a population changes its allele frequencies and therefore affects postulate 2. When migrants are included in a sample when testing for deviation from HW genotype proportions (postulate 1), this causes a Wahlund effect: an excess of heterozygotes. Nevertheless, in most cases we can expect that migration has only a negligible effect on HWE tests. This is because migration only affects HWE testing when there is a substantial proportion of migrants in the sample, that is, when the migration rate is high. However, such high migration rates very quickly even out the allele frequencies across populations. Conversely, in order to get substantial genetic differentiation among populations the migration rate between them should be so low that few, if any, migrants will be included in a typically-sized population sample. So migration is only expected to affect tests of HWE deviation when there is a high rate of migration between previously separated populations, for example, in cases of human induced secondary contact.

Overlapping Generations

In many long-lived species, mating is non-random with respect to age, if only because juveniles do not mate. When there are differences in allele frequencies among age classes, this will lead to a Wahlund effect and thus give rise to a lack of heterozygotes compared to HW expectations (postulate 1). Note that the development of allele frequency differences between age classes can only occur when at least one other assumption is violated, such as when there is genetic drift or selection. Therefore, overlapping generations in an otherwise ideal population does not lead to invalidation of either postulate 1 or 2.

Non-Diploid Inheritance

Both Hardy and Weinberg phrased the expected genotype frequencies in terms of diploid genotypes, and so did I in the introduction. This is no wonder since most species have a diploid genome. However, not all genomes are diploid: many species,

especially plants, are polyploid; other species, including some major insect groups, are haplo-diploid. Even predominantly diploid genomes may show variation in ploidy: sex chromosomes have a different ploidy in males than in females. The non-diploid inheritance does not mean a violation of the Hardy Weinberg principle per se, but only with how it was originally defined; ploidy level does not affect the stability of the allele frequencies (postulate 1) and the equations for the expected genotype frequencies (postulate 2) can be easily calculated for any ploidy level (Meirmans *et al.*, 2018). For example, for a hypothetical triploid the four possible genotypes at a biallelic locus are *AAA*, *AAa*, *Aaa*, and *aaa*; these have expected frequencies of p^3, $3p^2q$, $3pq^2$, and q^3, respectively. Similar adjustments are possible for sex-chromosomes and haplo-diploids. When the ploidy level or mode of inheritance is known, non-diploid inheritance should not pose a problem for tests of HWE deviation. However, there are possible complications. Sex chromosomes may contain pseudo-autosomal regions, where the degree of deviation from HWE may differ between loci depending on their degree of linkage with the sex-determining gene. In polyploid species, there may be variation in ploidy among or even within populations, and the exact ploidy level may not be known for every individual. Furthermore, in polyploids there may be a process called double reduction, which leads to a higher frequency of homozygote gametes than expected. This will lead to an increase in homozygosity compared to HW expectations. The rate of double reduction often differs among loci, depending on their location on the chromosome. Another important point that should be mentioned for polyploids is that the equilibrium genotype frequencies are not restored after a single generation of random mating. Instead, equilibrium is reached asymptotically over multiple generations, at a speed that depends on the ploidy level.

Testing

Testing whether genotype frequencies for a given sample of individuals match the expectations under HWE is a standard procedure in genetic data analysis. At first glance it seems like a problem out of a first-year statistics course: observations neatly fall into a limited number of classes (the genotypes) and the expected value for each class is easily calculated. So it basically comes down to comparing the observed and expected genotype frequencies. Despite this apparent simplicity, a large number of approaches has been developed for testing HWE. These approaches fall into four major classes: goodness-of-fit tests, exact tests, permutation tests, and Bayesian inferences. Here, I will first discuss the main aspects of these approaches before generally discussing issues of power, multiple testing and interpretation.

Goodness-of-Fit Tests

The simplest approach for HWE-testing is the chi-square test, which, despite its major shortcomings, remains widely used. In this test, a test statistic is calculated by for each genotype comparing the expected (n_e) and observed (n_o) number of individuals in the sample as: $(n_o - n_e)^2/n_e$. The overall value of the test statistic is then obtained by summing over all possible (both observed and unobserved) genotypes at a locus. This test statistic asymptotically has a chi-square distribution, which gives the test its name (it is also, more formally, known as "Pearson's goodness-of-fit test"). The *P*-value can thus be obtained by comparing the value of the test statistic to the chi-square distribution for the appropriate number of degrees of freedom. This number can be calculated by taking the number of genotypes minus one, and then subtracting the number of parameters estimated from the sampled data that are used to calculate the expected frequencies. This latter number equals the number of alleles at a locus minus one. So in practice the degrees of freedom can be obtained by taking the number of possible genotypes minus the number of alleles. For a locus with two alleles, there are three genotypes and therefore there is a single degree of freedom.

The main problem of the chi-square test is that for small sample sizes, the actual distribution of the test statistic is discrete; for small samples there are only a limited number of possible genotype combinations and thus a few possible values of the test statistic. This discrete nature of the test statistic does not match the continuous chi-square distribution. This non-continuity problem is especially prominent when one or more of the genotypes has a very low number of expected occurrences (<5), as it causes the value of the test statistic to become inflated. In genetic studies, this is quickly the case as alleles with a low frequency are common and sample sizes are usually small to moderate. For example, when the frequency of the minor allele is 10% and 50 individuals were sampled, the expected number of individuals with the corresponding homozygote genotype is only 0.5. The inflation of the test statistic is especially troublesome for multi-allelic loci such as microsatellites as these usually have several alleles that occur in only a few individuals. This problem can only partly be solved by lumping rare alleles together and/or by applying a continuity correction (Levene, 1949). The log-likelihood ratio test, another goodness-of-fit test with a test statistic that is asymptotically distributed as chi-square, suffers from this same problem. As a result, both these tests are best avoided and one of the other approaches described below should be used instead.

Exact Tests

An exact test is based on calculating the exact probability of obtaining the observed deviation from HWE proportions or a more extreme deviation. An exact test therefore requires a complete enumeration of all possible genotype arrays that have a more extreme deviation than the observed array. This enumeration is straightforward for loci with only two alleles, but with multiple alleles it quickly gets complex, even on modern multi-core computers. So for multi-allelic loci an approximation is needed, which can be done by using either random permutation of the data or by using a Markov Chain (Guo and Thompson, 1992). Either way, when such an

approximation is used, the resulting *P*-value is only an estimate of the exact *P*-value, so the test loses some of its "exactness." However, this should not be a problem when enough permutations or Markov Chain steps are used. Exact tests do not suffer from the non-continuity problems of the goodness-of-fit tests and are therefore preferred for testing for HW deviation for single loci.

Permutation of F_{IS}

As explained above, the F_{IS} statistic can be used to quantify the degree of deviation from HWE. It is therefore intuitive to use F_{IS} as a test statistic in a HWE test. This can be done using standard Monte Carlo permutations. First, the value of F_{IS} is calculated based on the observed genotype frequencies in the sample. Then a permuted dataset is generated by randomly combining alleles into genotypes, and then F_{IS} is calculated for the permuted dataset. When a large enough number of such permuted F_{IS} values are generated, these form a null distribution against which the observed F_{IS} can be compared. When the observed value falls within one of the 2.5% tails of the generated null distribution (or either the left or right 5% tail, in case of one-tailed testing), the deviation from HWE is deemed significant.

One problem arises when using the permutation test for loci with four alleles or more: in such cases it is possible to have genotype arrays that deviate from HWE and still have a low F_{IS}-value. For example, take a locus with four alleles *A*, *B*, *C*, and *D*, and a population sample that consists of 5 individuals each of genotypes *AA*, *BB*, *CC*, and *DD*, and 15 individuals each of genotypes *AC*, *AD*, *BC*, and *BD*. This sample is obviously not in HWE as genotypes *AB* and *CD* are completely lacking. Nevertheless the observed frequency of heterozygotes is exactly equal to the expected frequency of 0.75, so F_{IS} equals zero. Because of this problem permutation tests using F_{IS} are not recommended for single loci with multiple alleles. Their most important use, however, is for analyses involving multiple loci. A multilocus value of F_{IS} can easily be calculated by first averaging the H_O and H_E across loci, and then using these averages for calculating F_{IS}. The above problem is already unlikely to occur at a single locus, so it will almost certainly not happen across multiple loci simultaneously. Therefore, the multilocus permutation test is a suitable approach to get an single test of whether populations are in HWE. Averaging over populations is also possible to obtain a species wide estimate of the degree of deviation from HWE and a species-wide *P*-value.

Bayesian Inferences

Various Bayesian approaches to assessing deviation from HWE expectation have been proposed, but none of these has become very popular. The reason for this is probably that the HWE problem itself is relatively simple and the above frequentist methods are appropriate and straightforward. The most popular Bayesian method is the one proposed by Shoemaker *et al.* (1998), who approach the problem as one of parameter estimation. They developed a summary statistic for the degree of deviation from HWE, related to, but not analogous to, F_{IS}. They then use the Bayesian framework for obtaining the posterior distribution for this parameter, which can be studied to see whether there is any meaningful deviation from HWE. In this and several other developed Bayesian approaches, the choice of the prior distribution has a large effect on the results. Therefore great care has to be placed in the choice of prior.

Power

In statistical significance testing (here: the goodness-of-fit test, exact test and permutation test), there are two main types of errors: rejecting the null hypothesis when it is in fact true (type I error), and not rejecting the null hypothesis when it is in fact false (type II error). The rate at which the type I error occurs (α) can be controlled by setting the significance level in advance; usually this is set at $\alpha = 0.05$ for a single test. The rate at which the type II error occurs (β), however, cannot be set by the researcher, but is dependent on the selected significance level, the sample size, and the properties of the used test. The power of the test—the rate at which the test is expected to correctly reject a false null hypothesis—is then defined as $1 - \beta$. The concepts of type I error, type II error and power is only applicable to the frequentist analyses (goodness-of-fit, exact test, and permutation test), because Bayesian inferences do not rely on *P*-values.

Tests of Hardy–Weinberg equilibrium generally have a low statistical power, unless the deviation is strong or the sample size is large (Wittke-Thompson *et al.*, 2005; Graffelman, 2010). In evolutionary or ecological genetic studies, one usually only samples a limited number of individuals per population; a sample size of 50 individuals is already slightly above the standard. Small deviations from HWE, on the order of $F_{IS} = 0.25$, are difficult to detect using such small sample sizes. Even smaller deviations from HWE, on the order of $F_{IS} = 0.1$, are nearly undetectable, even when sample sizes are an order of magnitude larger. The power of HWE tests also depends on the minor allele frequency; when the minor allele frequency is low, the power also gets reduced. In general, the power of the goodness-of-fit test is much lower than that of the other two methods, especially at small sample sizes. This is in addition to the non-continuity problem discussed above, which leads to an inflation of the type I error (Wittke-Thompson *et al.*, 2005).

Multiple Testing

When analyzing data from multiple loci and/or populations, many separate tests for HWE will be performed. This multiple testing means that the probability increases that across all those tests there will be at least one locus for which the null hypothesis is falsely

rejected. In other words: the experiment-wide type I error rate increases with the number of tests. Many different methods have been developed to correct for this (e.g., Bonferroni, sequential Bonferroni (Rice, 1989), False Discovery Rate (Benjamini and Hochberg, 1995)) and it is generally advised that such a correction is applied when testing for HWE.

One major disadvantage of correction for multiple testing is that it greatly decreases the power of the test. In a standard Bonferroni correction—which is the most conservative of the available methods—the significance level is divided by the number of tests. So with 50 loci and two populations, and thus 100 tests, the corrected alpha becomes 0.0005. For $F_{IS} = 0.4$, $p = 0.5$ and a sample of 50 individuals per population, this means that the power drops from 78% to only 22%. Whether it is worth trading off type I error for such a high type II error depends on the type of question being asked and the reason why HWE tests are being performed. When HWE tests are used to weed out genotyping errors to prevent errors in later analyses, it would be unwise to have such a low power. With modern sequencing methods, it is easy to obtain tens of thousands of loci. In such cases it may be more prudent to sacrifice some loci to type I error rather than to leave in a lot of truly erratic loci.

Applications in Ecology and Evolution

As should be clear from the above, there are many ways to test for HWE deviation and those methods are also readily available in easy-to-use software packages (see the list of websites for some examples). In contrast with the ease of calculation, the interpretation of the results can be difficult (Waples, 2015). This is because the HW principle depends on so many assumptions that it is generally difficult to tell anything about the underlying cause of a significant deviation for a particular locus. It is also important to keep in mind that the absence of a significant deviation does not necessarily mean that all assumptions are met. Nevertheless, testing for deviation from HWE is an important part of any population genetic study. Its use falls into two main categories: checking for aberrant loci and testing evolutionary and ecological hypotheses.

Removing Genotyping Errors and Aberrant Loci

Despite the simple discrete nature of genotypic data, there are a lot of things that can go wrong in genetic studies: there may be null alleles, strand slippage, preferential amplification of alleles, stutter bands, dosage compensation, low coverage, genotype calling errors, etc. So, notwithstanding the many assumptions of the HW principle, genotyping errors are probably the most common cause of HWE deviation. Accordingly, this means that testing for HWE is a simple way of checking for genotyping errors. Besides genotyping errors, there are other locus-specific reasons why a certain locus may not conform to HW expectations and has to be excluded from further analysis. The locus may for example be under selection, be present in a duplicated gene, or it may be located on a sex chromosome, b-chromosome or on a cytoplasmic genome.

There are several important issues to keep in mind when using HWE tests for this purpose. First, the approach only works when the sampled population is indeed in HWE. A slight deviation from HWE might be difficult to detect, but may still lead to too many loci being discarded. Plus, after discarding these loci, the population may give a false overall impression of conforming to HWE. A second issue is that several bioinformatics pipelines for allele calling already make the assumption of HWE conformation. This is especially the case for pipelines that were developed for human genetics. This assumption makes subsequent testing for HWE on the resulting genotypes both redundant and biased; these pipelines are therefore unsuitable for species or populations where deviation from HWE can be expected. A third issue has already been discussed above: the low power of HWE tests combined with correction for multiple testing makes these tests highly inefficient.

Testing Evolutionary and Ecological Hypotheses

HW theory is not only suitable for weeding out erratic loci, but can also be put to much more interesting use, namely to test evolutionary and ecological hypotheses. Most of this use revolves around the analysis of non-random mating and inbreeding, and in this light it makes sense that the F_{IS} statistic is also called the inbreeding coefficient. When viewed across species, it becomes clear that species that are known to have strong inbreeding (e.g., self-pollinating plants) have much higher values of F_{IS} than species that are obligatory outcrossers (e.g., plants with a self-incompatibility system). For a species where the degree of inbreeding is not known, F_{IS} can be used to get a first insight into the mating system.

The use of F_{IS} is not limited to comparisons among species; also within species there may be differences in the degree of deviation from HWE. There are several ecological and demographic scenarios that can cause such differences. In animal-pollinated plants, the rate of outcrossing depends on the availability and efficiency of its pollinators. Therefore the inbreeding coefficient will be higher where insect diversity and activity is lower, such as at higher latitudes and altitudes and in less-suitable habitats. Small populations of a plant species may attract less pollinators and thus have increased inbreeding, causing a correlation of F_{IS} with population size. In animals, populations may differ in sex ratio, and more skewed sex ratios may lead to a higher deviation from HWE. Inbred individuals often have lower fitness than non-inbred ones, causing a correlation between individual heterozygosity and fitness. In long-lived species, the individuals with the highest heterozygosity may thus have the

longest lifespan. A comparison of F_{IS} across different age classes may then reveal that F_{IS} values decrease with age, being negative for the older age classes.

Generally, the use of HWE for testing evolutionary or ecological hypotheses can be done by calculating F_{IS} for every population or group and then correlate these F_{IS} values to a parameter of interest, such as population size, latitude, or sex ratio. In such cases, it is important that multi-locus F_{IS}-values are used for estimation and testing. Multi-locus values are relatively robust to locus-specific effects such as selection and genotyping errors. Nevertheless, it remains important to also calculate single-locus F_{IS}-values to check for consistency among loci. This is because the effects of non-random mating are expected to be similar across loci. Another advantage is that performing a single test that combines information across all loci gives much greater power compared to doing multiple single-locus tests. However, also here it is important to check that the results are not influenced by one or a few outlier loci.

Perspective

Overall, the HW principle presents a very complete theory with a well-described statistical toolkit. This toolkit can both be used for error-checking and for hypothesis testing. However, one disadvantage of the current approaches is that they cannot do both at the same time. HWE tests for error-checking are only possible when a population is truly in HWE. When using HWE for testing ecological hypotheses, they cannot simultaneously be used for error-checking. Therefore, there is room for an additional type of analysis that combines the two uses and that distinguishes locus-specific effects (that are due to genotyping errors) from population-specific effects (that are due to differences in mating patterns). Bayesian analysis would be a perfect framework for such a type of combined inference.

Isolation

JP Wares and TM Bell, University of Georgia, Athens, GA, USA

An important consideration in the design of ecological reserves and the potential for local adaptation within a species is the occurrence and degree of isolation between populations. Isolation can occur by many mechanisms. Individuals can be isolated 'physically' due to geographic or environmental barriers that limit effective dispersal between regions; 'numerically' (i.e., Allee effects in areas of low population size or reproductive success); 'reproductively' (depending on both recognition factors and genetic factors); or 'ecologically'. Isolation should primarily be considered in terms of demography – that is, individuals from different populations may come into contact with one another, but if that contact does not result in successful reproduction then it may indicate a form of isolation.

Isolation is a quantitative and potentially dynamic trait of populations. While the two extremes of this trait might be complete isolation (no interpopulation mating, gene flow, or interaction) or complete mixing of individuals and/or genomes from each population (panmixia), the greater challenge is to understand the mechanisms underlying intermediate patterns of isolation. Situations where isolation has not been completely achieved are a topic of great interest and in some cases are studied as examples of incipient speciation events.

Measuring Isolation

For example, two populations (e.g., distinguished by geographic separation) might be characterized as having only sporadic events of migration in which an individual successfully becomes established and reproduces in a non-natal population. These events may be measured directly, meaning that propagules must be followed for at least one generation; or indirectly, as with stable isotope markers or genetic markers. Genetic markers are frequently used to identify the relatedness of individuals from different populations, as the propagules of many species are difficult to track in terms of location and subsequent reproductive success.

Most genetic markers are assumed to be selectively neutral – that is, not under the influence of natural selection. Thus, the diversity and distribution of selectively neutral alleles at any given genetic locus are governed solely by the equilibrium between mutation (which adds novel alleles, or distinct markers), genetic drift (which stochastically eliminates alleles over time), and migration (which may introduce alleles that originally arose in a different population). The assumption of neutrality is important for understanding the degree to which populations are isolated from one another, because the diversity of genetic markers then reflects only the demographic characteristics of the populations, such as migration and reproduction.

For a given population size, the relative contribution of the mutation rate (μ) and the migration rate (m) to an inference of isolation will be important. If $\mu \gg m$, new alleles will arise in a population faster than they arrive from other populations, and the diversity in that population will become relatively distinct from that found in other regions. If $m \gg \mu$, then migration acts as a homogenizing force among populations and they will be composed of a similar set of allelic diversity. As an example, the populations shown in **Fig. 1** represent a continuum of isolation. If the individuals are distinguishable based on genetic markers, we can measure isolation by quantifying the amount of diversity within each population (d_w) relative to among-population (d_a) diversity. A class of statistics used to measure isolation in this case (Wright's F statistics) use a ratio of

$$(d_a - d_w)/d_a$$

to generate a value from 0 to 1, with 1 representing complete isolation. This class of statistics can be used to compare diversity among any hierarchical set of populations. Essentially, if there is equivalent diversity within a given group as among groups, there is little evidence for isolation. The top panel in **Fig. 1** illustrates 'complete isolation'; the diversity among populations (d_a) could be represented as 50% based on the frequency of two alleles across populations, while d_w would be 0% (there is no variation within either populations). Thus, the isolation for this set of populations is 1. Using similar rough methods, the isolation of the remaining illustrated populations is $(0.50 - (1/7))/0.50 = 0.714$ (significant isolation), 0.143 (some isolation), and 0 (no isolation). Similar statistics can be calculated for other forms of isolation (e.g., for measures of sexual isolation, the frequency of homospecific to heterospecific mating attempts, or successes compared to the total number of mating opportunities).

Effects of Isolation

Migration itself does not guarantee gene flow. If individuals are locally adapted to their natal environment, the reproductive fitness of those individuals in a different population residing in a new environment may be quite low, leading to an effective isolation of the populations. Selection may act differentially on parts of the genome that are most directly affected by environmental differences. For example, if an individual migrates into a population and successfully reproduces with a native individual, sexual recombination of gametes will generate offspring with combinations of 'native' and immigrant gene copies. Considering two physically unlinked genes A and B, where different copies at the A gene are selectively neutral but alleles at the B gene are not,

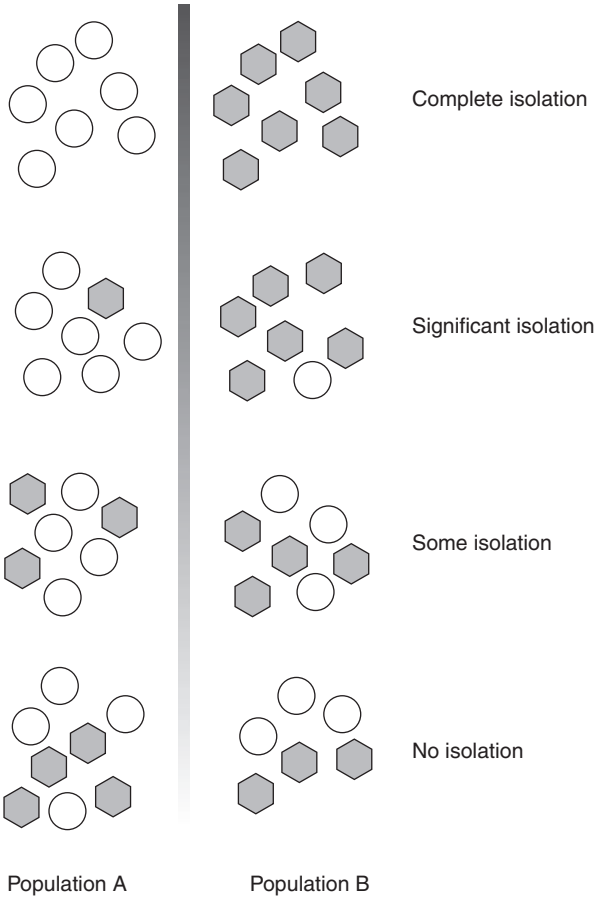

Fig. 1 Isolation is measured as the tendency toward different identity. In the case of sexual isolation, the ratio of homospecific to heterospecific matings is measured, considering all available interactions. In the case of using genetic markers to identify demographic isolation, the level of identity by state (e.g., sharing the same allele) is considered within a population relative to among populations. Ecological factors such as phenology differences among populations may contribute to both types of isolation. Here, two populations are shown. They may be defined based on their geographic location or any other distinguishing traits, and symbols within each population represent distinguishable traits of individuals, such as genetic markers, otoliths, or stable isotopic signatures.

many offspring may survive in the population that carry the immigrant allele at the A gene, but few or none may survive if they carry the immigrant allele at the B gene. Here, isolation is again quantitative in that the isolation may only be for particular elements of an organism's genome, rather than isolating two populations or species entirely.

The net result of these varying types of isolation is that to a certain extent, indirect techniques such as measuring allelic diversity at a variety of genetic loci in multiple populations can be used to characterize the degree to which populations fit the equilibrium neutral model governed by mutation, drift, and migration. There are a number of ways in which this model may be violated, particularly in cases where one or more populations being compared is or has recently expanded from a founder population (e.g., range expansions or species introductions); nevertheless, the comparison of isolation measures across many markers may be indicative of both demographic and selective forces that promote the evolutionary divergence of populations in isolation.

Isolation is not a static characteristic of populations. The Isthmus of Panama is an excellent case of complete contemporary isolation of marine populations on either side; there is no gene flow, no migration, and no interaction between individuals from the tropical eastern Pacific and the Caribbean. However, as the Isthmus formed over the course of a million years or more, populations that were initially freely mixing were slowly but increasingly isolated by the uplift of land masses and reduction of currents by freshwater inflows and mangrove swamps, and the final reduction in the number of pathways by which individuals could travel from one side to the other. This more realistic scenario of isolation allows for migration to persist beyond the initiation of the isolating event. Known as the isolation-migration model, this statistical approach allows more complete description of the cause and timing of isolation between populations. Without considering both factors, it is difficult to distinguish whether two populations share many alleles due to high migration, or recent (complete) isolation, or a mixture of intermediate migration and intermediate levels of isolation.

Complex scenarios may arise due to the interaction between historical and contemporary causes of isolation. While the variance in allele frequencies from one population to another is a standard method of measuring isolation it is not always clear whether that isolation is truly due to an equilibrium of mutation, drift, and migration – the isolation by distance model. It is also possible that ancestral events could separate a single population into two or more disjunct populations; subsequent environmental change, again permitting migration between the two areas, would cause a pattern of secondary gene flow. Geographic areas where two genetically or morphologically distinct groups interact, with incomplete isolation, are called clines. Many well-studied clines are caused by the secondary interaction between historically isolated populations.

One case study that illustrates both isolation by distance and the interaction of historically isolated lineages involves a 'ring species' of warblers in Asia. The geographic range of *Phylloscopus trochiloides* wraps around the Tibetan Plateau, and limited dispersal from the nest site results in populations from western Siberia through Tibet that exhibit a strong correlation of the geographic distance between sampled sites and the genetic distance measured at a mitochondrial gene. With greater geographic distance around the Tibetan Plateau, genetic distance gradually increases. However, there is a zone of overlap in central Siberia in which populations at one end of the 'ring' encounter populations from the other end – but in this region, the birds differ significantly in terms of plumage and song. This case is made more interesting by the isolation of eastern Siberian populations from those further south on the Tibetan Plateau due to deforestation – eventually, without any means of dispersal between the two sites, the east Siberia populations of *P. trochiloides* could become completely distinct (ecologically and demographically isolated).

Isolation and its subsequent effect on the evolutionary trajectory of a species has been the central theme of speciation literature over the past century. Only recently has this topic begun to be regularly incorporated into the study and theory of ecology and demography. Much of the diversity in form and function observed in our present-day environment can be thought to be the result of past isolation events and should therefore be considered a topic of much importance in fields of study other than evolutionary biology. Isolation events and their underlying mechanisms can have wide-ranging effects on a species. The effects of isolation may be detectable in genetic, ecological, and demographic patterns. Therefore, these topics should be of increasing relevance to current research focused on population ecology, local adaptive processes, and conservation biology.

Life-History Patterns

SH Alonzo and HK Kindsvater, Yale University, New Haven, CT, USA

Introduction

A life history can be defined as the timing of and relative investment of energy in survival, growth, and reproduction (Fig. 1). However, such a simple definition belies the complexity of life-history patterns we observe in nature. For example, trees may survive for hundreds of years while many insects live for only days. Marine mammals may have only a few offspring in a lifetime while some marine fish can produce hundreds of thousands of eggs every time they reproduce. This is the diversity of patterns that the study of life histories attempts to explain.

Ecological and evolutionary processes interact to produce variation in life history. For example, predator–prey interactions depend on the population dynamics of both predators and prey. Yet predation, as a source of mortality, influences the evolution of traits affecting body size and reproduction in prey. Prey reproduction will in turn affect prey population growth rate and thus the biomass of prey available to predators affecting predator reproduction and population size. When thinking about life-history patterns, it is impossible to disentangle evolution from ecology and ecology from evolution.

The study of life-history patterns has a long history of theoretical and empirical research. We generally understand the selective pressures that determine basic life-history traits such as age at first reproduction, number of reproductive bouts, partitioning of reproductive effort, and longevity. Yet many questions remain unanswered, such as how environmental variation and climate change may affect life histories and how the details of life-history variation affect ecological communities. In addition, new methods (such as novel genetic techniques and modeling approaches) continue to advance our knowledge and raise new questions.

Approaches and Paradigms

Tradeoffs

At some level all organisms experience constraints: genetic, energetic, physiological, developmental, and ecological. As a result, life-history theory is founded on a basic paradigm of tradeoffs. For example, given a set amount of energy, organisms must tradeoff the investment of that limited energy between growth and reproduction. Similarly, genetic correlations can cause changes in one trait (such as growth rate) due to selection on another trait (such as fecundity). Thus, a genetic correlation can limit the evolutionary response in both traits.

Phenotypic Models

The most common approach to modeling life-history patterns is optimality theory. This approach is based on the idea that natural selection will favor individuals or genes that confer the greatest fitness and thus asks which of all possible phenotypes is expected

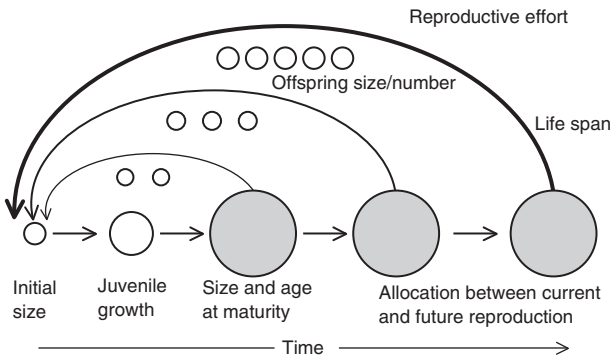

Fig. 1 An organism's life history can be represented by its survival, growth, and reproduction through time. However, a life history is actually a composite of many individual traits (such as initial size) and is influenced by multiple life-history tradeoffs (such as between offspring size and number). This figure presents one possible life-history pattern where each circle is a different age and the size of the circle represents body size. Arrow width represents survival between age classes and the contribution through reproduction to future generations. In this example, the hypothetical organism has an equal probability of survival across all age classes, does not grow following maturity, and total reproductive effort (offspring size and number) increases with age.

 doi:10.1016/B978-0-444-63768-0.00856-8

to confer the greatest fitness. Of course, this approach only makes sense in light of the tradeoffs or constraints discussed above. Otherwise a 'Darwinian Demon' (an organism that matures immediately, produces an infinite number of tiny offspring, and lives forever) would be predicted. Typically, phenotypic models examine a single tradeoff (e.g., between growth and reproduction) and predict the trait or traits expected to maximize fitness for that set of circumstances. The most common approach has been to examine how traits such as age or size at maturity (through their effect on birth rates) influence population growth rate (often referred to as the Malthusian parameter r) and find the life-history pattern that maximizes r. This links life history explicitly to population dynamics.

Another type of phenotypic model that has been influential in evolutionary ecology is game theory. This approach to modeling also predicts the phenotype that will be favored by natural selection but considers the situation where fitness depends on the traits of other individuals in the population. For example, if offspring survival depends on relative rather than absolute size, the size of offspring that maximizes individual fitness will depend on the size of offspring produced by other individuals in the population.

Both phenotypic approaches have been criticized for assuming any phenotype is possible, that organisms will be optimally adapted to their environment, and for ignoring the underlying genetic basis and dynamics of trait evolution. Despite these simplifying assumptions, optimality and game theory have successfully predicted observed patterns.

Genetic Models

In contrast, genetic models focus on how selection and the underlying genetic basis of traits influence life-history evolution. Population genetics examines how the differential fitness of genotypes (resulting from a few alleles and loci) leads to changes in allele frequencies over time. Quantitative genetics assumes that many genes of small effect contribute to the traits under consideration and that phenotypes are the result of an interaction between genetic and environmental factors. One advantage of quantitative genetics for life-history theory is its ability to examine the evolution of multiple correlated traits and to consider how various forms of environmental variation and genetic constraints affect the evolution of traits. In addition, the use of quantitative genetics has a strong empirical component where key parameters can be measured empirically and predictions can be readily compared to observed patterns in the lab and field (though many of the underlying genetic parameters are not known and are difficult to measure in wild populations). Research by Derek Roff and colleagues has illustrated the immense power of using quantitative genetic models and empirical studies in combination to illuminate our understanding of life-history evolution.

Summary of Phenotypic and Genetic Models

While phenotypic and genetic approaches each have strengths and weaknesses, they have also both made important contributions to our understanding of life-history patterns. We have learned the most about the evolution and ecology of life-history patterns by applying multiple methods to the same general questions.

Key Questions and Case Studies

Because of their inherent relationship to both fitness and population ecology, the study of life-history patterns has influenced many areas of research within evolution and ecology including: mating systems, sexual selection, migration, species interactions, and community dynamics. It is impossible to cover such broad influences and applications here. Therefore, we focus on a few classic life-history questions and discuss some new directions of research.

The Timing of Reproduction: Age and Size at Maturity

One of the most basic questions in life-history theory is when an organism should mature and reproduce. In general, size is positively correlated with fecundity and fertility. Because individuals tend to grow more slowly (if at all) when reproductive, there is an advantage to growing as large as possible before maturity. However, delayed reproduction will not be favored by selection if mortality risk is high. Additionally, resource availability also interacts with the strength of selection on growth and maturation. Classic predictions come from finding the age at maturity α that maximizes population growth rate (r) in the Euler–Lotka equation

$$1 = \int_{\alpha}^{\infty} e^{-rx} l_x m_x dx$$

where l_x represents expected survival to age x, α age at first reproduction, and m_x fecundity at age x. This approach makes the assumption that the population is at equilibrium. The life history that maximizes r and satisfies the above equation is predicted to be favored by natural selection. It is possible to examine different patterns of survival and fecundity with age (e.g., different functions for l_x and m_x with respect to α) and determine how they affect the optimal age at maturity. Theory and empirical studies have shown that higher adult mortality favors early age and size at maturity. Similarly, greater size-dependent reproductive advantages favor later maturity (all else being equal).

An interesting and relatively new application of this theory is in fisheries management. New research suggests that fishing mortality can act as a selective force leading to both plastic responses in individual traits and evolutionary change. For example, in

populations of Atlantic cod (*Gadus morhua*), a decline in observed age and size at maturity is associated with a long history of fishing (Fig. 2). Whether this represents an evolved or plastic response is still debated. However, an evolutionary change in size and age at maturity of cod may explain the fact that cod have not recovered despite reduced fishing mortality. Dave Conover and Steve Munch have shown a similar pattern experimentally in artificially selected populations of a small marine fish (*Menidia menidia*).

Current Versus Future Reproduction and the Evolution of Life Span

Another key tradeoff experienced by organisms is the tradeoff between current and future reproduction. For example, if a plant or animal invests most of their energy in their current reproductive event (e.g., produces more gametes or invests more in parental care), they may invest less energy in survival, growth, or future reproduction (Fig. 3). This has led to the question of how many times an organism should reproduce once mature. Organisms that reproduce only once are known as annual (plants) or semelparous (animals). Organisms with multiple reproductive bouts are known as perennials (plants) or iteroparous (animals). The probability of survival at each age or size class, combined with the relationship between offspring success and size or age affects the degree of iteroparity.

Longevity and senescence (increases in age-specific mortality or decreases in reproductive rates at higher ages) are related to the tradeoff between current and future reproduction. Immense variation in life span exists, with maximum age varying across taxa from days to hundreds of years. Some of this variation can be explained by selection on current versus future reproduction and the costs and benefits associated with delayed maturity. For example, if larger and older individuals have much higher reproductive rates and mortality is relatively low, theory predicts that organisms will be selected to delay maturity and invest in future growth and survival resulting in long life span. A more puzzling question, however, is why most organisms exhibit senescence. One body of theory explains senescence as the result of tissues accumulating damage over time. Another explanation has been that selection is much stronger on earlier age classes, and thus traits expressed later in life are less strongly selected. However, the evolution of life

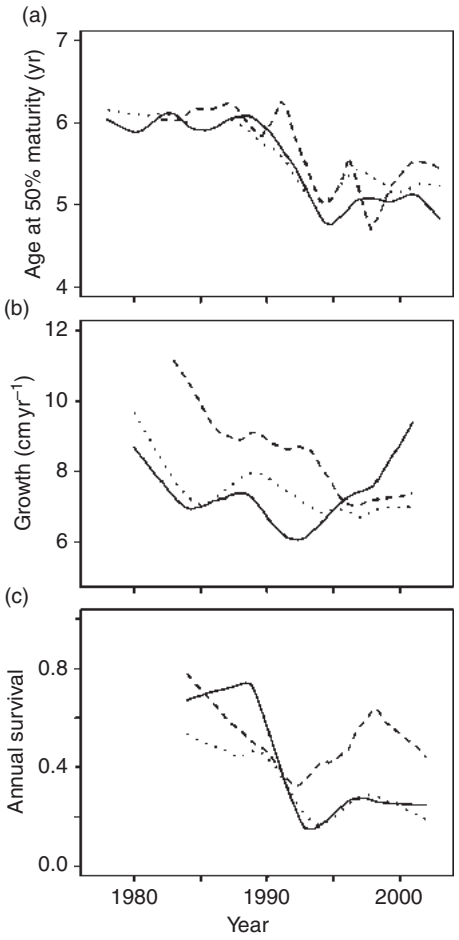

Fig. 2 Age at maturity (a) and annual growth based on length increments (b) have decreased in Atlantic cod over time in populations that have also experienced decreased expected annual adult survival (c) due to fishing. Each line represents a different region or division surveyed by the Northwest Atlantic Fisheries Organization (NAFO). Reprinted by permission from Macmillan Publishers Ltd: *Nature*, (Olsen EB, Heino M, Lilly GR, *et al.* (2004). Maturation trends indicative of rapid evolution preceded the collapse of northern cod. *Nature* 428: 932–935), Copyright (2004).

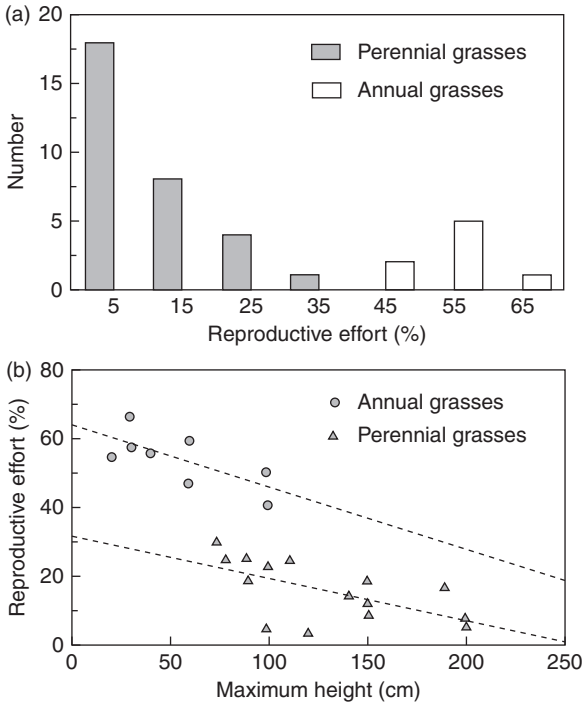

Fig. 3 Reproductive investment in annual versus perennial grasses. In general, life-history theory predicts a tradeoff between current and future reproduction. (a) A survey of 40 different species of British grasses found that reproductive effort in annual species was higher than for perennial grasses. (b) The relationship between plant size and reproductive effort also differed between annual and perennial species; annual species invest a larger portion of their energy in reproduction per year than perennial species. Fig. 4 The evolution of life span and mortality patterns. Linda Partridge and colleagues conducted artificial selection experiments on laboratory populations of *Drosophila melanogaster* (fruitflies). 'Young' lines of flies (filled circles and solid lines) were selected for early age at reproduction while 'old' lines of flies (open circles and dashed lines) were selected for late maturity. After 31 generations of selection, age-specific differences in mortality rates evolved. 'Old' lines exhibit lower mortality at intermediate ages demonstrating the evolution of mortality patterns and expected life span in response to selection. Reproduced from Partridge L, Prowse N, and Pignatelli P (1999). Another set of responses and correlated responses to selection on age at reproduction in *Drosophila melanogaster*. *Proceedings of the Royal Society of London series B* 266: 255–261, Fig. 3b with kind permission from The Royal Society of London.

span and the explanation of senescence itself remains an area of life-history evolution that is not fully understood. Some of the most promising research on life span and senescence has been conducted with artificial selection studies especially in *Drosophila melanogaster*. Linda Partridge and colleagues have shown that mortality patterns (and thus also life span) can evolve in response to differential selection on age at maturity (Fig. 4).

Investment Per Offspring and the Size/Number Tradeoff

A tradeoff between energetic effort per individual offspring and total offspring number is expected because resources are limiting for virtually every organism. Furthermore, an intuitive physiological constraint on maximum gonad or brood size exists for any body size. Larger eggs or offspring may have a higher per capita chance of survival or greater expected fitness later in life. Therefore, selection on offspring number and on offspring size is expected to determine the optimal effort per offspring in a given environment (Fig. 5).

The ornithologist David Lack approached this problem by assuming that as clutch size increases individual offspring survival must decrease, given that parents must feed or provision each offspring. He argued that the optimal clutch size in birds would depend on this tradeoff between offspring number and individual survival. To determine the 'Lack clutch', let N_e represent clutch size (or number of eggs laid), l_f the proportion of eggs surviving, and N_f the number of offspring that survive (or the number fledged). Imagine, however, that offspring survival decreases with clutch size such that $l_f = 1 - cN_e$. Then the expected number of surviving offspring (a proxy for individual fitness) is given by

$$N_f = l_f N_e = (1 - cN_e)N_e = N_e - cN_e^2$$

Using basic calculus, it can be shown that $N_e = 1/2c$ maximizes N_f (Fig. 6). Experiments manipulating clutch size in birds found that Lack's optimal clutch size could predict between species variation in clutch size qualitatively but that actual clutch sizes were often slightly lower than predicted. The primary explanation for this pattern has been that the tradeoff between current and future reproduction limits the optimal clutch size even further.

Sex Ratio and Sex Allocation

Another basic question in life-history theory is the relative allocation to sons or daughters in separate-sexed species and into male versus female gamete production in hermaphrodites. In general, most populations exhibit an equal primary sex ratio at birth (i.e., equal numbers of sons and daughters on average). In 1930, Fisher developed a model explaining this observation. If sons and daughters take an equal amount of energy to produce and every zygote is produced by the fusion of one male and female gamete, then it can be shown that sons have an advantage when males are rare and daughter have an advantage when females are rare. The evolutionary stable point occurs where on average individuals produce an equal number of sons and daughters at birth (Fig. 7). However, deviations from this classic expectation are observed. For example, studies in fig wasps (where females lay eggs in figs where offspring mate before leaving) have shown that females produce more daughters than sons when they are the only females laying eggs in a single fig (thus decreasing competition among their sons to fertilize their daughters). In addition, studies on red

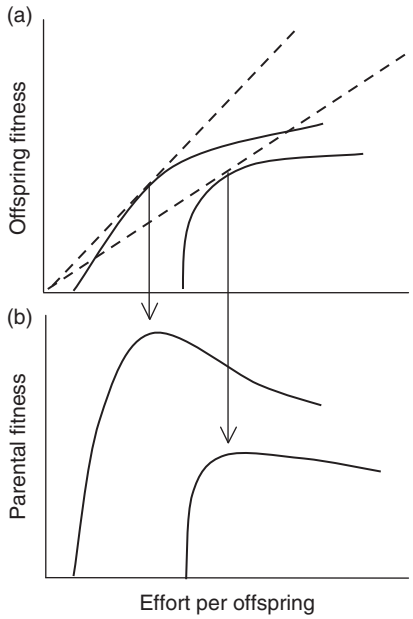

Fig. 5 A graphical model presented by Smith and Fretwell in 1974 that predicts the optimal tradeoff between offspring effort and offspring number for a given level of parental reproductive effort. (a) Offspring fitness for two environments. The model assumes offspring fitness is a convex function of parental effort. (b) Corresponding parental fitness for the two environments. Parental fitness is a function of offspring effort; the maximum occurs where the tangent of the curve in (a) intersects with zero. The shape of the curve in (b) is the product of the curve in (a) and by the shape of the tradeoff between offspring size and number (not shown). The model predicts a single optimal offspring size, set by the environment, that maximizes parental fitness, and that this size is 'less' than the size which maximizes offspring fitness. Much of the research on the offspring-size and -number tradeoff is rooted in these simple predictions.

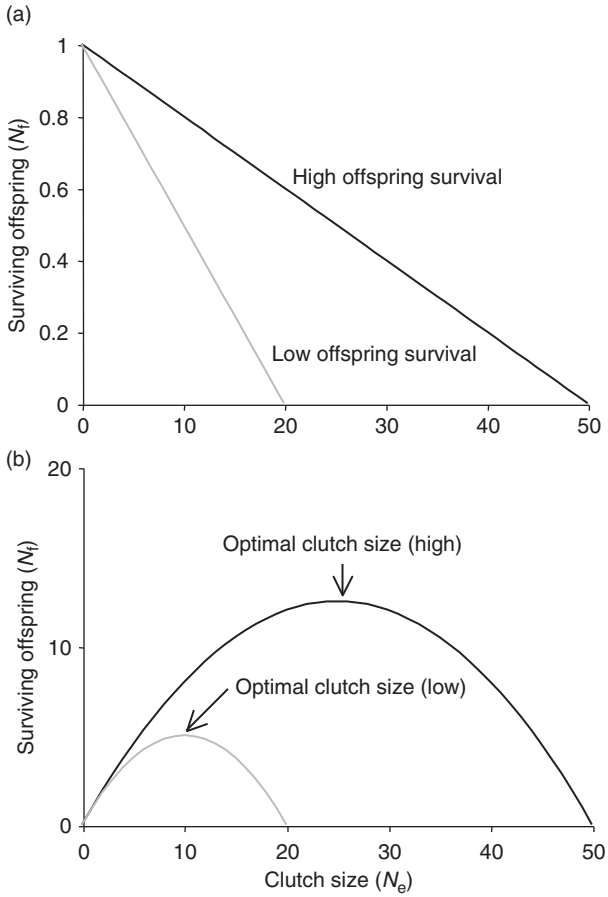

Fig. 6 Optimal clutch size. (a) Offspring survival as a function of clutch size for $c=0.02$ (high, black line) and $c=0.05$ (low, gray line). (b) Number of offspring fledged as a function of clutch size. Optimal clutch size is lower ($N_e=10$) for low offspring survival than for high offspring survival ($N_e=25$). For a description of the model and equations used see the text.

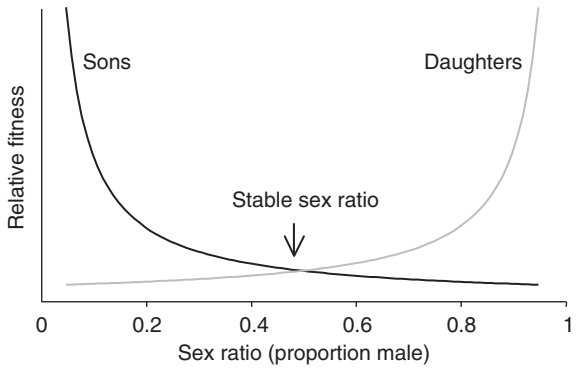

Fig. 7 Sex-allocation theory argues that the fitness of males and females is negatively frequency-dependent meaning that sons will have a fitness advantage when males are rare in the population while daughters will have greater relative fitness when females are rare in the population. The Fisherian evolutionary stable sex ratio is predicted to occur at a sex ratio of equal males and females (proportion male = 0.50).

deer have found that females in high condition are more likely to produce sons and females in poor condition are more likely to produce daughters. This pattern can be explained by the fact that daughters are able to produce offspring even if small, while small males from low-condition mothers tend to have no reproductive success (as a result of strong competition among males for access to females). Sex-allocation theory has also been able to explain the relative allocation to male and female gamete production in hermaphrodites (mainly in fish and plants) but has been less successful in explaining why any individual species is hermaphroditic instead of dioecious (separate-sexed).

Departures from Classic Theory

The power of life-history theory to predict observed patterns has been immense. Life-history models have been able to predict patterns of variation in traits such as age at maturity, number of offspring produced, life span, and the relative production of sons versus daughters. However, empirical support for predicted life-history patterns is sometimes equivocal. Phylogenetic history of a taxonomic group will often constrain the response to selection. For example, we would not expect to see an oak produce a single large acorn or a whale produce many tiny offspring. Furthermore, the detection of tradeoffs can be elusive, particularly in organisms with complex life-history traits (such as indeterminate growth, metamorphosis, or alternative reproductive tactics). In many cases, tradeoffs occur among a suite of life-history traits, which may become empirically intractable.

Environmental and genetic variation can also mask expected tradeoffs. In 1986, van Noordwijk and de Jong showed that variation in acquisition of resources will lead to undetected tradeoffs if that variation is greater than the variation in allocation. A common metaphor for this argument is the observation that people with big houses often drive expensive cars. We do not detect a tradeoff between size of house and size of car because variation in income in the population is so great. This idea has been largely successful in explaining deviations from expected life-history tradeoffs.

Future Directions

While life histories arise at the intersection of evolutionary and ecological dynamics, most of current life-history theory does not include ecological interactions (such as predator–prey or host–disease dynamics) and little empirical evidence exists examining the effect of life-history evolution on ecological interactions. Life-history theory must move from a dichotomous tradeoff approach to a more integrative concept of individual fitness in an ecological context. An understanding of how life-history patterns respond or do not respond to environmental change will be essential to species management and conservation in the future as will an understanding of how those life-history responses affect ecological- and ecosystem-level dynamics.

Limiting Factors and Liebig's Principle

K Mengel, Justus-Liebig-Universität Gießen, Pohlheim, Germany

Introduction

One of the most important resource for mankind is the fertile soil. Already in ancient times men knew that fertility is of utmost importance for living. The term fertility was associated with gods, the fertility of soils and animals including women. It was only in recent times due to the impact of modern philosophy, particularly the Enlightenment, men tried to explain fertility and also soil fertility in modern scientific terms. One of the first pioneers of this modern thinking was the French chemist Antoine Laurent de Lavoisier (1743–94). He carried out numerous field trials and came to the conclusion that the excrements of animals were the matter from which the humus was formed in soils and that the humus was the basis of soil fertility. It was shown that the incorporation of animal excrements into the soil improved crop yields. Based on these experiments the humus theory was formed which in the nineteenth century had a favorable impact on farming in France and Central Europe. Humus was considered as the nutrient of plants (humus theory). According to this theory animals would compete with men for fertile soils since animals were required for producing the matter by which soil fertility was maintained. This humus theory was accepted by farmers and had a favorable influence on farming in West and Central Europe.

Carl Sprengel (1787–1859), a German chemist at the beginning of the nineteenth century, analyzed plants and soils on their chemical elements and came to the conclusion that the actual plant nutrients were chemical elements. He disproved the humus theory.

Liebig's Principle

Justus Liebig (1803–73) carried out numerous analyses in plants and soils and he also came to the conclusion that plants feed from inorganic nutrients. According to his statement the first sources of plant nutrients are exclusively of inorganic nature. Liebig integrated his statement in a greater context as he speculated that plants in nature play a unique role in transferring chemical elements into organic plant matter. This organic matter when brought back into the soil is decomposed – in those days microbes were not yet known – and inorganic elements are released which again are taken up by plants as nutrients. To our knowledge Liebig was the first assuming a cyclic process in nature. According to this concept the limiting process of producing food for mankind was not the humus, and animals did not compete with man for arable land. He claimed that "the first sources of the plant nutrients are provided exclusively by inorganic nature" and he further wrote that "as the principle of agriculture must be seen that soils must receive in full measure what was taken from it." These were the inorganic plant nutrients and this was the start for producing and applying chemical fertilizers.

According to Liebig's concept, crop yield per hectare in Germany was increased by a factor of *c.* 3 in the last half of the nineteenth century. In addition, infertile soils, particularly sandy soils, were rendered fertile by the application of lime, phosphate, and potassium. This not only was the case in Germany but also in other European countries and in North America which applied Liebig's principle. Thus area and quality of soils limiting food production were increased.

In the beginning Liebig propagated that N fertilizer application was not necessary since according to his investigations ammonium N was taken up by plant leaves. This assumption contrasted with results of the French scientist Boussingault (1802–87) who according to his investigations held the view that fertilizing inorganic N was of great importance. Only later Liebig became convinced – particularly by the Rothamsted field trials – that inorganic nitrogen also should be fertilized. Liebig, however, immediately realized that the amount of potential inorganic fertilizer N, mainly guano, is limited and would run out quickly when farmers apply it in various countries. Liebig was interested when he heard that electrical discharges (lightning) oxidized the molecular nitrogen in the air and he speculated whether this could be a process by which nitrogen fertilizer could be produced. Liebig realized that nitrogen was a limiting factor in plant nutrition and he emphasized that farmers should carefully handle their farmyard manure and slurry thus avoiding N losses.

Liebig propagated the law of the minimum, originally going back on Carl Sprengel's idea that the limiting factor is controlling the crop yield. In the nineteenth century, nitrogen was limiting crop growth in many cases. Liebig's recommendation to fertilize soils with lime, phosphate, and potassium, however, had indirectly also a positive impact on soil nitrogen because lime, phosphate, and potassium are particularly required for the growth of leguminous species. The numerous attempts to grow clover mostly failed because soil pH was too low and potassium and phosphate were not available in sufficient quantities. These limiting factors were overcome by the application of lime, phosphate, and potassium, and leguminous crops thrived vigorously. These crop species living in symbiosis with N_2-fixing bacteria increased the level of available nitrogen in soils. Thus a further crop production limitation was overcome. This promoted farming enormously since farmers had more forage. They could feed their animals better and also increase the number of animals which produced more farmyard manure and slurry in the rotation which was brought back on fields and meadows.

In those days microbial dinitrogen fixation was not yet known until 1886. Liebig assumed that the broad leaves of leguminous species were able to absorb the ammonium from the atmosphere which actually is true but the quantities are too low for obtaining

satisfactory yields. Liebig recommended a rotation with two cereals followed by legumes or other dicotyledonous species (beets, potatoes). By this strategy infertile soils were rendered fertile and thus the area of fertile soils was enlarged. By increasing soil pH through liming, microbial activity also was promoted since most microbes require a neutral soil pH. Hence the decomposition of organic matter and thus the microbial production of ammonium and nitrate in soils was stimulated by which N nutrients are selectively taken up by plant roots. In addition, N_2 assimilation by free-living N_2 fixers and by microbes such as *Rhizobium* species living in symbiosis with higher plants profited from soil liming.

Synthetic Nitrogen Fertilizers

According to Liebig's principle, N supply of soils required leguminous crop species which not only supplied crops directly required for men but a substantial part of leguminous crops was required for animal forage. Hence men and animals competed for fertile soils. This situation changed drastically when the chemical production of N fertilizers was invented (Haber–Bosch technique). Now farming was possible without animals, which was the preposition for the separation of crop farming from animal farming. This had an enormous impact on the economics of farming and a disastrous one on ecology. In many animal farming systems land is overdressed with farmyard manure or slurry. In the Netherlands, the average surplus of mineral N, mainly nitrate, for all dairy farms is in the range of 200–400 kg N ha^{-1}. This quantity of plant-available N would suffice to produce 6000–12 000 kg wheat grain per ha per year. This surplus of N leads to an enormous nitrate leaching with a risk for the groundwater and also for denitrification by which N_2O, a greenhouse gas, is produced.

Australian sheep farmers did not follow Liebig's recommendation as they did not lime their pastures. Consequently, during a period of 50 years, soil pH gradually decreased from about 6 to 4.8. At this low pH, soluble and exchangeable Al and Mn oxides/hydroxides are formed which are toxic to plant roots, particularly to leguminous species and affect their growth, particularly that of *Trifolium subterraneum* which is the most important symbiotic N_2 fixer in Australian pastures. Thus the soils were rendered infertile. By this one of the most important worldwide resource, limiting resource, the fertile soil, is diminished. There are other soil processes which are less spectacular but still have a serious impact on soil fertility.

Potassium is an indispensable plant nutrient. In addition, it is indispensable in most fertile soils as an essential element of the structure of 2:1 clay minerals. Tributh *et al.* found that cropping fertile soils containing 2:1 clay minerals without K fertilizer application lose gradually their fertility because plant roots take up K^+ from the 2:1 silicate structure and thus finally destroy the mineral structure which means a loss of fertility. These minerals are capable to store K^+ and NH_4^+ and protect these important plant nutrients against leaching. Plant roots feed from thus-bound K^+ and NH_4^+. The nutrients thus taken up by the crop must be replenished by fertilizer application in order to maintain soil fertility as according to Liebig's principle what was taken from the soil should be given back. This degradation of a 'fertility mechanism' is a slow but irreversible process which renders eventually fertile soils infertile.

Worldwide Effects

For livestock farms the area of grassland and arable land has no major meaning if cheap imported concentrates, mainly soya, are available. This leads to serious environmental problems as already discussed above for intensive dairy farms. A great proportion of soya used for animal feeding is imported from Brasilia by European countries. In Brasilia large areas of the tropical forest are cut and the land is mainly used for the cultivation of soya. Under the tropical climate conditions, however, the humus of these soils is quickly oxidized and then soils are exposed to water and wind erosion and become irreversibly infertile within a few decades.

The surplus of nitrate in soils of Dutch farmers means also an accumulation of phosphate in soils as the animal excrements contain a substantial amount of phosphate. The latter, however, is a limiting resource which will be exhausted in a few centuries if mined with the actual rate. Therefore farmers should fertilize their soils according to soil analysis on available P. The same is true for N as a surplus of fertilizer N is not only an environmental hazard but also a waste of fossil energy required for the N fertilizer production. The production of NH_3 is associated with the release of CO_2. Precise N fertilizer rates based on soil analyses which take into account the inorganic soil N and a part of the organic N in the upper soil layer are highly profitable for farmers as recently shown by Mengel *et al.* Not considering the organic soil N leads to an overfertilization with N fertilizer with a disastrous impact on the environment.

Fresh water

In most countries where irrigation is applied, irrigation constitutes a major part of freshwater consumption. The efficiency of irrigation (percentage of water taken up by crops and total water applied) ranges between 50% and 90%, depending to a large extent on the type of irrigation. With drip irrigation, where the water drips through plastic types to individual plants, the irrigation efficiency is in the range of 90% whereas in furrow irrigation it is about 50%. The problem is not only the consumption of water but also the quantities of salt brought on the field with the water under arid conditions which finally results in soil salinity and thus soils become infertile. Already in ancient times, in North Africa and the Euphrates/Tigris lowlands, large areas became saline through irrigation and

went out of crop production. The drip irrigation cannot be applied to small crops such as cereals. These crops, however, are grown on a large area. Recently a new subsoil irrigation system was described which is based on irrigation techniques from ancient Persia. The clay types used are imbedded into the soil and have a porous structure which releases water into the soil according to the water requirement of plants. The moist zone around the pipe does not reach the soil surface. Hence no evaporation of water occurs and the risk of soil salinization is reduced to a minimum. The water-use efficiency (kg wheat grain/m^3 irrigation water) of the furrow irrigation system was on average 85 and for the subsoil irrigation 250.

High Na^+ concentration in soils affects soil structure and the uptake of other cationic species, particularly K^+. Hence plants suffer from K deficiency which particularly depresses protein synthesis and thus growth. Field experiments carried out under arid conditions in Turkey showed that the negative effect of saline water on the leaf growth of satsuma mandarins was efficiently counteracted by high K fertilizer rates.

Macroevolution

M Shpak, University of Texas at El Paso, El Paso, TX, USA

The term 'macroevolution' refers, broadly speaking, to evolutionary changes above the species level. The term can be used to refer to phenomena such as the origin of morphological (or biochemical) novelty, the origin and subsequent diversity dynamics of higher taxa due to changes in origination or extinction rates, and the role of regulatory genes and developmental constraints on the nature and rate of morphological change within and between clades.

There have been two schools of thought on the nature of macroevolution. While nearly all biologists recognize macroevolutionary phenomena as real patterns observable in the fossil record and from the reconstruction of phylogenies, it has been debated from the time of Darwin and the rediscovery of Mendel's laws whether the microevolutionary processes at the population level extrapolated over time account for all macroevolutionary patterns, or whether there are special evolutionary mechanisms, fundamentally different from those acting within species and populations, responsible for the major events in the history of higher taxa.

Historically, this debate has taken several forms since the resurrection of Mendelism in the early twentieth century. The first was the conflict between the 'gradualist' Darwinian school and the 'mutationist' school represented by geneticists such as H. de Vries and later R. Goldschmidt. While the work of R. A. Fisher reconciled the alleged conflict between Mendelian genetics and the quantitative traits studied by the biometricians, it left open the debate of whether the most important traits in evolution were polygenic quantitative traits (nearly normally distributed due to the small effects of many genes) or discrete traits under the control of small numbers of genes. The macromutationist view emphasized the importance of mutations with large effects for the origin of the type of evolutionary novelties that define higher taxa and allow organisms to invade new regions of ecospace, limiting the importance of gradual Darwinian adaptation to phenomena at the intraspecific population level.

Since that time, 'mutationism' in the form advocated by de Vries and Goldschmidt has fallen into disrepute due to the simple empirical observation that almost every observed macromutation severely reduces the fitness of an organism, while potentially beneficial macromutations are sufficiently rare to be of limited evolutionary importance. Nevertheless, the spirit of mutationist thinking, which emphasizes the importance of rare, drastic changes in phenotype and the importance of internal genetic and developmental factors rather than molding by selection, lives on as an active source of debate.

Neo-Darwinism and the 'New Synthesis' Paradigm

The groundwork of classical population genetics theory by Fisher, Wright, Haldane, and others formulated in mathematical language the forces underlying microevolution – mutation, natural selection, genetic drift, assortative mating, and migration. With later contributions, the theory would also incorporate the genetics of recombination and linkage, as well as the selective dynamics of frequency dependence and other complicating processes.

The question that remained to be answered was whether this impressive body of theory could account for all the phenomena of interest to evolutionary biologists. In terms of explaining the patterns of variation and rates of change in heritable traits within populations, microevolutionary theory made enormous headway. In the modeling and prediction of adaptive intraspecific change and variation, Neo-Darwinian theory was certainly a triumph and to this day is the foundation for active research programs directed toward explaining the enormous amount of information about intraspecific genetic variation at the molecular level that has recently become available.

Where traditional population genetic models were (at least initially) found wanting was in describing the origin of species and higher taxa. The first question, that of speciation, was reconciled with population genetics theory at a qualitative level in the writings of the 'new synthesis', most significantly in the writings of the new synthesis, most significantly in the work of T. Dobzhansky. More recently, the mechanisms of both allopatric and sympatric speciation have been given a firm mathematical foundation, one which represents the complicated interactions between assortative mating, migration, and frequency-dependent selection on phenotypic traits.

While the importance of allopatric versus sympatric speciation was broadly debated and the importance of genetic drift versus adaptation in species formation was a source of contention, it was widely recognized that the mechanisms driving speciation were entirely consistent with the processes of natural selection, assortative mating, and genetic drift in classical population genetics theory. Speciation could basically be understood as the origin of pre- or postzygotic isolating mechanisms through the standard processes of microevolution. Consequently, in the Neo-Darwinian worldview, speciation is a special case of microevolutionary change, and higher taxa are defined by the phenotypic changes associated with the origin of their ancestral species (i.e., since all monophyletic higher taxa begin as single species and the morphological or molecular traits that define that higher taxon originated in the 'stem' species of the clade).

Nevertheless, speciation introduces a new dimension into the evolutionary process. Since the local adaptive evolution during the history of an ancestral species can potentially be decoupled from the changes that take place during speciation (particularly in peripatric speciation where the incipient species consists of a small, isolated subpopulation separated from the ancestor), some of

 doi:10.1016/B978-0-444-63768-0.00806-4

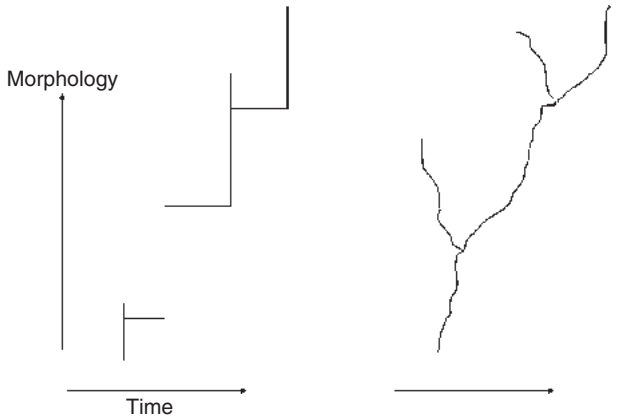

Fig. 1 A schematic illustrating the assumptions of how morphology changes through time under punctuated equilibrium (left) versus phyletic gradualism (right). In the former, most change in morphology is concentrated at speciation events; in the latter, speciation is a split in a lineage whose morphology has been evolving continuously.

the most visible recent challenges to the Neo-Darwinian worldview have focused on temporal patterns of speciation and cladogenesis in the fossil record.

Punctuated Equilibrium

It has long been observed in the fossil record that discontinuities between proposed ancestor and descendant species (and between closely related higher taxa) are quite prevalent. Paleontologists, following Darwin's own treatment of the subject, had traditionally assumed that this was due to the incompleteness of the fossil record itself.

Taking into consideration the implications of the peripatric model of speciation, S. J. Gould and N. Eldredge proposed that the observed discontinuities are often not an artifact of gaps in the stratigraphic record, but rather reflect the logical consequences of a supposedly prevalent mode of speciation. If most new species arise from small peripheral isolates rather than through a gradual transformation of a large population, then the change from ancestral to descendant morphology can be independent of the adaptive trends within the mainstream of the ancestral species' population. Furthermore, because the speciation event will involve a comparatively small marginal subpopulation, the transition is unlikely to be captured in the fossil record. What one observes instead is an ancestral species with either a static morphology, or a history characterized by random changes in phenotype unrelated to the differences between it and its descendant form. The phenomenon, combined by the subsequent sudden appearance of the descendant species, was referred to as 'punctuated equilibrium' by Eldredge and Gould.

As an empirical observation, punctuated equilibrium has been supported by a number of examples in the fossil record, although cases of phyletic gradualism (gradual transformative phenotypic evolution, as contrasted in Fig. 1) from one recognized morphology-defined species to another have also been documented in many fossil taxa.

The question remains whether this empirical observation constitutes a new model for evolutionary change inconsistent with population genetics theory. Following the arguments of C. H. Waddington on canalization and genetic assimilation, Eldredge and Gould postulated that the long periods of stasis reflect internal developmental homeostasis while the punctuations suggest a breaking of normally canalized development. Punctuated equilibrium proponents also argue that because of the supposed importance of non- or counteradaptive changes due to genetic drift during speciation (so-called 'founder flush' speciation leading to 'genetic revolutions'), the fact that most long-term trends in a lineage are due to speciation processes rather than a clade's history would imply that adaptation plays a limited role in macroevolutionary trends.

While acknowledging the empirical reality of punctuation in the fossil record, many population genetics theorists have convincingly argued that the punctuated equilibrium pattern does not require any exotic, hitherto-unknown processes in genetics or development. Though perhaps a small number of paleontologists and stratigraphers may have naively assumed that Darwinian evolution requires gradual, constant-rate changes through time, there is nothing in the Neo-Darwinian paradigm or population genetics theory that requires this to be the case, making the notion of a constant rate of evolution a kind of straw man.

During their history, populations can be subject to conflicting selective pressures. A relatively stable environment (or an ability to track a changing environment by changes in distribution) imposes stabilizing selection and hence stasis on phenotype, while the selective pressures that drive speciation generally involve directional selection on isolates or disruptive selection during sympatry. Indeed, the very nature of species as self-contained gene pools imposes stasis as a default and speciation as a comparatively infrequent phenomenon. Counter to the claim that evolutionary trends are nonadaptive because speciation is nonadaptive, speciation due to genetic drift alone has been demonstrated to be improbable and at best a rare event from both theoretical and empirical considerations. The evolutionary changes that lead to allopatric and sympatric speciation alike are generally driven by natural or sexual selection, with genetic drift usually (though not necessarily) playing a confounding role.

Thus the mechanisms involved in speciation, allopatric or otherwise, do not demand 'genetic revolutions' (for which there is no real empirical evidence) or any assumptions about developmental constraints, so as such the phenomenon of punctuated equilibrium does not require an explanation beyond what standard evolutionary theory already provided. In fact, a number of the original proponents of the 'strong' form of punctuated equilibrium, such as Eldredge himself, have in recent writings shown favor of this more conventional, Neo-Darwinian understanding of stasis and punctuation.

Nevertheless, the discussion of punctuated equilibrium and the distinction between 'phyletic' and 'cladogenetic' evolutionary change did lead to an evolutionary model that could not be so readily reconciled with Neo-Darwinism: the notion that species, and possibly higher taxa as well, are themselves units of selection and evolution.

Species Selection

Implicit in the work of Eldredge and Gould's original papers and explicit in S. M. Stanley's treatment of the subject is the connection of punctuated equilibrium with the concept of 'species selection'. The basic argument is that just like genes and individual organisms, species can reproduce (through speciation) and exhibit heritable variation (i.e., covariance between ancestral and descendant species traits). The basic idea is that certain traits relating to dispersal ability, tendencies toward habitat specificity, etc., predispose some taxa to have high rates of speciation, while other taxa have ecological or behavioral traits that make speciation infrequent.

From this perspective, the reason some clades have been species rich throughout their history and others species poor is not due to members of one clade having traits that lead to higher Darwinian fitness at the individual or population level, but rather because the species-rich clade consists of species that themselves are likely to speciate at an enhanced rate. At some level, the argument has intuitive appeal – it makes little sense to argue that individuals from species-rare 'living fossils' such as horseshoe crabs are 'unfit' when compared to individuals from, for example, species-rich beetles. It is more likely that there is something about the ecology of phytophagous insects that makes them speciate at higher rates than generalist benthic marine invertebrates. D. Jablonski and other paleontologists have proposed that generalist or eurytopic taxa will tend to be less species rich than specialist or stenotopic taxa. Specific habitat requirements tend to lead to strong competitive exclusion and character displacement, low rates of gene flow, and consequently high rates of speciation rates in specialists relative to generalists. It could also be argued that many observed long-term evolutionary trends, such as the increase in average body size observed in many lineages, occur not because of strong selection for the trait in question during the history of individual species or during speciation, but because taxa with the trait in question simply speciate at a higher rate.

Species selection has certainly been demonstrated to be a theoretical possibility based on the fact that any kind of heritable variation can be selected. However, species selection as a major force in evolution runs into the same problems as group or interdemic selection: the generation time of individual organisms is usually several orders of magnitude shorter than the 'generation time' for species. The former is generally on the scale of months or years, the latter on the scale of hundreds of thousands if not millions of years. The very argument that suggests species selection as a theoretical possibility, namely a decomposition of heritable variation into components following Price's equation, is what makes it of limited scope in practice. Specifically, rapid natural selection at the intraspecific level eliminates variance in trait at the interspecific level before higher-level selection can act.

Consequently, if a certain trait in an organism leads to a higher propensity to speciation, but is selected against among individuals in a population, then the trait in question will generally be lost prior to any speciation events. In recent studies, such as those of Sean Rice, it has been shown that under conditions when individual generation times are very long and speciation rates are very high, species selection can run counter to intraspecific selection, but these circumstances are probably exceptional.

Realistically, species selection may be important for traits that are on average neutral at the individual and genic (intraspecific) level. The possibility of species selection being important in such neutral traits remains an interesting empirical question, albeit one that is difficult to answer because in many cases it is impossible to disentangle the history of selection on a trait from its fossil or phylogenetic history.

Mass Extinction and Other Challenges from the Fossil Record

A number of other challenges to the view that macroevolution was simply extrapolated microevolutionary change have come from paleontology. While the process of speciation and its genetic explanation forge a strong conceptual link between microevolution and many of the morphological changes observed in fossil lineages, there are a number of events in the history of life that seem so striking and catastrophic that certainly no population genetic models, even with fluctuating selection intensity or strong frequency dependence, can account for them.

The first such case is that of mass extinction. It has been known since the inception of geology as a field of scientific inquiry that the major periods in geological time are defined stratigraphically by complexes of fossil organisms that are distinct from those in higher or lower strata. These complexes can be defined over many timescales, with eras being subdivided into periods and periods being subdivided into lower units still, most of which are defined by the presences or absences of characteristic flaural and faunal assemblages. One reason that such boundaries defined by distinct sets of organisms exist is that the history of life has been defined by catastrophic mass extinction events.

For example, it has been estimated that the mass extinction at the Permian–Triassic boundary was responsible for the extinction of nearly 97% of marine invertebrate species (~85% of genera) and strongly impacted terrestrial plants, insects, and vertebrates as well. The extinction at the Cretaceous–Tertiary boundary took a somewhat smaller but still catastrophic toll of *c.* 50% of marine invertebrate genera, as well as (famously) leading to the extinction of the dinosaurs and many other terrestrial animals and plants. Other significant mass extinctions characterized the Late Devonian and the Late Triassic, with lesser ones defining other stratigraphic boundaries. In the 1980s, D. Raup and J. J. Sepkoski argued from surveys of various fossil taxa that mass extinctions are periodic, on ~26-million-year cycles. Since then the notion has been attacked both on statistical grounds (i.e., a frequent lack of resolution of dating below 5-million-year intervals) and on the basis that no single geophysical cause accounts for all or even most mass extinctions.

While much debate surrounds the causes of mass extinctions, it appears that no one causal explanation can account for the half dozen or so documented mass dyings. Based on evidence of elevated iridium levels in the boundary strata, it is likely a comet impact that was responsible for the K–T boundary extinctions. On the other hand, there is little evidence that extraterrestrial impacts had anything to do with the much greater P–T extinction, which may have been driven by drastic changes in sea level, volcanism, and changes in methane and carbon dioxide levels in both terrestrial and marine environments. The earliest documented mass extinction, one in the Late Proterozoic (the Varangian ice age of *c.* 850 million years ago), which hit unicellular eukaryotes in the such as acritarchs, may have been the most catastrophic of all, as some geologists believe that it was caused by a severe and global cooling event ('snowball Earth') that froze most of the oceans and nearly wiped out all living organisms apart from those sustained near volcanic vents and similar warm refugia.

Regardless of specific causes, it is clear that such massive, sudden extinctions of species cannot be modeled meaningfully at the microevolutionary level, and what lineages persist versus which ones become extinct can be arguable due to matters of chance rather than matters of adaptation or fitness. It seems to be the case that specialist taxa are more vulnerable than generalist taxa, which again is a statement of 'selection' properties above the species level, one that introduces an intrinsically biological, rather than simply extrinsic, explanation for the outcomes of mass extinctions.

Whether ecological catastrophes caused by abiotic events can be considered evolutionary processes as such is a matter of semantics, but it is clear that to address questions such as 'why are brachiopods prevalent in the Paleozoic while bivalve mollusks are prevalent in the Mesozoic and Paleozoic?' or 'why are there no living trilobites or ammonites?' arguments based on superior or inferior Darwinian fitness are not the most meaningful way to seek answers. For such questions, an understanding of geology and random mass extinction is probably more informative than an understanding of Darwinian fitness in Mendelian populations.

But what of the other aspect of biostratigraphy? Geological boundaries are defined not only by the extinction of groups of taxa, but by the relatively sudden origin of many others. The extinction of large amphibians and pelycosaurs in the Permian was followed by a dinosaur radiation in the Mesozoic, just as the extinction of dinosaurs was followed by a radiation of mammals in the Cenozoic. The history of life contains many even more spectacular 'adaptive radiations' – the most dramatic being the Cambrian explosion, which was characterized by the rapid appearance of most of the major metazoan phyla in the Early Cambrian after the near absence of any but the most basal invertebrate taxa in the latest Proterozoic.

As with mass extinctions, such rapid evolutionary radiations are often due to major environmental changes (biotic or abiotic) in Earth history. For example, among the many competing explanations for the Cambrian explosion, one of the leading hypotheses involves the likely increase in atmospheric free oxygen in the Late Proterozoic. Other major radiations are to a large part due to the ecological niches vacated by the mass extinction of competing taxa; for example, large Cenozoic mammals filled niches once occupied by dinosaurs.

The issue of whether adaptive radiations are due to processes outside the scope of classical Neo-Darwinism is a question having two facets. The first is whether the phenomenon of high rates of speciation and adaptive evolution can be explained through classic Neo-Darwinian (population genetic) models; the second is whether the extensive changes in morphology characterizing the origin of higher taxa (as in the Cambrian explosion) require special genetic or developmental explanations.

Adaptive Radiations

The seemingly accelerated rates of evolution that occur in adaptive radiations have long been recognized by biologists and paleontologists. G. G. Simpson, who did much to reconcile paleontological data with Neo-Darwinian notions of adaptive change and speciation, referred to the phenomenon as 'quantum evolution', to distinguish it from the 'background' processes of adaptation and speciation that characterize most of a lineage's history. However, Simpson emphasized that quantum evolution did not entail any novel evolutionary mechanism. Rather, he saw the process as a consequence of the fact that external circumstances (such as a vacated ecological niche) imposed much stronger diversifying selection than that encountered by most taxa during their normative history.

That adaptive radiations can be seen as adaptation and speciation under special external circumstances has support from classical population genetics theory. In an important early paper, R. A. Fisher demonstrated that mutations with large fitness consequences have a higher probability of fixation early in the history of a species, with adaptive change having 'diminishing returns' as time progressed. This is the basic pattern with many evolutionary radiations – large-scale differences are established first, followed by lower-level changes later in the history of a lineage.

The basic argument is that if the space of possible changes in phenotype is represented in a multidimensional Cartesian coordinate system. In this multidimensional space, an ancestral genotype is some distance from an optimum. At first, mutations

with large phenotypic effects have a high probability of moving the population closer to the optimum and increasing mean fitness. However, as the population approaches the optimum, mutations with large phenotype effects are more likely to move the population further from the optimum and reduce fitness, so that only mutations with small effects have a high probability of fixation and increasing mean fitness. While the details of Fisher's analysis have been disputed, this general result has been vindicated in a number of recent papers. A related argument, based on the declining probability of moving to higher adaptive 'peaks' on a fitness landscape with multiple local optima, was advanced by S. Kauffman and other 'complexity' theorists.

The same principles that apply to tracking optima with intraspecific variation are applicable to differences between species. In the case of an ancestral species encountering a large number of open niches, each new niche colonized represents a large distance to be reached in genotype and phenotype space. Since there are many such niches, initially mutations with large-scale phenotypic effects are likely to be favored because they are likely to take the genotype to a better evolutionary place. Afterward, when at the 'coarse-grained' level the descendant lineages have occupied the new niches, mutations with large effects are more likely to move them into regions of inferior fitness. At that point, mutations with small phenotypic effects are likely to be fixed as the populations optimize their fitness within the new niche (i.e., the type of 'fine-grained' adaptation that constitutes normal adaptive evolution).

This dynamics has been observed in a number of computer simulations of adaptive evolution, and is consistent with the observed pattern in the phylogenies of many higher taxa where the deeper nodes define major changes in phenotype associated with colonizing new regions of ecological space, while the differences among lower-level taxa (e.g., interspecific differences within a genus) usually involve relatively minor differences in morphology and ecology.

In other words, adaptive radiations reflect adaptive evolution and speciation on fitness landscapes that are intrinsically coarser grained than those typically encountered by most evolving lineages. However, while such a perspective accounts for the types of adaptive radiations typically discussed in the literature (e.g., differences in trophic modes and coloration in African lake cichlids, beak morphology in finches on the Galapagos, etc.), it still leaves unanswered the other aspect of evolutionary radiations seen in the early fossil record – the origin of truly novel morphologies.

Evolutionary Novelty and Innovation

It has often been argued that the differences in morphology seen in the Cambrian explosion seem more 'fundamental' than the differences in body shape and color seen in recent adaptive radiations because of a retrospective fallacy, that is, we define certain characters as more fundamental simply because they are older. While this may be true for certain characters (e.g., traits that define higher taxa in some groups vary intraspecifically in others), it is hard to escape from the view that the presence or absence of a coelom, body segments, and limbs reflect greater and more fundamental differences in genetics, development, and ecology than the shape of a finch's beak or a cichlid's teeth. Therefore, evolutionists are left with the very real question of why certain periods in the history of life are characterized by major novelties in morphology and modes of life.

It was because of this question that macromutationism and Goldschmidt's "hopeful monsters" had such appeal. The theoretical edifice of Neo-Darwinism, population and quantitative genetics, assumed a fixed space defined by preexisting quantitative traits and loci. The theory of mutation, selection, and genetic drift described the dynamics of populations in this space, but had little to say about how the space itself changes through the addition of new genes and new characters.

The first steps toward ameliorating the lack of a theory of evolutionary novelty came from work on gene duplication, which looked at the origin of new genes rather than allelic variation at existing loci. The mathematical structure of gene duplication models and general representations of novel characters is quite different from the representations used in classical population and quantitative genetics, and recent progress has been made in defining the properties of 'evolutionary space' where the number of dimensions (characters, as opposed to states of a fixed number of characters) is itself fluid.

However, because the mathematical language of Neo-Darwinism was incomplete from the standpoint of describing evolutionary novelty, this does not imply that the biological mechanisms involved in morphological and genetic innovations are unknown and outside the scope of genetics. In a sense, the problem is analogous to the state of speciation theory in the first half of the twentieth century – while speciation (and evolutionary novelty) may not required any novel genetic or evolutionary mechanisms as explainations, the existing paradigm failed to incorporate these phenomena, because in the first case classical population genetics did not ask questions about the origin of isolating mechanisms, and in the second case it did not ask questions about how to represent the loss or gain of traits in the traditional framework.

As to the underlying mechanisms involved in the origin of evolutionary novelty, most of the current explanations focus on two classes of genetic phenomena: gene duplication and developmental regulatory genes. In the former case, the duplication of a gene through various means (such as unequal crossover or gene conversion) creates genetic redundancy that at least in principle permits one copy to take on novel functions while the duplicate maintains its original function. This allows for the origin of novelty without counteradaptive macromutational changes. A noteworthy and familiar example is the globin gene family in vertebrates, where gene duplication has allowed these oxygen-carrying molecules to evolve specialized functions such as fetal hemoglobin in mammals.

The other main empirical contribution to the understanding of evolutionary novelty is the discovery of regulatory genes (such as Hox genes in animals) that control the activation and timing of downstream regulatory cascades. Such genes have the property that a single locus mutation can have drastic phenotypic consequences. The evolution of Hox and other regulatory genes is also full of examples where one regulatory gene co-opts the function of others or is recruited in an entirely new function.

While many mutations in such regulatory genes are deleterious if not outright lethal, a number of experimentally induced Hox mutations in *Drosophila* and other laboratory animals have produced morphological variants (such as additional pairs of wings in normally two-winged flies, or limbs in place of antennae) that resemble the morphologies of distantly related taxa. For example, it is likely that the small amount of overall genetic difference between humans and great apes, which is observed in spite of the great morphological and behavioral differences, is quite typical of macroevolutionary changes in morphology. Specifically, mutations in a small number of regulatory genes lead to significant phenotypic divergence, including the losses of key traits such as appendages, change in their position, and sometimes even the seemingly *de novo* acquisition of traits.

Consequently, just as adaptive radiations can be seen as a special case of speciation and adaptive evolution under certain fitness landscapes, so large-scale changes in phenotype can be seen as special case of mutation and selection in regulatory genes.

Concluding Remarks

Much of the debate between the sufficiency of microevolutionary mechanisms to account for macroevolutionary phenomena stems from looking at problems at different spatial or temporal scales. By analogy, while nobody doubts that macroeconomic phenomena ultimately arise as a consequence of individual decision-making processes, nobody argues that macroeconomic phenomena are not real and that large-scale human institutions have emergent properties that can be studied and understood in their own right. In the same way, biological phenomena are 'real' and need not be reduced to physics and chemistry to be understood, even though no biological processes contradict the laws of chemistry or physics. In fact, it is often more instructive to study biological phenomena at their own scale and level of organization than by reducing them to the underlying physicochemical interactions.

By analogy, although most if not all patterns of interest of macroevolutionists (apart from catastrophic environmental changes that are more questions of geology than of biology) have their origins in the genetics and variational properties of ancestral species, this does not imply that problems such as the invasion of new ecological niches, or the distribution of characters in phylogenies, are best understood by studying population genetics. It simply means that these phenomena are not in violation of microevolutionary processes, and do not require the discovery of previously unknown mechanisms any more than the emergent properties of living organisms violate the laws of chemistry and physics.

Along similar lines, changes in regulatory genes that have major effects on phenotype differ quantitatively and qualitatively from those genes that have minor effects on size or color within species, yet it would be difficult to justify the claim that such major changes in phenotype are caused by fundamentally different processes at the molecular level than those that lead to the more typical material of intraspecific variation. Yet even though such variants are subject to the same underlying population biology and the same forces of natural selection, one can probably learn more about these processes through an understanding of developmental genetics than from population genetics theory. One must distinguish the claim that macroevolutionary phenomena do not contradict microevolutionary (almost certainly the case) from the claim that macroevolutionary events are simply epiphenomena of the former, which is harder to justify given the qualitative differences in time and scope.

Metacommunities☆

Marcel Holyoak, University of California, Davis, CA, United States

Glossary

Competition-colonization tradeoffs Occur when within a community or metacommunity the competitive ability (or rank) are negatively related to the dispersal ability of species. With either local disturbances that open up vacant habitat or through simple birth and death events opening up spaces within communities, species can then persist locally either by being good competitors or regionally by being good at dispersing to vacant habitat.

Lottery competition Is when individuals compete for the occupancy of sites or places within a community. The winner of competition is random with respect to individual and species identity.

Mass effect Represents a flux of individuals from a large community to a small community. Analogous to gravity larger bodies exert more effect than smaller bodies, and so larger communities contain more individuals summed across species and these are likely to spillover into smaller communities and enhance abundance, and potentially species richness.

Phylogenetic dispersion Represents the degree to which taxa within a community are clustered versus dispersed in their degree of relatedness. Filtering by the local environment would produce clustered communities, whereas competition between species would produce dispersed communities.

Rescue effect Is when individuals immigrate into a small population and augment abundance, thereby forestalling extinction of the small population.

Source-sink dynamic A flux from populations in a high quality (source) habitat to a poor quality (sink) habitat, which allows populations in the source habitat to persist. Rescue effects prevent extinction of the source population.

Spatial subsidy An ecosystem concept representing the movement of materials or individuals from one ecosystem to another. It includes dead organisms, sediments, and living organisms that bring energy, chemicals and nutrients from one system to another.

Introduction

A metacommunity is defined as a group of communities that are connected by the dispersal of one or more interacting species. The term was first used in 1991 and since then has grown into an important concept for studies of species diversity and community structure. The concept enlarges the scale at which community dynamics are considered. Metacommunities have several distinctions that make them a valuable unit for consideration in both theoretical and applied ecology, such as in considering the effects of habitat fragmentation on biodiversity and ecological communities.

First, traditional community ecology often relies on the assumption that communities are closed, isolated entities. This assumption arises from consideration of mathematical models such as the Lotka and Voterra competition equations, which are simpler if the community is assumed to be closed to movement. By contrast, theories like source and sink dynamics propose that immigration allows some species to be present even in sink habitats where conditions are insufficient to support viable populations in the absence of immigration, either due to low resources or the presence of predators or competitors. Therefore opening communities to immigration may change the species present in local communities, such that the conditions assumed in closed models do not apply to open communities. Movement of individuals might also modify species interactions and the local dynamics of individual species. It is widely acknowledged that numbers of individuals moving and the distances they move are some of the most difficult parameters to measure in ecology, and therefore our knowledge of the degree to which real communities are open or closed is limited. Robert Ricklefs argues that the concept of a local community is invalid, with assemblages being little more than a representation of the overlapping distributions of various species and the result of the interactions between them.

Second, the responses of species diversity to habitat change including partial destruction and fragmentation may arise either because of the responses of individual species or because species influence one-another. Hence mechanisms may arise at levels of populations, metapopulations, communities, and metacommunities. If we consider only some of these levels we will have at best an incomplete idea of the effects of habitat change.

Third, it is useful to recognize that regional metacommunity-level species diversity is determined by the sum of both local and regional processes. The local and regional parts merit elaboration. The local contribution to species diversity includes the structure

☆*Change History*: March 2018. M. Holyoak added a new Figure 2, Glossary, and new section "Combining Functional Traits and Phylogenetic Information with Species Composition Patterns". He updated the evidence for different kinds of metacommunity dynamics and made minor edits throughout the text.

This is an update of M. Holyoak and T.M. Mata, Metacommunities, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2313–2318.

 doi:10.1016/B978-0-12-409548-9.11114-5

of the local community, ideas that are recognized by traditional community ecology including niche theory. A variety of regional processes are possible: (1) there may be a balance between the extinction of species from local communities and their (re) colonization, creating a balance that allows species to persist regionally even if they do not have a predictable place in any given local community. Such dynamics may be rendered more likely if there are tradeoffs in the abilities of species to colonize new or vacant habitat and their ability to compete locally. (2) Immigration may forestall extinction from local communities, as in source and sink models and through so-called rescue effects where immigration raises population size and rescues local populations from extinction. (3) Differences in habitat type among local communities might create different niches for different species. (4) The potential for (1) to (3) may depend on the degree to which dynamics are independent (or asynchronous) in different local communities. There is also the possibility that immigration and emigration modify either the richness and composition of the community or the interactions of species within that community, which represent an interaction between local and regional processes. Although two spatial scales are recognized, local and regional, this is arbitrary and more spatial scales are often represented in metacommunity models. The feedback between local and regional scales differs sharply from the equilibrium theory of island biogeography, where species diversity is viewed as being fixed by a permanent mainland pool of species and individual habitat islands contain arbitrary subsets of this species pool.

Fourth, interaction among species means that the metacommunity is not simply a collection of metapopulations where species are largely independent from one-another. Single species, or those independent from others in communities, and pairs of interacting species have typically been considered in the literature about metapopulations. Whereas, larger numbers of species are increasingly considered to be the domain of metacommunity theory. Many-species spatial competition models were not originally termed metacommunity models but best fit this categorization. Ideas such as keystone species recognize that, relative to their abundance or biomass, some species may have disproportionate effects on other community members.

Empirical work has long recognized a spatial component to species diversity, through the division of regional (gamma) diversity into local (alpha) diversity and the turnover of species among sites (beta diversity). The existence of differences in species composition among sites (beta diversity) creates the potential for movement to alter local community composition if species are able to move among local communities. The concept of alpha, beta and gamma diversity also recognizes that regional diversity is made up of local diversity and the differences among local communities. Such diversity patterns do not, however, distinguish what is creating the diversity, in other words, whether local diversity contributes to regional diversity or whether it is a subset of regional diversity.

In the following sections we describe models of species diversity, and then describe some of the factors other than species diversity that are influenced by a metacommunity structure.

Mechanisms of Metacommunity Dynamics

Four broad kinds of metacommunity model have been described to describe the assembly and maintenance of communities at local and regional scales, each emphasizing different persistence mechanisms. These are termed neutral community models, patch dynamics, species sorting and mass effects models. It should be borne in mind that although the discussion is often in terms of patches, the same kinds of dynamics can occur in spatially continuous habitats without discrete patches.

The best known metacommunity models are neutral community models, which assume that all individuals have identical fitness. Neutral models were popularized by the publication in 2001 of Stephen Hubbell's book *The Unified Neutral Theory of Biodiversity and Biogeography*. Hubbell's model includes lottery competition among individuals that are all equal competitors on a spatially uniform habitat plane (Fig. 1). Competition in a uniform environment with no differences among species causes species to be transient, and for species diversity to drift through time (termed ecological drift by Hubbell). In Hubbell's model all individuals also have limited movement ability (Fig. 1), which causes different species to cluster in different parts of the habitat plane, slowing down competitive exclusion but not preventing it. To replace species that were lost, Hubbell included speciation as a source of new species. The mechanisms maintaining diversity in Hubbell's model are localized dispersal, and speciation that

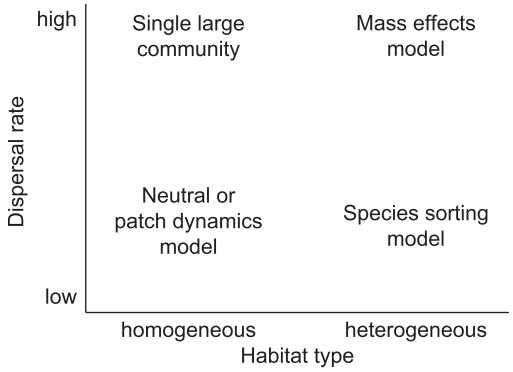

Fig. 1 Theoretical types of communities and metacommunities as a response to the similarity of habitat patches and the dispersal rate of species between communities.

replaces lost species. Hubbell's model was novel in including both ecological and evolutionary processes that might account for species diversity. Neutral models by other authors have often started with a fixed number of species and limited the time span of simulations so that numerous species are still present. Other, so-called neutral models have a fixed pool of species and all individuals are identical, but species cannot go extinct from the regional metacommunity. In such models persistence is determined by the permanent pool of species (like in the equilibrium theory of island biogeography), and this pool of species prevents neutral dynamics from determining diversity. Hence although individuals are neutral, the mechanisms determining diversity that are present in neutral models without permanent species pools cannot play out. Neutral models have surprised ecologists by predicting a number of patterns that are widely observed, such as the distribution of the rank abundance of species, or species-area relationships. Original tests were primarily in tropical trees, but neutral community models have been tested in a variety of taxa, from sedges, to bacteria, to gut parasites, and to bird assemblages. Unfortunately most work has concentrated on testing between neutral models and a single alternate null model, rather than accepting that there might be elements of neutral dynamics that occur along with other kinds of dynamics. For example, neutral models emphasize stochastic and transient dynamics, but such dynamics are also features of other kinds of models. In tests of a single alternative model, the best evidence leads to the rejection of neutral dynamics in all cases.

A second type of model has been termed patch dynamics, and differs from neutral dynamics because species differ in traits like colonization or competitive ability. Patch dynamics models are multispecies versions of classical metapopulation models. For large numbers of species to coexist permanently there needs to be a trade-off among appropriate traits. Most commonly they consider competing species that have a trade-off such that those that are better competitors are poorer dispersers. Inferior competitors can survive by living a fugitive existence where they arrive early at patches unoccupied by superior competitors. The habitat is uniform (**Fig. 1**), lacking environmental differences and can either be continuous or subdivided into separate patches. For coexistence a trade-off would need to be present, and species would need to have localized dispersal (like in neutral community models). Too much dispersal would cause species to show synchronous dynamics across all patches and inferior competitors would occur in the same patches as superior competitors until they were driven regionally extinct and a large single local community is left (**Fig. 1**). The model is hard to prove because it relies on the absence of environmental effects (that are present in the two models below) and it is difficult to demonstrate trade-offs for multiple species. There are recent demonstrations of such a trade-off among coexisting species in simplified laboratory systems where the environment is uniform but subdivided so that movement is limited.

A third type of model, termed species sorting, is based on classical niche theory, where niches are present either in different habitat types or at points along a habitat gradient (**Fig. 1**). Differences in habitats could be due to physical or biotic factors. Physical factors could include things like temperature, nutrient availability, resource availability, and tidal exposure, whereas biotic factors include the presence of habitat-forming species (e.g., trees or corals) or keystone species that exert disproportionate effects on other species. For species sorting to maintain diversity, species would need to be capable of reaching habitat to recolonize if they had gone extinct. If species dispersed so frequently that they often left good habitat, dynamics would become more like the next model, which involves mass effects (**Fig. 1**). For species sorting to operate, species could either select habitat actively and behaviorally, or they could have differential success in different habitats. The consequences of either of these would be that species survive and reproduce better in some habitats than others. Species functional traits that relate to responses to the environment are therefore an important part of community structure. The persistence mechanism in species sorting models is classical niche partitioning, in this case where niches are in different spatial locations. Niches are often contrasted with neutral models because individual responses to the environment would not be consistent with neutral models where all individuals are equivalent. Therefore species composition varying in response to environmental conditions would be evidence against neutral community models. Some of the best evidence for species sorting comes from differences in zooplankton composition among interconnected ponds with and without predatory fish. Dispersal of zooplankton between ponds seems to be somewhat frequent in such systems but species composition is strongly related to the presence of fish which do not move readily between ponds.

The fourth model, mass effects, results when there are different habitat types present and species are highly dispersive, so that they spillover from the habitats in which they reproduce and survive best to poorer habitats. These kinds of dynamics are described by source and sink models for individual species and are termed a mass effects for multiple species, where these is a mass flow of individuals from one place to another (**Fig. 1**). Habitat areas that are suboptimal and more distant in space from good habitat would be less likely to contain species that cannot maintain viable populations in the suboptimal habitat than for similar areas that are close to good habitat areas. This effect arises because species are likely to be limited in their dispersal ability. Were such dynamics present, there should also be a correlation between population productivity and the environmental factors that make habitat good or bad. The regional persistence mechanism is best described as a spatial storage effect, which Peter Chesson describes as differential survival and reproduction in different locations averaging out the success (finite growth rate) of a species such that the species can maintain a viable population within the metacommunity. Such dynamics have been modeled by Nicolas Mouquet and Michele Loreau in models with differences in habitat among patches and many competing species that differ in their response to environmental conditions.

If dispersal among habitat patches is high and habitats are relatively uniform across space, a single large local community is likely to result (**Fig. 1**). In this case it is not clear that anything is to be gained by considering the spatial dynamics of such a community. That is, the system is structured as a community rather than a metacommunity.

The most general form of evidence for and against the various metacommunity models comes from examining whether differences in community composition can be explained by differences in environmental factors or by the distance between the

local communities. Species sorting predicts a purely environmental effect, whereas mass effects predict both environmental effects and effects of distance. Both neutral and patch dynamic models predict effects of distance but not of environmental factors. A complicating factor in such analyses is that the environment may also be spatially structured. A survey of 158 natural community datasets by Karl Cottenie found that 22% of the total variation in community structure was explained by the pure environmental fraction, 16% by the pure spatial component and 10% by the spatially structured environmental fraction. From these data Cottenie concluded that 69 metacommunities (44%) best fit the species sorting model, 46 (29%) a mixed species sorting and mass effect model, and only 13 (or 8%) the neutral or patch dynamics models; 19 data sets could not be associated with these models, and 11 had no significant components. Therefore it is likely that species sorting and mass effects are relatively frequent in the natural world, but patch and neutral dynamics are less frequent. To date there are no natural communities that have been extensively examined and where we can conclude that the dynamics best fit neutral community models. A book edited in 2005 by Holyoak, Leibold and Holt, on metacommunities also found that more detailed studies most frequently identified species sorting, followed by mass effects and with patch dynamics being less common. There was no system that clearly showed neutral community dynamics. Likewise a 2011 review found that species sorting and mass effects were both the most commonly tested and supported metacommunity models.

It should be noted that the metacommunity models described above are useful as a starting point, but that they are theoretical representations of what is likely a continuum between different kinds of dynamics. A review of evidence for metacommunity dynamics in 2011 found that individual empirical systems often showed a mix of two of the four types of metacommunity dynamics. Currently the literature lacks models that can represent all of these kinds of dynamics within a single mathematical model, which would be useful for showing how the four different kinds of dynamics relate to each other. Consequently, more empirical and theoretical investigations are needed to ascertain the kinds of dynamics that are found and whether these relate to particular ecosystems or kinds of species. The above discussion also relates primarily to species diversity whereas in the following section we consider other aspects of community structure.

Metacommunity Topics Extending Beyond Species Diversity

Combining Functional Traits and Phylogenetic Information With Species Composition Patterns

Beyond the four metacommunity models described above, a wide range of studies use a combination of functional traits, environmental information and phylogenetic information to study patterns of species co-occurrence or species composition (Fig. 2). Functional traits are expected to be related to environmental conditions and/or species interactions, often stated as a dichotomy between the assembly of communities resulting from environmental filtering versus competition. Environmental conditions can include both abiotic conditions and biotic conditions such as habitats or ecosystem types, and interactions span the full range of species interactions not just competition. Analyses of community data such as "RLQ analyses," look at the correlations and partial correlations between species occurrence, environmental conditions and functional traits. Traits often include those related to dispersal (movement) capacity of species, making these essentially metacommunity analyses.

Phylogenetic information as a proxy for evolutionary history is used to exam hypotheses of niche conservatism, environmental filtering, or competition. If niches are conserved, certain refuge habitats would be expected to contain old lineages of species, and local communities are expected to be phylogenetically clustered. Environmental filtering would produce strong associations between certain taxa, with particular traits in certain habitats (or ecosystems); trait x phylogeny correlations are called the phylogenetic signal. Competition is expected to produce communities that show phylogenetic dispersion and dispersion of functional traits because similar species outcompete one another, or exclude each other through other kinds of species interactions. Hence, studying the relationships between communities or species co-occurrence patterns, functional traits, environmental conditions and phylogenetic patterns can help elucidate the mechanisms by which the composition of local communities are maintained. Pillar and Duarte developed methods that look at correlations between species composition, functional traits,

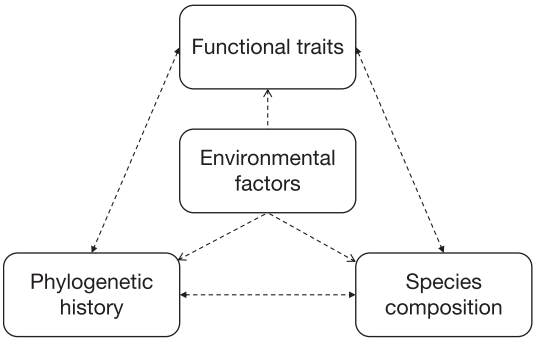

Fig. 2 The relationships between functional traits, evolutionary (phylogenetic) history and species composition, which are all modified by environmental factors.

environmental characteristics and phylogeny at both community and metacommunity scales. Such methods have the capacity to answer questions about community and metacommunity assembly mechanisms in systems which are hard to manipulate to study metacommunity dynamics. There are few applications to date, which limits our current insights.

Food Webs

Historically, food web research has focused on how local deterministic interactions will influence web structure. Considering food webs in a spatial context, however, provides alternative mechanisms for observed phenomena. When species do not interact, we expect that subdivision will only decrease population sizes and make species more vulnerable to stochasticity. Interacting, species, however, can use space as a mechanism of persistence and coexistence that promotes a more complex food web structure.

Ultimately, the degree to which metacommunity dynamics influence food web properties over local community dynamics will depend on dispersal, patchiness, and the interaction between the two. Spatial subsidies of immigrants, energy or materials can stabilize or destabilize local interactions that would otherwise be determined by environmental factors. Patchiness in the form of environmental heterogeneity will allow for site-specific demography and alternative food web states within patches, though the resultant food web structure will also depend on the rate of dispersal of and colonization by both competitors and their consumers. Lastly, patchiness in the form of the size and distribution of habitat patches will influence the extent to which species of varying life histories and dispersal abilities experience subdivision. Together, these factors will influence interactions within and between trophic levels. Where they contribute to the stabilization of local interactions, we expect to see longer food chains or more complex food webs.

Though there is a long history of seeking to explain food chain length with productivity, recent work has shown that ecosystem size may be a more consistent predictor of chain length. This could be a result of metacommunity dynamics. If a food web is under donor-control, the criteria for the existence of higher trophic levels will become stricter for each succeeding level. If basal species have low colonization and high extinction rates, and their habitat is rare, we might expect short food chains because, by virtue of being dependent on lower trophic levels for resources, each succeeding trophic level must have extinction rates equal to or higher than the previous trophic level. Increasing colonization rates or the number of habitat patches, or decreasing extinction should enhance regional mechanisms of persistence and coexistence, stabilize local interactions, and allow for greater trophic diversity.

Spatial structure can also influence the impact of consumers on their resources. A consumer's ability to optimize energy intake by switching prey and feeding location can dampen fluctuations in prey populations, stabilizing local food webs. Even when predators are not actively selecting prey and habitat, space can create refugia for prey populations and, in some systems, decrease top predator density and allow other predators to coexist. Dispersal by consumers can also link resources and habitats in ways that are detrimental for some prey species. For example, shared predation by a mobile consumer may cause two species that never co-occur locally to exhibit apparent competition, or, oppositely, may facilitate the coexistence of two species that otherwise could not coexist locally. All of these factors affect the stability of local interactions and thus the complexity of the food web.

Ecosystem Functioning

Ecosystem functioning reflects biotic effects on the physical and chemical properties of the environment and an emerging theme has been to link this functioning to metacommunity properties. A common theme in research on ecosystem functioning is the diversity-productivity relationship. Non-spatial models generally predict a positive relationship between diversity and productivity due to increasing niche complementarity, with eventual deceleration due to niche overlap (**Fig. 3**A). Though there is experimental evidence to support these predictions, there are also studies that show a neutral, unimodal, or negative relationship between diversity and productivity. Some of these conflicting results may be reconciled through a metacommunity framework that accounts for the spatial exchanges known to occur in real ecosystems.

Varying rates of dispersal between patches may explain a unimodal diversity-ecosystem functioning relationship at local scales and a positive linear relationship at regional scales. At the local level, diversity may increase productivity because of niche complementarity or sampling effects. This relationship may peak and become negative, however, if dispersal allows inferior

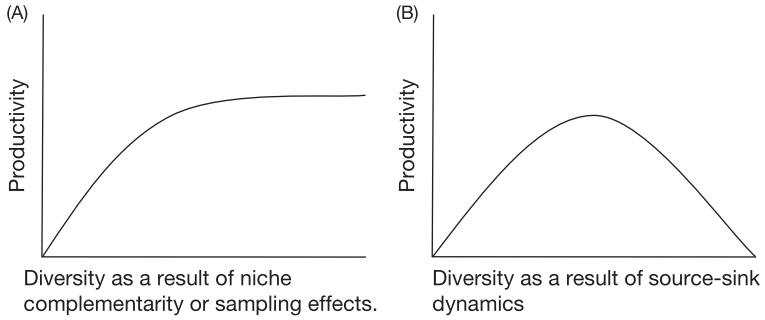

Fig. 3 Theoretical relationships between productivity and species diversity.

competitors to interfere with superior competitors through source-sink dynamics (Fig. 3B). At larger scales, increased diversity may allow species to coexist and complement each other regionally, increasing productivity linearly so long as the number of species does not exceed the number of limiting resources. A study examining productivity at the pond (local) and watershed (regional) scale found this scale-dependent relationship between diversity and productivity in nature, evidenced by low local diversity and increasing species dissimilarity between ponds in watersheds with higher productivity.

A form of spatial insurance could also result in a scale-dependent diversity-productivity relationship. If the dynamics of local communities and environments fluctuate asynchronously, dispersal will supply immigrants to localities where the environment has changed to be unsuitable for the current residents. Increasing regional diversity will increase the likelihood that there will be species appropriate for the various environmental conditions, which will enhance resource use efficiency and productivity. When levels of dispersal are intermediate, supplying enough immigrants to fill vacancies without leading to dominance by a species with intermediate traits, the temporal mean of productivity across the region will be higher and exhibit lower variability. When the system involves more than one trophic level, consumers that track resources can increase variability in productivity at a local scale, but decrease variability at the metacommunity scale by creating a heterogeneous environment that hosts a more diverse community capable of spatial insurance.

Evolution

Evolution influences communities on many timescales. In a metacommunity context, whether local adaptation promotes or deters coexistence will depend on how influential the change is on a given interspecific interaction and the level of immigration among communities.

Over long periods of time, evolution can promote coexistence through niche partitioning, competition-colonization trade-offs or mechanisms that make species regionally similar in fitness despite local competitive asymmetries. In addition to shaping the dynamics of interspecific interactions, evolution will impact the connectedness of a community, and thus the frequency of those interactions, by molding dispersal capabilities and habitat preference.

Empirical evidence also suggests that evolution can influence community dynamics within a short, ecologically relevant timeframe. Asymmetrical gene flow from source to sink populations can prevent efficient natural selection, leading to maladaptation in the sink and creating range limits. This type of source-sink dynamics can also decrease niche breadth and inhibit a species' ability to respond to changing biotic and abiotic environmental conditions. In the same way that intermediate dispersal can promote species diversity, intermediate gene flow can promote genetic diversity by supplying new alleles without extirpating the local genetic framework. If environmental conditions in a patch change, the genetic storage effect can provide immigrant genes adapted to the new conditions that can rescue maladapted populations. Therefore, maintaining genetic diversity on a regional scale promotes overall species diversity.

Summary

Metacommunity models offer the most complete view of the factors maintaining species diversity that has been described to date. The metacommunity concept realistically describes how both local and regional forces can contribute to species diversity, and how the structure of local communities can be altered by immigration from other communities within the region. To date, metacommunity models consist of four broad kinds, termed neutral, patch dynamics, species sorting and mass effects (or source-sink). There is a variety of empirical evidence for species sorting and mass effects models, whereas patch dynamics appear less common, and there is no good example of a system with neutral community dynamics. Often systems display a mix of two kinds of metacommunity dynamics, and further empirical and theoretical work is needed to understand the factors that produce a mix of the four metacommunity paradigms. A metacommunity structure is likely to alter the composition of local communities, food web structure, species abundances, and the potential for evolution. Studying the relationships between community composition, species' functional traits, environmental factors and phylogenetic relationships provides a rich source of information about community assembly at a metacommunity scale. Yet most studies of such relationships have not explicitly recognized the role of spatial structure, although methods exist to do so.

Metagenomics

Matthew Haynes, Joint Genome Institute, Walnut Creek, CA, United States

Glossary

Assembly Combination of multiple sequences from a metagenome based on overlaps of a defined size.
Community A collection of multiple species in close proximity.
Contig A DNA sequence assembled from smaller overlapping sequences.
Coverage The degree to which a metagenome contains all of the sequence information representing a given genome or gene.
Diversity The degree of complexity of a metagenome based on the number and relative abundance of different sequences.
Library A synthetic collection of DNA fragments that have been processed to facilitate DNA sequencing.
Metadata Information other than DNA sequences associated with a metagenome.
Metagenome A collection of DNA sequences derived from a sample containing a community of organisms.
Operational taxonomic unit (OTU) The genotype classification used to define species based on ribosomal RNA sequences.
Population A collection of organisms of the same species living in close proximity.

Metagenomics is the study of the combined genomes of multiple microbial or viral species within a sample. A metagenome can therefore be regarded as a community genome. The cumulative genetic information of an entire community of microorganisms will often have functional properties that transcend those of any individual species. Metagenomics requires extraction and sequencing of genomic nucleic acids of all organisms in a specific community or biome. Depending on the sample being analyzed, the organisms may be filtered or otherwise separated to yield a metagenome representing only a particular component (e.g., viruses or microbes). Because culturing all organisms within a complex sample is usually impossible, metagenomics requires an uncultured approach. Genomic nucleic acids (DNA or RNA) are directly isolated from a sample and sequenced. High-throughput sequencing is required to characterize a sample of significant diversity. Although obtaining sufficient material for sequencing may be an obstacle, the most challenging aspect of metagenomics is usually the data analysis.

Samples

Metagenomes have been obtained from a wide variety of sources, from seawater to soil to human body fluids and tissues. Procedures such as filtration and centrifugation may be used to fractionate the sample in order to produce a metagenome for microorganisms within a given size or density range. For example, it is often desirable to separate viruses from microbes.

DNA/RNA Isolation

Nucleic acids are isolated directly from the sample; attempts to culture microorganisms from most samples will inevitably result in the loss of genetic information for the vast majority of organisms. Small amounts of DNA may require sequence-independent amplification to produce a sufficient quantity for sequencing. Sometimes this method can alter the original relative abundance of taxa (sequence bias).

Sequencing

Modern high-throughput sequencing methods are a necessity to obtain the very large number of sequences required for accurate assessment of diverse natural communities. High-throughput sequencing technologies currently require the construction of some form of DNA library from the sample DNA to facilitate the sequencing process. In a shotgun library, genomic DNA is fragmented into pieces of a usable size and modified with sequencing primer adapters or other means appropriate for the chosen method. A shotgun library will yield sequences that randomly cover all of the DNA contained within the original sample. In order to sequence metagenomes from a number of samples simultaneously, a multiplex strategy may be used in which DNA from each sample is individually tagged with a short synthetic sequence that is later used to sort the data (Fig. 1). Depending on the complexity of the sample and the relative abundance of individual organisms, whole genomes may or may not be recovered. For ribosomal DNA (rDNA) metagenomes, a polymerase chain reaction (PCR) amplicon is derived from the desired rRNA gene (usually the small

subunit 16S gene), and this amplicon library is sequenced. Sequencing technology is advancing rapidly, and, soon, more sophisticated single-molecule DNA sequencing methods may become the standard.

Special Cases

A different approach is to create an amplicon library, using PCR to amplify specific ubiquitous and conserved sequences such as rRNA genes that can be used as a proxy for microbial species (operational taxonomic units (OTUs)). The typical microbial amplicon library targets some subregion of the 16S rRNA gene, although many other variations are possible. In addition to genomic DNA, viral genomic RNA can be isolated and sequenced after reverse transcription into DNA. Microbial messenger RNA (mRNA) can be isolated from a sample to yield a metatranscriptome that will reflect transcription at the community level.

Data Analysis

Bioinformatics methods are used to analyze metagenomic data. A rarefaction curve (Fig. 2) can be used to determine whether a sample has been sequenced to an extent sufficient to represent its true diversity. The overall diversity of a metagenome can be

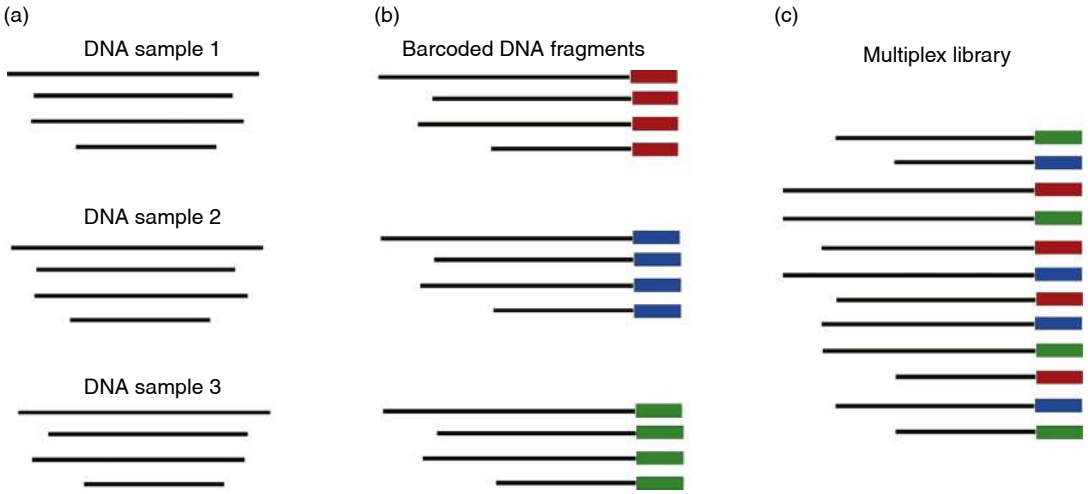

Fig. 1 Overview of multiplex sequencing strategy. (a) Viral DNA is isolated from each sample. (b) Each molecule of the individual DNA samples is tagged with a short sequence during the library preparation for sequencing. (c) Samples are pooled for pyrosequencing, but the sequence tags permit identification of the source of each sequence.

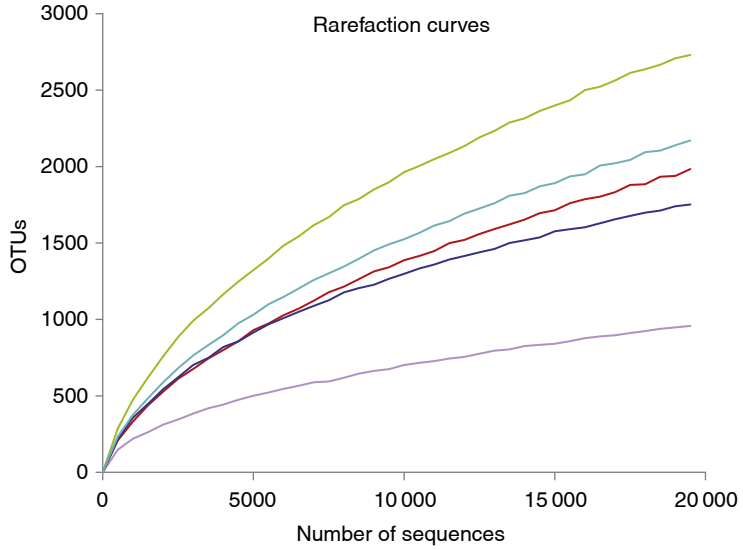

Fig. 2 Rarefaction curves. As the number of sequences from a sample increases, the number of species or OTUs converges on the true diversity.

viewed as the combination of the number of types of sequences present and the relative abundance of these sequences. The sequences in a typical metagenome, reflecting the distribution of species in most natural communities, are present in very unequal abundances. A small number of sequences (species) generally dominate, with a much larger number present in significantly smaller abundances (Fig. 3). There are three levels of classifying diversity: α diversity, which refers to diversity within a sample; β diversity, which refers to variation between two samples; and γ diversity, which is the diversity within a broad geographical area.

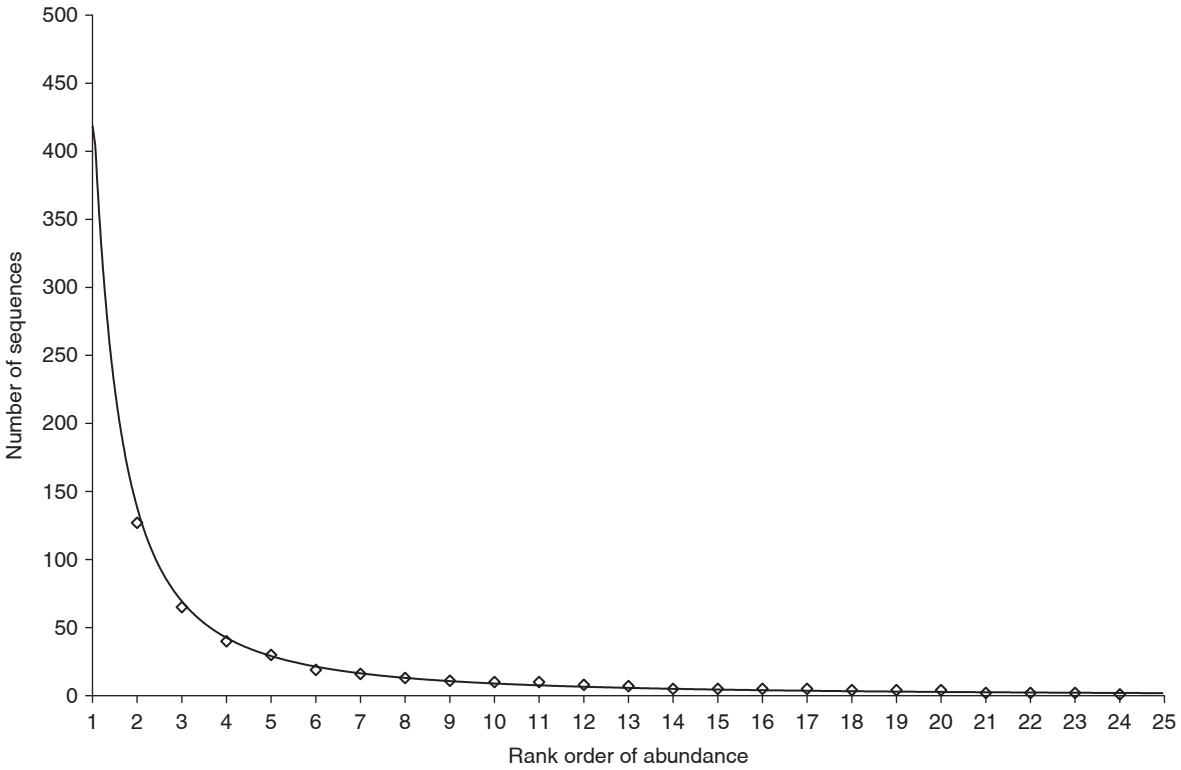

Fig. 3 Rank-abundance curve. A typical metagenome is dominated by sequences representing a few of the most abundant species. A much larger number of lower-abundance species yield only one or a few detectable sequences.

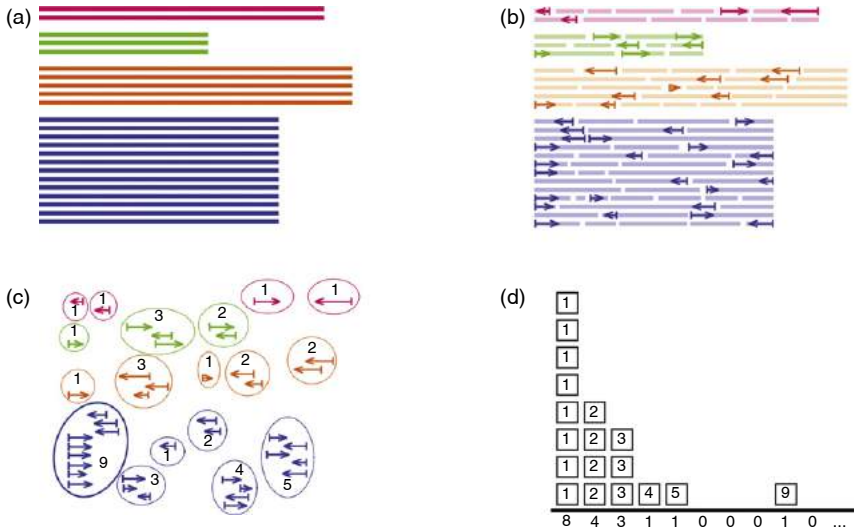

Fig. 4 Contig spectrum. (a) Four species of varying abundance in a sample. (b) The DNA is sequenced randomly. (c) Sequences that overlap are assembled. Sequences that are more abundant produce contigs made up of larger numbers of sequences. (d) Contigs are ranked by the number of sequences they contain (1-contigs, 2-contigs, etc.), and the number of contigs in each category gives the contig spectrum. The contig spectrum is a measure of the diversity of the original sample that does not require identification of any of the sequences.

Two or more sequences can be assembled into larger contigs (contiguous sequences) if the length and similarity of overlaps are sufficient. Sequences may be characterized on the basis of taxonomy or by encoded metabolic potential. Identification of genes that encode particular proteins can be used to create a profile of community metabolic potential. In some cases, the metabolic activity of an entire microbial community is more stable over time than its taxonomic composition. Certain environments or sample types (e.g., viruses) may yield a large number of sequences with no homology to any known sequences, for which taxonomic analysis is therefore impossible. Bioinformatics methods include several approaches that do not require identification by similarity to known sequences. The ability to assemble contigs of various sizes from a metagenome (contig spectrum) reflects the diversity of the metagenome and can thus be used to derive diversity information even when a large proportion of the sequences cannot be taxonomically identified (**Fig. 4**).

Microbiomes and Holobionts

Derek Skillings and Katarzyna Hooks, University of Bordeaux, Bordeaux, France

Glossary

16S rRNA Universally conserved bacterial ribosomal RNA gene. 16S rDNA is the most commonly used marker in microbial diversity studies.
Holobiont A host plus all of its symbiotic microbiota.
Hologenome The sum total of all genetic material from all members of a holobiont.
Metabolome Profile of existing intermediate and end products of metabolic pathways within a system under a given set of conditions.
Metagenomics The study of the combined genetic material extracted from environmental samples.
Metatranscriptome All RNA molecules, including mRNA, rRNA, tRNA, and other noncoding RNA transcribed in a population.
Microbiome (1) All the microbes in a community. More recently, (2) all of the genes of all of the microbes in a community.
Microbiota The community of commensal, symbiotic, and pathogenic microorganisms in a particular site, habitat, or geological period.
Mycobiome All the fungi in a community.
Symbiosis Two or more species living closely together in a long-term relationship.
Virome Collection of viral nucleic acids in a community.

Introduction

Microbes, or microorganisms, include microscopic organisms such as bacteria, archaea, protozoa, and unicellular fungi and algae. This is sometimes extended to include viruses. "Microbiome" started as primarily an ecological term, defined as a characteristic microbial community occupying a reasonably well-defined habitat, which has distinct physiochemical properties. It referred to the microorganisms, their activities and their immediate environment. The "-ome" in "microbiome" was related to the term "biome." Later usage started to distinguish the microbiota (the organisms) from the microbiome (their collective genome). Here the "-ome" is related to "genome" and "chromosome." The result is that current practice refers to both organisms and their molecular constituents as microbiomes. The methodology for studying such systems is similar and, thus, we define microbiome research as the analysis of the aggregated molecular components of a defined microbial community. When used in its most inclusive sense, the microbiome might also include the resident virome and mycobiome of the community under study. The virome is the collection of viral nucleic acids in a community, including both bacteriophages (bacterial viruses) and DNA- and RNA-encoded eukaryotic viruses, and the mycobiome is the microscopic fungal component of the community.

History

From Cultures to Sequencing

Microbiome research as it exists today is a recent development in the life sciences. It combines techniques from both microbiology and molecular genetics and has applications that go beyond the traditional domain of microbiology. Microbiology started as a laboratory-based science that focused on isolating microorganisms in pure cultures. This methodology dominated microbial studies because of the focus on isolating pathogens or other undesirable organisms. Microbial causality of disease states or food spoilage has been historically established using Koch's postulates. This procedure establishes a sequence of isolating, culturing and experimenting in hosts. Four criteria must be met in order to fulfill Koch's postulates and establish a microorganism is causal: (1) the microbe must be present in all sick individuals and absent from all healthy individuals; (2) the microbe must be isolated from sick individuals; (3) a pure culture of that microbe must cause the illness when administered to a healthy individual; and (4) the microbe must be re-isolated from the sick test individual and shown to be identical to the originally isolated microbe.

Koch's postulates have been adapted numerous times since their introduction in the late 19th century. Later techniques were imported from biochemistry in order to identify the biochemical pathways or important molecules that were produced by isolated cultures of microbes and responsible for the effect of interest. When successful, this narrowed the causal attributions from individual organisms to particular toxins or other molecular compounds. A biochemical approach was also used to explore the signature of microbial activity in natural environments outside of pure cultures in the lab. Environmental microbiology was transformed by the advent of molecular genetics. DNA sequencing allowed for the identification of microbes without culturing in isolation. The first studies focused on the genes for ribosomal RNA (rRNA), which had been established as a useful marker for phylogenetic analyses. This technique, when applied to environmental samples, uncovered an unprecedented amount of previously unrecognized microbial diversity.

Metagenomics

Improvements in sequencing technology and large-scale data analyses caused a shift from single genes to whole microbial genomes. Metagenomics started as the whole-genome sequencing of samples extracted from natural environments. The first use of the term "metagenome" was in 1998 by Jo Handelsman and colleagues, in reference to the combined genomes found in an environmental soil sample. The shift here was to treat the collection of genes recovered from an environmental sample in a way that is analogous to the study of a single genome. Metagenomics tells who is there, and early whole microbiome research was made up of primarily of microbial composition studies. As the field developed it started determining functionality and what the microbes are doing by looking at gene expression profiles and metabolite production (metatranscriptomics and metabolomics, respectively). The next step has been to identify how the microbes interact each other when in their natural habitats.

Holobionts and Hologenomes

It was becoming increasingly clear that the living world is dominated by, and completely dependent on, complex microbial communities. Evidence was also mounting that most microbes do not live independently, they interact in interconnected networks of communication, cross-feeding, genetic recombination, and coevolution. These interactions extend to the level of multicellular organisms, suggesting that multicellular organisms have been engaged in symbiotic relationships with microorganisms throughout their evolutionary history. It was long thought that all macroorganisms are routinely colonized by a large number of microorganisms, but the details and extent of macrobe–microbe interactions remained difficult to uncover. As the molecular tools for identifying microbial diversity grew, attention turned to multicellular organisms as sites of new and diverse microbial ecosystems with multiple environmental niches.

It is now widely accepted that microorganisms have always played many important roles in the lives of plants and animals. Symbiotic interactions between microbes and multicellular organisms have been documented across a diverse swath of life, and many researchers maintain that all large organisms engage in symbiotic interactions with microbes in natural settings. The term "holobiont" was coined by Lynn Margulis and used to refer to symbiotic associations that last throughout a significant portion of an organism's lifetime. It is derived from the Greek word *holos*, which means whole. The term first found wide usage in coral biology where it was defined as a coral colony and its associated photosynthetic algal symbionts and bacterial communities. The recent massive influx of interest in host-microbiome relations has led to a proliferation of the term "holobiont," now most often understood as a host and *all* of its associated microbiota, including bacteria, archaea, viruses, protists, fungi, and microscopic multicellular animals such as nematodes. Because the holobiont includes *all* associated microbiota, the interactions between holobiont partners may be harmful, beneficial or of no consequence.

The term "hologenome" originated more recently. It is defined as the collective unit made up of all of the host and microbial genomes of the holobiont, or in other words, the host genome plus the resident microbiome, virome, mycobiome and all other genomic material associated with the host. Hologenome is often used in place of the more familiar host + microbiome when researchers are trying to emphasize the interaction and integration of host and microbial genes in the formation of host traits or phenotypes.

Although there have been significant recent advances in our ability to understand the microbial world, converting microbiome data into meaningful biological insights remains very challenging. Barriers to a more thorough understanding include the difficulty in decoding the functional relevance of microbiota at appropriate scales, the difficulty in establishing causality in complex microbial networks, and our limited ability to make informed manipulations that lead to predictable outcomes in natural systems.

Methodology

Sampling Strategies

Microbiota research is interested in two general types of microbial communities: environmental and host-associated. Some of the microbes and their functions in the natural environments are known and well described (e.g., decomposition of organic matter and cycling of nutrients, especially nitrogen). There is an increasing interest in the built environments (buildings, vehicles, water systems, etc.) and their bacterial composition. Host-associated microbiota studies range from investigating microbes found in and on agriculturally important plants, marine invertebrates and different human body sites.

Early Methods

Traditionally identification of most members of a complex microbial community was challenging. It was especially true for the gut microbiome—a highly diverse and densely populated microbial community with only a small percentage of microbes that could be cultured.

Culture and culturomics

The early microbiome studies were stemming from traditional microbiology and involved pure culture or co-culture methods. Many bacterial species were excluded from such analyses since the optimal conditions for their growth were unknown. Cultivation-based approaches to study microbial communities are still important today, especially in the form of microbial culturomics (see Lagier et al., 2016). However, since culture methods are performed outside of the ecological environment, they fail to inform us about community dynamics and species interactions.

Hybridization methods

One of the first culture-independent methods for microbiome study relied on hybridization of nucleic acids, either in the form of in situ hybridization or Southern blotting. Usually the probes were designed to recognize 16S rDNA with specificity varying from the whole kingdom to species level. In situ hybridization is still in use in the field of environmental microbiology to visualize the spatial distribution of species (e.g., in biofilm).

Amplification

Amplification methods such as PCR and qPCR are able to detect and quantify particular taxa when taxa-specific primers are used. PCR can be also used to create a library, for example, by using a universal primer for 16S or 18S rRNA. Such libraries then can be used as an input for fingerprinting methods or more recently tag sequencing (see below). In both cases the success of the method depends on the specificity and sensitivity of the primers used and the prior knowledge of the target sequences.

Fingerprinting methods

Most popular fingerprinting methods were terminal-restriction fragment length polymorphism (T-RFLP), denaturing gradient gel electrophoresis (DGGE) and temperature gradient gel electrophoresis (TGGE). They allowed comparisons of the whole communities but offered little information regarding taxonomic composition driving the change. Sometimes low-throughput sequencing was used to complement the DGGE or TGGE analysis, where visibly differing bands were excised, sequenced and compared with bacterial sequences in the databases.

State of the Art Technology

Initially sequencing technology was slow and expensive. It involved cloning interesting fragments of DNA, like gene encoding 16S rRNA, cloning it into plasmids, transforming suitable hosts (usually *Escherichia coli*) and sequencing by Sanger method. However, even then it allowed for more precise and rapid taxonomic identification of bacterial communities than culture-based methods. Real revolution came with the advent of massively parallel next-generation sequencing and other –omics technologies (**Fig. 1**).

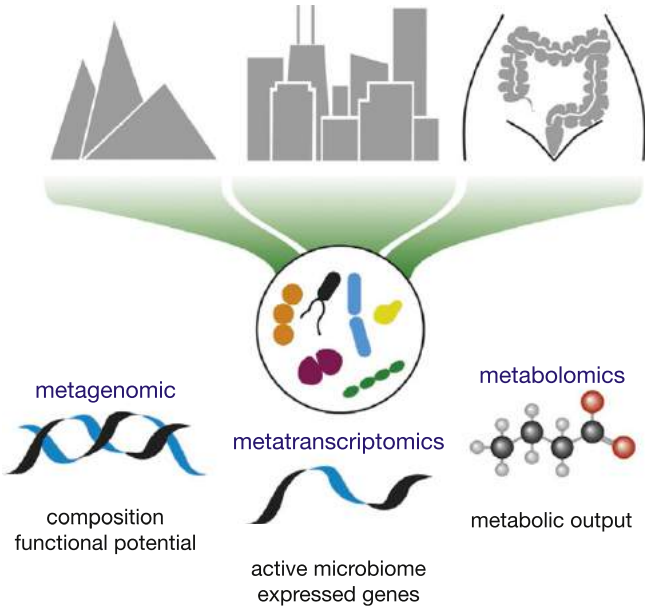

Fig. 1 Microbial community samples can be taken from natural, built, or living environments. Different analyses target different molecular components of the sample and provide complementary information on the identity and activity of the microbes in the sample.

Tag sequencing

In tag sequencing total DNA is isolated from samples, regions within universally conserved 16S/18S rRNA genes are amplified by PCR and amplicons are sequenced by one of the high-throughput methods. Identification of variations in specific regions of this gene allows for classification of bacterial taxa. Popular pipelines for bioinformatics analysis of 16S sequencing data include Quantitative Insights Into Microbial Ecology (QIIME) and Mothur.

With the ability to enrich templates with initial concentrations too low to detect, PCR-based sequencing technology allows identification of individuals with very low populations within complex communities. Tag sequencing is relatively inexpensive to perform but has limited resolution: not all bacteria can be classified and species-level identification may not be possible, nor can it detect viruses and eukaryotic communities. Questions are also raised about the biases introduced by the initial PCR step.

16S rRNA sequencing has generated a wealth of data on microbiome composition from different environments and conditions. Using this method the Human Microbiome Consortium published in 2012 reference metagenomes of microbes present within healthy humans.

Shotgun sequencing

Metagenome shotgun sequencing (MGS) extends the information provided by 16S/18S rDNA amplicon sequencing. It uses the entire DNA available in the microbiome sample to prepare a sequencing library. Additional amplification step might be necessary for environmental samples yielding small DNA amount. The resulting library can be sequenced either with the use of short (2×250 or 2×300 nt) or longer reads (500–4000 nt). Number of reads mapping to marker genes can be then used to quantify specific taxa and bacterial strains. Multiple different algorithms exist for metagenome assembly. There are also dedicated pipelines like EBI Metagenomics, CAMERA or MEGAN 6 performing the analysis and visualization of the MGS data.

MGS allows identification of not only bacterial, but also viral, fungal, and protozoan DNA. It produces a much better resolution of bacteria at the species level and allows for annotation of bacterial gene clusters and pathways based on direct sequencing of bacterial genes. The downsides of MGS are higher sequencing costs, higher bioinformatics load due to the large number of sequence reads produced, and the difficulty to analyze genomes absent in the reference databases or genes with unrecognized function. Contamination by host DNA is another challenge in MGS when biopsy or mucosal material is being collected.

Metatranscriptomics

Instead of studying the DNA present in the sample it is also possible to study the activity of microbes within complex communities by metatranscriptomics. Instead of describing the potential of metagenome to encode certain pathways, RNA sequencing (RNAseq) directly provides information about the bacterial gene expression. Such studies can complement compositional data and have a potential to show differences in gene expression before the compositional changes can be observed through metagenome analysis.

Metabolomics

To better describe the bacterial community, the totality of their metabolic products can be described by metabolomics analyses. Such information extends the knowledge about the functions performed by the microbes by measuring the quantities of products of their pathways. The most frequently used metabolomics methods are spectrometry (MS) and nuclear magnetic resonance (NMR). Further advances were offered by Matrix-Assisted Laser Desorption Ionization time of flight (MALDI-TOF), Secondary Ion Mass Spectrometry (SIMS), and Fourier transform ion cyclotron resonance MS that greatly improved the accuracy and throughput in metabolomics.

Extensive microbiome profiling led to saturation of information about the bacterial composition in certain environments, for example, human gut. In contrast, metabolomics profiles are not well described even for the routinely grown cell cultures exposing the gap in the knowledge about complex biological systems. Considering that the biosynthesis of oligosaccharides and lipids allows for many permutations in combining simpler molecules, the number of metabolome components is at least an order of magnitude higher than that of the protein-coding genes.

Data Analysis and Bioinformatics

The new high-throughput technologies generated a wealth of data that require a careful analysis. With the constantly decreasing price of sequencing the bottleneck lies now in the storage, analysis and interpretation of the results.

Typical microbiota study involves multiple steps of data analysis after sequencing. First the resulting reads undergo a quality checking and filtering. If the tag sequencing was performed, the reads are usually clustered into the Operational Taxonomic Units (OTUs)—a group of individual bacteria whose sequences are at least as similar as a chosen threshold (frequently 99% or 97% for species-level resolution when considering variable rRNA regions). OTUs can then be attributed to specific species or a group of species and used to describe the composition of the sample. Statistical methods borrowed from the ecological studies allow performing alpha and beta diversity analyses on the microbial composition matrices. Bioinformatics methods aid in the exploratory data analysis and visualization of taxonomic composition. They also make it possible to predict the genes present in

the microbiome using the taxonomic assignments, for example, with the Phylogenetic Investigation of Communities by Reconstruction of Unobserved States (PICRUSt).

The bioinformatics analysis of the metagenome shotgun sequencing is more complex but it can also yield much more robust results. With the information about the all DNA present in a sample, it is possible not only to find taxonomic composition of the sample but also describe the functionality of microbes within the community by comparing identified genes and predicted proteins from sequence data to databases.

With different big-scale microbiome projects completed, additional bioinformatics analyses and improved statistical methods can lead to new discoveries overcoming the spurious conclusions of small studies. Comprehensive meta-analyses combining in a principled manner taxonomic and functional profiling results can lead to meaningful synergy.

Mouse Models and Causal Inference Via Whole-Community Transfers

One of the experimental methods of manipulating and investigating the whole microbiomes has to do with the use of germ free rodents. Such animals are born through caesarian section and kept in the sterile environment including feeding with irradiated food and water that prevents them from being colonized by any bacteria. Germ free mice can then be infected with a specific microbiota—either from other mice, humans or artificially constructed communities. The microbiota transfer can happen in two ways—by relying on the mice coprophagy or by directly administrating microbiota orally through gavage feeding. This technique allows also observing in vivo effect of difficult to grow bacteria, interaction between microbes and host and within microbial communities. Researchers described physiological differences in the host after the administration of altered microbiomes. In particular, transfer of the whole organism phenotype like obesity, suggests that microbiota might be the cause of such changes.

Research Areas Associated With Microbiome Studies

Biogeochemistry

Microorganisms are the biogeochemical engines that support all life on earth. Phytoplankton (single-celled algae and photosynthetic bacteria) in the earth's oceans are major drivers of the carbon cycle, together responsible for half of the global atmospheric carbon that is fixed each year. Microbes are also primarily responsible for stabilizing and recycling the fixed carbon into terrestrial carbon stocks. Microbes are also responsible for nitrogen fixation. This process is so valuable that many plants and insects have formed long-lasting symbioses with nitrogen-fixing bacteria. Beyond being the backbone of the carbon and nitrogen cycles, microbes are also important for controlling and stabilizing the flux of important nutrients like nitrogen and phosphorus, leading to stable environments and complex ecosystems. How that is done is often unknown. The functions of most microbial genes are still mysterious, as are the products of those genes, the functions of those products, and how their production is regulated in natural environments. Large-scale high-throughput microbiome studies are necessary to unravel the microbial diversity and biochemical pathways underpinning these important biogeochemical processes.

Microbial Ecology

Microbial ecology aims to determine the patterns and drivers of microbial community distribution, interaction, and assembly. It has been well demonstrated that microbial community composition changes across most environmental gradients, such as geographic distance, nutrients, temperature, moisture levels, salinity, oxygen availability, pH, and day length. Broader patterns have been difficult to track because of the necessarily small-scale of individual studies. Initiatives like the Earth Microbiome Project bring together regional studies that tend to focus on one type of environmental sample in one locality in order to investigate microbial community dynamics at larger regional and global scales. Environmental microbiome samples from diverse environments are paired with metadata consisting of spatial, temporal, physiochemical, and animal/plant association variables. Initial studies looked at covariation between microbial diversity, measured in terms of operational taxonomic units (OTUs) clustered by single-gene sequencing (usually 16S rRNA), and environmental variables. These approaches have expanded to take advantage of whole-genome methods, strain-level diversity, and more fine-grained sampling. Initial results show a general pattern of hierarchical organization, with less-rich communities nested within richer communities at higher taxonomic levels.

Host Biology and Holobionts

Host-microbial symbioses are common in nature and have a long research history. Until recently, little was known about the details of these relationships and research was usually limited to the study of pairwise associations in a few familiar cases, such as in termites, ruminants, corals, and legumes. Metagenomics studies on the internal environments of eukaryotic organisms soon uncovered that nearly all visible organisms are hosts to a wide assortment of microbes. Furthermore, these microbes often have an influence on the physiology, anatomy, behavior, reproduction, and a fitness of their hosts. The ubiquity of host-microbiome interactions and the intimate ways by which microbes are integrated into host biology is what motivates thinking of the entire system as a holobiont—a new unit of biological organization.

Interactions between hosts and their microbes vary across the entire spectrum of possibilities. Relationships between partners may be coevolved or opportunistic, competitive or cooperative, obligatory or facultative. Some partner interactions are best considered as symbioses—ranging from mutualism to parasitism—where the partners mutually form a part of each other's environments. Other interactions long ago bound the individual lineages together into a higher-level lineage. This is what happened during eukaryogenesis—the origin of mitochondria and the birth of all eukaryotes. This new lineage was formed when an archaeon enveloped but did not consume its bacterial prey and the two continued to live together and reproduce as one higher-level unit.

Holobionts are an interesting level of biological organization because they can share features of both organisms and communities. Focusing on the processes, interactions, and relations that occur between holobiont partners has opened up a suite of research questions. What kinds of interactions and traits lead to increased metabolic integration and alignment of fitness? To what degree are holobiont partnerships species-specific coevolved consortiums versus generalist assemblages taking advantage of leaky products or stable environments? What is the relationship between different biological parameters: mode of transmission versus alignment of fitness versus degree of metabolic integration?

The Human Microbiome

Humans are associated with up to 10^{14} microorganisms. The vast majority of the microorganisms that make up the human microbiome are bacteria residing within the gastrointestinal tract. The human microbiome literature, in turn, tends to focus exclusively on bacteria. Many gut microbes can now be cultured in special conditions, but very little is known about what these microbes are doing and how they are interacting, especially regarding the anaerobes. After the success of the Human Genome Project, work began on using metagenomics tools to characterize the "the second human genome," the microorganisms making up the human microbiome. One such initiative is the Human Microbiome Project (Human Microbiome Project Consortium, 2012). By the numbers, it is likely that the largest portion of contemporary microbiome research is on the human microbiome, and in particular, the gut microbiome.

Although it was known that there can be extremely fine-grained microbial diversity at the species and strain level, much of the early human microbiome work was done at the coarse phylum level, mainly due to technical and database limitations. Most of the guts of healthy human so far sampled are dominated by only two phyla: Firmicutes and Bacteroidetes. Together they comprise about 90% of human microbial gut diversity. Based on this information it was assumed at the start of the Human Microbiome Project that humans would share a large core of microbial lineages, and there would a large diversity of rare lineages that make each person unique. This picture of the human microbiome will probably end up being wrong. The first 5 years of results using higher taxonomic resolution have consistently found that the differences between individuals are substantially greater than the differences within an individual at different environments along the gut. Other studies have routinely shown that healthy Western adults can be more than 90% different in terms of gut microbes at the species level. Even with the dominance at the coarse-grained taxonomic level, some studies have suggested that no bacterial species is present within 100% of subjects.

What explains the dominance of Firmicutes and Bacteroidetes then? It is likely because microbial diversity at the taxonomic level does not neatly map on to functional diversity. Microbiomes may be very diverse in terms of which species are present, but less diverse in terms of which higher-level taxa and metabolic functions are present. Different microbial communities appear to often converge on similar functional profiles.

The Human Microbiome and Its Relationship to Human Health

Once the composition of a host-associated microbiome has been roughly described and categorized it is often employed to look at links between composition and host function. Host-associated microbiomes have been shown to play key roles in the development, metabolism, homeostasis and immunity of the host. Particular compositional patterns have also been associated with disease, obesity, diabetes, cancer, and allergies. Most human microbiome research targets the links between the microbiome and human health or development in some way. Although these comparisons are done for numerous body niches, the colon and lower gut are the focus of much of this research. This is likely due to the ease of access to the gut microbiota, which is commonly done by proxy via fecal samples.

Some unhealthy states are correlated with signatures in the microbiome, and thus the composition of the microbial communities might serve some important diagnostic and predictive purposes. Numerous studies have shown that an elevated proportion of Firmicutes is associated with host obesity and the change in metabolism accompanying it. Crohn's disease is associated with a significant decrease in Bifidobacteriaceae populations and an increase in groups containing potential pathogens. A wide range of other diseases, including brain and behavioral disorders has now been associated with changes in microbiota diversity. Phylum-level patterns associated with conditions such as human obesity have been described as "highly conserved bacterial traits" that affect host phenotype. Many of these association studies do not, however, go on to examine any causal implications very thoroughly (i.e., whether changes in composition are causes or effects of disease states). There have been also attempts at genome-wide association studies pinpointing the genetic and nongenetic host factors influencing the microbiota. In order to effectively understand the impact of the microbiome on the host, it is critical to connect compositional and correlational studies to functional studies and the causal mechanisms underlying those functions.

(Micro)Biological Engineering

Microbes can live in nearly every environment on Earth and produce enzymes for every major biochemical transformation of organic or inorganic matter on the planet. The global microbiome is a reservoir of billions to trillions of genes that could be drawn upon to build valuable pathways and products. There is a long history of harnessing the wild capabilities of microbes to generate desirable products, from bread and beer to antibiotics and fuel. Microbiome methods have opened up the search for microbes, in isolation or in consortia that can synthesize compounds with environmental, industrial, and pharmaceutical value. Isolating and identifying the functions of single genes and biosynthesis pathways on large scales is also necessary for the construction of synthetic microbes. Microbe-based fuel manufacturing holds considerable promise for the future generation of alternative fuels with less waste and fewer toxic by-products.

Controversies

Dysbiosis

Gut microbiota has been investigated for many healthy and diseased people and significant differences have been observed in the composition of their bacterial communities. Because such remarkable changes cannot be always explained by specific taxa, the idea of a whole-community dysfunction was proposed instead. Such unusual states of the microbiome are sometimes referred to as "dysbiosis," a very loosely defined change in the microbial composition. Many microbiota researchers criticized the term due to its ambiguity, difficulties in defining the reference healthy or normal state and the uncertainty if observed dysbiosis is a cause or effect of the disease (see Hooks and O'Malley, 2017). More worryingly dysbiosis is sometimes reported as a result of a study rather than taken as a sign that a further research is needed to elucidate the mechanisms, by which the microbiota is interacting with and responding to the altered host environment.

The Hologenome Theory of Evolution

Recognition that holobionts are common in nature has led many researchers to reassess their views about various processes and concepts that are foundational in biological thinking (Skillings, 2016 has an overview of this debate). One suggestion is that there is now a need to upgrade fundamental theories about the action of natural selection because holobiont systems "raise the discussion of individuality and organismality beyond its historical perspective to a level that challenges and extends current thinking" (Theis et al., 2016). Several researchers now claim that holobionts, or similar multilineage assemblages of macrobes and microbes, constitute at least one level of organization at which natural selection acts. It is unlikely that there is any holobiont that is also a unit of selection or organism if the holobiont is defined as a macrobe host and *all* of its associated microorganisms. It is not impossible that a host and its symbionts could form a unit of selection, it is just that the conditions are unlikely to obtain. High partner fidelity and alignment of fitness are necessary. This is achieved by vertical inheritance or by strong mutual partner choice. Such high-fidelity associations are unlikely to occur across all of the partnerships within a holobiont. Where it does not, selective pressures at the level of the individual lineages will tend to put the partners into direct competition or active exploitation. Neither reducing the holobiont to a set of pairwise interactions between symbiont partners nor treating the entire community as a single biological individual is a universally appropriate approach for holobiont research.

Natural Selection

Kent E Holsinger, University of Connecticut, Storrs, CT, United States

Darwin, Wallace, and the Theory of Natural Selection

Charles Darwin (1809–82) spent nearly 5 years (December 1831 to October 1836) as a naturalist aboard the *Beagle* during its expedition around the world, in addition to spending many years studying natural history in southeastern England. Alfred Russel Wallace (1823–1913) spent 4 years in the tropical forests of Brazil and 8 more years in the forests of southeastern Asia. Their years of work and that of many biologists who preceded them revealed many examples of plants and animals whose physiology and habits made them well adapted to their environment. Darwin had completed the first draft of a book on species and speciation when he received a letter from Wallace including the draft of a paper entitled 'On the Tendency of Varieties to Depart Indefinitely from the Original Type'. In this paper, Wallace described the theory of natural selection, a theory Darwin had independently discovered 20 years earlier but was only now preparing for publication. In 1858, Wallace's paper was published in the *Journal of the Linnean Society* together with extracts from an essay Darwin wrote in 1844 but never published. One year later, Darwin's *On the Origin of Species* appeared.

The theory of natural selection that Darwin and Wallace presented is beguiling in its simplicity, yet it is sufficient to explain the many intricate adaptations of plants and animals.

(1) In every population of every species on Earth, more individuals are born than survive to reproduce.
(2) In most populations, individuals differ from one another in characteristics that cause them to differ in their chances of survival, in the number of offspring they produce if they survive to reproduce, or in both.
(3) Offspring tend to resemble their parents.

From these simple observations follows the obvious conclusion: Any characteristic that increases an individual's chance of survival or its fecundity will tend to become more common. Similarly, any characteristic that lessens an individual's chance of survival or reduces its fecundity will tend to become less common. Thus, individuals will tend to be well adapted to the circumstances in which they find themselves.

Mutations introduce variation into populations that may lessen the chance that some individuals survive. Genetic drift may have a greater influence than natural selection on the transmission of genetic variation from one generation to the next in small populations. A population may not have had time to adapt to recent changes in its environment, or its environment may be constantly fluctuating so that no single characteristic is always favored. For these and other reasons, organisms are not perfectly adapted to their environment. But the process of evolution by natural selection guarantees that most characteristics of most organisms will be well suited to the conditions in which they are found most of the time.

Genetic Consequences of Natural Selection

The genetic consequences of natural selection are the easiest to understand if we study how allele frequencies at one locus with two alleles change when genotypes differ in their probability of survival. An individual's fitness is its contribution to the composition of later generations, relative to the contribution of other individuals in the same population. Fitness differences may arise because individuals differ in their probability of survival, in their ability to find mates, in the number of offspring they produce when mated, and in many other ways. Differences in probability of survival are the easiest to understand. Fortunately, many of the genetic consequences of natural selection do not depend on whether fitness differences arise from differences in survival probability or from differences in some other component of fitness.

Suppose an individual with genotype A_1A_1 survives to reproduce with probability w_{11}, and suppose that the survival probabilities for genotypes A_1A_2 and A_2A_2 are w_{12} and w_{22}, respectively. If individuals choose their mates at random, then genotypes in newly formed zygotes will be found in Hardy–Weinberg proportions. So if the frequency of allele A_1 is p and that of allele A_2 is q, we can calculate the frequency of the three genotypes in zygotes and adults as follows in **Table 1**. $\overline{w}$, which is equal to $p_i^t w_{11} + 2p_t q_t w_{12} + q_i^t w_{22}$, is known as the mean fitness. It is the average survival probability in the population. From the adult frequencies in the last row of **Table 1**, we can calculate the allele frequency among newly formed zygotes of the next generation, namely,

$$p_t + 1 = \frac{(p_t^i w_{11} + p_t q_t w_{12})}{\overline{w}}$$

Suppose that the frequency of the A_1 allele in newly formed zygotes is 0.4 and that $w_{11}=0.9$, $w_{12}=0.8$, and $w_{22}=0.7$, then the above equation allows us to predict that the frequency of A_1 in newly formed zygotes of the next generation will be 0.43. Now

Table 1 .

Genotype	A_1A_1	A_1A_2	A_2A_2
Zygote frequencies	p_t^i	$2p_tq_t$	$q_{t>}^i$
Probability of survival	w_{11}	w_{12}	w_{22}
Adult frequencies	$p_t^i w_{11}$/*not found*	$2p_tq_tw_{12}$/*not found*	$q_t^i w_{12}$/*not found*

suppose that the survival probabilities were all cut in half, that is, $w_{11}=0.45$, $w_{12}=0.4$, and $w_{22}=0.35$. Then, we can use the above equation again to predict the frequency of A_1 in newly formed zygotes of the next generation, namely 0.43, exactly what we predicted before. These calculations illustrate a very important fact about natural selection: The change in allele frequency from one generation to the next as a result of natural selection depends only on the fitness of genotypes relative to one another. Even a genotype with a low probability of survival can be favored by natural selection if its probability of survival is higher than that of other genotypes in the population.

Since natural selection favors characteristics that increase the probability of survival, it is not surprising that the mean fitness of the new progeny generation is greater than that of the one that preceded it, unless the mean fitness is as great as it can be under the current conditions. When mean fitness is at a maximum, the allele frequency will not change from one generation to the next, even though genotype frequencies will differ between newly formed zygotes and reproductive adults. The population is at equilibrium.

We can predict characteristics of the population at equilibrium simply by knowing which genotype is most likely to survive, which is least likely to survive, and which has an intermediate probability of survival. Three patterns of selection are possible:

$w_{11}>w_{12}>w_{22}$ – Directional selection
$w_{11}<w_{12}<w_{22}$ – Directional selection
$w_{11}>w_{12}$ and $w_{22}>w_{12}$ – Disruptive selection (heterozygote disadvantage)
$w_{11}<w_{12}$ and $w_{22}<w_{12}$ – Stabilizing selection (heterozygote advantage).

Directional Selection

Directional selection occurs when individuals homozygous for one allele have a fitness greater than individuals with other genotypes and individuals homozygous for the other allele that have a fitness less than individuals with other genotypes. At equilibrium, the population will be composed entirely of individuals that are homozygous for the allele associated with the highest probability of survival. The rate at which the population approaches this equilibrium depends on whether the favored allele is dominant, partially dominant, or recessive with respect to survival probability. An allele is dominant with respect to survival probability if heterozygotes have the same survival probability as homozygotes for the favored allele, and it is recessive if heterozygotes have the same survival probability as homozygotes for the disfavored allele. An allele is partially dominant with respect to survival probability if heterozygotes are intermediate between the two homozygotes in survival probability. This pattern of selection is referred to as directional selection because one of the two alleles is always increasing in frequency and the other is always decreasing in frequency.

When a dominant favored allele is rare, most individuals carrying it are heterozygous, and the large fitness difference between heterozygotes and disfavored homozygotes causes rapid changes in allele frequency. When the favored allele becomes common, most individuals carrying the disfavored allele are heterozygous, and the small fitness difference between favored homozygotes and heterozygotes causes allele frequencies to change much more slowly (**Fig. 1**). For the same reason, changes in allele frequency occur slowly when an allele with recessive fitness effects is rare and much more rapidly when it is common. A deleterious recessive allele may be found in different frequencies in isolated populations even if it has the same fitness effect in every population, because natural selection is relatively inefficient when recessive alleles become rare, allowing the frequency to fluctuate randomly as a result of genetic drift.

Disruptive Selection

Disruptive selection occurs when heterozygous individuals are the least likely to survive. For that reason, this fitness pattern is also referred to as heterozygote disadvantage. If a population happened to start with an allele frequency exactly equal to $p^*=(w_{12}-w_{11}-w_{22})$, the allele frequency would not change, that is, the population would be at equilibrium. But the equilibrium is not stable. Selection magnifies even a tiny change in allele frequency until eventually one allele or the other is lost from the population. Which allele is lost depends on whether the initial allele frequency is greater or less than p^*. If the initial allele frequency is greater than p^*, A_2 will be lost and the population will be composed entirely of A_1 homozygotes at equilibrium. If the initial allele frequency is less than p^*, A_1 will be lost and the population will be composed entirely of A_2 homozygotes at equilibrium. This pattern of selection is referred to as disruptive selection because selection will cause two populations with similar allele frequencies to evolve in opposite directions if one has an allele frequency slightly less than p^* and the other has an allele frequency slightly greater than p^*

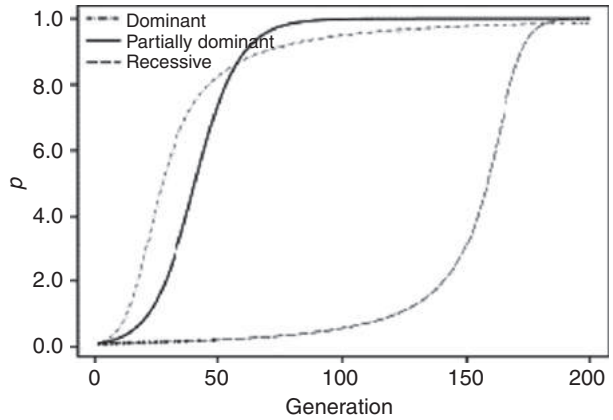

Fig. 1 Dynamics of directional selection.

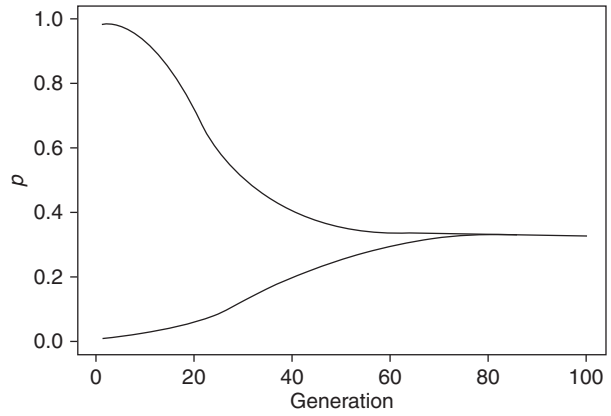

Fig. 2 Dynamics of heterozygote advantage.

Stabilizing Selection

Stabilizing selection occurs when heterozygous individuals are the most likely to survive. For that reason, this fitness pattern is also referred to as heterozygote advantage. As with disruptive selection, if a population happened to start with an allele frequency exactly equal to $p^* = (w_{12} - w_{11} - w_{22})$, the allele frequency would not change. When heterozygotes are more likely to survive than either homozygote, however, p^* is a stable equilibrium. Selection causes small departures from p^* to become even smaller with time. Moreover, the allele frequency in the population will evolve toward p^* regardless of the initial allele frequency, as long as both alleles are initially present. In Fig. 2, for example, $w_{11} = 0.72$, $w_{12} = 0.9$, and $w_{22} = 0.81$, and the population evolves toward $p^* = 0.33$ regardless of whether the initial allele frequency is 0.01 or 0.99.

Selection on Continuous Traits

Darwin and Wallace proposed the theory of natural selection almost 50 years before Mendel's rules were rediscovered. The logic is incontrovertible. If there are heritable differences among individuals that cause differences in reproduction and survival, then traits that increase the probability of survival and reproduction will become more common and those that decrease the probability of survival and reproduction will become less common. When geneticists study the inheritance of a continuous trait, they use the heritability of that trait to describe the extent to which offspring resemble their parents.

Response to Selection

Differences among individuals may arise because they have the same genotype but were exposed to different environments, because they were exposed to the same environment but have different genotypes, or because they have different genotypes and were exposed to different environments. The heritability of a trait is the proportion of phenotypic variation that can be transmitted from parents to offspring. In Fig. 3, the *x*-axis is half the summed body weight (in grams) of paired male and female laboratory

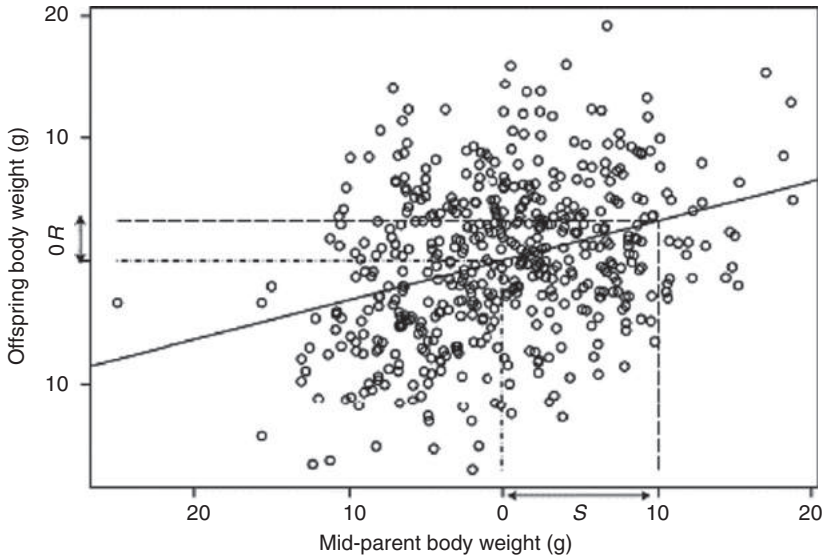

Fig. 3 Selection on body weight in laboratory mice.

mice. (This quantity is known as the mid-parent body weight.) The y-axis is the body weight (in grams) of offspring. The slope of the regression line running diagonally through the figure is equal to the heritability of body weight in this population of mice.

The regression line allows us to predict the body weight of offspring from the body weight of parents. Specifically, if we let x_s be the mid-parent body weight of a particular pair of parents in the population and $\bar{x}$ be the average mid-parent body weight in the population as a whole, then the expected body weight of their offspring is

$$x_0 = h^2(x_s - \bar{x}) + x$$

Suppose that natural selection causes a difference between the mean of a trait in those individuals that reproduce and the mean in a population as a whole. We can apply the above equation to the whole population. Now we interpret $\bar{x}$ as the mean mid-parent body weight 'before selection' and x_s as the mean mid-parent body weight 'after selection'. We can also rearrange the equation so that it directly predicts how much the mean body weight will change from parents before selection to offspring before selection (in the next generation):

$$x_0 - x = h^2(x_s - \bar{x})$$

The quantity $x_s - \bar{x}$ is called the selection differential, S. The quantity $x_0 - x$ is called the response to selection, R. The response of a trait to selection depends on both the heritability of the trait and the selection differential: $R = h^2S$. If a trait lacks heritable variation, $h^2 = 0$, there will be no change in response to selection no matter how strong the selection is.

Fisher's Fundamental Theorem of Natural Selection

We can use these results to study how fitness itself changes from one generation to the next. Intuition tells us that if fitness-enhancing traits become more common, the average fitness in the whole population should also increase over time, and that is just what we find. Let w_t be the mean fitness before selection, $\overline{w}_t^*$ be the mean fitness after selection, and w_{t+1} be the mean fitness in the next generation. Then,

$$w_{t+1} - w_t = h^2(\overline{w}_t^* - w_t)$$

The mean fitness of a population after selection ($\overline{w}_t^*$) is greater than that before selection (w_t) because individuals with a high probability of survival are more common in the population after selection than they were before selection. In addition, h^2 is necessarily positive. Thus, w_{t+1} must be greater than w_t. The only time when this inequality will not hold is when $h^2 = 0$, which means that the population has reached the maximum possible fitness. This equation embodies Fisher's fundamental theorem of natural selection, and it implies three things about the process of evolution by natural selection:

(1) The change in mean fitness between generations is proportional to the heritability of fitness.
(2) The mean fitness of a population will never decrease from one generation to the next and will remain constant only when the population has reached the maximum possible fitness.
(3) Evolution by natural selection gradually depletes the heritable variation in fitness that is required for it to continue.

Fisher's fundamental theorem of natural selection has many exceptions. In small populations, genetic drift may be a more important influence on the evolution of populations than natural selection, selection on fecundity differences need not follow the

same pattern as selection on viability differences, and fitness differences are rarely the same for more than a few generations, for example. Nonetheless, Fisher's fundamental theorem validates our intuition: As fitness-enhancing traits become more common, the average level of adaptation in a population will increase.

Detecting Natural Selection

When biologists say that a trait is subject to natural selection, they mean that

- Individuals differ in the probability with which they survive (viability selection);
- Individuals differ in their ability to attract mates (sexual selection);
- Pairs of individuals differ in the number of offspring they produce (fecundity selection); or
- Individual alleles differ in the probability with which they are incorporated into gametes (gametic selection).

Viability Selection

Differences in probability of survival are most often associated with natural selection. When we say that an organism is well adapted to its environment, we often mean that it has a high probability of survival. Detecting differences in survival probability is relatively straightforward.

When a wild-type female of *Drosophila melanogaster* heterozygous for the allele causing white eye color is crossed with a white-eyed male, we expect half of the offspring to be white eyed and half to be wild type, regardless of sex. In one such set of crosses, experimenters obtained the results shown in **Table 2**.

Since the rules of Mendelian genetics tell us that there were equal numbers of wild-type and white-eyed zygotes formed, the deficiency of white-eyed flies must be the result of a lower probability of survival. This experiment shows that there was viability selection against white eyes in this laboratory population of *D. melanogaster*.

Sexual Selection

The most obvious way in which individuals differ in their ability to attract mates is when males compete for control of a harem, as in North American elk (*Cervus canadensis*). This type of sexual selection is known as male–male competition. Males and females of most species differ in many characteristics that are not directly related to the reproductive process. Such characteristics are known as secondary sexual characteristics. When differences among males in secondary sexual characteristics cause females to choose some for mates in preference to others, it is a type of sexual selection known as female choice.

The pied flycatcher (*Ficedula hypoleuca*) breeds in Europe, northern Africa, and western Asia. Two color forms of male pied flycatchers are found in Europe. The black-and-white form has black feathers on its head, the nape of its neck, and its back. It has white feathers on its chin, the front of its neck, and its underside. The brown form has brown feathers instead of black ones on its head, the nape of its neck, and its back.

To determine whether a male's color affects the female's choice of mate, experimenters placed pairs of males, one black and white and one brown, in outdoor aviaries. The aviaries contained three compartments. Each male was placed in a separate compartment and prevented from seeing the other male. After the males were habituated to the aviary, a female was placed in the third compartment with two nest boxes, one close to each of the males. The female could see both males. When the female built a nest, the experimenters noted whether she built it in the nest box associated with the black-and-white male or in the one associated with the brown male.

Females for the experiment were collected from an area in central Europe where the closely related black-and-white collared flycatcher (*Ficedula albicollis*) also occurs. Out of 12, 10 females (5:1) built their nests in boxes associated with the brown male, showing that female choice leads to sexual selection in favor of the brown form in this region. In areas where the black-and-white collared flycatcher does not occur, similar experiments showed that sexual selection through female choice favors the black-and-white form of the pied flycatcher.

Fecundity Selection

Experiments in laboratory populations of *D. melanogaster* have repeatedly shown that differences among individuals in the number of offspring they produce contribute more to fitness differences among individuals than to differences in the probability of

Table 2 .

	Red eyed	*White eyed*	*Total*
Observed	2652	2088	4740
Expected	2370	2370	4740

survival. Experiments measure the magnitude of fecundity selection by counting the number of offspring produced from different types of matings.

Adults heterozygous for *Cy* have curled wings when pupae are raised at 25°C. To determine whether females with curled wings produce fewer offspring than those with normal wings, experimenters allowed each female to mate with one male and calculated the mean number of adult offspring each type of mating had produced 18 days after mating (**Table 3**).

The fecundity of *Cy* females was 95% of the fecundity of wild-type females when mated with a wild-type male and only 79% of the fecundity of wild-type females when mated with a *Cy* male. Similarly, *Cy* males produced fewer offspring than wild-type males regardless of whether they were mated with *Cy* or wild-type females. Fecundity selection favors wild type in both females and males. Moreover, the differences between *Cy* and wild type in female fecundity (5%–20%) are much greater than those in viability ($<1\%$).

Gametic Selection

Mendel's rules tell us that half of the gametes produced by a heterozygous individual will carry one allele and half will carry the other, but Mendel's rules are sometimes broken. In mice (both *Mus musculus* and *M. domesticus*), the genes of the major histocompatibility complex and many others are tightly linked in a region near the centromere of chromosome 17. Because recombination between these genes is rare, the entire region is usually transmitted as if it were a single Mendelian gene. Mutations in the *t* complex, as this chromosomal region is known, often affect viability. In addition, over 90% of the gametes transmitted by males heterozygous for a 'complete' *t* and a wild-type *t* haplotype carry the complete *t* haplotypes. The great excess of complete *t* haplotypes in the progeny of heterozygous males shows that gametic selection favors the complete *t* haplotypes over wild-type *t* haplotypes.

Levels of Selection

It is natural to refer to organisms when discussing natural selection and its consequences. But the example of the *t* haplotype in mice illustrates that natural selection can operate at the level of gametes too. In fact, the *t* haplotype illustrates that natural selection may act simultaneously at several different levels of biological organization, the gamete or the gene, the individual organism, and the population or group.

We have just seen how biased segregation in favor of the complete *t* haplotype leads to gametic selection in favor of the complete *t* haplotype. If gametic selection were the only evolutionary force affecting this trait, the complete *t* allele would rapidly sweep through mouse populations and eliminate the wild-type allele. But gametic selection is not the only force. Many complete *t* haplotypes carry recessive lethals, and many of those that do not carry lethals cause sterility when homozygous. Selection at the level of the individual organism favors the wild-type haplotype. If it were the only evolutionary force affecting this trait, the complete *t* allele would be rapidly eliminated from mouse populations. The balance between these opposing forces leads to maintenance of both alleles in mouse populations.

Mathematical models that combine gametic and individual selection, however, predict that the complete *t* haplotype should be found much more frequently than it is. Selection at the level of groups or populations may be responsible for the discrepancy.

Mouse populations are often small and founded by only a few individuals. As a result, genetic drift may have a large influence on allele frequencies within them. In a few populations, the complete *t* haplotype may become very common. When it does, there is also a possibility that, by chance, all the offspring produced will be homozygous for a complete *t* haplotype. If they are, the population is doomed to extinction. If the population is recolonized, the new colonists will probably have a lower frequency of the complete *t* haplotype. Selection among groups favors groups with a low frequency of the complete *t* haplotype, reinforcing selection at the level of individual organisms.

Evolution by natural selection among groups or populations is possible when

(1) Groups differ from one another in their probability of extinction, in the probability that migrants from them found new populations, or in the probability that migrants from them are incorporated into existing groups; and
(2) Migrants that form new groups or are incorporated into existing groups resemble the groups from which they were drawn. As the example of the complete *t* haplotype makes clear, evolution by natural selection need not produce the best possible results for a whole species or even for individual populations. The 'best' result for mouse populations would be if the

Table 3 Fecundity selection in *Drosophila melanogaster*

Female genotype	*Male genotype*	
	Cy	*Wild type*
Cy	90.0	111.8
Wild type	114.2	117.1

complete *t* haplotype were completely eliminated. Selection in favor of the complete *t* haplotype at the level of gametes ensures that this will not happen, and the result is an equilibrium (a compromise) between two extremes.

Phylogenomics and Phylogenetics

Rodney L Honeycutt, Pepperdine University, Malibu, CA, United States

Glossary

Character Attribute of an organism useful for distinguishing taxa and inferring relationships among groups of organisms.

Character state Variants of a character.

Clade Branch of phylogenetic tree considered to be monophyletic.

Cladogram Diagrammatic representation of groupings of organisms based on shared-derived characters.

Classification Hierarchal ordering of taxa into categories of different ranks with the hierarchy, such as species, genus, family, order, class.

Homology Similar characteristics resulting from a shared ancestry.

Homoplasy Similarity of a characteristic that is not the result of shared ancestry.

Monophyletic group Grouping of taxa based on a shared common ancestor.

Orthologous Homologous genes derived from a common ancestor.

Outgroup Taxon used in a phylogenetic analysis to establish the placement of the root of a phylogenetic network of a group being studied and to determine the polarity of characters (primitive to derived states) used to construct the phylogeny.

Paraphyly Group in a classification that does not contain all the descendants of the most recent common ancestor.

Paralogous Term describing duplicated genes that produce gene trees different from species trees.

Phylogeny Tree that represents the evolutionary history of a group of organisms.

Sister groups Two groups descended from a common ancestor.

Taxon (pl. taxa) A group recognized by taxonomists as being a unit based on the shared and uniquely derived characters; the rank ranges from groups of populations to higher taxonomic categories.

Taxonomic characters Morphological or molecular attributes used to identify similarities and differences among species or groups of higher taxonomic rank.

Tree of Life

"As buds give rise by growth to fresh buds, and these, if vigorous, branch out and overtop on all sides many a feebler branch, so by generation I believe it has been with the great Tree of Life, which fills with its dead and broken branches the crust of the earth, and covers the surface with its ever-branching and beautiful ramifications." This metaphor by Darwin (1859) reflects his view of all living organisms sharing a common evolutionary history characterized by a branching pattern of ancestor/descendant relationships that change through time as new species arise and others go extinct. Today, Darwin's Tree of Life is referred to as a phylogeny, an evolutionary hierarchy displaying ancestor/descendent relationships of groups of organisms (clades or monophyletic groups) sharing uniquely derived characteristics and a common ancestor. Once constructed, a phylogeny provides an interpretive framework for the development of a natural classification of organisms and for detailed examination of biological processes. As a result, phylogenies are being used in many disciplines of the life and earth sciences, anthropology, behavioral sciences, and applied sciences such as medicine, agriculture, and forensics. Even the origin of our domestic plants and animals is now being investigated through the lens of a phylogenetic framework.

Systematic Biology

Systematic biology focuses on organismal diversity, including the distribution of and relationships among populations and species. As a discipline, systematics is foundational to a broad spectrum of biology because it provides an ordered way of thinking about biological diversity and the processes responsible for that diversity. It is a comparative science that evaluates patterns of variation and uses that variation to recognize species and to infer relationships among populations and species. This latter component of systematics is known as phylogenetics. Another facet of systematic biology deals with taxonomy, which discovers and describes species and establishes classifications that reflect a hierarchy of groups based on their phylogenetic relationships. Phylogenetic classifications assign names (e.g., kingdom, phylum, class, order, family, genus) to groups of related organisms (clades) sharing a common ancestry (monophyly).

Reading a Phylogeny

Relationships among organisms, denoted 1–4 in Fig. 1, display a branching pattern, known as a phylogeny. Branches can be of two types, internal branches occurring between two nodes and branches connecting the tip with an ancestral node. Rooted phylogenies

 doi:10.1016/B978-0-12-409548-9.10578-0

also infer a time dimension with the oldest nodes and branches near the base of the tree with more recent branching patterns progressing toward the tips (Fig. 1A). Nodes of a tree represent hypothetical common ancestors, with bifurcation at a node representing points of divergence or speciation (Fig. 1B). Character states shared between the ancestor and descendants are considered primitive (plesiomorphic), denoted by the *dotted line*, whereas shared derived traits (synapomorphic) are denoted by the dashed line and unique changes along the solid lines are considered apomorphies (Fig. 1C). These shared derived traits define groups or clades sharing a common ancestor (monophyletic groups). In this figure, clade containing 1, 2, and 3 are defined by shared derived traits, while another clade (3, 4) share a separate set of derived traits. As a result of differences in the overall rates of evolution along particular lineages, branches can vary in length. When internode lengths are short, phylogeny reconstruction becomes more challenging. Outgroups are used to define the root of a tree containing a monophyletic group that is sister to the outgroup (Fig. 1D). Clades or sister groups are defined by a shared common ancestor (e.g., clades 1/2/3/4, 2/3/4, 3/4).

Phylogenetics

The goal of phylogenetics is to infer relationships among lineages (genes, individuals, populations, and species), with the underlying assumption that there is only one true phylogeny. Approximating that phylogeny requires an objective means of evaluating alternative phylogenetic hypotheses.

Early attempts at inferring phylogenetic relationships were based on morphological traits shared by extant (living) and extinct (fossil) forms of life. Approaches to phylogeny reconstruction have varied through time, and in many cases debate over the correct procedure has been contentious. Even with this disagreement, all systematic biologists agree that phylogenies should be derived from homologous characters (similarities derived from a common ancestor) rather than characters that are similar but not the result of shared ancestry (considered forms of homoplasy). A classic example of a homoplastic character is similarity (convergence) as a result of function rather than shared ancestry. For instance, the four chambered heart and homeothermy (ability to regulate body metabolically) are shared between birds and mammals, yet these traits should not be used to infer a direct common ancestry because they represent independent adaptations to an active lifestyle. An example of convergence at the molecular level is the shared similarity of amino acid sequences seen in the lysozyme c gene of leaf-eating monkeys and ruminant ungulates, two mammalian lineages that do not share a common ancestor. In this case, these similarities are in response to structural/functional changes associated with the activity of lysozyme c in foregut fermentation systems. Another form of homoplasy is reversal of a character to an ancestral state. Reversals are common with molecular data, especially nucleotide substitutions, as a result of the limited number of possible changes allowed. When referring to molecular data, the term orthology is used rather than homology, while paralogous characters reflect gene genealogies that run counter to the genealogies of species. For instance, the gene genealogy of gene duplications would fail to correspond to a species phylogeny.

Methods of Phylogeny Reconstruction

Several different methods have been used to infer phylogenetic relationships. These methods include distance-based approaches, maximum parsimony, maximum likelihood, and Bayesian inference. All these methods begin with a suite of characters (traits used

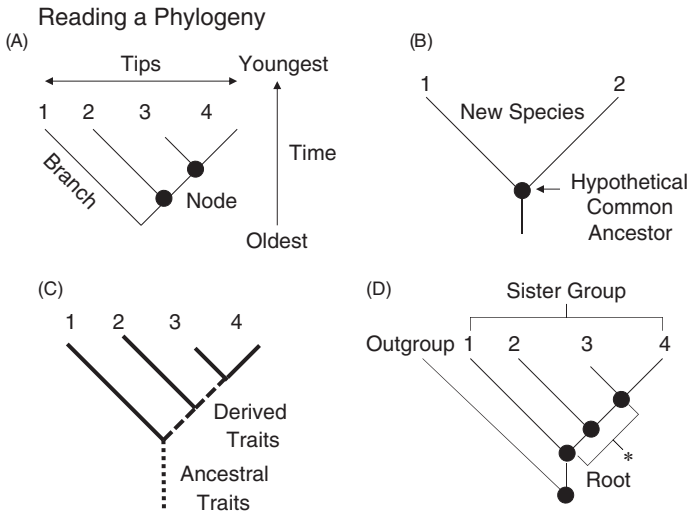

Fig. 1 (A) Components of a phylogeny with oldest being at the base of the tree; (B) species diversification from a common ancestor; (C) branching pattern characterized by ancestral (plesiomorphic) states denoted by *dotted line*, derived states (synaporphies) *dashed line*, and uniquely derived states (autapomorphies) denoted by solid line; (D) phylogeny showing the outgroup that defines the root as well as internal nodes of the tree (*).

to infer relationships such as a morphological feature or nucleotide and amino acid sites of a gene) used to create a data matrix, containing all taxa, characters, and character states (variants of each character) or in the case of distance-based approaches, a pairwise distance matrix. For some morphological traits, character states may be binary (present or absent), whereas molecular data can be represented as specific nucleotides (A, G, C, T), one of the 20 possible amino acids at each site, and an estimate of genetic distance based on the number of substitutions.

Phylogenies can be represented as either rooted or unrooted. An outgroup represents a taxon or taxa hopefully closely related (sister) to the group under study (the ingroup). The outgroup serves two purposes. First, it allows for the establishment of the root of the tree, and second, the polarity of character state transformations can be established. For instance, any character state shared between the outgroup and ingroup is considered an ancestral or shared primitive state (plesiomorphic). Derived (apomorphic) character states represent transformations from the ancestral state.

Finding the most accurate phylogeny becomes more complex as the number of taxa increases. For instance, the number of possible bifurcating trees for a matrix containing 10 taxa is over 34 million possibilities. Above 20 taxa, there is no exact solution, thus various methods of phylogenetic reconstruction use algorithms that perform some type of heuristic search of tree space to find the most optimal solution. How does one establish confidence in a branching pattern obtained from a particular analysis? All phylogenetic methods employ some type of analysis to establish confidence with respect to the interior nodes that join taxa into distinct groups or clades. Bootstrap methods are used for distance-based methods, maximum parsimony, and maximum likelihood to estimate support for particular branches of the phylogeny. The procedure takes random subsamples with replacement from a data matrix and performs replications of phylogeny reconstruction on the subsamples. This analysis is repeated hundreds or thousands of time, and the frequency at which the same nodes connecting particular taxa provides an estimate of support for that particular node. For instance, if 900 of 1000 iterations of bootstrap replications supported a node connecting guinea pig and mouse, the bootstrap support for that node would be 90%. Simulations and empirical studies suggest that a bootstrap value $\geq$70% is considered reasonable support. Bayesian inference estimates posterior probabilities denoting the level of support for a particular clade. These estimates are based on a majority rule consensus of all trees sampled during a run.

Distance-Based Methods

Over the years, methods of phylogenetic inference have varied. Phenetic approaches, using an estimate of overall similarity or distance to identify clusters or groups organisms, were some of the first to provide a more quantitative approach for inferring relationships. This particular method makes no distinction between ancestral and derived characters, and earlier methods, such as UPGMA (unweighted pair group method) assumed rate constancy. More recent methods employing pairwise distance matrices and clustering, such as neighbor-joining, do not assume rate constancy. For molecular data, this approach can allow for incorporation of models that correct for some variance associated with nucleotide sequence data. This method is still widely used in phylogenetic studies, and it is computationally fast and provides branch lengths. Two drawbacks are that it does not allow for an evaluation of discrete characters but relies on overall morphological or genetic distance among taxa, and distance estimates from highly divergent taxa are more likely to be inaccurate.

Maximum Parsimony

Maximum parsimony (MP) is a model-free method that uses discrete character states for inferring phylogenies. This particular method is advocated by those promoting a cladistic approach, whereby shared-derived characters (synapomorphies) are considered phylogenetically informative in terms of defining clades (monophyletic groups of organism). Shared ancestral character states (plesiomorphies or primitive) and autapomorphies (character states unique to a single linage or taxon) are both considered uninformative. A cladogram represents a dichotomous branching pattern characterized by the distribution of shared derived characters that identify monophyletic groups derived from a common ancestor. This approach argues that classifications should reflect the phylogeny.

The basic assumption of maximum parsimony is that the simplest explanation is the tree that most effectively minimizes homoplasy (convergence, parallelism, and reversal). Therefore, the tree with the shortest length is the most parsimonious tree. Maximum parsimony has been used extensively for the analysis of morphological data, and for more recently diverged taxa, it works well for molecular data. However, MP underestimates branch lengths, and it fails to provide a means for addressing evolutionary processes associated with molecular data, such a base composition bias, among-site rate variation, and multiple substitutions at a single site. This can result in inaccurate tree construction for deeper levels of molecular divergence as well as when branches differ in length and are connected by short internodes.

Maximum Likelihood

Maximum likelihood is a model-based method that allows for the use of models to address differences in the probability of some types of nucleotide substitutions. These models can range from the treatment of all substitutions and base frequencies as being equal to those that accommodate variance in base frequencies as well as all six classes of nucleotide substitutions and among site rate variation. An increase in model complexity increases the number of parameters that need to be assessed, and over

parameterization can result in inaccurate phylogeny reconstruction. Therefore, model selection is important prior to initiating maximum likelihood analysis. Maximum likelihood is computationally expensive because of its method of evaluating trees, and as such, its use for large molecular datasets is limited.

Bayesian Inference

Another probabilistic method used in phylogenetics is Bayesian inference, which is becoming very popular for analyzing large molecular datasets currently produced in the era of phylogenomics. Like maximum likelihood, Bayesian inference requires selection of a model of molecular evolution and uses a likelihood function, and it allows for a range of model complexity. Unlike maximum likelihood, which determines likelihood scores for all parameters of a particular model, Bayesian inference uses a prior distribution of trees in combination with the Markov Chain Monte Carlo (MCMC) method and parameters set by the selected model to estimate the posterior probability of trees. This method allows for a random search in tree space with sample trees taken at a designated number of steps. Assuming a prior distribution for phylogenetic studies is difficult. Therefore, most molecular phylogenetic studies assume a uniform prior distribution, thus allowing tree differences to be based on the likelihood of fit with the chosen model's parameters. In addition to phylogenetic inference, Bayesian methods are also used to estimate divergence times from molecular data. Finally, as with maximum likelihood, model selection is important for retrieval of accurate phylogenies and estimates of divergence times.

Phylogeography

Phylogeography combines gene genealogies with geography to explain the current distribution of populations and species resulting from various historical events. Phylogeographic patterns, especially those that are similar across unrelated groups (genealogical concordant), allow for an investigation of the processes (dispersal and vicariance) responsible for the biogeographic distribution of distinct gene lineages. In some cases, this approach helps identify common geographic events responsible for the patterns observed. A classic example is the concordant subdivision of unrelated freshwater fish populations into distinct haplogroups (phylogenetically related mitochondrial haplotypes) occurring in the southeastern United States and Florida relative to more western groups along the Gulf Coast. Such patterns suggest a common cause for the separation of these two major lineages.

The most common molecular marker used in phylogeographic studies is mitochondrial DNA (mtDNA), a maternally inherited genome derived from the mitochondrion. In comparison to the nuclear genome, the mitogenome evolves considerably faster, and this rapid rate of mutation in combination with its lack of recombination (resulting in haplotypes) provides strong geographic signal for divergence of populations as a result of isolation by distance or barriers to dispersal. Additionally, the mitochondrial clock is used to determine the geological date of events that occurred throughout the evolutionary history of a species or group of species.

Early studies of mtDNA variation relied on the estimation of genetic distances derived from an examination of restriction fragment length polymorphisms. Later, nucleotide sequencing of specific mitochondrial genes or the noncoding control region was used to infer mitochondrial phylogenies and estimate divergence times. Rapid and less expensive sequencing technologies have allowed for whole mitochondrial genomes of individuals to be sequenced. These mitochondrial genome sequences (termed mitogenomics) are being used to infer phylogenetic relationships across more divergent lineages, such as mammalian orders and families.

An example of the utility of mitogenomics can be seen from studies of human origins. Mitochondrial DNA appears to be better preserved in ancient samples, and today with genomic techniques, whole mitochondrial genomes have been sequenced from early modern humans and other hominins. Some of the hominin fossils have archeological dates as old as 300,000 years. This information has helped confirm the African origin of modern *Homo sapiens* as well as the dispersal patterns used by humans as they colonized regions out of Africa. Moreover, mitogenomics has allowed for the investigation of phylogenetic patterns of modern humans relative to Neanderthals and Denisovans, and comparisons based on nuclear genomes reveal evidence of genetic exchange among humans and these early hominins.

The current trend in phylogeography is to use a multilocus approach that combines information from both the nuclear (sequences from the Y-chromosome and autosomes) and mitochondrial genomes. In many cases, nuclear and mitochondrial markers provide concordant geographic patterns. For phylogeographic studies of human populations, variation in non-recombining regions of the Y-chromosome is being compared to patterns seen for mitochondrial DNA haplotypes. The phylogeographic trend observed for these paternal and maternal markers suggests a similar pattern of the movement of human populations out of Africa.

Phylogenomics

The advent of next-generation sequencing is revolutionizing studies designed to investigate the architecture of the genome and the function of various components of the genome. These same types of data also are being used to enhance our knowledge of molecular evolution and molecular phylogenetics. Genome level databases can be obtained at a small portion of the cost relative

to that formally required for the Human Genome Project, and this is allowing for detailed studies of broad areas of the Tree of Life. Phylogenomics emphasizes the use of genome-scale sequence data to construct phylogenetic trees depicting the relationships among organisms and to examine patterns of genome evolution and the function of genes.

The impact of phylogenomic approaches to phylogeny reconstruction is obvious from the plethora of recent students on many divergent groups ranging from prokaryotes to mammals. Large sets of data, derived from sequencing genes from both mitochondrial and nuclear genomes, are providing a better perspective of the placental mammal Tree of Life, which is now divided into four major superorders. One particular superorder, Afrotheria, contains a group of seven morphologically divergent and old lineages (elephants, sea cows, hyraxes, aardvarks, elephant shrews, golden moles, and tenrecs) that have an African origin. At the other end of the scale of divergence, phylogenomic approaches are providing insight into the genealogical consequences of adaptive radiations, characterized by the rapid origin of species connected by short branch lengths. For instance, Darwin's finches located in the Galapagos Islands represent a classic case of adaptive radiation, characterized by differences in the beak and ecology of the various species occupying these islands. Rather than a simply phylogeny, Darwin's finches reveal evidence of both hybridization (previously documented from ecological studies) between lineages and polymorphisms shared prior to divergence of lineages, resulting in incomplete lineage sorting. In addition, variation at one particular locus appears to associate with changes in shape of the beak, thus linking an adaptive phenotypic trait with underlying patterns of genetic variation. Lake Victoria cichlid fishes represent another group of species that experienced a recent adaptive radiation, and determining the phylogenetic relationships among this swarm of species has proven rather intractable. Phylogenomic methods, employing genome-wide sequencing, appear to be making progress in resolving relationships among sympatric groups of species.

Conducting phylogenomic research

Application of phylogenomics is the direct result of high-throughput methods for sequencing portions of or entire genomes in a fast and cost effective manner. Some of these next-generation sequencing platforms include Illumina, Ion Torrent, and Roche 454. In comparison to traditional Sanger sequencing, these platforms produce shorter sequence reads (a few 100 base pairs) with higher error, which requires multiple reads of the same sequence to reduce the rate of error. Third generation sequencing, such as single molecule sequencing in real time, offers the ability to provide sequence reads in the tens of thousands of base pairs. As this technology develops, genomics will enter a whole new era in terms of speed, accuracy, and cost.

A number of methods can provide genetic markers that span the entire genome, while enhancing the size of datasets used in population genetics, phylogeography, and phylogenetics. For species with a reference genome sequence, large scale deep genome sequencing is possible. Tens of thousands of human genomes are being sequenced with high levels of sequence coverage ($30–40\times$). This information offers opportunities for detailed studies of genetic disease as well as trends of human population divergence and movements. Whole microbial genomes are being sequenced, and the current results thus far suggest a tangled ancestry near the base of the Tree of Life. Whole genome sequencing of organisms that do not have an appropriate reference genome sequence (termed de novo sequencing) present more challenges in terms of assembling and annotating the new genome sequence. They also require considerably higher sequence coverage.

Other than whole genome sequences, there are a number of markers that can be used in phylogenomics. Transcriptome sequencing provides sequences from expressed genes (exons only). Use of this approach requires high quality mRNA, which is reverse transcribed into cDNA, followed by sequencing the paired ends of each cDNA. Sequences from these paired ends can be used to assemble contigs (contiguous sequence) representing overlapping reads that allow for construction of a consensus sequence for a particular gene. Alternatively, expressed sequence tags (ESTs) can be obtained from randomly sequencing the end of cDNA clones. Single nucleotide polymorphisms (SNPs) are widely distributed and abundant markers occurring in plant and animal genomes. Variation at these sites tends to be biallelic, and given their abundant distribution, they provide thousands of potential markers. These markers appear useful over a broad range of evolutionary time, being informative to investigating the origin of the domesticated dog as well as providing phylogenetic information for divergent ruminant artiodactyls including extinct and extant species.

Ultraconserved elements (UCEs) represent conserved regions of the genome that can be found across divergent taxa. Identification of these markers requires comparisons of genome alignments in search of regions that are highly similar. Sequences from these elements as well as more variable flanking regions provide larger numbers of orthologous loci that can be used to infer phylogenetic relationships among highly divergent taxa. For instance, the phylogenetic position of turtles represents a long-standing problem for those interested in the evolution of reptiles. Recently, a phylogenetic study using UCEs provided strong support for turtles being sister to the crocodile/bird clade.

Restriction site-associated DNA sequencing (RADSeq) is another method that produces large number of markers especially useful for population genetic and phylogeographic studies as well as for discovery of SNPs. These markers can be obtained from organisms for which little is known about the genome sequence, and large numbers of individuals can be screened for polymorphisms. Finally, the genome offers great potential for identifying other types of phylogenetically informative markers. The presence/absence of retrotransposons distributed throughout the genome and genome organization (as seen in comparisons of mitochondrial DNA) offer markers that may be useful in cases where standard sequencing fails to resolve relationships.

Processing phylogenomic data

Regardless of whether a phylogeny is constructed from portions of genes, single genes or whole genomes, there are several procedures that must be followed prior to organizing a data matrix for phylogenetic inference. Many of these procedures rely

heavily on bioinformatic techniques. Two of the first steps in processing sequence data prior to phylogenetic analysis are the elimination of sequence reads containing potential errors and the assembly of small sequence reads into a single contig. Such assembly can be computationally demanding, and sequencing errors must be minimized prior to sequence assembly.

As noted early, accurate inference of phylogenetic relationships requires the use of orthologous (homologous) sequences and annotation or gene prediction of those sequences. This means that proper identification and validation procedures must be performed prior to creation of a data matrix. Without a reference sequence based on whole genome sequences or sequences from transcriptomes, identification and annotation of orthologous sequences is less straightforward, but there are a number of analytical tools (e.g., tools found at the National Center for Biotechnology Information or NCBI) that can be used in the annotation and identification of orthologous sequences. One means of identifying orthologous sequences is to conduct a search of sequence databases. BLAST searches (implemented at NCBI) employ alignment procedures that allow for comparison of an unknown sequence to known sequences in the GenBank database. Positive matches are displayed in order of the overall significance of the match, and alignments for each match are provided. There are various options that can be used to optimize a search and allow for different degrees of similarity between the unknown and known sequences. In addition, different types of queries can be made including blastn (nucleotide search), blastp (amino acid sequences of proteins), and blastx (translates a nucleotide sequence into all six reading frames). In the case of blastx, open reading frames for translation of nucleotide sequences to amino acid sequences can be identified, thus allowing for the elimination of potential pseudogenes. Another method for identifying orthologous sequences is to perform a phylogenetic analysis, such as clustering, that can be used to compare gene trees with species trees.

The accuracy of inferring phylogenetic trees derived from either nucleotide or amino acid sequences depends on the multiple alignment used to establish positional homology of the individual nucleotides or amino acids being compared across species. There are several bioinformatic techniques available for aligning sequences. Clustal is a widely used program for multiple alignment, which uses estimates of pairwise distance between sequence pairs to construct a tree based on a clustering method that identifies the most closely aligned sequences. Alignment scores are provided, and newer versions of the program allow for selection of different gap penalties and other forms of weighting. As organisms become more divergent, establishment of positional homology becomes more challenging, thus requiring the alignment of amino acid sequences rather than nucleotide sequences. Another popular program is MUSCLE, which provides a fast algorithm that is useful for large sets of data.

Matrices containing pairwise comparisons of either nucleotide or amino acid sequences of taxa are constructed from multiple alignments. In most cases, sequences from all genes for each taxon are concatenated into a supermatrix, which provides the baseline for subsequent phylogenetic analyses. Nevertheless, inferring relationships from a supermatrix does not guarantee phylogenetic accuracy. Placement of some taxa may either remain ambiguous or display incompatibility with phylogenies obtained from other studies based on a different dataset of gene sequences, morphological characters or both. There are two perspectives as to how accuracy can be increased, and they are not mutually exclusive because both involve increasing the size of the supermatrix.

Some argue that taxon sampling is important for increasing accuracy, whereas others suggest that increasing the amount of sequence data is more useful for enhancing accuracy and addressing unresolved relationships. Both simulations as well as empirical approaches have been used to address this issue. It is clear that the use of large amounts of data with only a few representative taxa can produce misleading results. One example pertains to the use of a small number taxa to argue for the mammal order Rodentia not being monophyletic, with the guinea pig placed in a clade separate from rodents. The basis for this claim used complete mitochondrial genome sequences but only three rodents (guinea pig, mouse, and rat). This finding highly contradicts all the morphological and paleontological evidence that clearly identified all rodents, including the guinea pig, as monophyletic. Later molecular phylogenetic studies, using larger taxon sampling as well as nuclear gene sequences, provided strong support for rodent monophyly. Another reason for increased taxon sampling pertains to the elimination of long-branch attraction, which is a consequence of grouping lineages with a mixture of long and short terminal branches resulting from either unequal rates of change or missing taxa. In the latter case, inclusion of more taxa increases the probability of breaking up long branches, thus increasing accuracy. At the same time, inclusion of increased amounts of molecular data has the potential to resolve ambiguities associated with taxa connected by short internodes. For instance, lineages that separated over short periods of time as a result of rapid speciation are likely to be connected by short periods of shared ancestry.

Other than taxon sampling, the increase in taxa and amount of data can result in an increase in missing data for some taxa, and this represents another factor that might influence the accuracy of phylogenetic inference. Again, both empirical studies and computer simulations have been used to investigate the impact of missing data. Most studies suggest that incomplete sets of data do not necessarily decrease the placement of taxa, and the inclusion of taxa with incomplete datasets may help prevent systematic error from long-branch effects. However, too much asymmetry in missing data still has the potential to reduce phylogenetically informative character states required for determining relationships among some taxa.

Challenges to phylogenomics

Phylogenies derived from both the nuclear and mitochondrial genomes do not always agree (are incongruent) in terms of depicting the species tree. There are many explanations for why gene trees and species trees can provide contradictory patterns. Some of the more obvious molecular evolutionary processes that can result in incongruence include lateral (or horizontal) gene transfer, incomplete lineage sorting, and gene duplication (**Fig. 2**).

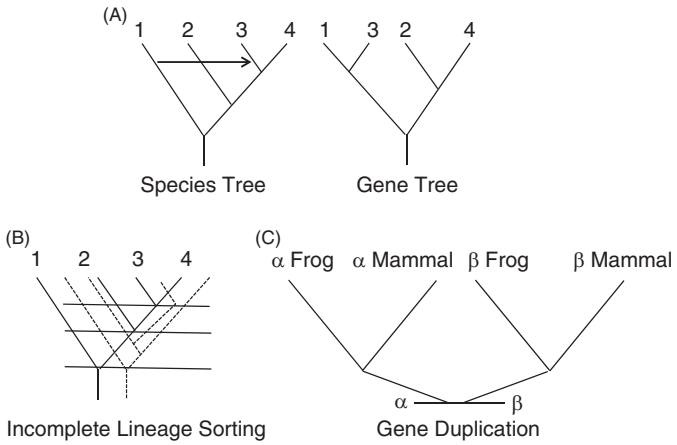

Fig. 2 (A) Species tree with lateral gene transfer shown with *arrow*, resulting in a different gene tree; (B) species tree denoted by the solid line phylogeny and relationships resulting from incomplete lineage sorting denoted by dashed lines, horizontal lines represent speciation events; (C) phylogeny of duplicated globin genes.

Lateral gene transfer (LGT), a phenomenon more common in prokaryotes, is a process that results in the exchange of genes between species that are not the result of vertical transmission from ancestor to descendent (**Fig. 2**A). In the case of groups that have experienced widespread horizontal gene transfer, a branching Tree of Life may not be the best representation of that group's evolutionary history. This process appears more pronounced in prokaryotes, resulting in some genes being positively misleading in terms of reflecting species trees. Views on the extent of LGT in prokaryotes differ in that some argue that it occurs extensively, whereas others suggest that the frequency is not extensive enough to preclude retrieval of the species tree. Obviously for prokaryotes, LGT among phylogenetically unrelated groups would yield a complex network displaying extensive reticulation. The frequency of LGT between either prokaryotes and eukaryotes or different eukaryotes is less clear. Endosymbiosis resulting in transfer of mitochondrial and chloroplast genomes from bacteria to animals and plants clearly represents an early exchange. There appears to be other evidence for LGT between bacteria and herbivorous insects and round worms. Within the eukaryotic genome, plant mitochondrial genomes show evidence of receiving genes from the nuclear genome, and segments of the mitochondrial genome are known to transfer to the nuclear genome of animals. Although some related fungi exchange genes, the frequency of LGT between eukaryote taxa is less clear. One reason for disagreement over the frequency of LGT in both prokaryotes and eukaryotes relates to the methods available for identifying cases of LGT. Most methods use phylogenetic incongruence between trees of the same taxa, unusual base composition in some genes relative to that seen in the whole genome, and high sequence similarity between genes from divergent lineages. Unfortunately, other processes (positive or purifying selection, hybridization, incomplete lineage sorting, gene duplication) can just as easily explain these anomalies, especially in eukaryotes.

Incomplete lineage sorting (ISL) occurs when an ancestral polymorphism is retained in lineages after speciation. If multiple lineages arise rapidly, the internode connecting those lineages will be short. As variation along each lineage coalesces, similar alleles may be retained in lineages not sharing a direct common ancestor (**Fig. 2**B). The consequence of ISL is incongruence between gene trees and species trees. For instance, resolving relationships among human, chimpanzee, and gorilla has been a challenge for decades, primarily because divergence of these three lineages occurred over short periods of time relative to their closest relative, the orangutan (**Fig. 3**). Morphologically, chimpanzee and gorilla are similar, yet most extensive genomic data (from DNA hybridization and sequencing) support a human/chimpanzee sister group. Nevertheless, genome wide comparisons suggest that a percentage of genomes support different topologies (**Fig. 3**A–C). This result is consistent with ISL.

Whether or not ISL is responsible for incongruence of genes at deeper levels of divergence has stimulated considerable debate, especially with respect to resolution of branching patterns in the mammalian Tree of Life. Some researchers suggest that algorithms that address coalescence and ISL provide better support for portions of the placental mammal phylogeny, especially when using a supermatrix of concatenated sequences that may have different gene genealogies. These coalescent methods attempt to deal with phylogenetic incongruence among individual gene trees. Others argue that ISL is a minor cause of incongruence, and that large molecular datasets of gene sequences should offset the effect of ISL.

Finally, gene duplication and loss of genes can influence phylogenetic inference. As indicated earlier, orthologous rather than paralogous sequences are required for inferring species trees. Gene trees can represent a family of genes that consisting of paralogs that are the result of gene duplication and serve similar functions, and mechanisms responsible for gene duplication include unequal crossing over and retrotransposition. The inability to correct for inclusion of duplicated loci can result in incongruence between gene trees and species trees. For instance, globin gene evolution in vertebrates involved gene duplication. Therefore, paralogous genes provide a history of the gene genealogy rather than the species genealogy (**Fig. 2**D). This implies that accurate identification of orthologous genes is necessary for retrieval of the species tree.

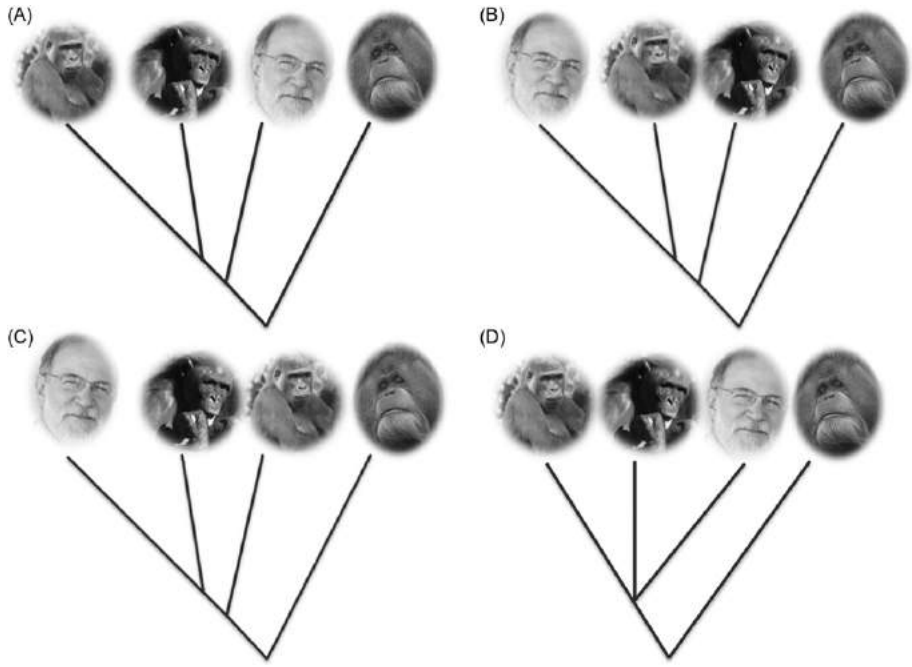

Fig. 3 There are three possible arrangement of human, gorilla, and chimpanzee. Although some early anthropological studies supported an unresolved polytomy as seen in (D), molecular data support the relationships shown in (C). Organutan is considered an outgroup.

Current and Future Uses of Phylogenies

As indicated earlier, a phylogeny provides an interpretive framework necessary for testing biological hypotheses associated with biogeography, ecology, functional anatomy, gene function, and molecular evolution. Therefore, an accurate phylogeny has many uses other than determination of relationships among taxa.

One of the original suggestions of a phylogenetic approach emphasized the use of a phylogeny for predicting the function of unknown genes. In this approach, gene trees provide a framework for mapping the function of known genes relative in an effort to infer function of unknown genes.

Phylogenies allow for comparison of groups of species that show as an evolutionary association, such as parasites and hosts, plants and pollinators, hosts and pathogens. Such comparisons allow for an examination of host switching in terms of parasites and diseases, as well as an evaluation of cospeciation between interacting organisms. For instance, *Mycobacterium tuberculosis* represents a disease of modern humans that shows congruent phylogeographic patterns to its host, suggesting that humans and tuberculosis coevolved and followed a similar migration pattern out of Africa.

Traits representing key innovations associated with an adaptive radiation can be identified with the species tree. The beak of the finch is a good example as well as changes in the feeding mechanism of cichlid fishes. This allows for an evaluation of the trait and patterns associated with the phylogeny, especially adaptive traits resulting from response to changing environmental conditions. Such traits covary in a phylogenetic context.

In recent years, interest in phylogenetic community ecology has increased. Such an approach examines how communities are structured based on the occurrence of phylogenetically related and phenotypically similar versus dissimilar lineages or species. Do phylogenetically related lineages share similar life histories and ecologies? What is the phylogenetic relatedness of members of a community? Such estimates of phylogenetic relatedness provide a metric for the structure of communities and the formation of island communities. Phylogenetic relatedness is also a proxy for levels of functional differentiation related to ecosystems.

Phylogenies provide information pertaining to the origin of diseases as well as the sources of particular infectious agents, and they can aid in drug discovery by identifying groups of organisms that may offer potential chemical agents similar to that found in a single representative from a particular clade. They also allow for examination of the spread of pathogens and to identify changes in the genomes of pathogens as they become more virulent and resistant to various drugs. Additionally, phylogenetic methods can help determine the origin of emerging diseases as well as the dispersal of diseases from their origin. For instance, HIV is now known to be derived from two different primate hosts.

Forensics is another area where phylogenetics is making inroads, and phylogenetic methods are used in criminal cases. One example is the use of phylogenetics to identify the source of anthrax sent through the postal system.

Finally, aside from inferring phylogenetic relationships, molecular data are used to estimate divergence times for various parts of the Tree of Life. Some of these temporal estimates provide information otherwise unavailable from direct evidence of fossils (e.g., estimating chimpanzee/human divergence). Since the 1960s, the concept of a molecular clock has fostered a plethora of studies

designed to estimate both recent (e.g., modern *Homo sapiens*) and ancient (e.g., Metazoa) origins. Ultimately, fossils do provide the primary means of calibrating the molecular clock. This requires calibration points derived from fossils that are reliable. Sometimes, fossils and molecules disagree, with the former suggesting considerably younger dates than the latter. A good example is the disagreement of data obtained for the origin of placental mammals. Some of the first dates based on molecules suggested the origin of placental mammals in the late Jurassic, which is 50–60 million older than the oldest fossil. The inclusion of more complex models that deal with rate heterogeneity, as well as more well-verified fossil calibration points, has resulted in estimates of divergence dates for placental mammals that are consistent with dates provided by fossils.

Future of Phylogenomics

Separating signal from noise in phylogenetics is a challenge when using any type of character. The real issue with phylogenomics is that with the ever-increasing size of datasets comes an almost exponentially increasing level of complexity. As we know, the genome is a mixture of coding and noncoding sequences with sometimes very different evolutionary histories in terms of the degree of selective constraint, recombination, gene conversion, duplication, horizontal gene transfer, chromosome rearrangement, unequal crossing over, and other genetic and demographic (e.g., generation time and effective population size) processes that create a nonhomogenous suite of characters. Separating the wheat from the chaff in an attempt to accurately depict the Tree of Life is computationally challenging, especially when attempting to include the deeper nodes of the tree near its roots. How does one increase reliability in the search for the most optimal solution, especially when a particular tree is positively misleading, yet well-supported by the optimality criterion selected? Is it better to use complex models that attempt to either correct for or identify sources of heterogeneity in the way molecules evolve? Is it better to remove potentially ambiguous genes or is it better to include all of the data with the assumption that the real phylogenetic signal will be obtained? These are not trivial questions, and to date no final solution exists. Rather, we are in a period of debate as to the best approach, which is reminiscent of earlier debates over many of the same issues. Nothing is new under the Sun.

Pioneer Species

JW Dalling, University of Illinois Urbana-Champaign, Urbana, IL, USA

Introduction

In early ecological literature, the term pioneer was used to describe those plant species that initiate community development on bare substrate (primary succession). More recently, usage of the term has included microbial and invertebrate taxa, and describes the first colonists of sites affected by less extreme disturbance which undergo secondary succession. Pioneers of primary and secondary successions share some traits; in both cases colonization of new habitat depends on effective dispersal, which generally selects for high reproductive output and small propagule size. However, differences in resource availability between these habitat types result in different opportunities for growth and reproduction. Few species can be successful on both primary and secondary successions.

Pioneers in Primary Succession

Primary succession occurs when extreme disturbances, such as landslides and volcanic eruptions, create new habitats by removing or covering existing vegetation and soil. Pioneers that initiate primary succession must be able to establish and grow on substrates that are nutrient poor and that often have unfavorable moisture conditions. The most extreme sites are exposed unweathered rock surfaces. Here, colonization may be limited to cyanobacteria ('blue-green algae'), lichens, and bryophytes, with no further vegetation development. Somewhat more nutrient-rich conditions associated with weathered or fragmented bedrock surfaces, such as the scree slopes of landslides, are often dominated by tree species. Sites still richer in mineral nutrients, which may contain some residual organic soil, such as the depositional zones of glacial moraines, in turn are often colonized by herbaceous species and grasses with faster growth rates (Fig. 1).

For pioneers in primary successions, nitrogen is often the most limiting resource. Unlike other mineral nutrients that can be released through weathering of underlying rock, nitrogen must either be transported to primary successions through leaching and deposition, or fixed *in situ*. Some of the most inconspicuous pioneers on exposed rock faces are nitrogen-fixing cyanobacteria. Rates of nitrogen fixation by cyanobacterial 'biofilms' on rock surfaces may be considerable; thus, nitrogen-rich leachate from these surfaces may affect community development at down-slope sites. Cyanobacteria may also form symbiotic associations with lichens (e.g., *Stereocaulon* spp.). These lichens are among the first colonists of landslides and lava flows (Fig. 2). Nitrogen fixation by lichens on these sites (0.2–0.4 kg N ha^{-1} yr^{-1}) may be important in facilitating the later colonization of these sites by vascular plants.

Relatively few vascular plant pioneers are nitrogen fixing. An exception is the perrenial lupine (*Lupinus lepidus*). Lupine is a conspicuous pioneer of the extensive ash and pumice fields that were created by the eruption of Mt. St. Helens (Washington State, USA) in 1980. In the first decade after the eruption lupine patches spread rapidly, increasing available nitrogen in the soil tenfold, potentially facilitating the growth of other colonizing plant species. More recently, however, the spread of lupine patches has slowed as specialist insect herbivores have colonized the plants. The patchiness and unpredictability of vegetation colonization on Mt. St. Helens also highlights the importance of constraints other than nutrient availability that limit recruitment success. Dispersal limitation, described as the failure of seeds to arrive at suitable establishment sites, may limit the rate at which pioneers colonize available substrate, and may be important in shaping the trajectory of successional change. Similarly, requirements for safe sites that provide favorable conditions for seedling establishment may account for the nonrandom distribution of pioneers on substrates such as glacial till. Small seed size and wind dispersal are particularly common traits among vascular plant pioneers.

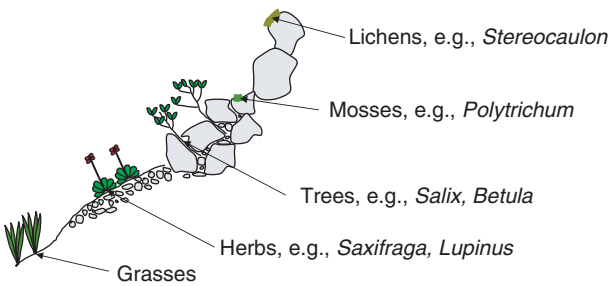

Fig. 1 Pioneer species typical of substrate types exposed following deglaciation. More fertile (nitrogen-rich) substrates often support herbaceous species and grasses, whereas rock surfaces and glacial till support lichens, bryophytes, and woody species. Modified from Grubb PJ (1986) The ecology of establishment. In: Bradshaw AD, Goode DA, and Thorp E (eds.) *Symposium of the British Ecological Society, Vol. 24: Ecology and Design in Landscape*, pp. 83–97. Oxford: Blackwell.

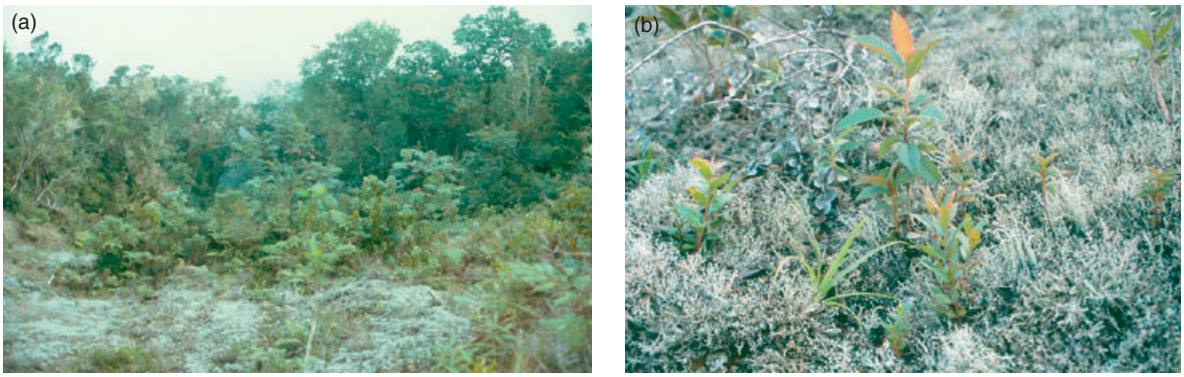

Fig. 2 (a) A 15-year-old landslide scar at 1500 m in the Blue Mountains, Jamaica. (b) The whitish appearance of the landslide surface results from its coverage by a dense mat of *Stereocaulon* lichen (note recruitment of woody species).

Table 1 Characteristics of pioneer tree species in tropical forests that distinguish them from nonpioneer species

Pioneer species	*Nonpioneer species*
1. Juveniles recruit from seed following disturbance; seedlings are unable to survive beneath a forest canopy	Seedlings and saplings persist in the shade of a forest canopy
2. Seeds germinate in response to cues provided by changes in light, temperature, or soil nitrate concentrations indicating disturbance to canopy vegetation	Seeds germinate immediately after dispersal or seasonally during periods favorable for establishment
3. Seeds generally small; frequently dispersed by wind	Seeds may be large; frequently dispersed by vertebrates
4. Seeds often persist in the soil (weeks to decades after dispersal)	Seeds lack dormancy or remain in the soil for less than a year
5. High height growth rate and juvenile mortality rate	Lower height growth, crowns often show lateral spread in the shade
6. High maximal photosynthetic rate, light compensation point, and foliar nutrient concentrations	Low maximal photosynthetic rate, light compensation point, and foliar nutrient concentrations
7. Short-lived leaves with high leaf area per unit leaf mass	Leaves of juvenile plants may persist for several years with low leaf area per unit leaf mass
8. Open canopies with sparse branching	Closed canopies
9. Low wood density	Medium–high wood density
10. Low investment in chemical anti-herbivore defense	High investment in chemical and structural defenses
11. Often form defensive mutualisms with ants	Defensive mutualisms uncommon
12. Adult lifespan typically <100 years	Adult lifespan up to 500 years
13. Wide geographic and ecological range	Often restricted geographic range and habitat requirements

Adapted from Swaine MD and Whitmore TC (1988) On the definition of ecological species groups in tropical rain forests. *Vegetatio* 75: 81–86.

Wind dispersal is favored when animal dispersal vectors are rare. Small seed size may increase the probability of seeds becoming trapped in cracks and small depressions where germination and seedling survival are likely to be enhanced. Conversely, it has been suggested that small seed size limits the initial nutrient resource supply available to the plant and may prevent seedlings from developing mutualisms with nitrogen-fixing bacteria.

Pioneers in Secondary Succession

Secondary succession occurs when the severity of disturbance is insufficient to remove all the existing vegetation and soil from a site. Many different kinds of disturbances, such as fire, flooding, windstorms, and human activities (e.g., logging of forests) can initiate secondary succession. Pioneers of secondary successions face quite different conditions from those that accompany primary succession. Secondary successions often start with resource-rich conditions associated with high light availability and reduced competition for nutrients and moisture. Disturbances may also be short-lived; for example, gaps created in forest canopies close as the crowns of surrounding trees expand and as seedlings and saplings in the understory grow up in response to increased light. Pioneers rely on recruitment from propagules present in the soil, or that disperse into the site after disturbance occurs. Pioneers are able to outcompete established vegetation that survived the disturbance by maintaining high juvenile growth rates. Some of the fastest growing trees are pioneers in tropical rain forests. Individuals of the balsa tree *Ochroma pyramidale*, for example, can grow from seedlings to adults with >30 cm trunk diameter in <10 years.

The difference between pioneer and nonpioneer species is difficult to delineate (**Table 1**). Attempts to define distinct life-history strategies (implying coordinated evolution of life-history traits) are confounded because key traits such as propagule size and

juvenile growth rate can vary over several orders of magnitude within a community and show broad overlap among species with contrasting habitat requirements. Nonetheless, interactions among traits can be used to describe some life-history tradeoffs that largely constrain the habitat requirements of pioneers. For vascular plants, paramount among these is a tradeoff between growth in the sun and survival in the shade (**Fig. 3**). The high growth rates of pioneers are maintained by allocating a large fraction of the plant's resources to new leaf area production, and by investing in nutrient-rich leaf tissue that can attain high-maximum photosynthetic rates. A consequence of preferential allocation to leaf production is that few resources remain that can be used to defend the plant against herbivores and pathogens, or to recover from physical damage. This results in high mortality, particularly in the shade, where resources needed for tissue replacement are most limiting.

For pioneers growing in high light environments, abundant supplies of carbohydrate fixed through photosynthesis can be used to co-opt the services of predaceous insects that defend the plant against herbivores. Many pioneers have extra-floral nectaries that provide food for insect mutualists. Two of the dominant genera of pioneers in tropical forests – *Cecropia* (Urticaceae) in the neotropics and *Macaranga* (Euphorbiaceae) in the Asian tropics – have developed a more elaborate mutualism that provides a striking example of convergent evolution in morphological traits. In both genera the hollow stems of saplings are colonized by queen ants (*Crematogaster* in *Macaranga; Azteca* in *Cecropia*). The ant colonies are then provisioned with carbohydrate and lipid-rich food bodies produced on leaf surfaces, stipules, or petioles (**Fig. 4**).

The transient and unpredictable occurrence of secondary successional habitats has selected for high dispersal ability among pioneers. Typically, pioneers are small-seeded reflecting selection for high reproductive output. Even so, seed mass may vary over four orders of magnitude among pioneers within a plant community, reflecting a second life-history tradeoff between colonization success (selecting for small seeds) and establishment success (selecting for larger seed reserves). For pioneers with limited dispersal, the probability of colonizing disturbances can be increased by maintaining populations of viable seeds in the soil. These soil seed banks may be transient, with seeds lasting a few weeks or months following dispersal, or may be persistent with seed surviving for decades. In temperate forests most seed bank-forming species are annual or perennial herbs. These are typically small-seeded species (<1 mg seed mass) that germinate in response to an increase in the intensity or red:far-red ratio of light associated with openings in the canopy or in the litter layer. In tropical forests both trees and herbs form seed banks with greater seed persistence common among the larger-seeded species (1–100 mg seed mass). Many of these species germinate in response to diurnal temperature fluctuations in the soil associated with large canopy gaps.

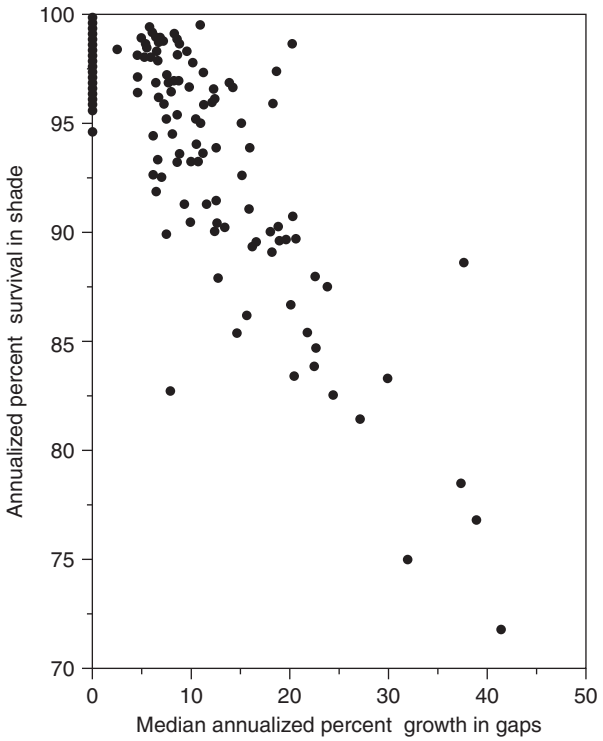

Fig. 3 The negative correlation between annual survival of rate of saplings 1–4 cm diameter at breast height in understory shade versus the median annual growth in the sun in tree fall gaps. Data are for canopy and mid-story tree species growing in semi-deciduous tropical forest in the 50 ha forest dynamics plot on Barro Colorado Island, Panama. Each data point is an individual species. Pioneer species have high growth rates in gaps and low survival in shade. Note that there is a continuum of responses to sun and shade that prevents a clear delineation of the pioneer guild. Reproduced from Hubbell SP and Foster RB (1992) Short-term dynamics of a tropical forest: Why ecological research matters to tropical conservation and management. *Oikos* 63: 48–61, with permission from Blackwell Publishing.

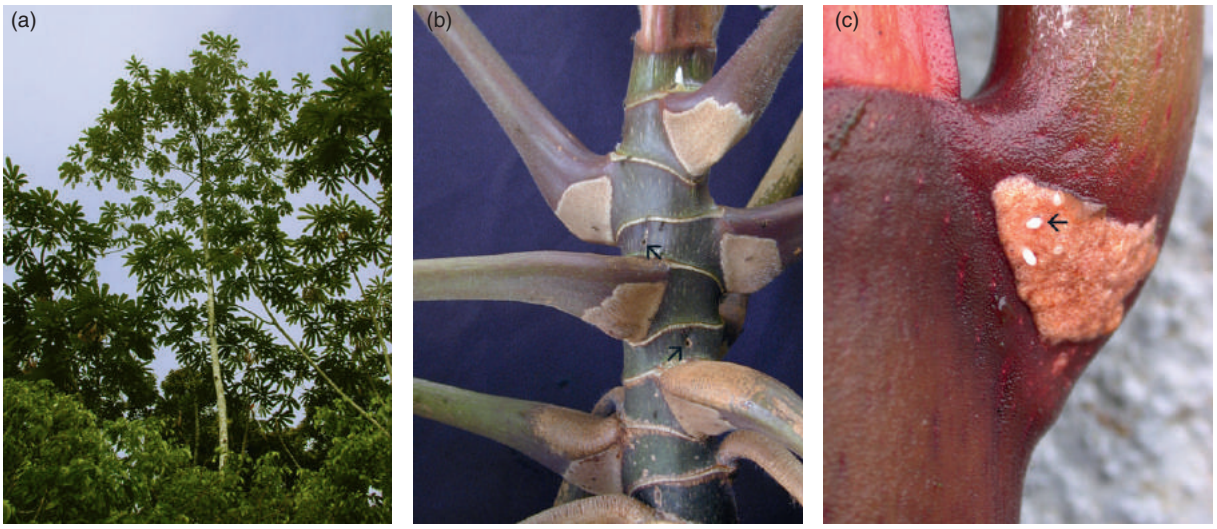

Fig. 4 (a) *Cecropia engleriana*, growing along a roadside in Yasuní National Park, Ecuador. *Cecropia* spp. are the dominant pioneers of young secondary forests in the neotropics. (b) The hollow stems of most *Cecropia* species are inhabited by aggressive ants (*Azteca* spp.) that predate insect herbivores. Arrow shows nest entrance. (c) In return, the plant provides the ants with Mullerian food bodies (shown by arrow) produced on the trichilium, a structure at the base of the petiole.

Changing land-use patterns have led to large increases in the abundance and distribution of many pioneer species. Many of the herbaceous pioneers that were originally restricted to forest gaps, or marginal habitats such as stream banks, have now become economically important weeds in agricultural systems. Similarly, in the tropics, clearance of old-growth forests, and abandonment of unproductive agricultural land has provided new habitats for pioneer tree species. Some of these pioneers can be quite long-lived and can produce valuable timber (e.g., teak, *Tectona grandis;* and laurel, *Cordia alliodora*).

Kayla King, University of Oxford, Oxford, United Kingdom

Glossary

Coevolution Changes in the genotypes of two or more species that are a direct consequence of the species' interaction with one another.

Coevolutionary arms race Occurs when an adaptation in one species reduces the fitness of individuals in a second species, thereby selecting in favor of counter-adaptations in the second species. These counter-adaptations, in turn, select in favor of new adaptations in the first species, and so on.

Eco-coevolutionary dynamics eco-evolutionary dynamics where coevolution is the central evolutionary process. In eco-evolution, ecological and evolutionary processes occur at the same time and pace and therefore interact with each other.

Genetic specificity in host parasite interactions—each host genotype resists only specific pathogen genotypes or species and each pathogen genotype or species infects only specific host genotypes.

Genetic polymorphism The long-term occurrence in a population of two or more genotypes in frequencies that cannot be accounted for by recurrent mutation. Such polymorphism may be due to mutations that are (a) advantageous at certain times and under certain conditions and (b) disadvantageous under other circumstances, and which exist in habitats where situations (a) and (b) are encountered frequently. Genetic polymorphism may also result if genotypes heterozygous at numerous loci are generally superior to any homozygous genotype.

Matching-allele type of model A model that explains the genetic background of parasite infectivity and host resistance, and states that genetic resistance in host–parasite interactions involves multiple genes: a host is resistant when the alleles of the host resistance genes match the alleles of the parasite virulence (infectivity) genes. It is mostly used to model host resistance and parasite infectivity in animal-pathogen associations. The MHC-system in vertebrates is a typical example of a system which is modeled by a matching-allele model.

Metapopulation A group of partially isolated populations belonging to the same species; subpopulations of natural populations that are partially isolated one from another and are connected by pathways of immigration and emigration.

Red Queen hypothesis The hypothesis that states that the adaptive importance of genetic recombination (and sex) can be found in its ability to create genetic variation among the offspring, which is important in confrontation with fast-evolving environmental conditions, including the coevolving parasites.

Transmission The process by which a *parasite* passes from a source of infection to a new *host*. Horizontal transmission is transmission by direct contact between infected and susceptible individuals or between disease vectors and susceptible individuals. Vertical transmission occurs when a parent conveys an infection to its unborn offspring, as in HIV in humans.

Virulence The morbidity and mortality of a host that is caused by parasites and pathogens.

Introduction

If we think of evolution, we often think of macro-evolutionary processes, long-term processes, which are difficult to imagine. Nevertheless, adaptations shaped by natural selection often occur over very short time frames. These adaptations lead to fast genetic changes over time. One type of interaction that plays a key role in ecological and fast evolutionary processes is the antagonistic interaction between hosts and parasites. Parasites are widely defined as organisms living in or on another organism—the host—, feeding on it, showing some degree of structural adaptation to exploiting it, and causing it some harm. Parasitism is the most common life style on earth: considering the high abundance and diversity of parasites, we can fairly say that every species is affected by parasites (Lafferty *et al.*, 2006). Empirical evidence has shown that new crop varieties have to be frequently renewed, as old ones are susceptible to their evolving pest populations. New diseases emerge and mutate (e.g., HIV), and the genetic composition of traditional diseases (influenza, malaria) changes continuously (Little, 2002). An example of a fast evolutionary process is the development of antibacterial resistance, for example, MRSA. Before the use of antibiotics, a large number of bacterial types were present, some were susceptible, others were resistant to antibiotics. Once antibiotics resistance occurred, only the most resistant bacterial strains remained, which became difficult to eradicate. It is this process that has lead to the fact that *Staphylococcus aureus* became resistant to methicillin such that due to mutations, methicillin can no longer block the cell wall synthesis of the bacteria. A next step in the antagonistic interaction between the pathogens and humans, is to find a new antibiotic or technique to eradicate these resistant bacterial strains.

The specificity of host–parasite interactions, their density-dependent transmission and the negative influence of parasites on the survival and reproduction of the host enable them to have an important influence on host population density and dynamics. The intense and reciprocal interactions between hosts and parasites may lead to coevolution: genetic changes that two (or more) species undergo as answer on their mutual interactions. The interaction between pathogenic microorganisms and their hosts is often compared with a "coevolutionary arms race," referring to the fact that the parasite searches for a new tool to attack and the host a new tool to defend. As microparasites adapt fast to their host genotype, it is beneficial for the host to pass its genes to genetically diverse offspring. Consequently, the host–parasite arms race is important for the maintenance of genetic polymorphism in natural populations (Otto and Michalakis, 1998), and idea posited by The Red Queen Hypothesis. This hypothesis states that the adaptive importance of genetic recombination (and sexual recombination, Jaenike, 1978; Bell, 1982) can be found in its production of genetic variation among the offspring, which is important in confrontation with fast-evolving environmental conditions, *in casu* fast genetic adaptation of parasites to their hosts (Maynard Smith, 1989). Parasites here can evolve quickly and continuously in response to the ongoing evolution of the defenses in the host (Paterson *et al.*, 2010). New mutations that influence host resistance and the possibility of the parasite to overcome that resistance are the fuel of host–parasite coevolution. When the environment changes, previously neutral or deleterious alleles can become favorable. If the environment changes sufficiently rapidly over time (i.e., between different generations), sexual reproduction reintroducing these alleles can be advantageous. This is especially so in systems in which parasites continuously track specific and common host genotypes, resulting in parasite driven time-lagged, negative frequency-dependent selection. The selective value of a host resistance allele is dependent on its frequency of occurrence in the population. In a host–parasite arms race, the parasite will increase its fitness by specializing on the most common host genotypes. Rare host genotypes have a selective advantage, until they become abundant and are no longer resistant. The production of genetic variation among offspring provided by sexual recombination is thus important in confrontation with the fast and specific genetic adaptation of parasites to their hosts. The genetic changes of trait values, hosts and parasites use to cope with each other in their evolutionary race are not always advantageous in the absolute sense, that is, as a remaining and increased impact on fitness. Rather, there is a constant need to adapt to avoid extinction driving by antagonism (cf. "in this place, it takes all the running you can do, to keep in the same place," said the Red Queen in Through the Looking Glass by Lewis Carroll; hence Red Queen hypothesis).

The consequence of these fast reciprocal interactions is fluctuating frequencies of allelic variants of the host and the parasite genotypes over time. These fluctuations in allele frequencies of host and parasite genotypes result in the above mentioned "coevolutionary arms race," where there is no net change or remaining increase in the fitness of both partners over time. Thus, who stands still, looses the game, but, no one progresses neither, at least not in terms of absolute fitness. The negative, frequency-dependent selection by parasites results in cyclic dynamics of host and parasite genotypes, each with their own resistance and infectivity, the so-called Red Queen dynamics. Host–parasite Red Queen coevolutionary dynamics are expected to be evolutionary unstable, as they are characterized by fluctuations in the frequencies of alleles of resistance and virulence associated traits. These coevolutionary "Red Queen dynamics" have been suggested to play a role in widespread biological phenomena such as the evolution and maintenance of sexual reproduction, and to shape the structure of natural populations and communities with consequences for biodiversity (Wood *et al.*, 2007). Rapid evolution and coevolution must therefore be one of the working hypotheses for explaining even short-term patterns and processes in the ever-changing web of life. There is no reason to think that the rapid evolutionary changes found in Darwin's finches, some invasive plants and insects, microbes in laboratory microcosms and responsible for antibiotics resistance are in any way exceptions (Thompson, 2009).

Experimental Model Systems of Red Queen Dynamics

Daphnia–Parasite Interactions

Coevolutionary interactions between the invertebrate water flea *Daphnia* and its micro-parasites have been studied intensively in the last decade. The *Daphnia*-parasite system is becoming a model system for biomedical questions and, more particularly, as an evolutionary framework for epidemiology (Ebert, 2005, 2011; Decaestecker *et al.*, 2009). *Daphnia* pathogens belong to a multitude of taxa. The main focus is on bacterial and microsporidian species, as these pathogens infect the *Daphnia* internally and have been shown to induce reduced fecundity and survival in the *Daphnia*. These bacterial and microsporidian pathogens are obligate intracellular pathogens that are mostly transmitted horizontally by means of infective spores (Ebert, 2005). It has been shown that *Daphnia* and its micro-parasites show characteristics that are expected to lead to strong coevolutionary responses: there is ample genetic variation in *Daphnia* resistance to parasites; host–parasite interactions are genotype specific (Carius *et al.*, 2001; Decaestecker *et al.*, 2003); and the genetic structure of *Daphnia* shifts during epidemics. There is also evidence of local parasite adaptation and short-term parasite-mediated selection in *Daphnia* (Haag and Ebert, 2004), which affects host–parasite dynamics (Duffy and Sivars-Becker, 2007). Also, on a higher taxonomic level, it has been shown that an under-infected taxon of a *Daphnia* hybrid system became over-infected after an increase in frequency and that this over-infection had a genetic basis (Wolinska *et al.*, 2006).

It is, however, notoriously difficult to study coevolutionary dynamics and the under-laying genetic mechanisms in nature, because often long-time series are needed. So far, direct empirical proof for the process of host–parasite coevolution is rare. In the *Daphnia*-parasite system, it is possible to circumvent this time constraint, as *Daphnia* and its parasites produce dormant stages resulting in

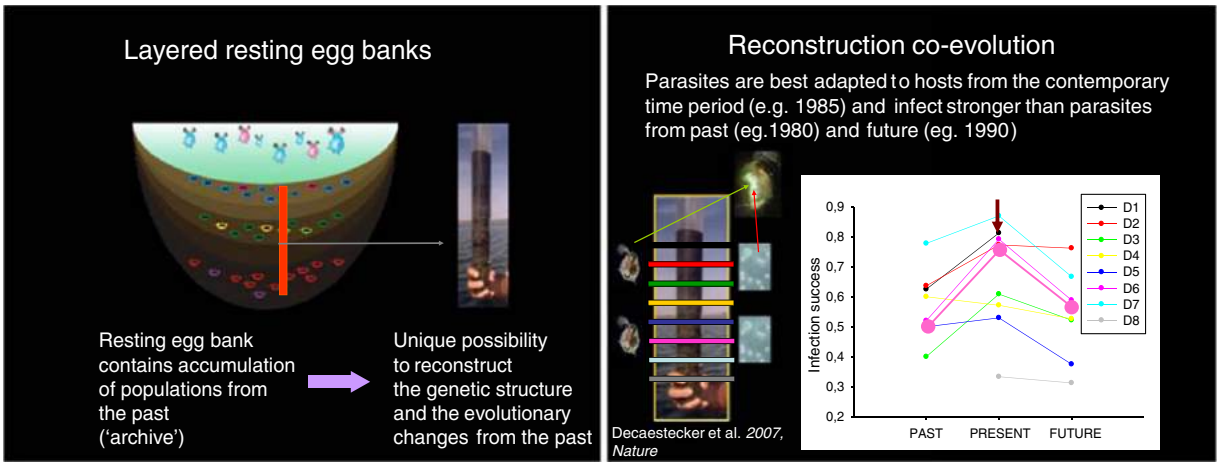

Fig. 1 "Resurrection ecology" approach to reconstruct Red Queen coevolutionary dynamics of *Daphnia*-parasite interactions (Decaestecker *et al.*, 2007; Houwenhuyse *et al.*, 2017).

dormant stage banks in layered pond sediments. Dormant stage banks confer a reflection of the populations from the past and provide a unique archive of past gene pools of both antagonists that can be reconstructed via the hatching of dormant stages from different sediment depths (this discipline is referred to as "resurrection ecology," Kerfoot and Weider, 2004, Orsini *et al.*, 2013). As such, genetic structure and evolutionary changes from the past can be reconstructed. In an earlier phenotypic study, a historical reconstruction of the coevolutionary process between *Daphnia magna* and its bacterial *endo*-parasite *Pasteuria ramosa* in a natural setting was made (Decaestecker *et al.*, 2007, 2013). In this study, coevolution was documented based on changes in host and parasite fitness parameters in infection experiments, where *Daphnia* clones were confronted with parasite isolates, both isolated out of different depths of sediment cores, reflecting different time frames of this interaction (cross infection experiments with parasites of the "past," "present" and "future", **Fig. 1**). Here, *Daphnia* and its *endo*-bacterial parasite *Pasteuria* were shown to adapt relatively fast and continuously, resulting in no net increase in parasite infectivity over time. This result reflects Red Queen dynamics, suggesting that the *Daphnia–Pasteuria* interaction is characterized by highly specific interactions and frequency-dependent selection across evolutionary time.

Potamopyrgus antipodarum Snail-Trematode Parasite Interactions

The New Zealand freshwater snail *Potamopyrgus antipodarum* and its coevolving sterilizing trematode parasite *Microphallus "iveyi"* is a powerful system to study Red Queen dynamics in nature. The snail exhibits polymorphism in its reproductive strategies, being either obligately parthenogenetic or sexual and dioecious; asexual *P. antipodarum* lineages are derived on multiple separate occasions from sexual progenitors (Neiman *et al.*, 2005). Infection by the castrating trematode generates negative frequency-dependent selection favoring sexual forms of *P. antipodarum* and diversity among the clonal forms all via Red Queen dynamics (Koskella and Lively, 2009; Jokela *et al.*, 2009; King *et al.*, 2009).

Multiple studies suggest that snail-trematode interactions here fit the "matching alleles" infection genetics model (Agrawal and Lively, 2001; Lively *et al.*, 2004; King *et al.*, 2009). This is an essential assumption underlying Red Queen dynamics, whereby infection is determined by whether a particular parasite genotype matches host genotypes that code for resistance. This match between host and parasite alleles enables *M. livelyi* to appear to the snail as "self" and evade immune defenses, ultimately establishing a successful infection. Strong selection is imposed reciprocally in this interaction because infected *P. antipodarum* are sterilized, and snails kill trematodes that cannot infect (King *et al.*, 2011a).

These snails and their parasites occur across multiple glacial lakes on the South Island of New Zealand, thereby providing the opportunity to examine Red Queen processes over space. The reciprocal selection for host resistance and parasite infectivity generated by *P. antipodarum–M. livelyi* interactions varies across these lakes, with parasite infection frequencies highest (and constant) in lakes where sexual snails are maintained in the face of competition with asexual conspecifics (Lively, 1987; Lively and Jokela, 2002). A similar pattern between sex and infection is observed within lakes whereby shallow regions, where parasites can be recycled and duck final hosts commonly forage, are coevolutionary hotspots (King *et al.*, 2009, 2011a). Deeper regions of lakes are coevolutionary coldspots where infection is rare and asexual snails dominate. In addition, the independent coevolutionary trajectories of each population are demonstrated by the strong patterns of parasite local adaptation to *P. antipodarum* populations, particularly in those where sex is maintained. There is a drastically higher infection rate in snails experimentally exposed to sympatric (same lake) vs. allopatric (different lake) parasites (King *et al.*, 2009).

Theoretical Models of Red Queen Dynamics

Mathematical models have confirmed that coevolving parasites should promote host genetic diversity, with immune system genes often showing striking levels of polymorphism, as well as species-level diversity. As such, antagonistic coevolution may be a key

driver of biodiversity in nature. However, despite extensive knowledge that variation in susceptibility has a genetic basis, we lack understanding of the genes involved, and of the underlying evolutionary and coevolutionary dynamics that these genes experience (Paterson *et al.*, 2010). Without such understanding, we lack the capacity to determine how adaptation arises at defense-related genes, how rapidly evolution can occur, and what drives the evolution of parasite susceptibility.

The most important models in host–parasite coevolution describing the underlying genetic control of infections are the matching-allele type of model and the gene-for-gene type of model. Host–parasite interactions explained by the gene-for-gene model are most commonly observed in plant-pathogen and bacteria-viral parasite interactions. The most important feature of this model is that one parasite genotype has universal virulence, such that it can infect all host genotypes. It is a model that describes generalist parasite and host strategies. A cost of virulence is needed to prevent this general genotype spreading throughout the parasite population. Thus, in a gene-for-gene interaction, there are susceptible and resistant host alleles and avirulent (non-infective) and virulent (infective) parasite alleles. Resistant hosts can only be infected by virulent parasites. Once a dominant resistance allele is present in the host population, it will spread (given that resistant hosts can defend themselves in the presence of avirulent parasites) and reciprocally lead to the spread of a virulent parasite allele (virulent parasites have an advantage in the presence of resistant hosts). Fluctuations in allele frequencies continue as once the parasite virulence allele is fixed in the population, the resistant allele of the host has no longer use, and the frequency of it will decline via selection (if resistance contains a cost), mutation or genetic drift.

A second type of model leading to allele frequency cycling more befitting the Red Queen is that assuming a highly specific, matching-alleles type of infection genetics. Matching-allele type of models are based on "self" versus "nonself" recognition in invertebrates, and describe the interactions of many animal-parasite interactions. The most important feature of these models is that infection and resistance contains a perfect "match" between the host and the parasite genotypes, such that parasites are recognized as "self" by the host and thus avoid detection. "Universal" virulence is not possible in these models and polymorphism can be sustained via negative frequency-dependent selection. In a matching-allele model, the parasite "wins" if it perfectly "matches" the host genotype. Parasites that match the host genotype, will have a higher fitness by which the frequency of the host genotype decreases, which leads to an increase of other host genotypes and consequently to an increase of other parasite genotypes.

Spatial Patterns of Red Queen Dynamics

The constant process of adaptation and counter-adaptation may lead to patterns of local adaptation dependent on the evolutionary potential of hosts and parasites. Parasites are expected to have a higher evolutionary potential than their hosts, because of similar mutation and recombination rate, combined with a much shorter generation time. Natural populations of many species are organized as a geographic structure existing of local populations between which migration (of parasites and/or host individuals) takes place and which have a largely independent population dynamic and chance of extinction (metapopulation structure, Olivieri *et al.*, 1990, Hanski and Simberloff, 1997). This has resulted in a growing interest of interactions between local populations on host–parasite relationships (Thompson, 1999). The interactions within local host–parasite interactions can be dependent on neighboring populations because populations might differ in their resistance and virulence genes. Through gene flow, new resistance and virulence genes can enter a given local population (Gandon *et al.*, 1998). On the one hand, gene flow can increase local genetic diversity in both parasites and hosts, but on the other hand, gene flow may also homogenize regional genetic variation and prevent local adaptation of both host and parasite (Little, 2002). In a temporal variable environment, gene flow is not necessarily maladaptive. A relatively high level of colonization can also restore the loss of genetic diversity through extinction. Moreover, a combination of local interactions, high virulence and limited gene flow can enhance genetic differentiation between populations, resulting in local adaptation (Gandon *et al.*, 1998; Lively, 1999). In this way, it is possible for the host to increase its chances in the coevolutionary arms race with the fast-evolving parasites (Jousimo *et al.*, 2014). For the host, gene flow may then act as a second mechanism, next to sexual recombination, to reduce the disadvantage of its long generation time and low evolutionary potential in comparison with its parasite. With its different, sometimes conflicting effects, gene flow is an important aspect of the geographic mosaic of coevolution. Genetic drift, founder effects, and local extinctions can also shape the interaction and contribute to the large-scale picture (Thompson, 1999).

Environmental Variation in Red Queen Dynamics

Awareness has grown that host–parasite coevolutionary interactions are strongly influenced by changing environments, both abiotic (Wolinska and King, 2009) and biotic (Betts *et al.*, 2016). This is a concept that originated in the "geographical mosaic of coevolution" concept (Thompson, 2005) that focuses on coevolutionary interactions in a spatial context and that is based on the observation that interspecific interactions vary depending upon genetic factors as well as environmental variation. Environmental modification can be the driver in the spread of allelic variants, for example a host genotype that is the least susceptible at one temperature, may be the most susceptible at another ($G \times E$ interactions, Vale and Little, 2009). As such, these processes will influence host–parasite frequency-dependent coevolutionary dynamics. Furthermore, the environment in which hosts and parasites interact may also substantially affect the strength and specificity of selection ($G \times G \times E$ interactions). In addition, various components of host–parasite fitness, for example, costs of resistance and infectivity can be differentially altered by the

environment (Wertheim *et al.*, 2003; Morgan *et al.*, 2009). Nevertheless, environmental fluctuations are often excluded from experimental coevolutionary studies and theoretical models as "noise." Because most host–parasite interactions exist in heterogeneous environments, it is argued that there is a need to incorporate fluctuating environments into future empirical and theoretical work on host–parasite coevolution (Wolinska and King, 2009).

The expected pattern of host–parasite coevolution depends, among other things, on the time lag between the host and parasite coevolutionary dynamics, on the time scale separating the various samples of the host populations and on the number of generations of hosts and parasites considered (Gandon *et al.*, 2008). For instance, seasonal changes in temperature and predation alter the interaction between the water flea *Daphnia* and its parasites such that differences in temperature and predation pressure will change parasite mediated selection, resulting in the maintenance of genetic variation of the traits involved (Duffy *et al.*, 2005; Hall *et al.*, 2006; Vale *et al.*, 2008). Also changes in environmental resource quality can modify the epidemiology of host–parasite interactions, but are also suggested to change the strength and direction of selection in host–parasite interactions. If environmental nutrient enrichment is translated into higher population sizes, then increased host–parasite interactions, in terms of within-host competition and parasite transmission, may intensify the coevolutionary arms race between hosts and parasites. Evolutionary host population responses with respect to resistance toward parasites are assumed to be strongest in highly productive systems. Larger host and parasite populations broaden the genetic variation available for selection and increase encounter rates between hosts and parasites. Higher encounter and transmission rates are associated with more virulent parasite strains, which pose stronger selection pressures for host defenses, further increasing the selection pressure on parasites for counter-defense. High environmental nutrient levels are found to favor rapidly growing species (growth rate hypothesis, GRH) which would then offer high-quality resources for parasites, and this could again favor rapidly growing parasites that have high nutrient demands and consequently express high virulence. Fast growth rates can thus be expected to intensify coevolutionary cycles via accelerating population turnover and increasing the number of mutations. Thus, environmental nutrient enrichment is expected to direct host evolution toward higher resistance, and parasite evolution toward higher virulence, intensifying the coevolutionary arms race and reducing the period of coevolutionary frequency-dependent oscillations (Decaestecker *et al.*, 2013; Aalto *et al.*, 2015).

The Red Queen in Eco-Coevolutionary Dynamics

It has become clear that evolutionary and ecological processes may occur at the same time and pace and therefore interact with each other ("eco-evolutionary dynamics," as defined in Hairston *et al.*, 2005, Hendry, 2016, De Meester *et al.*, 2016). This notion has led to many discussion papers about the need to integrate both evolution and ecology if we really want to understand ecosystem dynamics (Matthews *et al.*, 2011). The future challenge is going beyond understanding one-way interactions between ecology and evolution and to study how the reciprocal effects of organisms change their biotic and abiotic environment (Urban *et al.*, 2012). In a full "eco-evolutionary feedback loop," evolutionary processes significantly alter ecological dynamics and in return the altered ecological dynamics influence the evolutionary processes (Fussman *et al.*, 2007; Becks *et al.*, 2012; Turcotte *et al.*, 2013). Recently, there has been considerable interest in the interaction of ecological and evolutionary dynamics in an attempt to understand them as coupled "eco-evo" processes. Such eco-evolutionary feedbacks can occur at multiple levels, such as in demographic parameters, community composition, food webs, nutrient cycling and productivity (Hairston *et al.*, 2005; Urban and De Meester, 2009; Hendry, 2016). At the population level, natural selection and population dynamics are closely linked because both are affected by the birth and death of individuals. Thus, if natural selection acts on a trait through survival or reproductive success, it will leave a population dynamical signature. At a larger scale, changes in the genetic composition of a species can affect its fitness dependencies with other species (e.g., through trophic interactions or competition) and hence alter the ecological dynamics of an ecosystem, and vice versa.

Parasites play a crucial role in regulating and shaping host populations by altering their density, genetic structure and diversity. Such population level effects can mediate changes up to the community level through alteration of interspecific competition or through changes in host behavior (Penczykowski *et al.*, 2014). Finally, one can expect that effects of parasites on community structure may be propagated throughout the whole ecosystem by changing food web interactions and dynamics, thereby influencing energy flow and nutrient cycles. Parasites can greatly add to our knowledge on the role of "eco-coevolutionary dynamics" (i.e., eco-evolutionary dynamics in which coevolutionary processes are the crucial drivers) for ecosystem functioning with respect to biogeochemical processes. Rapid coevolutionary responses between hosts and parasites may play a critical role in shaping ecological processes (Hiltunen and Becks, 2014). Parasites have relatively short generation times and show strong and fast adaptation (Decaestecker *et al.*, 2007), increasing the potential of time scales for ecological and evolutionary responses to be congruent. The evolution of parasite phenotypes have been shown to induce changes in important ecological processes, such as nutrient cycling (Lennon and Martiny, 2008), but we lack demonstrations of a complete feedback loop between coevolutionary and ecological dynamics (Hiltunen and Becks, 2014).

Beyond the Pairwise: Red Queen and Microbiota

While pathogens may drive evolution with a stick, mutualistic symbionts can achieve similar feats by offering the carrot. Mutualists are facilitators of niche adaptation and are thought to have prominent roles in host speciation (Vavre and Kremer, 2014). While

examples of species evolution driven by specific pathogens or mutualists are numerous, the full picture is likely more complex, as animals (and plants) harbor complex communities comprising diverse microbes, some more adapted to their host, others generalists, or transient, representing a broad spectrum of potential contributions (Shapira, 2016, Macke *et al.*, 2017a).

By mediating interactions between hosts and other organisms, such as parasites, symbionts that protect hosts from infection ("defensive" or "protective" microbes) can play a direct role in the process of host–parasite coevolution (Kwiatkowski *et al.*, 2012; Parker *et al.*, 2011; Ford and King, 2016). So far, most models and laboratory experiments investigating coevolution processes, such as the Red Queen Hypothesis, have been mainly based on pairwise-species interactions (Lively *et al.*, 2014). However, in natural environments a lot of factors, such as diverse species interaction networks may affect coevolution, and should thus be more systematically considered in future research (Koskella and Brockhurst, 2014, Betts *et al.*, 2016, Macke *et al.*, 2017b). Whole microbial communities and individual microbial symbiont species can be associated with specific host genotypes driving patterns of host–parasite interaction specificity (Koch and Paul Schmid-Hempel, 2012; Rouchet and Vorburger, 2012), a fundamental assumption of coevolutionary dynamics (Agrawal and Lively, 2002). If parasites adapt to these genotype-specific microbes then defensive symbionts have the potential to mediate host–parasite coevolutionary interactions (Kwiatkowski *et al.*, 2012) and even evolve themselves (Ford *et al.*, 2016a,b). By integrating defensive microbial symbionts into host–parasite interactions at the mechanistic level with evolutionary theory, Ford and King (2016) predict how defensive microbes might alter the evolution of host and parasite traits, such as resistance and virulence, which in turn might greatly affect host population dynamics. First, direct coevolution between defensive microbes and parasites would provide "real time" control of the infection, whereby evolutionary changes in parasites are met by rapid reciprocal evolution in defensive microbes (Ford *et al.*, 2016a). Second, given that defensive microbes protect hosts from parasite-induced fitness costs, they could reduce selection for costly immune or behavioral defense mechanisms in the host. Over evolutionary time, a host may thus become dependent on microbe-mediated protection, a hypothesis that has been invoked to explain the loss of immune genes in pea aphids and honeybees (Gerardo *et al.*, 2010; Kaltenpoth and Engl, 2014). Finally, defensive symbionts can shape the evolution of parasite virulence (Ford *et al.*, 2016b), through mechanisms similar to interactions occurring between co-infecting parasites, such as resource competition, interference competition or immune mediation (Macke *et al.*, 2017a).

These observations can in principle be extended to interactions other than host–parasite coevolution, such as plant–insect coevolution, and may be valuable for a more realistic understanding of coevolutionary processes. Through the horizontal transfer of bacteria, species or populations of the same species can affect the fitness, and thus potentially the evolution, of each other (Feldhaar, 2011). Gut symbionts can also act as ecosystem engineers and contribute to modifying the biotic and abiotic environment of their host, potentially affecting other species of the community. For example, by contributing to food digestion, gut symbionts play a major role in the food web and can contribute to the stability of the whole community.

Glossary

Carrying capacity *K* The maximum number of individuals from a given population that a given environment can sustain under constant conditions.

Fast–slow continuum A continuum of species from fast to slow life histories, which are typically characterized by early reproduction (slow life histories: late reproduction), a short (long) interbirth interval, high (low) fecundity, small (large) offspring, small (large) adult body size and a short (long) lifespan.

Intrinsic growth rate *r* The difference between per capita birth rate and death rate at very low population densities.

***K*-selection** The *K*-endpoint of the *r*-*K* continuum, representing the qualitative extreme: density effects are maximal and the environment is saturated with organisms; competition is keen and the optimal strategy is to allocate resources to maintenance and the production of a few extremely fit offspring (based on Pianka, 1970).

Life history An organism's lifetime pattern of growth, differentiation, storage, reproduction, and survival. Life-history traits determine individual fitness and are often phenotypically plastic. Complex theories have been developed to predict how selection shapes life histories.

***r*-selection** The *r*-endpoint of the *r*-*K* continuum, representing the quantitative extreme: a perfect ecological vacuum, with no density effects and no competition; the optimal strategy is to allocate resources to reproduction, producing as many offspring as possible (based on Pianka, 1970).

Introduction

The concept of *r*-strategists and *K*-strategists lies at the interface between ecology and evolution. It was developed in the 1960s and 70s mainly by the three US-American scientists Robert H. MacArthur (1930–1972), Edward O. Wilson (1929–), and Eric R. Pianka (1939–). The concept was especially important in the 1970s. One short paper by Pianka from 1970 titled "On *r*- and *K*-selection" has been cited more than 3000 times according to Google Scholar. Although the concept as a whole is not seen as accurate anymore today, parts of it still are.

In this article, we outline the historical development of the *r*/*K* concept, followed by its problems as seen today. We then describe its aspects that are still in use, namely the observation that life histories show patterns within and among species and the idea that selection regimes vary with population density.

Historical Development of the *r*/*K* Concept

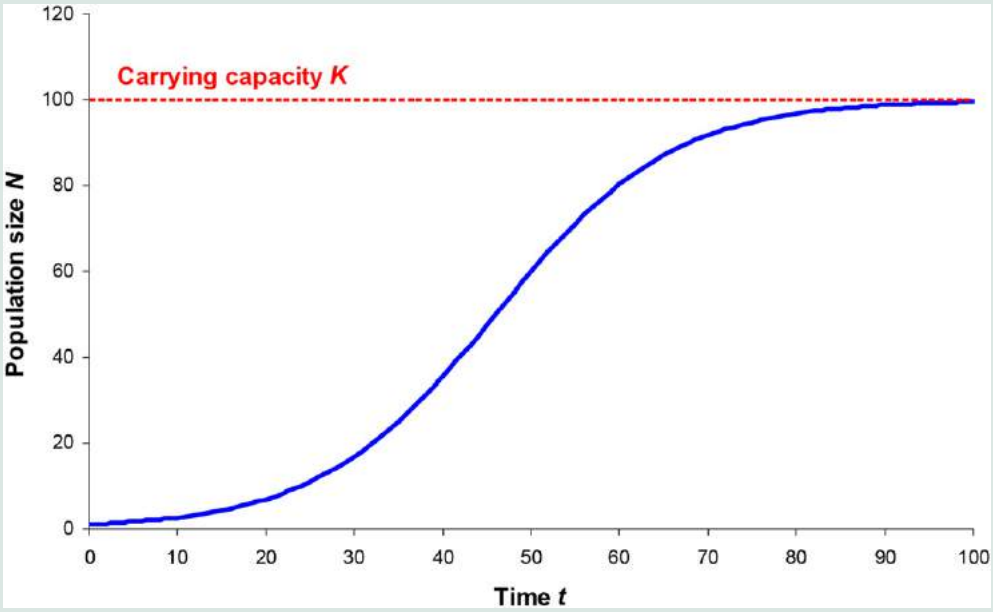
The *r*/*K* concept is based on the idea that environments differing in population abundance and fluctuation should select for different phenotypes. In a paper published in 1950, Theodosius Dobzhansky compared evolution in the tropics to evolution in temperate environments. The tropics are more stable and populated by different species than temperate environments, so "interrelationships between competing and symbiotic species become the paramount adaptive problem." (p. 220 in Dobzhansky, 1950) On the other hand, "Physically harsh environments, such as arctic tundras or high alpine zones of mountain ranges, are inhabited by few species of organisms. The success of these species in colonizing such environments is due simply to the ability to withstand low temperatures or to develop and reproduce during the short growing season." (p. 220).

The idea that environments differing in stability and population select for different phenotypes was formalized by MacArthur and Wilson (1967) in their landmark book "The theory of island biogeography" from 1967. In contrast to Dobzhansky (1950), however, MacArthur and Wilson did not look at the population of environments by different species (i.e., biodiversity) but at the population density of species. Given the title of their book, it is no surprise that they focused on species colonizing islands. They formally found that successful colonizers should have a high intrinsic growth rate *r*, which is the difference between per capita birth rate and death rate at very low population densities. Looking at empirical evidence, they concluded: "The evidence for birds and ants […] points to a preference for unstable, scattered habitats as a preadaptation to successful colonization" (p. 82). Regarding population persistence, they found that a

☆*Change History*: January 2018. Jonathan M Jeschke, Wilfried Gabriel, and Hanna Kokko updated the text and bibliography, and added the glossary and relevant websites.

This is an update of J.M. Jeschke, W. Gabriel and H. Kokko, r–Strategist/K–Strategists, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3113–3122.

Box 1 The logistic equation with its parameters *r* and *K*



Visualization of the logistic equation $\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right)$, where N is population size, t is time, r is intrinsic growth rate, and K is carrying capacity. The time-discrete analog is $N_{t+1} = \frac{e^r N_t}{1+aN_t}$ with $a = \left(\frac{e^r - 1}{K}\right)$.

The parameter r, intrinsic growth rate, is the difference between per capita birth rate and death rate at very low population densities. It is part of the logistic equation and also of the Euler–Lotka equation: $1 = \sum_x e^{-rx} l_x m_x$, where l_x is the probability of surviving from birth to age x and m_x is the number of daughters per female at age x. The Euler–Lotka equation links the parameter r with the life history of individuals. Hence, r is an individual trait that can be selected.

The parameter K, carrying capacity, can however hardly be considered an individual trait. It is really not more than a parameter representing density dependence in the logistic equation. It is phenomenological, thus not directly biologically interpretable.

high carrying capacity K equals a long expected persistence time, where K is the number of individuals the island maximally can hold in equilibrium. The two parameters r and K form the basis of the logistic equation (Box 1). MacArthur and Wilson then extended their findings to populations beyond islands. Based on work by Fisher, Haldane, and Wright, it was already known that r generally is an appropriate measure of fitness at low and increasing population densities. MacArthur and Wilson added that K is an appropriate measure of fitness at high densities and accordingly coined the terms r-selection and K-selection: in fluctuating environments, populations are repeatedly diminished, so r-selection will dominate. In stable environments, on the other hand, populations will grow to a rather constantly high size where K-selection will dominate. They argued that r-selection tends to lead to "a shorter developmental time, a longer reproductive life, and greater fecundity, in that order of probability" (p. 157). In other words, r-selection should lead to high and fast productivity, whereas K-selection should lead to efficiency, especially of resource utilization.

In a short note published in 1970, Pianka made the connection between r-selection, K-selection, and life history more explicit and thereby gave the r/K concept its final form (**Table 1**). He wrote: "Certainly, no organism is completely 'r-selected' or completely 'K-selected,' but all must reach some compromise between the two extremes.[…] We can visualize an r-K continuum, and a particular organism's position along it. The r-endpoint represents the quantitative extreme – a perfect ecologic vacuum, with no density effects and no competition. Under this situation, the optimal strategy is to put all possible matter and energy into reproduction, with the smallest practicable amount into each individual offspring, and to produce as many total progeny as possible. Hence r-selection leads to high productivity. The K-endpoint represents the qualitative extreme – density effects are maximal and the environment is saturated with organisms. Competition is keen and the optimal strategy is to channel all available matter and energy into maintenance and the production of a few extremely fit offspring. Replacement is the keynote here. K-selection leads to increasing efficiency of utilization of environmental resources" (p. 592 in Pianka, 1970). This is the reasoning behind **Table 1**, so Pianka gave no formal justification of the attributes of r-strategists and K-strategists. Synonyms for r-strategists are r-selected species, fugitive species, and opportunistic species. For K-strategists, the synonyms K-selected species and stable species have been used. As typical r-strategists, Pianka mentioned insects (with the exception of 17-year cicadas and similar species), whereas vertebrates were typical K-strategists (except some amphibians). Within each taxon, of course, some species are more on the r-end of the continuum while others are more on the K-end.

Table 1 Attributes of *r/K*-strategists

	r-strategists	*K-strategists*
Climate	Variable and/or unpredictable	Fairly constant and/or predictable
Mortality	Often catastrophic, nondirected, density-independent	More directed, density-dependent
Survivorship		Population size	Variable in time, nonequilibrium: 	Fairly constant, equilibrium: Intra- and interspecific competition	Variable, often lax	Usually keen
Life history	Rapid development	Slow development, greater competitive ability
	High r_{max}	Lower resource thresholds
	Early reproduction	Delayed reproduction
	Small body size	Large body size
	Semelparity: single reproduction	Iteroparity: repeated reproduction
	Short lifespan	Long lifespan

Problems of the *r/K* Concept

"The theory of *r*-selection and *K*-selection […] helped to galvanize the empirical field of comparative life-history and dominated thinking on the subject from the late 1960s through the 1970s. […] By the early 1980s, sentiment about the theory had changed so completely that a proposal to test it or the use of it to interpret empirical results would likely be viewed as archaic and naïve" (Reznick *et al.*, 2002, p. 1509). Similarly, Roff (2002, p. 79) wrote: "it may be preferable to avoid use of the terms [*r*- and *K*-selection] altogether." As these quotes show, the *r/K* concept was very important in the past but today, it is in its whole basically not used anymore. It has fallen into disfavor due to the recognition of several problems, in particular: (1) the concept's assumption of a trade-off between *r* and *K* is often not valid; (2) the parameter *K* is not directly biologically interpretable; and (3) the life-history traits attributed to *K*-strategists are not justified, neither theoretically nor empirically.

(1) The assumption of a trade-off between *r* and *K* is often not valid. The *r/K* concept assumes that *r*-selection and *K*-selection are in opposition although there is no logical necessity to this assumption. A trade-off between *r* and *K* has not often been found empirically, either. Although it has received some support in experiments with *Drosophila melanogaster*, this was not the case for experiments with *Escherichia coli*, the rotifer species *Asplanchna brightwellii*, or the cladoceran *Bosmina longirostris*.

(2) The parameter *K* is not directly biologically interpretable. While *r* is the difference between per capita birth rate and death rate at very low population densities and can be directly related to the life history of individuals, *K* is a quite complex parameter: it is meant to give the maximum number of individuals that a given environment can sustain under constant conditions. This phenomenological parameter cannot be determined in natural populations and is thus not directly biologically interpretable. In models, *K* is defined as the unstable or stable point of equilibrium where death rates equal birth rates ($dN/dt=0$ in time-continuous models, $N_{t+1}=N_t$ in time-discrete models). In real populations, such points of equilibrium are rarely constant over time. How *K* relates to life-history traits is indefinable, too. Stearns (1977, p. 155) wrote: "*K* is not a population parameter, but a composite of a population, its resources, and their interaction. Calling *K* a population trait is an artifact of logistic thinking, an example of Whitehead's Fallacy of Misplaced Concreteness. Thus *r* and *K* cannot be reduced to units of common currency." In other words, the *r/K* concept is comparing apples and oranges.

(3) The life-history traits attributed to *K*-strategists are not justified. There is no reason why species living in constant environments should have the combination of traits proposed by Pianka and reproduced in **Table 1**. The linkage between the environment and

the life history made by Pianka is at the heart of the *r*/*K* concept but has never been theoretically justified, neither by Pianka nor anyone else. To achieve a high *r*, a species can either maximize its birth rate and/or minimize its death rate, and the corresponding strategies will result in different life-history traits. This ambiguity questions the life-history attributes of *r*-strategists. But while these attributes can still be logically defended, the main reason for the traits of *K*-strategists seems to have been the intuitive assumption that they should be the opposite of those of *r*-strategists. As mentioned above, however, there is no necessary trade-off between *r* and *K*. When we take a closer look at the attributes, we may for example ask why, as claimed by Pianka, a population of large aggressive individuals should have a higher carrying capacity than a population of small peaceful individuals. Larger individuals need more resources than smaller ones, so a given amount of resources provided by the environment can be used either by a small number of large individuals or a large number of small individuals. Under many circumstances we can therefore expect a smaller carrying capacity for larger individuals, while the *r*/*K* concept claims the opposite. In defending the concept, we could reinterpret *K* and measure it in biomass rather than individuals. This trick does not help with the problem of aggressiveness, however. Intraspecific aggression should often lead to a smaller population size and thus a smaller carrying capacity, again in contrast to the *r*/*K* concept. Of course, there are situations where selection on individuals leads to at least a specific life-history stage being maximized (i.e., the number of individuals in it), but this is not interpretable as giving support to a broad-brush categorization of traits like in the Pianka scheme.

The linkage between the environment and life history made by Pianka also lacks empirical support. For example, when fruit flies (*Drosophila melanogaster*) were reared at low or high densities, the low-density lines evolved a higher capability to increase in population size at low densities but a lower capability to increase at high densities. In the high-density lines, the fly larvae were more competitive due to a higher feeding rate and pupation at a greater height above the medium compared to low-density lines. These experimental results are in accordance to the general predictions of the *r*/*K* concept about the differences between selection at low versus high densities. However, they are not in accordance to the explicit predictions about the linkage of these differences to specific life-history traits. The same is true for experiments with pitcher-plant mosquitoes (*Wyeomyia smithii*) where differences in population densities again led to differences in competitive ability but not to differences in life-history traits. Although some supportive empirical data do exist (Sæther *et al.*, 2016), a direct relationship between population density or fluctuation on the one hand and life-history characteristics on the other hand, as proposed by the concept, has not been generally established. It is true that life-history patterns exist, but apparently the *r*/*K* concept cannot explain them.

Aspects of the *r/K* Concept Used Today

As the last section has made clear, the reason why the *r*/*K* concept is included in today's ecological textbooks and this encyclopedia is not because it is still widely used or considered to be correct. The reasons are that the concept is historically important and that two of its aspects are still in use. The first one is that life-history traits show patterns within and among species: they do not vary randomly but correlate to each other, an observation that has led to the concept of fast and slow life histories. The second preserved aspect is the basic idea of Dobzhansky, MacArthur, and Wilson that heavily populated and stable environments select for different traits than less populated and fluctuating environments. We shall comment on both aspects below.

Fast and Slow Life Histories

Observed patterns

According to the concept of fast and slow life histories, species with fast (slow) life histories have certain life-history characteristics that are similar to those of *r*-strategists (*K*-strategists) in the *r*/*K* concept (**Table 2**). In contrast to the *r*/*K* concept, however, fast and slow life histories are primarily observed patterns and not necessarily connected to an explanation.

The fast–slow concept is based on the observation that certain life-history traits of species often correlate to each other in a similar way. These traits are age of first reproduction, interbirth interval, fecundity, offspring size, adult body size (usually measured as body mass), and lifespan (**Table 2**). Based on this suite of correlated traits, many species fit on a continuum from fast to slow life histories. For example, the bank vole (*Clethrionomys glareolus*) and the house mouse (*Mus musculus*) are mammals with fast life histories: they reproduce early, have a short interbirth interval, a high fecundity, small offspring, are also small as adults,

Table 2 Life histories of species on the fast–slow continuum with body size included

Fast	*Slow*
Early reproduction	Late reproduction
Short interbirth interval	Long interbirth interval
High fecundity	Low fecundity
Small offspring size	Large offspring size
Small adult body size	Large adult body size
Short lifespan	Long lifespan

Note: When body size is factored out, a second continuum can be observed among the remaining variables.

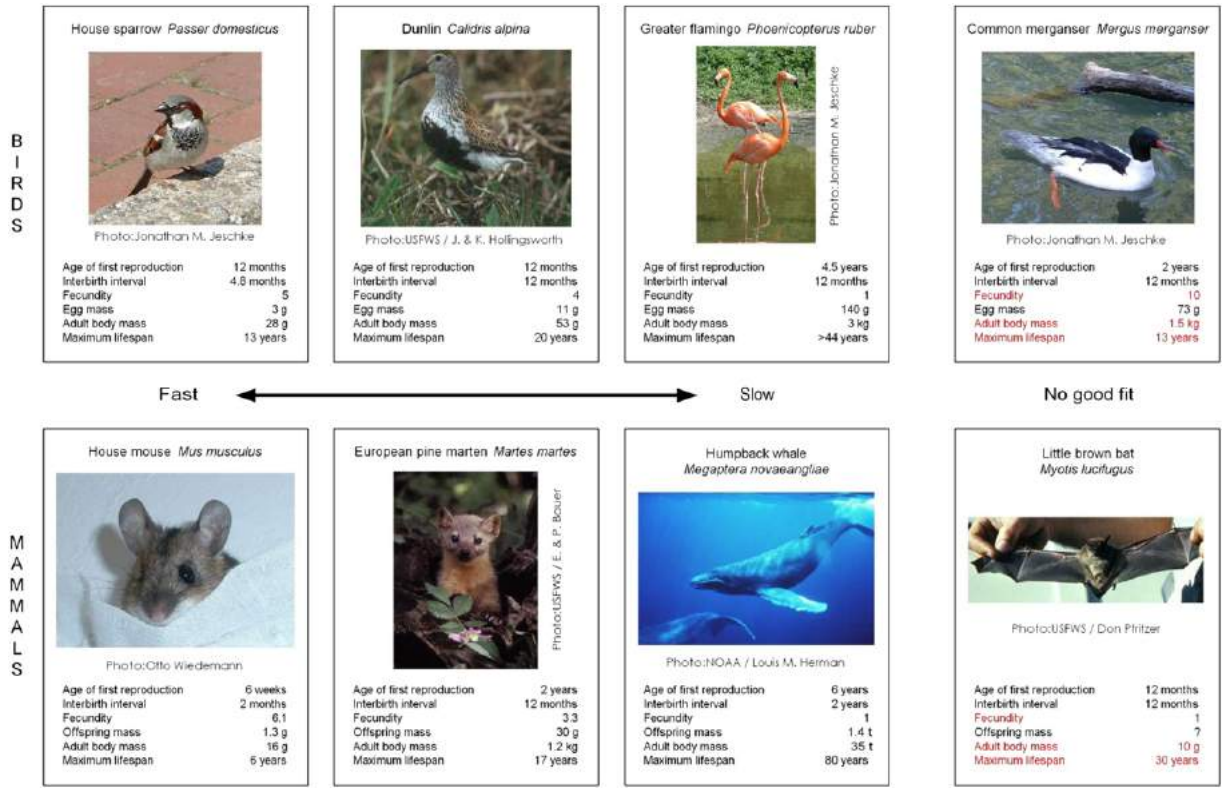

Fig. 1 Examples of species on the fast–slow continuum according to **Table 2** and of species that do not fit well on the continuum.

and have a short lifespan (**Fig. 1**, **Table 2**). The opposite is true for *Homo sapiens* and the humpback whale (*Megaptera novaeangliae*) which are mammals with slow life histories. Naturally, many species are on neither extreme end of the fast–slow continuum but in between, for example, the arctic hare (*Lepus arcticus*) or the European pine marten (*Martes martes*) (**Fig. 1**). The position of a species on the continuum depends on the focal taxonomic level. For example, on the level of all mammals, the bat-eared fox (*Otocyon megalotis*) has a rather slow life history, but on the level of carnivores, it has a relatively fast life history. Within birds, examples for species with fast life histories include the blue tit (*Parus caeruleus*) and the house sparrow (*Passer domesticus*). Birds on the slow end of the continuum include the California condor (*Gymnogyps californianus*) and the greater flamingo (*Phoenicopterus ruber*). Finally, examples for birds with intermediate life histories are the dunlin (*Calidris alpina*) and the magpie (*Pica pica*) (**Fig. 1**).

Of course, the fast–slow continuum cannot explain all the variation. Many species do not neatly fit on the continuum, for example, the little brown bat (*Myotis lucifugus*) which has an exceptionally low fecundity and long lifespan for its body size (**Fig. 1**). Other bat species share this deviation from the overall mammalian pattern, however, so the little brown bat is not exceptional within bats. The European rabbit (*Oryctolagus cuniculus*), on the other hand, has a too short interbirth interval for its size to neatly fit on the overall fast–slow mammal continuum: its average adult body mass is 1.6 kg and its interbirth interval 2.4 months. Within birds, the common merganser (*Mergus merganser*) has an exceptionally high fecundity and short lifespan for its size (**Fig. 1**), while Costa's hummingbird (*Archilochus costae*) has an exceptionally low fecundity (2 eggs) and long interbirth interval (12 months) for its size (average adults only weigh about 3 g). Many other hummingbirds and very small organisms in general seem to more often deviate from the fast–slow continuum than medium-sized and large organisms, which might be caused by size constraints at the low end of the body size distribution: when you are tiny, it may, for example, be hard to produce a huge number of offspring simultaneously, so your fecundity may be limited.

Thus far, we focused on the fast–slow continuum according to the traits given in **Table 2**. When body size is factored out, a second fast–slow continuum can be found among the remaining variables: age of first reproduction, interbirth interval, fecundity, offspring size, and lifespan. The two fast–slow continua are different, so some species that have a fast life history when body size is included have a slower life history when body size is factored out and vice versa. Also, some species fit better on the continuum when body size is factored out and vice versa. For example, the European rabbit fits well on the fast end of the continuum when body size is factored out, while it does not fit well on the continuum when body size is included (see above). Both fast–slow continua share the same name and are thus rarely discriminated, which is fine in some contexts. But the discrimination would be necessary in other contexts. In this article, we refer to "fast–slow continua" when we consider the discrimination not necessary but otherwise indicate the continuum we are referring to.

The existence of fast–slow continua has been established in vertebrates by a number of studies. For invertebrates, less information on life histories is available which makes comprehensive tests difficult. Furthermore, the concept of fast and slow life

histories has mainly attracted the attention of zoologists, so tests beyond the kingdom of Animalia are relatively rare as well. Particularly unknown is the general applicability of the concept to intraspecific differences in life history.

It is also uncertain whether and, if yes, how fast–slow continua are connected to other species traits. For example, it has been proposed that species with fast life histories have higher population densities than species with slow life histories, but empirical data have been inconclusive so far. In birds, there is some evidence that fast species have more variable population dynamics than slow species. The fast–slow continua may be helpful in conservation biology, for species with slow life histories tend to be more endangered of extinction (Jeschke and Strayer, 2008). On the other hand, nonnative species with a fast life history do not seem to have a higher invasion success than nonnative species with a slow life history, although this is frequently assumed (Jeschke and Strayer, 2008).

Some researchers have combined the fast–slow concept with other concepts, for example, the one of wasteful and frugal strategies: wasteful species are those that are adapted to good environmental conditions; they have a low production efficiency but a high mass-specific metabolic rate, and grow fast. Frugal species, on the other hand, are adapted to poor environmental conditions; they have a high production efficiency but a low mass-specific metabolic rate, and grow slowly. As fast and slow, wasteful and frugal are considered to be two ends of a continuum. Combining wasteful–frugal with fast–slow leads to a square with the four corners wasteful-fast, wasteful-slow, frugal-fast, and frugal-slow.

The concept of fast and slow life histories describes patterns but does not, as such, link the patterns to an explanation. The observation certainly hints at a trade-off between traits: it appears, for example, easier to achieve high fecundity at the expense of lifespan, or vice versa, than to maximize both simultaneously. The challenge of life-history theory is therefore to identify the important trade-offs and to explain why certain environmental conditions favor particular solutions along them. Most explanations have focused on explaining a single trait, for example, clutch size, but other approaches have focused on suites of traits, for example, fast or slow life histories. One of these approaches was the r/K concept but it failed in its pure form, as outlined above. Another approach are age-specific demographic models in which fluctuating juvenile mortalities select for slow traits, for example, delayed reproduction or low reproductive effort, while fluctuating adult mortality leads to fast traits. These models did originally not include density-dependent selection but have later been extended to do so. They now consider density in a much more precise way than the r/K concept: for example, a general result by Charlesworth (1980) shows that natural selection will under very general conditions maximize the number of individuals in the life stage that is subject to density dependence, and this obviously corresponds to increasing K if the population consists of identical individuals. Although models have usually focused on a single trait, they may also have the potential to explain suites of traits, as we will outline below. Before, we shall explain allometric scaling models that also shed light on fast and slow life histories.

Allometric models

Allometric models try to explain one or more of the many allometric relationships that have been found among species traits. An allometric relationship between x and y can be expressed in power form as $y = a\,x^b$ or logarithmically as $\log y = \log a + b \log x$, where a is a constant and b is a scaling exponent. If b equals 1, the relationship is called isometric. The interest of science in allometry dates back to the 17th century when Galileo noted that large animals have limb bones that are proportionally thicker than small animals. In other words, b is larger than 1 in this case which is called a positive allometry. Negative allometries, on the other hand, are those where b is smaller than 1. An example is the relationship between metabolic rate and body mass which has been found about two centuries ago. There has been much debate about the "true" value of the scaling exponent b in this relationship: whether it is 2/3 or 3/4 or neither of these two attractive numbers. It is undoubted, however, that b is smaller than 1, so although heavy animals have a higher metabolic rate than lighter animals in absolute terms, their metabolic rate per g-body mass is lower than that of lighter animals. For example, an average adult humpback whale weighs about 2 million times more than an average adult house mouse (**Fig. 1**), but its metabolic rate is not 2 million times higher than that of the house mouse. Per g-body mass, the humpback whale's metabolic rate is much lower than that of the house mouse. Besides the thickness of limb bones and the metabolic rate, there are many other species traits that scale allometrically to body mass. Originally, only single relationships have been addressed by allometric models, but their use now has been extended to suites of relationships, for example, fast or slow life histories. Allometric models now connect the traits body mass, age of first reproduction, interbirth interval, and lifespan.

The allometric models developed by James H. Brown and colleagues are currently the best known. Their so-called "metabolic theory" (Brown *et al.*, 2004) looks at the structure of biological networks, for example, blood vessels in vertebrates, and assumes that: (a) these networks are space-filling and branch hierarchically to supply all parts of the body; (b) the terminal tubes of these fractal networks do not vary with body size; (c) metabolic rate equals the rate at which the networks transport resources; and (d) evolution has minimized the time and energy needed for this transport. Based on these assumptions, the theory predicts b to be 3/4 for the scaling of metabolic rate to body mass, a prediction that appears to match empirical data, although this is controversial (see above). Because the mass-specific rate of metabolism is the metabolic rate divided by body mass, it is predicted to scale to body mass with $b = -1/4$. Brown *et al.* wrote: "the metabolic rate is the fundamental biological rate, because it is the rate of energy uptake, transformation, and allocation" (Brown *et al.*, 2004, p. 1772). The theory therefore predicts that other biological rates scale to body mass with $b = -1/4$ as well, for example, heart rate, which again seems to match empirical data. Furthermore, because times are the reciprocals of rates, biological times are predicted to scale to body mass with $b = 1/4$, for example, time to maturity, interbirth interval, or lifespan which are relevant to the fast–slow concept. Here again, predictions appear to match data. The basic models of this theory apply to endotherms only, but later models include temperature as the second determinate besides body mass and hence also apply to ectotherms.

The metabolic theory is broader than depicted here and was not specifically designed to explain fast or slow life histories. It has several limitations and weaknesses. For example, the network structure assumed by the theory does not match all network structures realized in nature, for example, the insect tracheal system, but the theory nonetheless correctly predicts metabolic rates of such organisms. Critiques say this suggests that another mechanism than the one proposed by the metabolic theory causes the scaling of metabolic rate to body mass. As already mentioned above, critiques also question that the quarter-power scaling predicted by the theory (that b is a multitude of 1/4) is empirically as universal as claimed by Brown *et al.* Depending on the statistical method, multitudes of 1/3 are observed, too, and other numbers in between as well. Kozłowski and Konarzewski questioned the consistency of the theory. To make it consistent, they argued, either metabolic rate had to scale isometrically to body mass or the assumption that the terminal network tubes are size-invariant needed to be relaxed. The first option does not agree to empirical data, but Kozłowski and Konarzewski cite empirical studies that challenge the assumption of size-invariance of the terminal tubes. Opponents of the theory have raised more critical points but an extensive discussion is beyond the scope of this article.

Various other models have been developed by different researchers to explain the allometric relationship between metabolic rate and body mass. These models differ in their assumptions and math but combined with the above-mentioned reasoning by Brown *et al.*, they all offer a linkage between body mass and—via metabolism—age of first reproduction, interbirth interval, and lifespan.

Density-Dependent Selection

Scientists today agree that environments differing in population abundance or fluctuation select for different strategies. This insight is, besides fast–slow continua, the second aspect that has been preserved from the r/K concept. An empirical example comes from the island of St. Kilda, Scotland, where Soay sheep (*Ovis aries*) with a darker coat had a higher survival rate at high densities compared to sheep with a lighter coat. Similarly, sheep with unscurred horns survived better at intermediate densities, while sheep with scurred horns did better at high densities. Other empirical examples for density-dependent selection come from *Drosophila* flies reared in the laboratory, tadpoles in temporary ponds, guppies (*Poecilia reticulata*) in Trinidad, or great tits (*Parus major*) in the Netherlands.

The r/K concept suffered from not deriving an explicit (and correct) link between density-dependent selection and the life-history traits favored by selection. In modern models that consider density-dependent regulation, such a link is made specific: an increase in population density affects the life history which feeds back negatively on population growth. For example, an increase in population density could lead to a lower fecundity. Which trait or traits change and how they change exactly depends on the nature of the specific model.

The procedure used in such models is clear in principle: a population consisting of individuals with particular life-history traits will obey characteristic fluctuations that depend on the traits themselves but also on the resources available (resource use being perhaps a function of the life-history traits in question), as well as any environmental fluctuations. An alternative life history can invade if it enters the population in a way that eventually creates more descendants than what the original strategy was able to achieve. "Eventually" here refers to the fact that the number of descendants left in one generation is not necessarily maximized; for example, if fast reproduction is essential, then a strategy that leaves few but early offspring may eventually win over others. Counting the "eventual" offspring is made mathematically precise by calculating the so-called invasion theta, or Lyapunov exponent, of the linearized system describing the invasion of a population.

Calculating the Lyapunov exponent is not a trivial procedure, however: one can liken it to a tool that is so general that it sometimes resembles a hammer while at other times it provides the scissors needed to dissect a given problem. Put more precisely, the effect that density regulation has on the optimal life history has been shown to depend strongly on the exact type of life cycle and on the way stochasticity is incorporated. It would consequently be useful to know what shape this tool takes for biologically relevant questions, such as the traits that underlie fast–slow continua. Some progress has been made in this direction. An important paper published by Mylius and Diekmann (1995) showed that there are conditions under which natural selection will always favor strategies that maximize r: an example is density regulation that increases the mortality of all age classes. Density-dependent juvenile mortality, on the other hand, implies that the correct measure of fitness is R_0, the expected lifetime reproductive success. However, for many situations neither r nor R_0 are correct measures of fitness and there is then no other escape than to have exact knowledge of the type of density regulation present—or at least make the assumption explicit—while deriving the invasion prospects by calculating the demographic consequences of each strategy.

That the mathematics of fitness measurements produces such nontrivial conclusions regarding individual fitness estimation is bad news for empiricists, who are rarely blessed with easy estimates of density regulation in the populations they study. In terms of ease of calculation, the two most practical measures of individual fitness are λ, which is the discrete-time version of r ($\lambda = e^r$ if λ and r are measured at equivalent time scales), and the lifetime reproductive success R_0, which simply equals the number of offspring and is often abbreviated as LRS. A typical pragmatic approach is to draw conclusions based on detailed analysis of one measure or to calculate both λ and LRS and compare the results. There are also examples where more detailed data on individual performance in density-regulated populations allows building tailor-made models, giving therefore much more power to draw inferences regarding optimal strategies in a particular species. However, it has also been argued that for many practical applications, simple measures such as the lifetime reproductive success perform quite well.

It is probably fair to say that theoretical work is currently better equipped to answer questions about a single trait, for example, age of first reproduction, than about suites of traits such as fast or slow life histories. Clearly, trade-offs between current and future investment must lie behind such suites but we do not know enough about how they evolve exactly according to prevailing environmental conditions, including the different stochastic components of life cycles, as exemplified by those determining recruitment of birds into territorial populations. Some theoretical results exist where variable nonequilibrium dynamics select for

slower rather than faster life history, and they clearly pose a puzzle to be solved in this context. The solution may lie in the fact that detailed knowledge of the density regulation really matters. Indeed, alternative assumptions concerning variability and temporal correlations of vital rates lead easily to opposite conclusions regarding the effect of variability on the "speed" of a life history. Thus, it is unclear whether or under which conditions different types of density regulation evolve and how density regulation is related to life-history traits. Future work in this area might help to find explanations for observed life-history patterns.

Summary

The concept of *r*-strategists and *K*-strategists links population dynamics to life history: strongly fluctuating environments lead to a strongly fluctuating population density that is low on average. According to the concept, these circumstances select for a high intrinsic growth rate *r* which is achieved by a distinctive life-history strategy consisting of rapid development, a small body size, early reproduction, semelparity, and a short lifespan. Species with these characteristics are called *r*-strategists. On the other hand, relatively constant environmental conditions allow a population to reach its carrying capacity *K* and thus a high average population density. The concept says that these circumstances select for a high *K* which is achieved by slow development (associated with great competitive ability), a large body size, delayed reproduction, iteroparity, and a long lifespan. Species with these characteristics are called *K*-strategists. The concept proposes to classify natural species on a continuum from *r*-strategists to *K*-strategists. It was developed from the 1960s to the 70s and very popular at that time. However, its popularity has vanished due to the recognition of serious problems, for example, the lack of a theoretical or empirical justification for the proposed life-history traits of *K*-strategists.

The *r*/*K* concept nonetheless is not only of historical importance, for two of its aspects are still in use today: the first one is the observation that life histories show patterns within and among species, and the second is that selection regimes vary with population density. The best known life-history patterns are continua from fast to slow life histories: species with a fast (slow) life history have characteristics similar to those that were proposed for *r*-strategists (*K*-strategists). Explanations for fast and slow life histories offered by the literature include allometric scaling and demographic models. The latter often include density-dependent selection in a way that is much more precise than in the *r*/*K* concept.

Units of Selection

M Shpak, University of Texas at El Paso, El Paso, TX, USA

Natural and artificial selection act on the heritable variation in traits that correlate with fitness (defined in terms of viability and fecundity of the entity in question). Biological entities replicate and survive at different rates and probabilities, and when these rates and probabilities are correlated with the measured values of heritable traits, those trait values will evolve through the action of selection.

The most obvious and familiar instance of the process involves selection on differential fitness between individual organisms in a population and the subsequent change in phenotype or genotype frequencies. However, because selection acts on any form of covariation between fitness and heritable traits, it has been argued that entities above and below the level of the individual organism (or genome) in a population can be units of selection. Selfish genetic elements which increase in frequency at the expense of the fitness of the genome represent units of selection below the individual, while various interpretations of kin, interdemic, and species selection suggest at least the theoretical possibility of selection at levels above the individual genotype.

To see how a self-reproducing entity at any level of organization can (at least in theory) respond to selection, it is instructive to look at the equations for genic selection as special cases of a more general expression. The standard Fisher–Wright equation for the selection on the frequency of the ith allele p_i at a diploid locus is

$$\Delta p_i = \frac{p(W_i^* - \overline{W})}{\overline{W}} = \frac{p_i(1-p_i)}{2\overline{W}}\frac{\partial \overline{W}}{\partial p_i} \quad [1]$$

where $\overline{W}$ is the mean and W^* is the marginal fitness at the ith allele; $\overline{W} = \sum_i p_i W_i^*$, $W_i^* = \sum_j p_j W_{ij}$. To see how this can be derived from a more inclusive model of selection, we note that for any trait X (which can be the measured value of a gene, genotype, phenotype, higher moments of trait or frequency values), the rate of change in the mean value of X can be described by Price's theorem:

$$\Delta \overline{X} = \frac{1}{\overline{W}}(\mathrm{cov}[W, X] + E[W\overline{\delta}]) \quad [2]$$

In the second term on the right-hand side, $\overline{\delta}$ is a measure of average deviation between an individual's (or any reproducing entity's) phenotype X and that of its offspring (due to mutation, recombination, or any number of other factors). In the absence of this second term, from the definition of covariance and regression,

$$\Delta \overline{X} = \frac{1}{\overline{W}}(\mathrm{cov}[W, X]) = \frac{1}{\overline{W}}\beta_{W,X}\sigma_X^2 \quad [3]$$

where $\beta_{W,X} = \partial \overline{W}/\partial \overline{X}$ (the regression coefficient of trait value X on fitness W, i.e. the slope of predicted mean value of W given a mean trait value X) and σ_X^2 is the variance in trait X. In previous example, X is the value (0 or 1) of an allele with two states, 0 (absence) and 1 (presence), $\overline{X} = p$, the variance in X is the variance of a Bernoulli random variable, $p(1-p)$. Making the substitutions, one obtains the Fisher–Wright equation.

Note that in deriving eqn [1] from [2], it was assumed that the second term (representing 'transmission') on the right-hand side $E[W\overline{\delta}]$ was equal to zero. This basically states that an individual of a given genotype or phenotype produces offspring identical to itself. If one introduces multiple loci and recombination, of course, this condition is not satisfied and any derivation of the rate of change in mean trait value has to incorporate transmission values. These considerations arise when one wishes to derive equations for selection acting on genotypes defined by the allelic states at two or more loci. It is instructive to look at this example, as it illustrates the conflict between selection at the level of genes and at the level of genotypes.

Are Genes the Units of Selection?

R. C. Lewontin and K. I. Kojima were the first to derive the state equations for selection–recombination dynamics at two loci, which since then has been extended by various authors to more general multilocus models. The equations for selection on the frequency at two recombining diploid loci i, k (with alleles i=A or a, k=B or b) are

$$\begin{aligned} \Delta p_{i,k} &= \frac{1}{\overline{W}}(\mathrm{cov}[W, X_{i,k}] \pm rDW_{ABab}) \\ &= \frac{1}{\overline{W}}\left(\left(W_{i,k}^* - \overline{W}\right)p_{i,k} \pm rDW_{ABab}\right) \end{aligned} \quad [4]$$

Here r is the recombination rate (r=0.5 in the absence of physical linkage), $W_{ij}^* = \sum_{j,i} W_{ij,kl}$ is the marginal fitness of the i,kth haplotype (averaged over all possible diploid backgrounds j,l), and D is the linkage disequilibrium, defined as a measure of deviation from random association of alleles at different loci,

 doi:10.1016/B978-0-444-63768-0.00810-6

$$D = p_{i,k} - p_i p_k \quad [5]$$

It was also shown by Lewontin and Kojima that when the fitness of a two-locus genotype is nonadditive (i.e., the fitness of genotype AB cannot be written as a sum $W_A + W_B$) the selection–recombination system will evolve toward nonzero values of D. What this means is that in general one cannot determine genotype frequencies in the system as the product of allele frequencies at individual loci.

Furthermore, implicit in the equations for selection on a single locus [1] is that the measured fitness of an allele is a marginal fitness, not only against the corresponding sister allele in the diploid state, but against all possible genetic backgrounds at other loci. In other words, the fitness values of W_{ij} (of genotype ij at the first locus) are themselves marginal fitness values that depend on the frequency and fitness interactions at a second locus (or in general, over all other loci), that is,

$$W_{ij} = \sum_{kl} p_{ij,kl} W_{ij,kl} \quad [6]$$

In general, the fitness of an allelic combination at a given locus will depend on the frequencies of alleles at other loci. If allele frequencies at the second locus change, W_{ij} will not be constant for genotype ij from one time step to the next. In fact, it can be shown that one may only calculate [1] with W_{ij} as constant parameters in the special case when genotype fitnesses are multiplicative across loci, that is, when $W_{ij,kl} = W_{ij} W_{lk}$. The use of these marginal fitness values as constants also requires linkage equilibrium, when $p_{ij,kl} = p_{ij} p_{kl}$.

So one is left with a situation where [1] is dynamically sufficient (in the sense of being able to predict the frequency of an allele frequency in the next generation from the current state at that locus alone), only when $D = 0$ and the fitness contributions at each locus are multiplicative. However, when the fitness effects across loci are multiplicative, there are equilibria where $D \neq$ zero, while the additive model where the only equilibrium state has $D = 0$ requires one to calculate marginal fitnesses from the effect of other loci. Consequently, the single locus approximation should only be valid under relatively weak selection.

If one equates units of selection with dynamically sufficient state variables it is not meaningful to refer to individual genes (allele frequencies at a single locus) as the unit of selection. In contrast to the genic selection interpretation of eqn [1], selection acts on the entire genome, complete with epistatic interactions and linkage disequilibria between its myriad genes. Genic selection is only an approximation that applies under weak epistasis, when additive and multiplicative interactions are essentially equivalent.

These results are in a sense congruent with the philosophical debate that focused on the ontology of the selection process. Contrary to the claims in the popular writings of R. Dawkins and other advocates of genic selection, Eliot Sober and colleagues have argued that a unit of selection must be both a replicator (i.e., can reproduce itself as an independent entity) and an interactor (i.e., compete or otherwise interact with entities like itself). Under most circumstances, individual genes fail to fulfill these conditions, since they only replicate in the context of a whole genome, and, as demonstrated by the multilocus equations, only 'interact' as components of genomes and organisms. Of course, under this criterion, the case where [1] is dynamically sufficient is simply a special case of selection at the individual/genomic level where certain symmetry properties are satisfied, as opposed to genic selection as such.

When Genes Are Units of Selection: Selfish Genetic Elements

There are cases where genes can replicate independently of the genome, with retrotransposons being the most obvious example. While DNA transposons are mobile elements that can self-excise and insert to new sites, retrotransposons can make copies of themselves and proliferate within the genome through reverse transcription mechanisms. They not only replicate independently of the cell's mitosis mechanism, they often do so at the expense of the rest of the genome and the organism's fitness by inducing mutations at the insertion sites and bloating the size of genomes (imposing constraints on cell division rate and cell size, most notably in amphibians). Thus transposons are truly examples of 'selfish genes'. A similar example comes from plasmids in bacteria, which can propagate independently of the rest of the bacterial genome via conjugation.

In addition to transposons (a clear case of an entity that is both a 'replicator' and an 'interactor'), there are a number of other genes that exhibit selfish behavior and seem to satisfy Sober's ontological conditions for being units of selection. Among these are genes that exhibit meiotic drive. Unlike transposons, such genes still require the molecular machinery of meiosis and mitosis to replicate. However, they use a number of mechanisms (such as the killing of gametes containing sister chromatids by the well-studied t-locus in mice) to distort Mendelian segregation ratios, so that they effectively replicate at higher rates than the rest of the genes on the chromosome.

Another example of selfish genetic elements comes from the genomes of plastids (mitochondria and chloroplasts). While normally plastids replicate synchronously with their 'host' cell, there are mutations that allow for selfish replication of mitochondria within a cell, or else mitochondria that induce male sterility to guarantee their propagation through female lines.

The conflict between (true) genic selection on the selfish element and selection on the genome can be best understood from Price's equation. If in [2] the variable X refers to the presence or absence of a 'selfish' allele at a given locus, the first term on the right-hand side reflects genomic (individual) selection against the allele (negative covariance between X and fitness) while the second term $\overline{\delta}$ will be positive due to the enhanced replication rate of the selfish gene. Rearranging the terms in [2], one obtains

$$\Delta\overline{X} = \frac{1}{\overline{W}}(\mathrm{cov}[W, X + \overline{\delta}]) + E[\overline{\delta}] \quad [7a]$$

If $\overline{\delta}$ represents the transmission bias due to selfish replication, one can see clearly how selection at the lower level (positive $\overline{\delta}$) runs counter to selection at the genomic or individual level (negative selection against an increase in X).

The drawback of Price's equation in this form is that it treats the $\overline{\delta}$ term as a black box of 'transmission bias', even in cases where it is in fact due to selection at another level. In the case of selfish genetic elements, what is transmission bias with respect to genome (individual)-level selection is actually selection at the genic level (which can further be decomposed recursively into a selection and bias term).

The results of conflicts between levels of selection depend on the strength of genomic versus genic selection, and on the rate at which the genes replicate relative to the generation time of the organism (since the 'transmission bias' term is averaged over the timescale relevant to individual selection). To see that this is the case, note how $\overline{\delta}$ from [7a] can be further expanded to model selection at the lower (genic) level as the source of transmission bias at the organismal level, that is,

$$\Delta\overline{X} = \frac{1}{\overline{W}}\left(\mathrm{cov}[W, X] + E\left\langle W, \frac{1}{\overline{w}}E\{\mathrm{cov}[w_i, X_i] + E[w_i\overline{\delta}_i]\}\right\rangle\right) \quad [7b]$$

The first term in the outer parentheses represents selection at the individual level, while the second term (w_i, X_i) represents selection at the ith lower level entity explicitly, with $\overline{\delta}_i$ being the transmission bias among individuals at the lower level, and $\overline{W}$ the mean fitness of lower-level entities. For example, if X represents the number of transposons in a genome, the first covariance term represents selection on the genome, and the second set of terms to intragenomic selection of 'selfish' transposons.

Note that an expansion of the form [7b] can include an arbitrarily high number of levels and represent any situation where there is a conflict between these levels of selection, since the respective covariance terms need not have the same sign. Furthermore, it can be used to model different modes of selection across levels: genomes and selfish genes, groups and individuals, and so forth.

Kin Selection and Group Selection

Just as the discovery of selfish genetic elements challenged the primacy of organism and genic selection from below, the phenomenon of altruism challenged it from above. It is well known that organisms will make sacrifices to their own fitness to benefit near relatives (in extreme cases such as worker castes in social insects, forfeiting reproduction). Darwin saw this as a challenge to his own theory which was based on individual-level selection, even though he had the largely the correct intuition about tradeoffs between benefits to self and benefits to kin. These issues were formally addressed by W. D. Hamilton in his work on kin selection and inclusive fitness.

Hamilton's solution to the problem of altruism was conceived in terms of genic selection, that is, from the analysis of pedigrees one can calculate the coefficient of relatedness ρ, which is the probability that an allele at a given locus is shared by an individual and its relatives ($\rho = 1/2$ for siblings and for parents/offspring, 1/4 for half-sibs, 1/8 for first cousins, etc.). Hamilton showed that an allele for altruism will be selected if the cost to the altruist is outweighed by the benefit to recipients in inverse proportion to their relatedness, that is,

$$\rho B > C \quad [8]$$

where C is the cost to the altruist, B the benefit to the relative. The theory of kin selection helped resolve many questions dealing with the evolution of social behavior, and was shown to give a robust prediction of sex ratios in hymenopteran (ant, bee, and wasp) colonies. From the above inequality, it was argued that kin selection (for altruism in family groups) was reducible to individual or genic selection.

However, it can be shown that whether an altruist allele increases in frequency depends critically on the structure of the social group in which an organism interacts. As a predictor of whether an altruistic allele can invade and spread in a population, [8] is incorrect – it is a criterion for the increase in the absolute number of altruists, not in their relative frequency. In order for an altruistic genotype to increase in frequency in a population at the expense of a selfish type, the altruists must interact preferentially with their fellow altruists. If altruists and selfish individuals are distributed randomly, altruism can be shown to always decrease in frequency even when [8] is satisfied. In other words, selection for altruism requires not only variance in individuals within demes, but also variance between demes. **Box 1** illustrates how intrademic selection will decrease the frequency of altruists regardless of whether Hamilton's inequality is satisfied, while interdemic selection can increase its overall frequency.

Interpreted from the standpoint of Price's equation, kin selection acts on covariance between group differences in frequency and fitness. The correct form of Hamilton's inequality can be derived from

$$\Delta\overline{X}_D \frac{n(\mathrm{var}[X_i])}{\overline{W}}[\beta_{x_i,x_D}\beta_{\overline{W}_D,X_D} + \beta_{W_i,X_i}] \quad [9]$$

where n is the number of individuals in a deme, W_i is individual fitness, X_i the ith individual phenotype, X_D the trait value in deme D (e.g., the frequency of the trait in a given deme), and $\overline{W}_D$ the mean fitness of the Dth deme. The first terms in the brackets represent selection on the trait at the demic level (weighted by the regression value of individual traits against deme means), the second represents individual selection within demes. Interpreted in terms of [2], the term $\overline{\delta}$ corresponds to selection at the lower

level (individual selection) biasing trait values at the higher (group or deme) level, as opposed to being driven by transmission dynamics as such.

The condition for increase of the altruist allele or any other trait subject to both interdemic and individual selection is that

$$\beta_{X_i,X_D}\beta_{\overline{W}_D,X_D} + \beta_{W_i,X_i} > 0 \qquad [10]$$

Traits such as altruism will be selected against at the intrademic level, so that the second term will be negative. Selection for altruism requires that there is strong interdemic selection and an association between mean deme value and trait value (i.e., altruists tend to associate in demes with other altruists, as do selfish individuals, as given by the first coefficient of the first term in [9]). From this interpretation, kin selection is actually an extension not of individual or genic selection but of group selection, because the covariance relationship that determines the magnitude of eqn [10] is a group property, one that is the ultimate target of selection.

Group selection has been a source of controversy since V. C. Wynne-Edwards proposed that behavioral traits such as territoriality evolved for the good of populations or species, as a means of preventing overcrowding and population crashes. It was demonstrated in the critical writings of J. Maynard Smith and G. C. Williams that these population regulatory mechanisms were a by-product of selection at the individual level, and that group selection, while theoretically a possibility, was in practice improbable because selection at the individual level acts over much shorter time spans (individual generation time) than the 'generation time' (colonization and extinction rates) of demes. Therefore, individual selection would eliminate variance in a 'good of the species' trait before interdemic selection could act in favor of it.

Since that time, group selection has been proposed to be much wider in scope and potential importance than was initially recognized, even though the scenarios proposed by Wynne-Edwards are untenable. For example, it can be seen from eqn [9] that interaction between relatives is not necessary for interdemic selection to operate. All that is necessary is a correlation between individual genotype/phenotype and group trait value, $\beta_{X_i,X_D} > 0$, so that individuals of similar trait values tend to group together. Since many organisms interact in family groups, kin selection may be a particularly effective form of group selection. Furthermore, it is not necessarily true that the 'generation time' for groups is on a vastly different timescale than individual selection, as the generation time for many animal colonies and societies can operate on the same general timescale as the generation time for constitutive individuals.

Equations [9] and [10] also demonstrate that selection on group trait value (even counter to individual selection) can be effective under a number of other scenarios where there is strong covariance between deme trait values and their rate of propagation. The most familiar example comes from the evolution of parasite virulence. Individual selection favors high virulence in parasites under many circumstances; however, if all parasites in a host are maximally virulent, they will kill the host and themselves in the process. Thus strong group selection will override individual selection for virulence, since 'benign' groups will survive and propagate for longer periods of time along with their hosts, while virulent groups will become extinct at a high rate.

To consider another example, R. A. Fisher demonstrated that individual-level frequency-dependent selection will lead to 1:1 sex ratios in organisms (because the rarer sex has higher fitness with unequal ratios), which is the rule in most organisms. However, strong deviations of this sex ratio in favor of females have been observed in a number of organisms, such as parasitoid wasps. The reason for this deviation is that populations with large numbers of females have a higher rate of propagation than those with an even sex ratio, so if interdemic selection is strong (as it is for many parasites and parasitoids within a host animal or plant), selection on the group trait for high propagation can run counter to individual selection for equal sex ratios.

Interestingly, the question of the origin of eusociality in insects, which has long served as the textbook example of kin selection, has been recently challenged on a number of fronts. Recently, E. O. Wilson and other social insect specialists have suggested that because many primitively social insects have colonies founded by nonrelated females (and because kin selection generate strong parent–offspring conflicts that select against colony altruism), group selection on colony fecundity and viability may have played a more important role in driving the evolution of advanced sociality and altruism than has kin selection.

It should also be noted that Price's theorem and equations derived from it do not require that a trait (group or individual) under selection be genetic in nature, simply that it be heritable and covary with fitness. It has been argued by D. S. Wilson and colleagues that group selection probably plays an important role in the evolution of human culture, since cultural traits are transmitted at the individual and group level and exhibit high variance (and differential propagation) both within and among groups. Certainly, altruism in humans extends far beyond family units to encompass groups defined by nationality, religion, and political beliefs, so an evolutionary model other than kin selection is necessary to account for these social phenomena.

Species Selection

A number of paleontologists (most notably S. Stanley and S. J. Gould) have made the intriguing suggestion that species-level traits are subject to selection and that this plays an important role in various trends observed in the fossil record. The basic argument is that certain traits in an organism related to habitat specificity and low dispersal ability lead to enhanced rates of speciation and therefore greater representation of these traits among species, even when they are non- or maladaptive at the individual level.

The theoretical possibility of species selection can be demonstrated through applications of Price's theorem, since the focal point of selection can be any replicating entity with the property of heritability (as species do have, since they give rise to new species with properties that correlate with those of the ancestor). Unlike eqn [9], which combines group and individual selection

acting on the same timescale, models of species selection (or any kind of hierarchical selection where the timescale at one level is orders of magnitude different from the other) require that the effects of rapid individual-level selection be averaged with respect to the higher-level timescale. If X is a species-level trait also subject to individual selection, the equations for the rate of change have the same form as eqn [7b], where w_i now represents selection at the individual level and W at the species level.

Since the focal point of selection here is the species level, the expectation within the brackets representing the 'transmission bias' $\overline{\delta}$ at the species level due to lower-level selection, $\overline{\delta} = E[(1/\overline{w})\mathrm{cov}[w_i, X_i] + \overline{\delta}_i]$, is calculated by averaging over the waiting time to speciation, that is, it measures the expected change in X until the time of a speciation or extinction event. The same arguments used against Wynne-Edwards apply here, that is, it can be shown that if selection is strong and the waiting time is large, the trait value will be fixed in the species long before species selection can act.

It has been shown by S. Rice and others that species selection (or any form of group selection where there is a large difference in generation time of the group vs. the individual) is indeed weak when selection at the individual level is strong and in a consistent direction. On the other hand, if selection fluctuates so that some species (or populations) are fixed for one trait value and others for the opposite, individual-level selection can actually facilitate species or group selection by generating variance at the higher level. As expected, species selection would be most effective in taxa with long individual generation times and high speciation rates, or in those where population sizes are small so that high interspecific variance can be generated through genetic drift.

Hierarchical Selection and Evolutionary Novelty

Because any form of heritable variation at any level of biological organization may be the target of selection, there is much potential for conflict between the demands of selection at different levels. The resolution of such conflicts has evidently played an important role in a number of key events in the history of life.

Selfish genetic elements demonstrate the potential conflict of interest between a genome (which is effectively a 'colony' or group of genes) and individual genetic elements. It is likely the case that the DNA replicative machinery and the complex processes of mitosis and meiosis evolved as the genome's mechanisms of keeping selfish genetic elements in check, with segregation distorters and transposons finding ways around these mechanisms to advance their own fitness at the expense of the rest of the genome.

Similar problems arise in the symbioses that were the likely origin of mitochondria, choloroplasts, and other eukaryotic organelles. In order to prevent their proliferation at the expense of the host cell, the hosts gradually co-opted much of the organelle genomes within the cell nucleus and evolved mechanisms to limit the genetic variance and independence of plastid elements. Specifically, it is likely that anisogamy evolved as a mechanism to prevent the proliferation of deleterious selfish mitochondria, as it reduces the genetic variation within the cell, which restricts the potential for selection at the level of selfish plastids.

At a yet higher level of organization, multicellular organisms are composed of entities – cells that can themselves reproduce via mitosis. In order to minimize conflicts caused by the proliferation of 'selfish' cell lines, various mechanisms such as germ line segregation and development from single (as opposed to multiple) zygotes minimized the genetic variation among cells within an organism. Since natural selection requires covariance between fitness and trait value, having nearly identical genomes in all cells makes intraorganismal selection weak when compared to the strong selection (due to high variance in phenotype) within the colony or organism. Cancers can be regarded as a breakdown of the safeguards against selfish cells in the same way that transposons and meiotic distorters break down the genome's safeguards against selfish DNA.

Finally, there are the conflicts that arise within societies and colonies, including human societies. Since there is generally much more genetic and phenotypic heterogeneity among animals in societies (excepting clonally reproducing invertebrates), selection at the individual level remains strong even as selection at the higher group level can be seen to emerge. From the perspective of Price's equation, both the higher-level selection and 'transmission bias' due to lower-level (individual) selection are significant, without any one unit or level of selection dominating others.

Abundance

JT Harvey, Moss Landing Marine Laboratories, Moss Landing, CA, USA

Introduction

The abundance of an organism, often considered as total population size or the number of organisms in a particular area (density), is one of the basic measures in ecology. Ecologists often are interested in the abundance and distribution of organisms because the number and spatial extent of an organism reflects the influences of many factors such as patterns in nutrients (fuel), predators or herbivores, competitors, dispersal, and physical conditions. Organisms generally are more abundant where conditions are favorable, such as locations with sufficient quantity and quality of food or nutrients, fewer herbivores or predators, fewer competitors, and optimal physical features. The physical features that affect abundance could be substrate type, moisture, light, temperature, pH, salinity, oxygen or CO_2, wind, or currents. Ultimately, the abundance of an organism is dependent on the number of individuals that survive and reproduce. Therefore, any factors that affect survival or reproduction will affect abundance.

Abundance can be measured at many levels, such as the number of individuals of a certain sex or age within a population, the number in a certain geographical region, the number in a certain population (possibly defined as the interbreeding individuals of the same species in a certain geographical area), or the number of individuals of a certain species. Species or populations have different levels of abundance and different population dynamics because of inherent biological characteristics (vital rates), such as the number of young produced per individual, longevity, and survival, and because the species may be adapted and exposed to various environmental conditions. Estimating abundance, however, can be difficult depending on the distribution, visibility, density, and behaviors of the organism.

Estimates of abundance can be obtained by counting all individuals in the population or sampling some portion of the population. A census or total count of all individuals is a common technique used to assess abundance of organisms that are relatively rare and easily observed. If the organism is too numerous or not easily counted then a representative portion of the population is sampled using various techniques such as (1) counts within randomly selected sampling units (e.g., quadrats, cores, nets, or traps); (2) mark-recapture; (3) strip or line transects, which is essentially sampling a long thin quadrat; and (4) distance methods (e.g., nearest neighbor). Most of these methods have a well-developed theoretical and analytical basis. Based on whether the organism is numerous and relatively stationary (e.g., plants), or rare and mobile (e.g., many vertebrates) certain techniques are appropriate. Numbers of individuals within a sample can be determined directly by visually counting individuals or indirectly using acoustics, such as hydroacoustics for assessing fishes or counting calls of bird or whales. Other indirect methods include counting the number of eggs or juveniles, which is an indication of the number of adults (sometimes used to assess fish abundance) or counting nests (such as used for birds). Recently the amount of genetic variation in a population has been used to estimate abundance.

If an actual number of individuals cannot be determined, scientists have used indices of abundance, such as changes through time, percentage cover or harvested biomass (e.g., for plants), and catch per unit effort (e.g., for fishes). Ecologists are always striving for an accurate and precise estimate of abundance; therefore, a thorough knowledge of the organism and its environment is necessary to design the proper sample unit and best allocation of that sample unit in space and time. Estimates of abundance can be made more accurate or at least accuracy assessed by eliminating or decreasing biases and by using various methods to determine abundance. Determining whether there is an accurate estimate of abundance is difficult because usually the true abundance is unknown and the estimate may contain unknown biases. Being aware of the potential biases and striving to minimize and investigate biases will increase the chances of an accurate abundance estimate. Different sampling designs will help ensure a representative sample is obtained that also will increase accuracy. Variability in the estimate of abundance, or precision, is affected by the natural variability in abundance among the samples and by the number of samples. Because natural variability cannot be controlled, the single best means of increasing the precision of the abundance estimate is to increase sample size (e.g., number of transects, cores, marked individuals). An understanding of sampling design (or the observation of sample units in space and time) can help determine whether there are enough independent and representative sample units to provide an accurate and precise estimate of abundance.

The spatial and temporal patterns of abundance (i.e., dispersion) often indicate fluctuations in physical or biological factors. Abundance is a measure of how many organisms are within an area whereas dispersion is how those organisms are arranged within the area. We usually recognize three basic patterns of abundance in space or time: uniform, random, or aggregated (**Fig. 1**). A uniform abundance in space or time is one where the organism is spaced evenly. Rarely is this the case for organisms because biological factors (e.g., attraction, aggression, competition) will cause nonuniformity and most environmental features that affect organisms are not uniformly distributed. With a random distribution we assume that the probability that an organism can inhabit any location or time is equal. This also is rare for the same reasons that organisms are not uniformly distributed. Finally, organisms can be aggregated if they occupy very specific locations, such that in some locations or times the probability of encountering that organism is nearly one and in

 doi:10.1016/B978-0-444-63768-0.00454-6

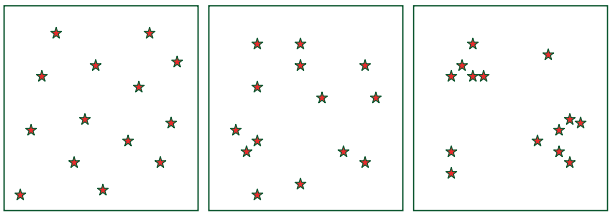

Fig. 1 Various forms of dispersion in space (uniform, random, and aggregated) are depicted using red stars as individual organisms. In reality, there is a continuum of dispersion from the extremely uniform to greatly aggregated, with random in between these two forms.

other locations or times it is zero. At some spatial scale all organisms are grouped or aggregated. Sea bird nests may be uniformly distributed within a colony because the birds place their nests just far enough apart to not be pecked by their neighbor, but the nests are very much aggregated because some sea birds only nest on isolated islands. If you focused your attention at the scale of the colony, the bird's nests would be distributed uniformly, but at the scale of the world, the nests are aggregated. Aggregations typically occur where local conditions are optimum for survival and reproduction. For instance, certain plants require specific soil types, light exposure, moisture, and nutrients. Through adaptive radiation, species have evolved specific requirements; hence, they cannot live just anywhere. The aggregated distribution of organisms implies that individuals of a population will be abundant in some locations and rare or absent from other locations. The same patterns and rationale can be used to assess abundance patterns in time. Certain periods of time are more conducive to some species; hence they are more abundant, than other times. The timescales that affect abundance can be days for short-lived organisms like insects, or thousands of years like large trees. Natural and anthropogenic changes in environmental conditions will cause changes in abundance for all organisms, and these changes can be predicted using mathematical models of population dynamics. The actual patterns of dispersion in space and time form a continuum, where populations can have varying levels of uniform, random, or aggregated patterns. Because organisms in space and time have an infinite array of patterns it makes it difficult to accurately model and test patterns of dispersion.

Population Dynamics and Growth Models

Population growth rate is defined as the change in number of individuals in the population through a certain amount of time. Changes in abundance often are assessed at the population level, because that is where the effects of biological and environmental conditions are most evident. Later the modeling of metapopulations (groups of populations that share individuals) will be discussed. Often ecologists measure population changes using density (the number of individuals per area) because interactions among individuals and between an individual and its environment are more affected by density than actual population abundance. Changes in abundance of a population, called population dynamics, are caused by many factors, but at the most fundamental level the number of individuals in the population at some later time period (N_{t+1}) is simply the number of individuals at the beginning of the time period (N_t) plus the number of births (B) and immigrants (I) minus the number of deaths (D) and emigrants (E) that occur during the time period:

$$N_{t+1} = N_t + B - D + I - E \quad [1]$$

We can rearrange the terms to determine the change in population abundance ΔN:

$$(N_{t+1} - N_t) = \Delta N = B - D + I - E \quad [2]$$

If we assume the population is closed, that is, there is no movement of individuals into the population (immigration) or movement out of the population (emigration), then the equation becomes simplified. In this case, we are modeling only the changes that occur within a population. Although most populations are not closed (i.e., there is immigration and emigration), it allows for some easier calculations and allows us to provide details on a specific population. For a closed population, with $I=0$ and $E=0$, the equation simplifies to

$$\Delta N = B - D \quad [3]$$

If we also assume that the period of time between estimates of population abundance is extremely small (i.e., t is nearly 0), then we can treat population growth as continuous. If we estimated population abundance only after a large period of time then population growth would not be modeled as continuous but would be a discrete function. Modeled as a discrete function the estimate of the population abundance would be the same or changing during the time period, then at the end of the period it would change to a new level, stepping from one abundance level to another after each time period (**Fig. 2**). By assuming population growth is continuous we can use a differential equation to describe the change in population size (dN) that occurs during an extremely small period of time (dt):

$$\frac{dN}{dt} = B - D \quad [4]$$

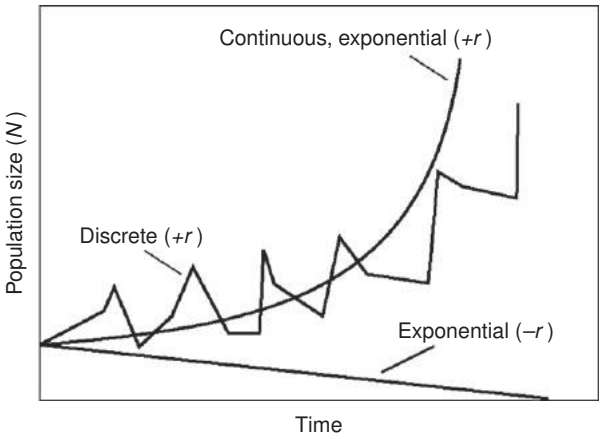

Fig. 2 Various models of population change: a continuous exponential population increase (when r is positive), a continuous exponential decrease (when r is negative), and a discrete model (when r is positive).

B and D now represent rates, or the number of births or deaths in this population during these short periods of time. The birth rate (B) can be thought of as the number of births per individual per time period (b), called the instantaneous birth rate, times the number of individuals in the population (N) at that time. The death rate (D) also can be calculated using the instantaneous death rate (d) times the population abundance (N). The continuous differential equation is now

$$\frac{dN}{dt} = bN - dN = (b - d)N \quad [5]$$

This is very much a simplification of the real world (a model) because it assumes that the instantaneous birth rate and death rate are constants, thus per capita birth and death rates are the same no matter what the population abundance. We know this is not true, because for many populations the birthrate will decrease and the death rate increase when populations become larger. Thus the factors affecting population growth are dependent on the population abundance or density, hence are called density-dependent factors. The concept of density-dependent factors will be discussed later.

The instantaneous rate of increase of the population (r), often called the intrinsic rate of increase, is $b - d$, so substituting r for $(b - d)$ produces a new model for population growth that is

$$\frac{dN}{dt} = rN \quad [6]$$

This simple equation allows us to predict that the change in population abundance per unit time is exponential and proportional to a constant value of r (**Fig. 2**). If the intrinsic rate of increase is zero then the reproductive rate and mortality rate are equal ($b - d = 0$). If r is positive or greater than 1 (per capita birth rate exceeds per capita death rate) then the population would increase proportional to the population abundance (N) in an exponential fashion. If r is negative or less than 1 (death rate exceeds the birth rate), then the population would decrease exponentially (**Fig. 2**). The greater the value of r the more rapidly the population will change. The intrinsic rate of increase can be used to model or predict future population abundance (N_{t+1}) by integrating the population growth model and knowing the time interval (t) over which you want to predict abundance and the initial population abundance (N_t):

$$N_{t+1} = N_t e^{rt} \quad [7]$$

This simple exponential model has many assumptions. We assumed the population is closed, a simplification to eliminate the effects of immigration and emigration. This assumption will be removed during a discussion of metapopulation models. We assumed that per capita birth and death rates were constant, but they do change with changes in population size, and with different age and sex classes. We also assumed that population growth was continuous; however, many species have discrete generations, where births and deaths are measured not instantaneously but at certain longer time frames. Population dynamics of species that reproduce once per year, for instance, often are modeled not with a continuous but with a discrete model. Finally, this model is deterministic; it will always predict the same abundance given an initial population size and a specific r and t. Adding variability to the model produces a stochastic model (i.e., the effects of random variation that may be more realistic), and predicted abundances are affected by the variability in the intrinsic rate of increase. If r is positive but has a great deal of variability, the population will increase and the predicted abundances will have greater variability through time. The consequence is that through random chance, the population could go extinct because of an extreme negative random effect although the population was increasing previously.

As a population begins, growth rate is minimal because there are few individuals and many are probably young and not producing offspring. After the early stages, growth becomes more rapid, often increasing exponentially, because there are now more individuals that are reproducing and factors that may restrict population growth, such as food resources, space, predators,

diseases, are not affecting the population in a large manner. During this phase as the exponential model would predict, population growth is proportional to the population size and magnitude of r. Eventually, as the population increases in size, nutrients become more difficult to locate or obtain, predators or herbivores are more abundant, competition among individuals within the population increases, mortality, because of disease, parasites, and movements into suboptimal areas increases, and space or shelter becomes limiting. These factors to some extent control the ultimate size of the population, causing density-dependent regulation. The maximum size that the population can achieve is often referred to as the carrying capacity (labeled K). Carrying capacity is not really constant nor is it the maximum capacity but the population often fluctuates through time as various conditions within and outside the population change. The carrying capacity is more realistically determined by examining the long-term average of abundance. Species that live in relatively stable environments (e.g., invertebrates in the deep sea) may have relatively constant population numbers around the carrying capacity, whereas those populations in unstable environments (e.g., nearshore invertebrates) may have variable numbers through time. Large regime shifts or major changes in environmental conditions caused by natural or anthropogenic factors can produce a shift in the carrying capacity for the population.

Because organisms cannot increase exponentially forever, the concept of a carrying capacity (K) was developed for the population growth models. The simplest relationship is to assume that changes in per capita birth rate (b) or death rate (d) are linearly related to population size. As population size increases b decreases linearly and d increases linearly. The concept makes sense; as the population increases, reduced resources, competition, predation, and other density-dependent factors would cause an increase in deaths and decrease in births. It probably is intuitive also that the relationship between b and d with population size is not linear, but more likely some nonlinear function, with the changes in b and d becoming more pronounced as density becomes extreme. Carrying capacity occurs when the population abundance reaches a maximum equilibrium ($N=K$), when birth rate and death rate are equal. The population model that depicts the effect of carrying capacity on population growth is the logistic model:

$$\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right) \quad [8]$$

This is basically the exponential growth model with another term $(1 - N/K)$, that is, the portion of the carrying capacity that can still be filled with the population. When the population is in its infancy (N is extremely small compared with K), then N/K is small and $(1 - N/K)$ is nearly equal to 1. At this early stage the population grows exponentially (rN). As the population increases and approaches K, the ratio of N/K approaches the value of one, $(1 - N/K)$ approaches zero, and the change in population size (dN/dt) approaches zero (**Fig. 3**). Thus as the population approaches K the rate of change in the population slows or decreases, effectively stopping exponential positive growth (**Fig. 4**). If the population should exceed K, then $(1 - N/K)$ is negative and the rate of change will be negative and the population will decrease, presumably toward K. In the logistic model, the greatest population growth rate is achieved at half the carrying capacity ($K/2$), and populations with a greater value of r will reach K more rapidly (in less time) than populations with lesser values of r.

Because the various density-dependent factors do not affect the population growth rate immediately, often there is a time lag between the change in population size and effects on population growth. This lag time effectively creates an oscillation of the population abundance around carry capacity, because the population adjustment by the carrying capacity does not take effect immediately; so abundance will go past K, and then dip below K. If the combined effects of lag time and response time $(1/r)$ are small then the population will increase in a smooth logistic fashion; if the effects are moderate, the population will oscillate around K, eventually decreasing in oscillation until the population is at K. If the combined effects of lag time and r are large, the population abundance will oscillate around K without reaching an equilibrium value. The amplitude of the oscillation around K will be greater if the population grows rapidly (r is great) and the time lag is great. Many populations oscillate around K because the effects of reaching carrying capacity, such as increased number of predators, decreased reproductive output, and increased

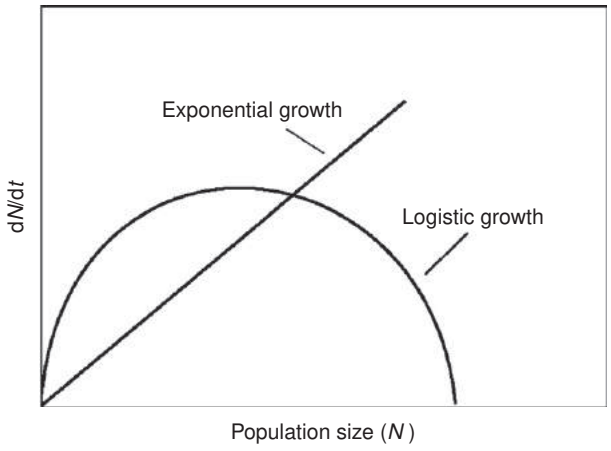

Fig. 3 The change in population per unit time (dN/dt) relative to population size (N) for a population increasing exponentially and one using a logistic model.

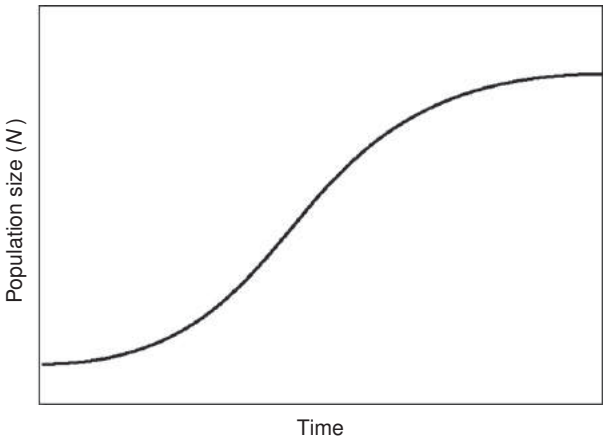

Fig. 4 The logistic population model plotting the population size (N) through time.

aggression, take some time before they have an effect (there is a substantial lag time). With greater levels of r, population dynamics can become chaotic, in the sense that there is no stable equilibrium and no stable cycles. In a chaotic system you cannot predict the cycle, but the population could still fluctuate around a long-term mean.

The previous models best approximate population growth rates for smaller organisms (e.g., bacteria), where the organisms reproduce rapidly (r is great) and have short generation times. Many larger organisms, however, can be modeled using age- or stage-based models often called life table models (**Table 1**). In these models, probability of survival to the next age class (l_x) and mean number of female offspring per female of an age class (m_x) are computed for each age class and used to compute net reproductive rate (R_o):

$$R_o = \sum_{x=0}^{k} l_x m_x \qquad [9]$$

where x=age class, and k=final age class.

R_o is the potential number of female offspring produced by a female during her lifetime. If R_o is greater than 1 then the population will increase because a single female is producing more offspring than she needs to replace herself. If R_o is less than 1 then the population will decrease, and if R_o is one the population is stable. Generation time is the average age difference between a cohort (a group of individuals born at the same time) and their parents or the amount of time it takes a cohort to replace another cohort. Generation time is calculated as

$$G = \frac{\sum_{x=0}^{k} l_x m_x x}{\sum_{x=0}^{k} l_x m_x} \qquad [10]$$

Using these age-based models, r is determined by solving in an iterative fashion, the following equation:

$$1 = \sum_{x=0}^{k} e^{-rx} l_x m_x \qquad [11]$$

The value of r can then be used in the logistic equation. The advantage of using age-based models is that the number of individuals in each age class can be estimated. Often the age-based life table is converted to an age-class matrix (a Leslie matrix) that is used to model changes in the age structure with population growth. In these models, with a constant birth and death rate, the population will attain a stable age distribution (i.e., relative numbers in each age class will remain equal as the population increases), no matter what the initial age structure.

These previous models have depicted the changes in abundance for a single isolated population, but most populations are not isolated and are affected by the immigration and emigration of individuals (a open population). Certain population models have been determined that allow for open populations, and treat the system as a metapopulation (a group of populations that are linked by individuals that emigrate from one population to be immigrants in other populations). The long-term existence of the metapopulation is dependent on the probability of extinction of populations and probability of colonizing new spots (based on emigration rates). If there is a reasonable amount of emigration, even large probabilities of population extinctions usually predict the continued existence of the metapopulation because new recruits always are arriving to colonize new locations. The continuation of the metpopulation also is positively related to the emigration of individuals into populations that already exist, which increases numbers within existing populations, thereby decreasing the probability of population extinction. The theories associated with mark-recapture techniques are fairly well developed, allowing the observations of marked individuals in future sampling to be used to model immigration and emigration and population size.

Table 1 A theoretical life table, perhaps of a mammal, because mortality is greatest in the early years, less during midlife, and increases again near maximum age

Age, x (years)	*No. alive at beginning of age interval, n_x*	*Proportion surviving until beginning of age interval, l_x*	*No. dying within age interval (from x to x+1), d_x*	*Finite rate of mortality, q_x*	*Finite rate of survival, p_x*	*Mean no. of female offspring produced within age interval, m_x*	$l_x m_x$
1	1000	1.000	480	0.480	0.520	0	0
2	520	0.520	300	0.577	0.423	0	0
3	220	0.220	120	0.545	0.454	0	0
4	100	0.100	15	0.150	0.850	0.5	0.050
5	85	0.085	23	0.271	0.729	1.5	0.128
6	62	0.062	21	0.339	0.661	2.2	0.136
7	41	0.041	13	0.317	0.683	3.3	0.135
8	28	0.028	11	0.393	0.607	3.1	0.087
9	17	0.017	10	0.588	0.607	2.8	0.048
10	7	0.007	7	1.000	0.000	1.8	0.013
11	0	0.000					
						$R_0 = \sum l_x m_x = 0.597$	

In this theoretical case, the population would be expected to be decreasing because R_0 is less than one ($R_0 = 0.597$).

r-Selected versus *K*-Selected Organisms

If the intrinsic rate of increase (r) is large, as is true for many small organisms like many species of insects, populations can increase rapidly in an exponential fashion for some period of time. Likewise, the greater duration of time (t) would predict greater numbers of individuals in the future. Of course, no organism can increase exponentially forever; various density-dependent factors cause a slowing of population growth and eventual possible stabilization and variability around a carrying capacity. As the population reaches maximum numbers, various factors act to decrease reproductive rates and increase mortality rates, hence the per capita growth rate diminishes. Species with a greater intrinsic rate of increase generally have lesser generation times (average time between initiation of parent and initiation of their offspring) and greater reproductive potential, such as increased fecundity and reproduction starting at earlier ages. Abundance of these organisms can change rapidly, either increasing or decreasing. They have been called *r*-selected species because they have evolved traits that enhance their intrinsic rate of increase, and allow them to exploit times or areas of optimum conditions. *r*-selected species also are short-lived because the traits that increase reproductive potential and decrease generation time have a negative influence on survival. Therefore, there is an assumed tradeoff between increased reproductive capacity and survival and longevity. Organisms that put a large amount of energy into reproduction, via decreased age at first reproduction and increased fecundity will have less energy placed in growth and survival. These species have greater values of r and perhaps greater lag times so their oscillations around K may be great. At the other end of the continuum are so called *K*-selected species that have a greater body size, greater generation time, lesser reproductive potential, and greater longevity. These species presumably are adapted to maintain abundance in regions with minimal environmental variability, so their abundance is less variable around the carrying capacity than *r*-selected species. Life-history traits might also be affected by physiological, physical, or behavioral limitations. For instance, many large vertebrates must reach a certain size, maturity, and understanding of the reproductive system before they can defend territories or gain access to females for mating. Because the intrinsic rate of increase is less for *K*-selected species and lag time may be less, the oscillations around the K may be more dampened than *r*-selected species. These are all generalities, for instance, not all species that are *K*-selected have relatively invariant abundances, and their populations can change dramatically with changes in intrinsic and extrinsic forces. Recognize also that there is a continuum of *r*-selected and *K*-selected species, and that many species have combinations of *r*-selected and *K*-selected traits that affect their population growth rate. The idea of *r*–*K* selection has not really proven useful for predicting life-history traits; hence some researchers have abandoned the concept. The idea that environmental conditions affect life-history traits, however, is useful.

Factors Affecting Abundance

The upper boundary of abundance (carrying capacity) or abundance in general is controlled by numerous factors; however, determining how these factors control populations can be difficult. Internal factors (e.g., interspecific competition for space, food, or light, life-history traits, and cannibalism) can control abundance as can external factors (e.g., environmental conditions). As an organism becomes abundant it can drive down the abundance of the nutrients or energy that they require. Increasing numbers of plants can decrease the quantity of nitrogen, phosphorus, potassium, and other essential elements. Increasing number of heterotrophs (organisms that ingest other organisms or organic particles) can reduce their food supply. Hence, with increasing abundance these organisms can no longer increase at a rapid rate because their supply of fuel is decreasing. Competition between organisms that are using the same fuel resources or space/shelter that become in short supply will lead to reduction in population

growth. The manner in which competition can affect abundance of animals is through the need for food, territories, mates, or space, whereas plants may compete for light, nutrients, water, or space. As organisms become more abundant generally, there is an increase in predation or herbivory, disease, and in animal's antagonistic behavior. All of these factors by themselves or often in combination serve to increase mortality, hence decreasing population growth rates. These were examples of density-dependent controls on population changes but there are examples of density-independent factors. For example, in some instances bycatch of fishes could be considered density independent because the number of fishes caught in bycatch may not be determined by the size of the fish population. Mathematical modelers have predicted that when a population's growth rate is greatly affected by density-dependent factors, its abundance is more likely to fluctuate.

The effects of competition can be amazingly complex. Lotka and Volterra (in the mid-1920s) developed a simple model to predict the competition between two species. The change in abundance for each species was dependent on r, N, K for each species and a competition coefficient (i.e., the effect of one species on the growth of the other species). Depending on the strength and nature of the interactions, the two species could exist with stable populations, one or the other species dominates forcing the extinction of the other, or lastly that they could both exist in an unstable equilibrium. Competition will ultimately affect abundances negatively, by reducing the amount of resources to each of the competitors, and this interaction becomes increasingly complex when there are more than two competitors, as is the norm in nature.

Predation also affects abundance, and is often a density-dependent factor. As abundance of a species increases, organisms that consume that species likely increase. Hence, herbivores respond to an increase in a species they consume, as would a predator population increase with the increase of a prey species. The predator–prey relationship is another mechanism that regulates to some extent the size of populations in a density-dependent manner.

Species, through the process of natural selection, have developed certain life-history traits that affect their abundance. Population change is affected by individual traits, such as reproductive output, age at first reproduction, and survival. Species have evolved these traits to maximize their fitness (i.e., maximize their genetic contribution to future generations), which affects the intrinsic rate of increase of the species. Population change also is affected by characteristics affecting the population, such as many of the density-dependent factors. Abundance is affected by factors that affect metapopulations, such as immigration, emigration, and genetic exchange. The study of abundance is fascinating because it incorporates so many of the important factors of a species: individual traits, population controls, and metapopulation dynamics.

Age-Class Models☆

David H LaFever, Texas A&M University, College Station, TX, United States

Glossary

Age structure The number or proportion of individuals in each age group.

Cohort A group of organisms of the same species and roughly similar ages.

Compartment models Mathematical models commonly used to represent many different ecological systems.

Fecundity Reproductive rate of an organisms or population, typically measured by the number of present gametes (eggs), seeds, or asexual propagules.

Matrix models A specific type of population model that uses a form of algebraic shorthand for summarizing a larger number of often repetitious and tedious algebraic computations (matrix algebra).

Stochasic Random processes are used to represent systems or phenomena that seem to change in a random way.

Introduction

This article presents an overview of single-species age-class models. The first section discusses the construction of life tables, which are then used to construct age-class models. A life table is an age-specific summary of mortality rates operating on a cohort of individuals. The second section focuses on compartment models, which can consist of systems of differential equations, integral equations, or matrix models with one equation or matrix for each compartment. The third section discusses matrix models including age- and stage-based matrix models. The fourth and final section focuses on stochastic models that incorporate the probabilistic nature of biological systems by treating one or more parameters as random variables.

Life Tables

A life table is an age-specific summary of mortality rates operating on a cohort of individuals first developed by human demographers and introduced to ecologists by Raymond Pearl in 1921. The mortality schedule is generally calculated based on the known number of survivors in each age class. In order to create a life table, an age interval must be decided upon in which to group the data. For longer-lived species, such as trees or turtles, an age interval of several years may be appropriate, whereas for shorter-lived species, such as birds, some plants, or insects, 1 year or less may be appropriate. These age intervals are known as age classes. Two different types of life tables can be calculated: a static life table (also called a stationary, time-specific, current, or vertical life table) and a cohort life table (also called a dynamic, generation, or horizontal life table). A static life table is calculated based on a cross section of a population at a specific time. In this case, the mortality schedule would be calculated for each age class at a specific time. A cohort life table is calculated for a cohort of organisms followed throughout life. In this case, one age cohort would be followed throughout their life (**Table 1**).

The columns of a life table include x (age), n_x (number alive at age x), l_x (proportion of organisms surviving from the start of the life table to age x), d_x (number dying during the age interval x to $x + 1$), and q_x (per capita rate of mortality during the age interval x to $x + 1$). Given x and n_x, the following equations can be used to obtain the remaining survivorship information:

$$l_x = n_x/n_0 \tag{1}$$

$$d_x = n_x - n_x + 1 \tag{2}$$

$$q_x = d_x/n_x \tag{3}$$

Fertility data can also be included in a life table. Additional columns include b_x (fertility schedule or the average number of female offspring produced per female aged x during time x), and l_xb_x and $x(l_xb_x)$. The fertility schedule is observed in the field or laboratory, while l_xb_x and $x(l_xb_x)$ are used to calculate the net reproductive rate (R_0), which is the multiplication rate per generation of the population:

$$R_0 = \sum_0^\infty l_xb_x \tag{4}$$

2	215	0.430	107	0.498	1.000	0.430	0.860
3	108	0.216	36	0.333	1.000	0.216	0.648
4	72	0.144	53	0.736	1.000	0.144	0.576
5	19	0.038			1.000	0.038	0.19

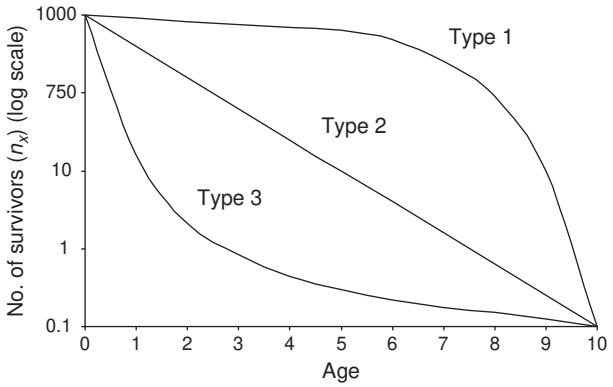

Fig. 1 Hypothetical survivorship curves (n_x). Adapted from Pearl, R. 1928. The Rate of Living. New York: Knopf.

The mean length of a generation:

$$G = \sum l_x b_x x / R_0 \tag{5}$$

The intrinsic capacity for increase (r), derived by Alfred Lotka in 1925, combines the natality and mortality demographic parameters. Lotka showed that a population subject to constant mortality and natality rates would gradually approach a fixed or stable age distribution. When a population has reached a stable age distribution, it will increase according to the differential equation:

$$\frac{dN}{dT} = rN \tag{6}$$

or in the integral form:

$$N_0 = N_0 e^{rt} \tag{7}$$

Based on the number of survivors, Raymond Pearl described three general types of survivorship curves on log-transformed scale (Fig. 1). A type 1 curve describes populations with low per capita mortality for most of the life span followed by high mortality of older organisms. A type 2 curve describes a linear survivorship curve that implies a constant per capita rate of mortality independent of age. Lastly, a type 3 curve describes a population with high per capita mortality early in life, followed by a period of much lower and relatively constant mortality. Humans in developed nations tend to follow the type 1 survivorship curve, while many birds exhibit a type 2 curve and many fish a type 3 curve. These curves are idealized and thus few, if any, populations have survivorship curves that exactly follow these curves.

Age-Structured Models

Compartmental Models

Compartment models are mathematical models and are commonly used to represent many different ecological systems. In age-structured compartment models, each age class is represented by a compartment or state variable. State variables are connected to the ages that precede and succeed it in time. Further, each age class can have separate mortality and natality rates. These models typically consist of systems of equations with an equation for each compartment. Individuals move through compartments by aging or are removed from the population by dying. These models are often used to determine the effects of different assumptions about the age, size, or spatial structure of a population on the dynamics of the population. Modeling approaches include using

(A)

$$\mathrm{M_A} = \begin{bmatrix} F_0 & F_1 & F_2 & \dots & F_{m-1} & F_m \\ P_0 & 0 & 0 & \dots & 0 & 0 \\ 0 & P_1 & 0 & \dots & 0 & 0 \\ 0 & 0 & P_2 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & P_{m-1} & 0 \end{bmatrix}$$

(B)

$$\mathrm{M_B} = \begin{bmatrix} G_1 & F_2 & F_3 & \dots & F_{m-1} & F_m \\ P_1 & G_2 & 0 & \dots & 0 & 0 \\ 0 & P_2 & G_3 & \dots & 0 & 0 \\ 0 & 0 & P_3 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & G_{m-1} & 0 \\ 0 & 0 & 0 & \dots & P_{m-1} & G_m \end{bmatrix}$$

Fig. 2 Population projection matrices. (A) An age-structured Leslie matrix ($\mathbf{M}_A$). (B) A stage-based Lefkovitch matrix $\mathbf{M}_B$. Subscripts represent the age or size class with m being the oldest or largest class, respectively.

differential equations, or difference equations. The type of mathematics used in the model depends on the questions asked by the researcher. Compartments may represent different parts of an ecosystem, stages of the development of an organism, or subdivisions of a population.

Matrix Models

Realized fecundity and survival rates change as organisms age. Matrix models separate populations into different age classes with each age class having the potential to possess different fecundity and survival rates. Matrix models are similar to compartment models, but matrix models are almost exclusively solved using linear algebra. The importance of specific population parameters for certain age classes can be tested using matrix models by investigating the sensitivity of the model to variations in parameter values for each age class. This is important for informing management decisions for target species, in particular, threatened and endangered species.

Leslie Matrix

The most common matrix model is an age-based matrix, also known as the Leslie matrix. In the age-based matrix, individuals in a population are separated into equal age classes (N_x) with each age class assigned a realized fecundity (F_x) and a probability of survival to the next age class (P_x). Within the transitional matrix $\mathbf{M}_A$, F_x is put along the top row and P_x along the subdiagonal, while all other elements in the matrix are assigned a value of zero (Fig. 2). Future population states can be projected by placing the current number of individuals in each age class into a vector $\mathbf{n}$ and obtaining the product of the $\mathbf{Mn}$ matrices:

$$\mathbf{M}\mathbf{n}_t = \mathbf{n}_{t+1} \tag{8}$$

where $\mathbf{n}_t$ is the vector whose elements are the number of individuals in each age class, and $\mathbf{n}_{t+1}$ is the vector containing the number of individuals in each age class at time $t + 1$.

Other Matrix Models

For some species, age is not a good indicator of condition. A stage-based matrix is a more general matrix model where life history stages replace age classes. The fundamental assumption of the stage-based matrix, also known as the Lefkovitch matrix, is that all individuals in a given stage are subject to identical mortality, growth, and fecundity schedules. The population projection matrix $\mathbf{M}_B$ describes the number of offspring born to each stage class that survive a given time period as well as the proportion of individuals in each stage class that survive and remain in that stage as compared with those that survive and enter a new stage (i.e., the transition probability). The elements of the matrix are F_x (stage-specific fecundity), G_x (probability of surviving and remaining in the same stage), and P_x (probability of surviving and growing to the next stage). Within the Lefkovitch matrix $\mathbf{M}_x$, F_x is put along the top row, P_x along the subdiagonal, and G_x along the diagonal while all other elements in the matrix are assigned a value of zero (Fig. 2). The primary differences between the Lefkovitch stage-class matrix and the Leslie age-class matrix are that the stages may incorporate several ages (i.e., they may differ in their duration and that individuals may remain in a stage from one time to the next).

Stochastic Models

The models so far discussed are deterministic models. This means that given certain initial conditions, there will only be one outcome. Stochastic models include the variation (i.e., the probabilistic nature) inherent in biological systems by representing one or more variables in the model as random variables. Stochastic variables can be based on a probability of occurrence (i.e., probability of breeding at any given time step, or probability of having a certain number of offspring during a given reproductive bout). These probabilities are generally assigned based on previous knowledge of the system. Random variables can also be chosen from a frequency distribution of historical data or from a statistical distribution fitted to historical data. With stochastic models and the addition of random variables one will not get the same output each time the model is run. When modeling an endangered species, for example, the population may grow after one simulation and decline to extinction after another.

Glossary

Adaptive A trait is adaptive if it results in greater fitness of individuals possessing that trait compared to individuals lacking that trait.

Clade A group of organisms that includes a common ancestor and all of the descendants of that ancestor. Synonymous with monophyletic.

Ecotypes A genetically distinct geographic form or type of a species which is adapted to a distinct habitat.

Fitness The ability of an individual to survive and reproduce in its environment.

Genetic drift Random changes in the genetic makeup of a population across generations.

Gene flow The movement and integration of alleles from one discrete population to another.

Molecular clock The concept that biomolecules, particularly DNA and RNA, evolve at a relatively constant rate, and that the number of molecular differences between species can be used to infer divergence times.

Natural selection Differences in the survival and reproduction of individuals possessing different traits or characteristics.

Reproductive isolation Intrinsic, genetically-based mechanisms that prevent individuals of different species from interbreeding. Isolating mechanisms operate either at prezygotic or postzygotic stages of sexual reproduction.

Sister-species Two species that are each others' closest relatives.

Introduction

Allopatry, meaning "in another place," describes populations or species that are physically isolated from other similar groups by a geographic barrier to dispersal (Fig. 1A). In the fields of ecology and evolutionary biology, allopatry is often used to describe populations that are geographically isolated to an extent that gene flow is severely reduced or absent, such that populations are evolutionarily independent. For that reason, allopatry is not usually defined by the characteristics of barriers per se, but by the effects of barriers on gene flow and genetic differentiation. For example, a wide river may restrict the dispersal of many small terrestrial mammals, but the same barrier will not hinder the movements of most birds.

"Allopatry" and "allopatric" are most often encountered in discussions of speciation, the process by which one species splits into two. In fact, allopatry is often used synonymously with "allopatric speciation," the process in which intrinsic (i.e., genetic) reproductive isolation evolves between geographically separated populations. Although new species may also arise from populations in sympatry (Fig. 1B, also see Sympatry) and parapatry (Fig. 1C), all evolutionary biologists agree that geographic isolation is a common, if not the most common, mechanism by which new species arise (Futuyma, 2013).

Origin and Early Use

The role of geographic isolation in the generation and maintenance of biological diversity has been long recognized by naturalists and evolutionary biologists, even well before publication of Charles Darwin's *The Origin of Species* in 1859. However, it was not until publication of seminal volumes by Theodosius Dobzhansky and Ernst Mayr, and subsequent research during the period of the mid-20th century known as the "Modern Synthesis" of evolutionary biology, that allopatry gained wide acceptance as a common mechanism of speciation.

By combining population genetics theory and observations of natural history, Dobzhansky's *Genetics and the Origins of Species* (Dobzhansky, 1937) described a basic model of speciation initiated by geographic separation: populations that were geographically isolated will, given enough time, accumulate genetic differences that would eventually cause them to lose their ability to interbreed. Later, in *Systematics and the Origins of Species* (Mayr, 1942), Mayr coined the term "allopatry" to describe two populations isolated in different geographic areas. Using examples and verbal theoretical arguments, Mayr argued persuasively that a severe reduction of gene flow between allopatric populations was typically the first step in the process of speciation.

Mayr called attention to the fact that most species exhibit substantial geographic variation, forming distinct races, varieties, and subspecies; the most distinct varieties were often geographically isolated with respect to the main range of the species. Mayr

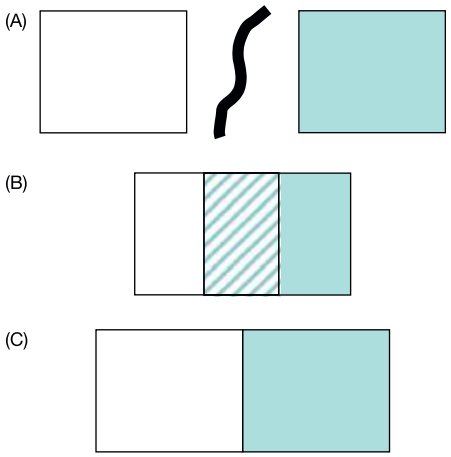

Fig. 1 Diagrammatic representation of (A) allopatric, (B) sympatric, and (C) parapatric distributions. Allopatric taxa are often separated by a physical barrier to dispersal, such as a river or mountain range. Sympatric taxa may have partially or completely overlapping geographic distributions, whereas parapatric taxa have abutting or continguous distributions.

asserted that geographic variation represented adaptation to local environments and that the features that distinguish local geographic variants are usually the same kind that typically differentiate reproductively isolated species. In other words, Mayr felt that distinct geographic variants represent intermediate stages in the process of speciation. Both Dobzhansky and Mayr reasoned that completely geographically isolated populations would ultimately evolve reproductive isolation as a byproduct of adaptive divergence to different geographic regions. Like Dobzhansky, Mayr hypothesized that natural selection, brought about by different environmental or ecological conditions, causes an accumulation of adaptive genetic changes between allopatric populations that eventually result in development incompatibilities that cause either sterility or inviability in hybrids. Therefore, if the barrier separating newly formed allopatric species broke down and the two species came into contact, they would remain genetically and phenotypically distinct due to the evolution of reproductive isolation, a byproduct of adaptive allopatric divergence. Hybrid inviability and sterility are examples of "postzygotic" isolating mechanisms because the isolating mechanism affects individuals after a zygote is formed. Alternatively, allopatric populations might evolve "prezygotic" isolating mechanisms that prevent successful mating or zygote formation, such as courtship differences or gametic incompatibilities.

Types of Allopatric Speciation

Vicariant Speciation

In vicariant allopatric speciation, a species is split into two relatively large populations by the formation of a barrier to dispersal (**Fig. 2**), such as mountain building, glaciation, changes in ocean circulation, or even human activities that disrupt gene flow between populations. Vicariant speciation corresponds to the geographic mode of speciation emphasized by Mayr in *Systematics*, and since then, a steady accumulation of case studies provide good evidence that the formation of geographic barriers are often involved in speciation. Most examples focus on sister-species found on opposite sides of geographic barriers in which the geological history of the formation of the barrier is well-understood. For example, drops in sea level during the Pleistocene created the Indo-Pacific barrier, a nearly continuous land barrier between Asia and Australia that subdivided many marine species into genetically distinct Indian and Pacific oceans lineages (e.g., Gaither *et al.*, 2011).

The most compelling examples of vicariant speciation involve species whose biogeographical histories are also temporally consistent with the history of barrier formation. For example, molecular-clock analyses of flowering plants show a striking temporal congruence in divergence times between many North American and Asian species pairs and the loss of continuous Northern Hemisphere mesophytic forest in the fossil record (Xiang *et al.*, 2000). Similarly, divergence times between sister-species of marine invertebrates and fish found on opposite sides of the Isthmus of Panama indicate that most sister-species were formed in the last 12 million years, corresponding to gradual isthmus uplift that incrementally interrupted interoceanic exchange during this period (O'Dea *et al.*, 2016). However, molecular data also indicate that roughly one-third of all transisthmian species pairs diverged before any restriction on water flow between the two oceans. This pseudo-congruence (Cunningham and Collins, 1994), a lack of temporal coincidence between divergence times and the time of formation of a geographic barrier, may be explained by different rates of molecular evolution in different taxa, but is more likely a consequence of extinction of one of the two daughter species created by the Isthmus (Marko *et al.*, 2015). Similarly, molecular data indicate that spatially congruent patterns of genetic differentiation in the southeastern USA (associated with the Atlantic vs. Gulf drainage pattern), likely arose at different times, possibly by different mechanisms (Near and Peck, 2005; Soltis *et al.*, 2006).

Because landscapes and seascapes are constantly changing, many species formed in allopatry will likely establish sympatric distributions in response to the breakdown of geographic barriers to dispersal. For that reason, Mayr argued that recently-diverged

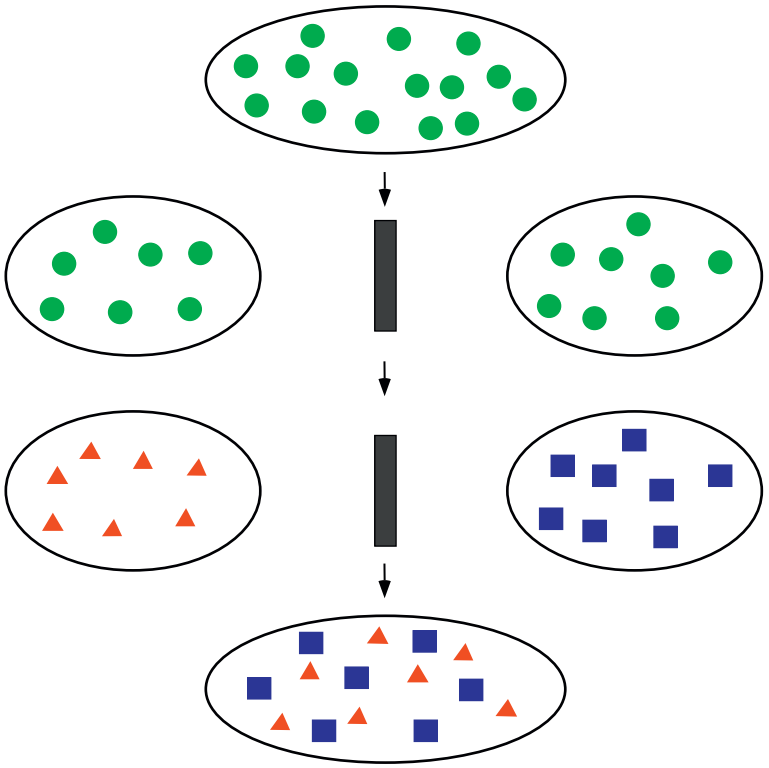

Fig. 2 Vicariant allopatric speciation. The appearance of a physical barrier divides a broadly distributed species into two physically isolated populations that diverge in traits that cause reproductive isolation in hybrids if the barrier breaks down and the two species come back into contact. The evolution of an intrinsic isolating mechanism causes both species to remain distinct when they develop overlapping geographic distributions.

species should be most informative about the geography of speciation because they are more likely (than relatively ancient speciation events) to reflect the spatial distribution of populations at the time of speciation (Mayr, 1954a). Using that rationale, molecular phylogenetic studies have compared species divergence times within clades to corresponding patterns of geographic overlap. For both terrestrial and marine organisms, these types of studies have found that the most sister-species—the most recently separated lineages within clades—are allopatric (Berlocher, 1998; Coyne and Price, 2000; Fitzpatrick and Turelli, 2006; Quenouille *et al.*, 2011; Choat *et al.*, 2012).

The Genetics of Vicariant Speciation

Natural selection is widely regarded as an important evolutionary force causing divergence in vicariant speciation, especially if populations are large (and have high genetic variation for selection to act on) at the time of speciation. How this actually happened was not immediately obvious to evolutionary biologists because it is difficult to explain how a beneficial mutation at one locus, present in only a single individual, could be maintained if it caused hybrid sterility or inviabilty given that the mutation would be initially only exist in heterozygotes? Dobzhansky (1937) and Muller (1942) provided a simple, yet elegant solution in the form of a two-locus model that approximates the kinds of genetic changes envisioned by Mayr, and can be easily generalized to multiple loci. Consider a population fixed for the two-locus genotype $A_1A_1B_1B_1$ that is split into two populations by the formation of a barrier restricting gene flow. If selection in one population favors replacement of the A_1 allele with a newly mutated A_2 allele, but in the other population B_1 is selectively replaced by B_2, the two populations will be fixed for the $A_2A_2B_1B_1$ and $A_1A_1B_2B_2$ genotypes, respectively. If the A_2 and B_2 alleles are incompatible, causing hybrid sterility or inviability (i.e., complete postzygotic isolation), the two populations will be reproductively isolated if they come back into contact. Many examples of Dobzhansky-Muller incompatibilities have been described in plants and animals, particularly those for which closely related species can be hybridized in the laboratory (e.g., Coyne and Charlesworth, 1986; Orr, 1995; Turelli, 1998).

Evidence of Natural Selection

Several investigators have shown that reproductive isolation has evolved as a by-product of adaptive divergence, a process called "ecological speciation." For example, the evolution of mimicry appears to have played an important role in speciation in the butterfly genus *Heliconius* (Jiggins *et al.*, 2001). The recently split sister species *H. melpomene* and *H. cydno* have diverged to mimic

the color patterns of different model taxa (Fig. 3A), but strong assortative mating (preferential mating among individuals with similar phenotypes) based on the mimetic coloration results in substantial prezygotic isolation (Fig. 3B). Rare hybridization events produce individuals with poorly adapted intermediate phenotypes, demonstrating that divergent patterns of mimicry also result in some postzygotic isolation. Among plants, species in the genus *Mimulus* have evolved highly divergent floral morphologies that appear to be adaptations to different types of pollinators (either bees or hummingbirds) that in turn effectively reproductively isolate sympatric populations (Schemske and Bradshaw, 1999). Using controlled laboratory experiments, several studies have also generated strong assortative mating among replicate lines of houseflies and species of *Drosophila* by subjecting them to artificial divergent selection on behavioral, morphological, and physiological traits (e.g., Dodd, 1989). Control populations exposed to the same selective pressures show little behavioral isolation, indicating that divergent selection, rather than genetic drift, caused the incidental evolution of prezygotic isolation.

Sexual selection is also probably important in allopatric speciation given that divergence in sexually selected traits will necessarily diminish interbreeding (Ritchie, 2007). Many experiments have shown that among species where a female chooses males to mate with, females make choices based on sexually dimorphic traits in males, such as large body size, bright coloration, large antlers, and elongated tail feathers. Sexual selection is likely involved in the evolution of gametic (sperm and egg) incompatibilities and isolation in some marine organisms that release their gametes into the water column in mass spawnings, a scenario that results in intense sperm competition among males. Analysis of the underlying DNA sequences for some sperm and egg surface proteins indicates that the evolution of these proteins is driven by selection (Galindo *et al.*, 2003). Rapid development of gametic incompatibility may explain how some populations evolve reproductive isolation during only brief periods of transient geographic isolation (Levitan and Ferrell, 2013).

Genome-wide patterns of genetic divergence between evolving species or ecotypes have provided numerous examples of the potential role of natural selection in speciation. Scanning thousands of loci across the genome allows identification of very strongly differentiated loci ("outliers") between geographically isolated populations, a pattern often interpretted as evidence of natural selection (Luikart *et al.*, 2003). However, as with any difference between recently-evolved species or ecotypes, it remains difficult to determine if outlier loci are a cause or consequence of reproductive isolation. Genome scans of allopatric ecotypes that have evolved more than once (repeated or parallel evolution) provide much greater power to identify the genetic loci responsible for adaptation and reproductive isolation between allopatric lineages. For example, in sticklebacks, whole-genome sequencing of

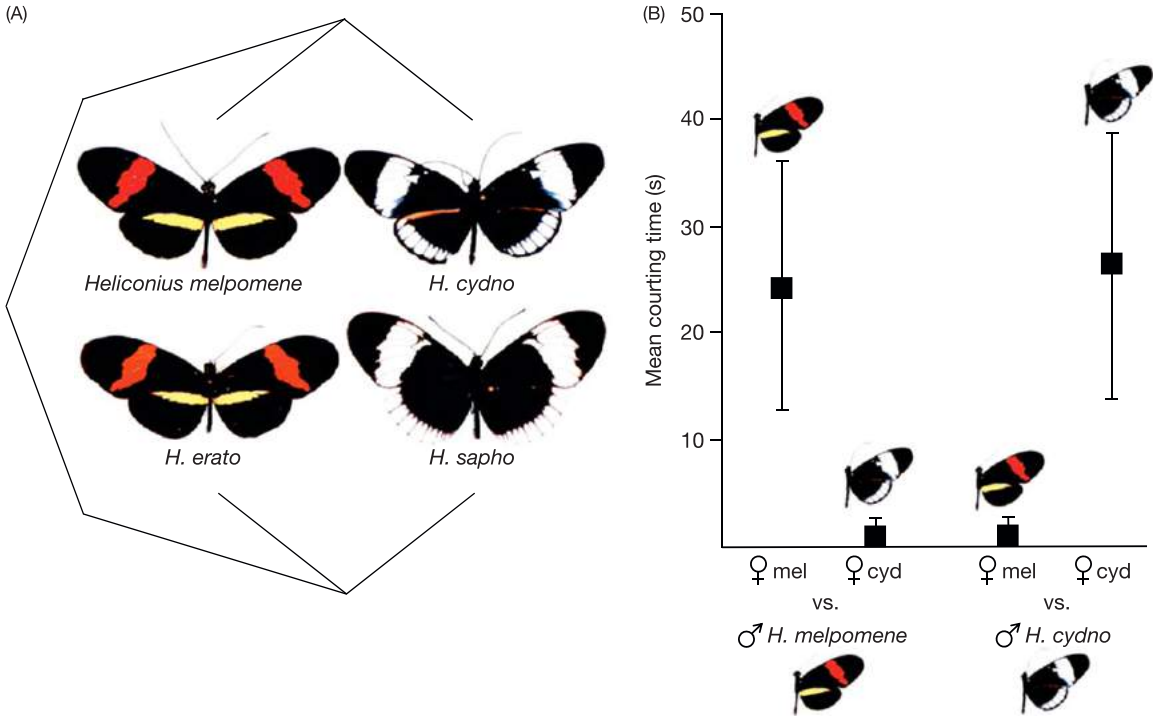

Fig. 3 Ecological speciation in *Heliconius* butterflies in which strong behavioral (i.e., prezygotic) isolation evolved as a by-product of mimicry. (A) Molecular phylogenetic relationships of *H. melpomene*, *H. cydno*, and their comimics *H. erato* and *H. sapho*. The molecular phylogeny establishes that similar coloration patterns involved the evolution of mimicry in one or both of the *H. melpomene*/*H. cydno* and *H. erato*/*H. sapho* lineages (rather than entirely as a consequence of common ancestry). (B) Time spent by males courting females with 95% confidence intervals for both *H. melpomene* and *H. cydno* from sympatric populations in Panama. Allopatric populations show weaker isolation, a pattern consistent with reinforcement of speciation. From Jiggins, C. D., Naisbit, R.E., Coe, R.L., and Mallet, J. (2001). Reproductive isolation caused by color pattern mimicry. *Nature* **411**, 302–305. Photos courtesy of C. Jiggins.

several freshwater ecotypes, that each repeatedly evolved independently from a marine ancestor, reveals that many outlier loci are shared among freshwater ecotypes (Jones *et al.*, 2012).

Reinforcement

During a period of allopatric isolation, populations may evolve only partial postzygotic isolation such that if they came back into contact they would produce viable hybrid offspring with lower fitness compared to pure genotypes. Dobzhansky introduced the concept that if hybrid genotypes have reduced fitness, natural selection should favor the evolution of enhanced mate discrimination. This process, in which prezygotic isolation evolves as an adaptation to minimize the costly production of low fitness hybrids, is called "reinforcement of speciation" or simply "reinforcement." Although intuitively appealing, several significant theoretical objections to reinforcement were initially raised and the idea quickly fell out of favor with most evolutionary biologists. However, the emergence of several compelling examples (e.g., Coyne and Orr, 1989) of reproductive character displacement, a pattern in which prezygotic isolation is stronger between species in sympatry than in allopatry, has fostered a revival of the hypothesis of reinforcement (Servedio and Noor, 2003). That said, even though the pattern of stronger behavioral isolation in sympatry than in allopatry is consistent with reinforcement, other processes can often explain the pattern of "reproductive character displacement." For example, populations with strong premating isolating mechanisms that evolved in allopatry may simply be capable of coexisting, whereas populations with weaker isolating mechanisms may freely interbreed and genetically fuse back into a single population when they come into contact. The expectation of population fusion, however, assumes that many evolving allopatric species pairs should have strong prezygotic isolation, a pattern that is not consistent with allopatric sister-species of *Drosophila* (Yukilevich, 2012). Similarly, prezygotic isolation appears to lag behind postzygotic isolation in snapping shrimp species isolated by the Isthmus of Panama (Knowlton *et al.*, 1993). Although recent experimental work with *Drosophila* confirms what theoretical studies have established, that reinforcement can evolve relatively quickly if gene flow is low or if selection against hybridization is strong (Matute, 2010), evidence for reinforcement in natural populations remains equivocal.

Peripatric Speciation

A second type of allopatric speciation is peripatric speciation, a theory developed by Mayr (1954b) more than 10 years after the publication of *Systematics*. From both biogeographical and genetic points of view, peripatric speciation represents a significant departure from the speciation process originally outlined by Mayr. Peripatric speciation, also called "founder effect speciation," occurs when a few individuals establish a small subpopulation on the periphery of the main range of a species and evolve reproductive isolation (**Fig. 4**). Under this model, the more widespread species is considered "parental" or "ancestral" with respect to the small, peripherally isolated "daughter" or "derived" species. Peripatric speciation was developed from observations by Mayr, mainly of birds on islands in the south Pacific, that small, peripherally isolated populations are often highly morphologically divergent despite existing under ecological conditions similar to those experienced by the parental population (Mayr, 1963).

The Genetics of Peripatric Speciation

An important component of Mayr's peripatric theory—and a significant shift in his opinion about the genetic basis of adaptation—is that gene flow, stabilizing selection, and complex epistatic interactions among numerous genetic loci all place constraints on phenotypic evolution. Therefore, Mayr felt that unusual genetic conditions might be necessary for speciation, suggesting that a new species may arise if the "sampling" of a small number of colonists leaves a small population with a highly nonrepresentative sample of genetic variation at some loci. The genetic drift associated with this sampling of individuals is called "the founder effect." As a result of epistatic interactions among different genes, Mayr argued that a substantial change in allele frequencies at a small number of loci will briefly change the relative selective values of alleles at many other loci across the genome, triggering massive genetic change and ultimately reproductive isolation (Mayr, 1954b, 1963).

Unlike the Dobzhansky-Muller model of adaptive divergence, in which ecological differences experienced by allopatric populations drive phenotypic divergence that leads to reproductive isolation, Mayr's original peripatric model contends that changes in the 'genetic environment' of the peripheral isolate, caused by the founder effect, allow natural selection to generate novel combinations of alleles at numerous interacting genetic loci ('adaptive gene complexes'). Mayr noted that due to geographical localization and rapid phenotypic evolution within peripheral isolates, intermediate phenotypes are probably rarely recorded in the fossil record. This last idea became an important component of Eldredge and Gould's (1972) highly influential but contentious theory of "punctuated equilibrium," which united Mayr's peripatric model with the observation that new species often appear suddenly in the fossil record, fully morphologically differentiated from their closest relative.

Evidence for and against Peripatric Speciation

Peripatric speciation was favored by many evolutionary biologists in the 1970s and 1980s. Widespread support for peripatric speciation was fostered in part by extensive research on Hawaiian picture-winged *Drosophila* (**Fig. 5**), led by Hampton Carson, Kenneth Kaneshiro, and Allan Templeton (Carson and Kaneshiro, 1976; Carson, 1983; Carson and Templeton, 1984). High

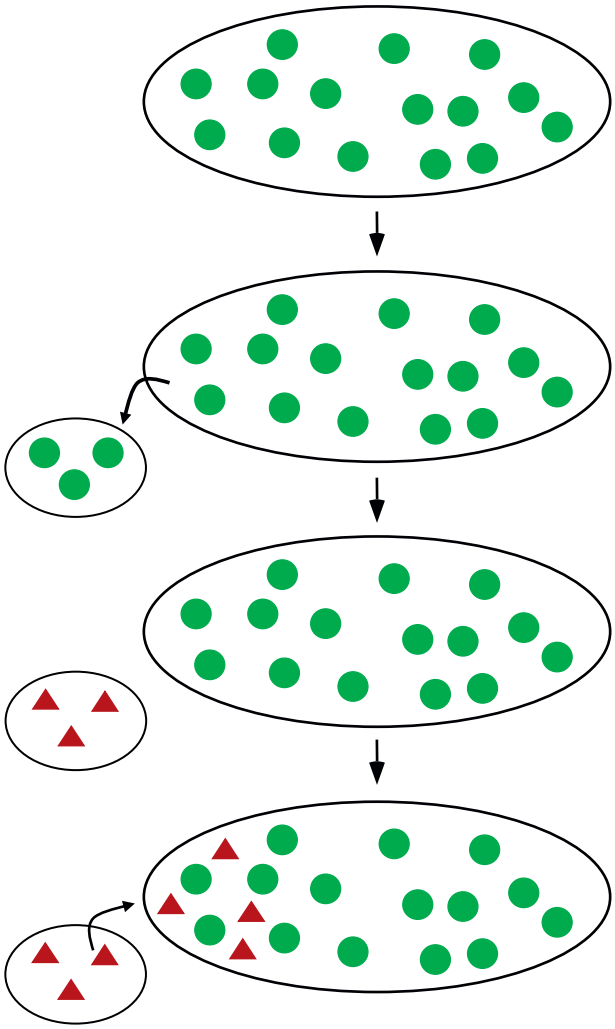

Fig. 4 Successive stages in the process of peripatric speciation. A small "daughter" population on the periphery of a more widespread "parental" population evolves reproductive isolation. Both species remain distinct if the peripherally isolated species invades the geographic range of the parental species. Under this model, the peripherally isolated population diverges from the parental population such that the latter remains unchanged.

endemnicity of species to single islands, with more recently derived species tending to occur on geologically younger islands, provides clear evidence that most speciation events in this group are associated with the colonization of newly formed islands from parental populations on older islands. Additional biogeographical evidence from a wide variety of island taxa provides a obvious link between speciation and dispersal, such as for flightless crickets in the Hawaiian genus *Laupala* (Mendelson and Shaw, 2005) and Darwin's finches in the Galapagos (Vincek *et al.*, 1997). The leaders of the *Drosophila* research program also developed their own genetic models of divergence. Although their models differed somewhat from Mayr's, most emphasized the role of the founder effect and the importance of changes in the genetic environment within a peripheral isolate.

Evidence of peripatric speciation is harder to come by for continental organisms, possibly because of a greater likelihood that the biogeographical evidence will be lost as a consequence of postspeciation range expansions. However, by comparing the relative sizes of the geographic distributions of species to their times of divergence, Barraclough and Vogler (2000) showed that many recently split lineages from a wide variety of taxa show unexpectedly high asymmetry with respect to their geographic ranges. Although other explanations are possible, a large asymmetry in geographic range between parental and daughter species at the time of speciation is consistent with peripatric speciation.

Phylogeographic studies also provide support for peripatric speciation if a putative daughter species possesses a small subset of the genetic diversity found in the parental species, indicating that the daughter species was formed from a relatively small population (Ovenden and White, 1990); the parental species' genome may also have many loci that are paraphyletic with respect to the daughter species, meaning that some alleles or haplotypes found in the parent are more closely related to those found in the daughter species, but all alleles or haplotypes in the daughter species are derived exclusively from a single lineage (Harrison, 1991; Marko, 1998). One of the most widely cited examples of peripatric speciation comes from a pair of species in the plant genus

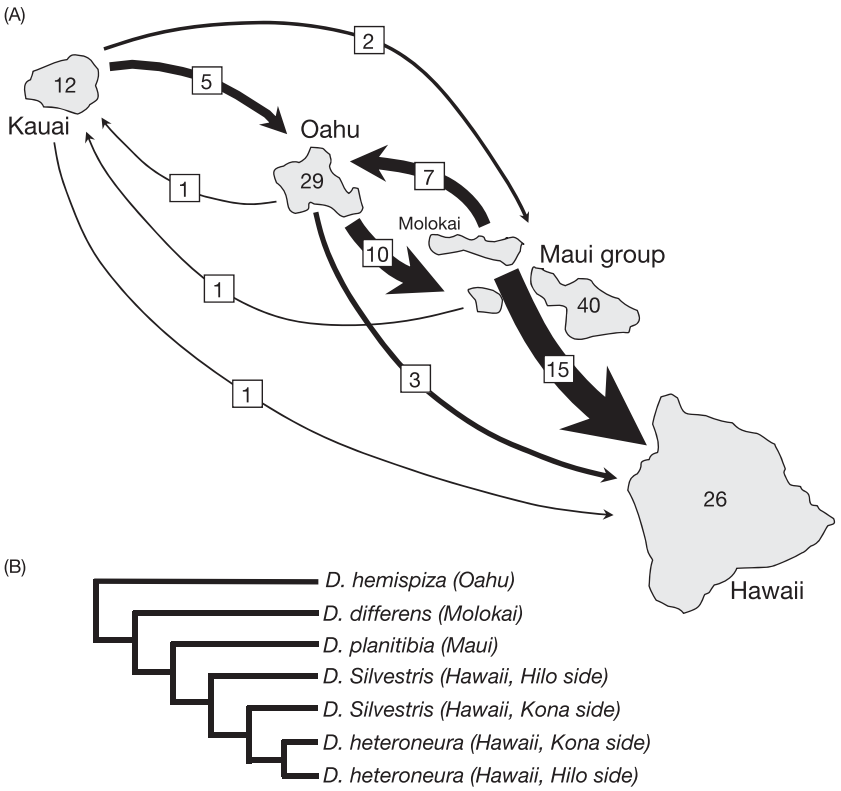

Fig. 5 Inter-island colonization and speciation in picture-winged *Drosophila* of Hawai'i. (A) Arrows indicate the minimum number of colonization events between islands, with the width of arrows reflecting the relative number of dispersal events (actual numbers are given in boxes). Note that colonization events are predominantly from older to younger islands. Numbers inside each island (or island group, in the case of Maui and Moloka'i) are the number of species found on each. (B) Phylogenetic relationships based on mitochondrial DNA for a subset of these species. More recently evolved species are found on younger islands, a pattern that corroborates the hypothesis that speciation is associated with dispersal between islands. Genetically distinct lineages of both *D. silvestris* and *D. heteroneura* on the Kona (southwest) and Hilo (northeast) sides of the island of Hawai'i suggest that intra-island speciation has also occurred in this group. (A) Modified from Carson, H. L. (1983). Chromosomal sequences and interisland colonizations in Hawaiian Drosophila. *Genetics* **103**, 465–482. (B) Reproduced from DeSalle, R. and Giddings, L. V. Clarkia, in which the putative daughter species is restricted to only two sites at the edge of the geographic range of the parental species in central California; the daughter species possesses less phenotypic variation and only a subset of the genetic diversity of the parental species (Gottlieb, 2004). This mode of speciation could be common in plants, in which relatively small genetic changes have the potential to rapidly reproductively isolate a localized population.

Even if many species arise as a consequence of colonization events (the existence of many endemic species on isolated islands and archipelagos makes this conclusion self-evident), the mechanism driving genetic divergence in a peripheral isolate cannot necessarily be attributed to the founder effect. In fact, as biogeographical evidence supporting peripatric speciation has grown, support for the role of the founder effect has diminished, mainly for two reasons. First, few species putatively formed in peripatry show strong genetic evidence of a severe bottleneck in their recent past (Barton and Charlesworth, 1984). Furthermore, even if a putative daughter species has low genetic variation across its entire geographic range, it remains difficult to determine if a bottleneck happened at the same time as speciation or after (Harrison, 1991). For example, low genetic variation throughout nearly all of the geographic of the marine snail *N. emarginata* (relative to it's sister-species) in California is consistent with peripatric speciation, except that the southermost population of this species has as much genetic variation as any population in the parental species, indicating that a severe bottleneck was not involved in speciation (Marko, 1998). Extinction of (or failure to sample) the high diversity population, would easily lead to the erroneous conclusion of a founder effect. In this case, low diversity across most of the daughter species' range is likely a consequence of a postglacial population expansion that happened after a period of allopatry.

A second reason why the popularity of genetic models of peripatric speciation has waned is that theoretical population geneticists have developed persuasive arguments against the potential role of the founder effect (Barton and Charlesworth, 1984; Charlesworth, 1997). Although more recent models of founder effect speciation have been more successful demonstrating that bottlenecks may actually facilitate speciation (Gavrilets and Hastings, 1996), laboratory tests involving bottlenecked populations of fruit flies (*Drosophila*) provide equivocal results (Powell, 1978; Dodd and Powell, 1985). In fact, the mixture of outcomes from

these experiments have been interpreted by both proponents and critics of peripatric speciation as either favoring or refuting, respectively, the importance of the founder effect in speciation.

Animal Physiology

Animal physiology is the study of how animals work, and investigates the biological processes that occur for animal life to exist. These processes can be studied at various levels of organization from membranes through to organelles, cells, organs, organ systems, and to the whole animal. Animal physiology examines how biological processes function, how they operate under various environmental conditions, and how these processes are regulated and integrated. The study of animal physiology is closely linked with anatomy (i.e., the relationship of function with structure) and with the basic physical and chemical laws that constrain living as well as nonliving systems. Although all animals must function within basic physical and chemical constraints, there is a diversity of mechanisms and processes by which different animals work. A comparative approach to animal physiology highlights underlying principles, and reveals diverse solutions to various environmental challenges. It can reveal similar solutions to a common problem, or modifications of a particular physiological system to function under diverse conditions. The discipline of animal physiology is diverse and here the major areas of research and investigation are outlined.

Homeostasis and Regulation

An important characteristic of animals is the ability to self-regulate the extracellular environment in which their cells are bathed and function. The extracellular environment is a buffer between the intracellular environment and the external environment of an animal, which consists of an aquatic or terrestrial environment in exchange with the atmosphere. These external environments can be highly variable with respect to their physical characteristics, which would affect the intracellular physiological processes necessary for animals to function. Therefore, some aspects of the intracellular environment of an animal are invariably kept different from their external environment. Consequently, an important role of homeostasis in animals is the regulation of aspects of the extracellular environment different from the external environment to provide an optimal internal environment in which the cells function.

Homeostasis is an underlying principle of animal physiology, and physiological systems are the means by which homeostasis is maintained. Homeostatic processes maintain the internal environment, although not all animals regulate all physiological variables to the same extent. Animals may conform with respect to some physiological variables, with the internal variable the same as for the external environment.

For both conformers and regulators, there is a range of environmental conditions over which the animal can survive. Beyond this range, conformers experience sufficient change in the internal environment that physiological processes no longer function effectively, and regulators can no longer regulate against the environmental gradient and their internal environment changes sufficiently to prevent normal physiological function.

Homeostasis does not necessarily require a regulatory mechanism. Equilibrium homeostasis and steady-state homeostasis are nonregulatory means by which an internal variable is kept constant; for example, a body fluid solute can remain relatively constant if the rate of excretion balances the rate of synthesis (**Fig. 1**). Many other homeostatic mechanisms, however, require regulation to maintain constancy. Negative feedback control is the most common regulatory system whereby a change in a variable is detected by a sensor and then counteracted by a response from an effector organ that is opposite to the perturbation (**Fig. 1**). Many physiological systems are controlled by several regulatory effectors, resulting in multiple control systems with greater overall precision of regulation. The nervous and endocrine systems are responsible for integrating physiological functions in an animal. They ensure that the physiological processes of different cells, tissues and organs occur in a controlled and coordinated manner, and result in whole-body homeostasis.

Nervous System

The nervous system integrates physiological functions and ensures that the physiological processes of different cells, tissues and organs occur in a controlled and coordinated manner, and result in whole-body regulation. It is responsible for coordinating rapid and precise responses to perturbations in the animal's internal and external environment by sensing changes in a physiological variable, integrating and interpreting the changes, and eliciting an effector response to counteract the change.

The nervous system consists of aggregations of two cell types, neurons that generate and conduct action potentials (a change in polarity of voltage across a cell membrane) and glial cells that are accessory cells which support and assist the function of neurons.

 doi:10.1016/B978-0-444-63768-0.00456-X

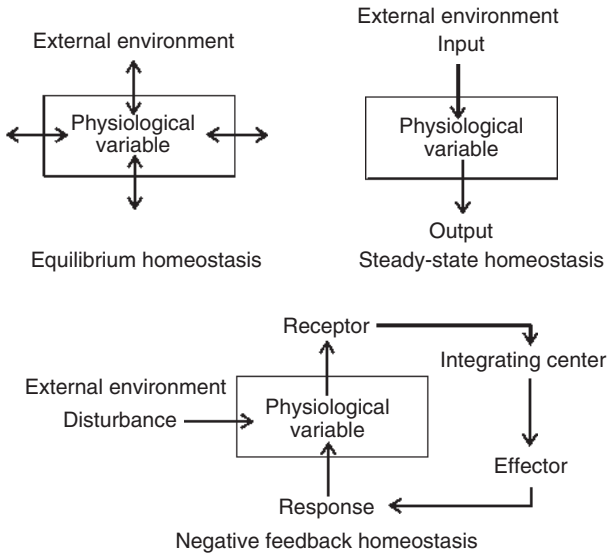

Fig. 1 Schematic of equilibrium, steady-state, and negative-feedback regulatory mechanisms.

Neurons can be classified as sensory (or afferent), inter (or internuncial) or motor (or efferent) and connect to one another, and to sensory or motor effector cells, via synapses (Fig. 2). In primitive animals (and simple reflexes in complex animals) there is a direct connection between sensory and effector cells by a single motor neuron, resulting in a simple three-cell sensory–motor circuit. However, in more advanced animals additional interneurons between the sensory and motor neurons allows for much greater complexity, permitting more complex integration and interpretation of sensory information, sophisticated motor control, and the development of complex behaviors.

The most primitive nervous systems are nerve nets; they occur in coelenterates and some flatworms. The development of cephalization (a head region) led to the concentration of neurons at the anterior end of the animal, forming the brain, and nerve cords consisting of concentrated groups of neurons transmitting information to other regions of the body. The nervous system is most highly developed in vertebrate animals. Here the brain and spinal nerve cord form the central nervous system while the peripheral nervous system consists of many paired nerves that run from the spinal cord to the peripheral regions of the body. These transmit sensory information to the central nervous system and return motor commands to the peripheral effectors. The somatic nervous system innervates efferent organs under conscious control (e.g., skeletal muscle), while the autonomic nervous system innervates involuntary visceral organs (e.g., gut and heart).

Endocrine Systems

Like the nervous system, the endocrine system regulates an animal's internal environment but it is a much slower control system. Chemical messengers (hormones) provide communication between sensory and effector cells. Hormone systems occur in all animals; they have become increasingly complex throughout evolutionary time compared to the basic neuron–endocrine systems of primitive animals. The endocrine system controls a wide range of physiological processes including reproduction, growth, development, metabolism, and osmo- and iono-regulation. It can respond to short- and long-term variations in internal and external environments and is important for the maintenance of homeostasis. Neuro-endocrine systems consist of neural sensory and interpretive pathways but instead of directly innervating an effector organ there is release of a chemical messenger into the blood at a hemal organ. This chemical messenger is then distributed to peripheral target organs where it has an effector action.

Hormones are secreted by endocrine glands (and neurohormones by nerve cells) in response to perturbing stimuli, and are then transported via the circulatory system or diffuse through tissues to target organs and cells. Thus a key characteristic of hormones is that they exert their action at a distance from the site of their secretion. Hormones do not initiate any unique cellular activities; rather they modify the rates of existing activities. Hormones may have inhibitory or excitatory effects on target cells, usually by inducing or repressing enzyme activity within cells, although they may act on the nucleus to influence the expression of genes or influence the permeability of cells to solutes.

Historically, hormones were considered to be chemicals released from endocrine glands (glands of internal secretion in contrast to exocrine glands such as salivary, sweat, and digestive glands that produce external secretions) but hormones may also be secreted by a variety of other tissues. Traditionally, hormones were considered to differ from neurotransmitters, which function only locally at the site of release (synapse) but this distinction is no longer so clear. Hormones function at very low concentration (e.g., 10^{-12}–10^{-9} M). Target organs have specificity for particular hormones due to the properties of receptors that are either on the surface of the cell membrane or inside the cell. Receptors reversibly bind the hormones with high specificity and affinity. Water-

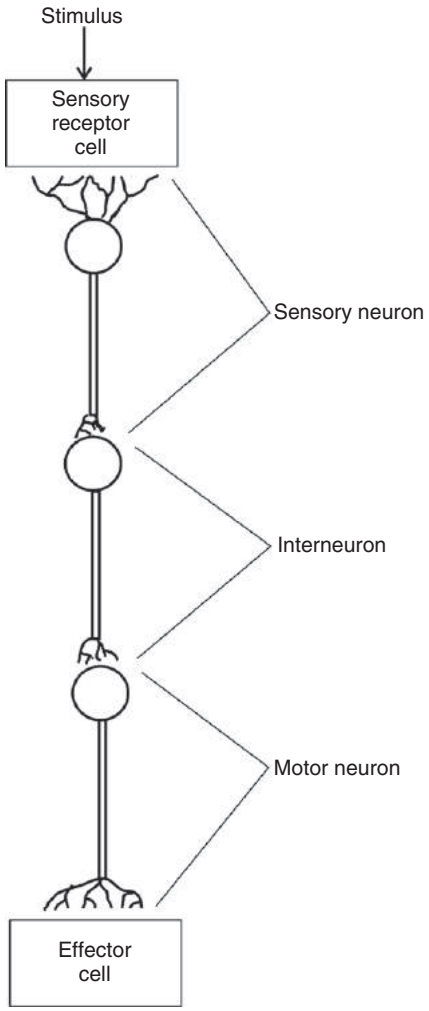

Fig. 2 Schematic sensory–motor neuron system consists of a sensory neuron input, integrative and interpretative interneuron, and an effector motor neuron.

soluble hormones are derivatives of amino acids (catecholamines, peptides, proteins) or fatty acids (eicosinoids). These interact with surface receptors that span the cell membrane. Often they trigger a secondary 'messenger' inside the cell. In contrast, lipid-soluble hormones such as steroids (adrenocortical and gonadal steroids in vertebrates, ecdysones, and juvenile hormones in invertebrates) and thyroid hormones usually pass through the cell membrane and interact with intracellular receptors. Some bind to membrane receptors which are then internalized. Many hormones that are transported in the circulatory system (in particular the lipid-soluble hormones) bind to a water-soluble carrier protein to aid transport.

Hormones are classified by the distance over which they travel to have their effect (Fig. 3). Autocrine hormones affect the cell that secreted them. They react with receptors on their own surface to produce a response and are usually involved in cell division. Paracrine hormones act over a very short distance, diffusing through extracellular fluid to affect local tissues. Endocrine hormones affect distant organs and tissues. They are secreted into the circulatory system and are transported by the hemolymph or blood. Pheromones are an additional form of chemical communication that occurs between rather than within individuals. They are highly volatile compounds released into the external environment and detected in small concentrations by receptors (usually on the nasal epithelium of vertebrates or antenna of insects) of another individual. Pheromones function to synchronize and induce reproductive activity, and to define territorial boundaries.

Water and Ion Balance

Maintaining water and ionic balance is a fundamental physiological process for animals because animal cells can only function effectively over a specific, relatively constant range of body fluid composition. For unicellular animals, the intercellular environment is juxtaposed with the external environment. For multicellular animals, the extracellular space is a buffer between the

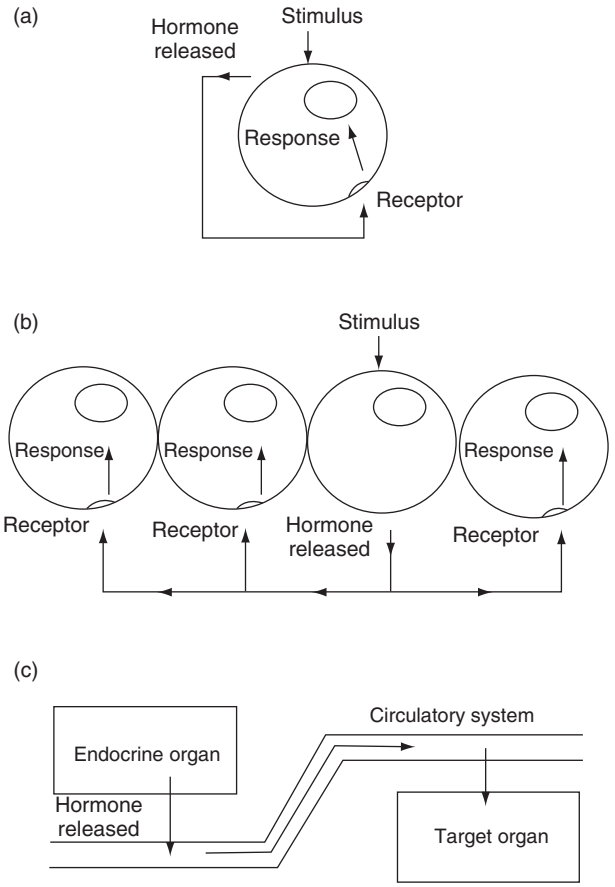

Fig. 3 Hormone systems. (a) Autocrine hormones affect the cell that secreted them. (b) Paracrine hormones affect local tissues. (c) Endocrine hormones are transported in the circulatory system to affect distant organs.

intracellar and external environments. In all animals, the intracellular environment has a different ionic composition from the external environment. For some animals there are osmotic differences, but their intracellular and extracellular environments must have the same osmotic concentration to maintain constant cellular volume (but invariably they have different ionic concentrations). The challenges associated with maintaining osmotic and ionic homeostatis differ with the external environment of the animal, and so there are various strategies for animals to maintain fluid and ion balance.

Aquatic Environments: Seawater

With respect to extracellular fluid, animals in marine environments either osmoconform (have the same osmotic concentration) to seawater (1000 mOsm; **Fig. 4**) or osmoregulate at a lower osmotic concentration (usually 300–400 mOsm). In addition, they either ionoconform with respect to their extracellular fluid, having the same ionic composition as seawater, or they ionoregulate and maintain different ionic concentrations. Animals that conform to seawater do not have to overcome the problem of continual osmotic loss of body water to and gain of ions from the environment, but high ion concentrations adversely influence cellular metabolic processes. Most marine invertebrates osmoconform and ionoconform to seawater, but a few osmo- and ionoregulate. Hagfish are the only vertebrates to both osmo- and ionoconform. Marine bony fish both osmo- and ionoregulate. Marine elasmobranchs osmoconform at 1000 mOsm but ionoregulate at about 600 mOsm; urea and trimethylamine oxide (TMAO; which counteracts the negative effects of the urea on proteins) make up most of the 400 mOsm osmotic gap between the ions and seawater (**Fig. 4**).

Aquatic Environments: Freshwater

Freshwater animals must both osmo- and ionoregulate as it is impossible to osmo- or ionoconform to such a dilute environment. Freshwater animals gain water by osmosis from their environment, and lose ions by diffusion. Excess water is eliminated as copious dilute urine and ions are obtained by active transport across the gills, skin, or gut.

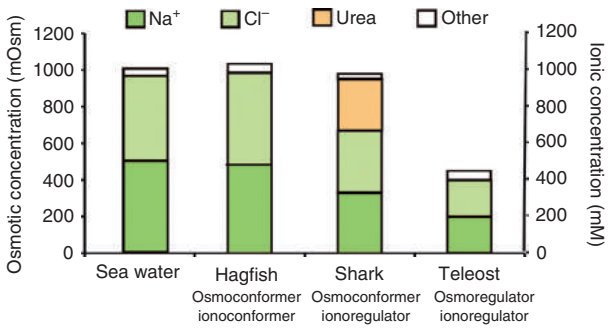

Fig. 4 Patterns of extracellular ion and osmotic regulation in vertebrate animals.

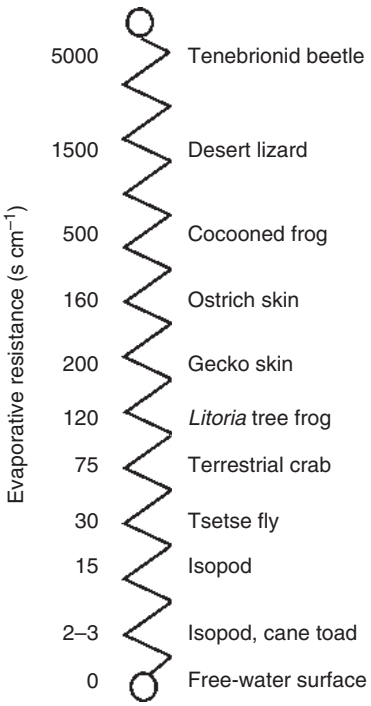

Fig. 5 Scale of resistance to evaporative water loss, from about 0 s cm^{-1} for a free-water surface to 5000 s cm^{-1} or more for animals that are very resistant to EWL.

Terrestrial Environments

Terrestrial environments are characterized by limited water availability, so dehydration is a major threat. Evaporative water loss (EWL) across the skin and respiratory tract is a major avenue of water loss by terrestrial animals. Water is also lost in feces and urine. Water is gained in a terrestrial environment via drinking, as preformed water in food, and as metabolic water production. Water may also be absorbed across the body surface. Ions are gained from food and by drinking, and are excreted in urine and feces and sometimes by salt glands.

Many invertebrates (e.g., mollusks, crustaceans) and amphibians are restricted to moist terrestrial habitats, at least when active, but many are more successful terrestrial animals because they have adaptations to minimize EWL. Arthropods have a chitinous exoskeleton, covered in a waxy cuticle that forms a barrier to evaporation. Birds, mammals, and especially reptiles have a cornified epithelium that increases resistance to EWL (Fig. 5). Insulating fur (mammals) or feathers (birds) is a further barrier. Nasal counter-current exchange of heat and water in the respiratory passages of reptiles, birds, and mammals reduces respiratory EWL. Arthropods, birds, and reptiles typically produce insoluble uric acid as their nitrogenous waste material, and the mixing of urine and feces in their hindgut (where water is reabsorbed) minimizes excretory water loss. Many desert reptiles and mammals survive without drinking, maintaining water balance with preformed and metabolic water alone. Most birds are able to travel long distances to obtain drinking water, although some can also survive without access to free water. Excess ions are lost by many reptiles and birds via cranial salt glands. Mammals do not have salt glands, and remove excess ions by producing urine that is

hyperosmotic to blood (up to 9000 mOsm). Some birds are also able to produce hyperosmotic urine to excrete excess ions, but not to the same extent as mammals.

Excretion

Excretory organs are essential for maintaining iono- and osmohomeostatis as they balance the gains and losses of water and solutes. They regulate the concentrations of ions and water in the body and play a vital role in excreting waste products including inorganic and organic solutes derived from the animal's diet, metabolic processes or foreign materials, preventing these wastes from accumulating to toxic levels. Thus excretory organs must selectively retain or remove a range of solutes from the body.

Simple animals rely on diffusion and membrane transport systems to remove wastes. However, the evolution of larger and more complex animals necessitated specialized excretory organs. Although in most animals the integument is relatively impermeable to water and solutes, specific epithelial regions can be specialized for the regulation of particular solutes or water. Tubular excretory organs are more generalized than these epithelial organs, and occur in most multicellular animals. They evolved primarily for water and solute excretion, but in a terrestrial environment they also play a crucial role in eliminating nitrogenous wastes and osmoconcentrating urine in some species.

Four major organ systems are responsible for excretion in animals. The respiratory system (lungs or gills) removes CO_2, and gills also play a vital role in ammonia, carbonate, and ion excretion, by both diffusion and active transport. The digestive system, in addition to eliminating undigested food, is also a site of ion and water absorption and excretion, and the vertebrate liver excretes bilirubin (derived from the breakdown of red blood cells) into the gut. The integument and various glands of animals may have a primary or secondary excretory function, for example, water and ion uptake by the skin of amphibians, salt glands of reptiles and birds, rectal glands of elasmobranchs, and sweat glands of mammals. Renal organs, including protonephridia, nephridia, Malpighian tubules, and coelomoducts (e.g., the vertebrate kidney) consist of tubules that filter body fluids and then selectively secrete or reabsorb water, organic molecules, and ions. The major functions of these excretory tubules are initial formation of excretory fluid, typically by filtration, then reabsorption of fluid and 'useful' solutes and secretion of specific 'waste' solutes. Only a few terrestrial animals are able to excrete urine that is more osmotically concentrated than their blood; the vertebrate kidney can excrete hypoosmotic or isoosmotic urine but only mammals and birds can excrete hyperosmotic urine due to the counter-current multiplication role of the renal medulla.

Gas Exchange

Most animals require oxygen to sustain their metabolic demands. Food is oxidized to produce adenosine triphosphate (ATP) and carbon dioxide is produced as a waste product, so animals must obtain oxygen from their environment and release carbon dioxide back into the environment. Gas exchange between the internal and external environment in all animals occurs through passive diffusion. For small, simple animals, diffusion across the body surface is sufficient to meet their metabolic demands. However, an evolutionary trend among animals for increased size and metabolic rate requires specialized surface regions for specific functions such as gas exchange (as well as locomotion, feeding, digestion, and sensory reception). So, a large body size and complexity necessitates specialized respiratory structures. Most respiratory structures require ventilation, the continual replacement of the external medium at the respiratory surface with fresh medium to maintain favorable concentration gradients for diffusion (**Fig. 6**). Animals are classified as air and/or water breathers. The physical characteristics of these two media constrain the ventilatory mechanisms necessary to maintain gas exchange across the respiratory surface, and therefore the nature of the surface itself.

Aquatic animals have gills, evaginated and highly folded external surfaces, for gas exchange. Water is dense and viscous (compared to air) so unidirectional flow over the gill surface is preferable. This also means that gills can have a counter-current flow of external medium (water) and internal fluid (blood/hemolymph) for very efficient O_2 extraction by counter-current exchange (**Fig. 6**). The O_2 concentration is also much lower for water (5–6 ml l^{-1}) than for air (210 ml l^{-1}) so a high efficiency of counter-current exchange is important. CO_2, however, is extremely soluble in water so its loss to the aquatic environment is not so problematic as O_2 uptake. Consequently, aquatic animals generally have low body fluid CO_2 levels.

Terrestrial animals have internalized respiratory structures, lungs or trachea, because avoiding desiccation is a major challenge. Moist externalized respiratory structures such as gills can have an excessively high EWL, but internalized structures have a lower EWL. Air is much less dense and viscous than water, and has a higher oxygen concentration, so lung ventilation by a tidal pool or cross-current system is not too inefficient or energetically restrictive. Lungs may be ventilated by positive pressure 'buccal pumping', as in amphibians, or by negative pressure inspiration, as in reptiles, mammals, and birds. Unlike the one-way tidal ventilatory pattern of most vertebrates, birds have a system of air sacs before and after the lung, which enables a one-way flow of air over the respiratory surface and allows a more efficient cross-current exchange system between the air and blood. The gas exchange system of arthropods consists of a series of air-filled tubes (tracheae) that infiltrate the body tissues and open to the external environment through spiracles at the body surface. Tracheal systems are generally not actively ventilated, relying on diffusion for gas exchange, a factor that limits the size of arthropods. The lungs of pulmonate snails are similarly diffusion driven.

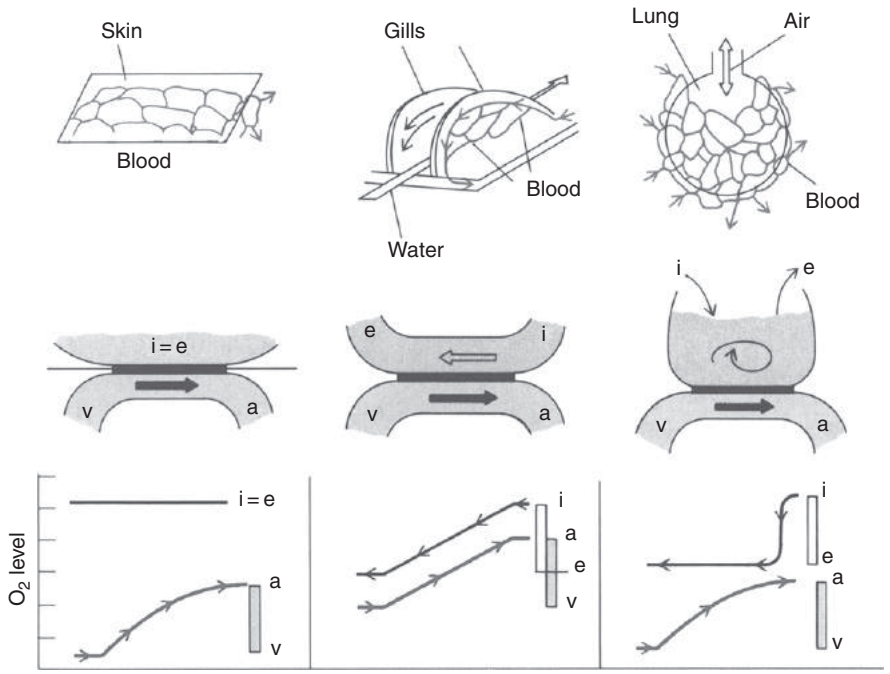

Fig. 6 Schematic diagrams of respiratory gas exchange across skin, gills, and lungs, showing patterns of fluid flow and O_2 exchange between the medium and blood, showing complete equilibration between the water (or air) and blood for skin exchange (left), typical counter-current arrangement of water and blood flow for gills (center), and a tidal pool of air for lungs (right). i, incurrent; e, excurrent; a, arterial; v, venous. Circulation

Small, simple animals rely on diffusion to move solutes throughout their body. However, for larger and more complex animals the rate of diffusion is too slow so a circulatory system is needed for rapid transport of gases, nutrients, chemicals, and waste products. Circulatory systems may be open, where the circulating fluid is not always contained in vessels and is at times in direct contact with tissue cells (e.g., arthropods), or closed, where the circulating fluid is always contained inside vessels (e.g., vertebrates; **Fig. 7**). The circulating fluid is known as hemolymph (open systems) or blood (closed systems). It consists of plasma, a fluid containing water, ions and organic molecules, and various blood cells. These cells can be involved in transport of O_2 (erythrocytes), defense (leukocytes), or hemostasis (thromobcytes).

Blood and hemolymph flow is maintained by positive pressure created by the contraction of muscles in the body wall, or by the pumping of one or more hearts. Animal hearts are classified as neurogenic if they require innervation for contraction (e.g., arthropods), or myogenic if the contraction is spontaneous (e.g., mollusks and vertebrates). The complexity of animal hearts varies from the simple tubular hearts of insects that push blood by peristaltic contractions of the muscular wall, to the multichambered hearts of mollusks and vertebrates. Chambered hearts have a varying number of muscular-walled compartments, which contract in a coordinated manner to circulate blood. Generally circulatory systems transport oxygenated

blood from the respiratory surface(s) to the tissues and deoxygenated blood from the tissues to the respiratory surfaces. They can also be important in supplying nutrients to the tissues from the digestive system, transporting hormones from sites of synthesis to target cells, circulating cells of the immune system throughout the body, transporting heat, and generating a hydrostatic pressure.

Metabolism and Digestion

The use of chemical energy is a fundamental characteristic of living animals. It is necessary to maintain cellular order and is vital to almost all physiological processes. Catabolic metabolism breaks down macromolecules for production of usable energy by cellular processes such as active transport, muscle contraction, ciliary movement, and production of heat, electricity, or light. Most cellular reactions need 20–40 kJ of energy per mole of reactants, which is much less than the energy yield of the complete oxidation of a typical metabolic substrate. Therefore high-energy phosphate compounds (phosphagens) are used as intermediary chemical energy stores. ATP is the most common phosphagen. Free energy is released by the hydrolysis of its terminal phosphate to form adenosine diphosphate (ADP) and inorganic phosphate (P_i) that is, $ATP \leftrightarrow ADP + P_i + 30.5\ kJ\ mol^{-1}$. There is a cyclic formation of ATP from ADP (by cellular metabolism) and subsequent breakdown of ATP by energy-requiring processes.

Animals are heterotrophs, and as such are unable to synthesize their own organic compounds from inorganic molecules and so rely on other organisms for nutrients. Energy is obtained from nutrients such as carbohydrates, lipids, and sometimes proteins (amino acids are required for protein systhesis but also produce energy when oxidized). Essential vitamins, minerals, and fatty acids are also needed for proper cell functioning and must also be obtained via the diet. Single-celled animals and sponges ingest food particles by phagocytosis. These are chemically and enzymatically reduced within a food vacuole to a few constituent substances (e.g., monosaccharides, fatty acids, and amino acids) that are transported into the cytoplasm. Most multicellular animals have a digestive system specialized for extracellular digestion. Food particles enter the digestive system where a series of physical and chemical digestive processes break down food particles into constituent molecules that are absorbed and distributed to the cells. These molecules can then be used for energy metabolism, or for cell maintenance or growth.

Metabolism may be aerobic or anaerobic. Aerobic metabolism is the oxidation of carbohydrates, lipids, and proteins by oxygen to provide energy in the form of ATP. There are three major steps in the aerobic process: glycolysis, where glucose is converted to pyruvate with a net gain of 2 ATP (and 2 $NADH/H^+$), the citric acid (or Kreb's) cycle where pyruvate is converted to acetyl-CoA before undergoing a cycle of chemical reactions resulting in a further net gain of 2 ATP (and 6 $NADH/H^+$ and 2 $FADH_2$), and finally the mitochondrial electron transfer system. Ninety-five percent of the ATP is generated by electron transfer, where electrons from $NADH/H^+$ and $FADH_2$ are transferred to electron carrier proteins, passing through several protein complexes and generating 34 ATP. Oxygen is the final electron receptor in the chain, and water is formed as the end product.

Anaerobic metabolism is an alternative to aerobic metabolism, but it is very inefficient by comparison, forming as little as 2 ATP per glucose molecule. Consequently most large and complex animals rely on aerobic metabolism to meet their resting requirements, but they may use anaerobic metabolism for supplemental energy, for example, during intense activity or anoxia. Build-up of lactate as an anaerobic end product of glycolysis is a major inhibitory factor in the long-term use of anaerobic metabolism in tetrapod vertebrates. However some (e.g., carp) can convert pyruvate to ethanol as the end product, which can be easily excreted to the environment and therefore does not inhibit glycolysis.

Many factors affect the metabolic rate (MR) of animals, including temperature, developmental stage, diet, photoperiod, taxonomy, habit, environment, activity, and circadian rhythm. Body size is a major determinant of MR and is probably the best studied but least understood topic in animal physiology. Larger animals have a higher overall MR than small animals but have a lower MR per gram of body mass, so the relationship (eqn [1]) between mass (M) and MR

$$MR = aM^b \qquad [1]$$

does not scale isometrically (i.e., $b \neq 1$). Rather, $b < 1$ since small animals use proportionally more energy (i.e., per gram) than larger animals. This relationship is remarkably uniform for all animals, from single-celled protists to birds and mammals. Although there is some debate as to what the scaling coefficient actually is (and why), b appears to generally fall between 0.67 (the value expected if MR scales with surface area) and 1 (the value if MR is proportional to mass); b is typically about 0.75. The intercept of the scaling relationship (a) is lowest for unicellular organisms, higher for ectothermic animals, and highest for endothermic animals, but the slope is consistently about 0.75 (**Fig. 8**).

Temperature Relations

Body temperature has major significance for an animal's physiology. Temperature determines the state of matter and influences the rate of chemical reactions in biotic as well as abiotic systems. The body temperature of active animals generally ranges from $-2\ ^\circ C$ (freezing point of seawater) to $+50\ ^\circ C$ (where protein structure becomes unstable). This body temperature range can be even greater for animals in an inactive or dormant state; some can survive temperatures as low as $-200\ ^\circ C$ or as high as $120\ ^\circ C$!

All animals exchange heat with their environment. The vast majority of animals passively thermoconform to the temperature of their surroundings. However, some manipulate their thermal exchange to thermoregulate their body temperature within

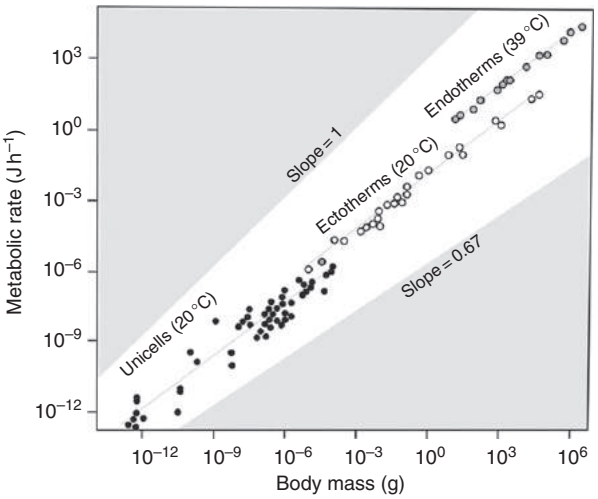

Fig. 8 Scaling of metabolic rate for unicellular organisms, and ectothermic animals (at 20 °C) and endothermic mammals and birds (at 39 °C). Fig. 9 Avenues of thermal exchange between an animal and its environment; conduction, convection, radiation, and evaporation. Photograph by P. Withers.

reasonably constant limits (typically 35–40 °C) and maintain an appreciable temperature gradient between themselves and the environment.

The thermal environment of an animal is complex. Heat exchange between an animal and its environment occurs by conduction, convection, radiation, and evaporation/condensation (**Fig. 9**). Conduction is direct heat transfer between two solid objects in physical contact. The rate of exchange depends on the area of physical contact, temperature difference, distance the heat must diffuse, and thermal conductive properties. Convection is transfer of heat by fluid movement (liquid or gas), and depends on the surface area, the temperature differential between the fluid and the surface of the solid, and the thickness and conductivity of the convective boundary layer. Forced convection occurs if the fluid movement is a result of external forces (e.g., wind), while free convection is induced by the temperature of the object itself. Radiation transfers heat between two objects that are not in physical contact by electromagnetic waves. The higher the surface temperature of an object, the greater is the radiative heat loss. Animals both emit and absorb radiation. Environmental sources of radiation for animals are complex and include direct solar radiation, diffuse scattered radiation, reflected radiation, and infrared radiation from surrounding objects and the ground. The structural and optical properties of an animal's surface are important determinants of its radiative heat load. Evaporative heat loss can be substantial because the latent heat of vaporization is about 2200 kJ g^{-1} (and condensation has an equivalent warming effect). Terrestrial animals lose heat via cutaneous and respiratory evaporation, and may have adaptations to reduce or augment this loss depending on environmental conditions.

Ectothermic animals have no physiological capacity to regulate their body temperature using internal metabolic heat production. They must either thermoconform to their environment, if their environmental temperature is relatively constant or if they can tolerate fluctuations in T_b, or use behavioral regulatory mechanisms to maintain a T_b that is somewhat independent of

environmental temperature. For example, many ectothermic reptiles remain largely independent of ambient temperature by using thermoregulatory behaviors such as basking, shuttling between warm and cool microhabitats, and postural adjustments to keep T_b about 36–38 °C. Endothermic animals, such as birds, mammals, and some insects, have physiological control of body temperature (typically 35–42 °C). They utilize heat produced as a by-product of metabolism to maintain their high and constant T_b independent of ambient conditions. Insulating fur and feathers reduces heat flux between endotherms and their environment. Endotherms may also employ behavioral thermoregulatory strategies to reduce the energetic costs of endogenous heat production, especially when the gradient between T_b and T_a is large.

Applied Ecology

A Georges, LJ Hone, and RH Norris, Institute for Applied Ecology, Canberra, ACT, Australia

Applied Ecology

The science of ecology involves the study of interactions between organisms and their environment, both biotic and abiotic, with particular focus on those interactions that determine their distribution and abundance. Applied ecology is the science of the application of ecology to contemporary problems in managing our biological resources. It includes scientific study of the effects of humans on the interactions between organisms and their environment, but excludes human ecology.

Applied ecology has two broad themes. The utilitarian theme concerns the interests of humans in their food, shelter, welfare, and health, that is, the material services the natural environment provides. Such ecosystem services, once compromised, can be very expensive to replace despite our technological advances. How do we bring ecology to bear in maintaining and improving these ecosystem services where they currently exist, in restoring or replacing them if they have been lost, or in mitigating the impact if those services are under threat? A second theme concerns nonconsumptive values of the biota, for recreation, tourism, psychological well-being, or simply because humans have an ethical responsibility as custodians of the natural environment and the species it contains. How do we bring ecology to bear in conserving these important nonconsumptive values?

These two broad themes overlap, since the nonconsumptive values of the environment are connected through biodiversity to the services healthy environments deliver. Naturally biodiverse systems are typically more resilient to human-induced perturbation than are systems that are highly modified, structurally simplified or degraded, and so are better able to sustainably provide the ecosystem services we expect.

Topics included under the broad discipline area of `applied ecology' are those where ecological knowledge and understanding are brought to bear on policy setting, decision making, and practice. The directions of the discipline are very much driven by the problems given priority by contemporary society, its governments and industry.

Some Iconic Examples

The scope of `applied ecology' is very broad indeed, possibly best illustrated by way of example. It is now widely accepted that the global climate is changing, that part of the cause is associated with industrial development, and that the impacts on human communities and the biota are potentially profound. Can we predict how natural ecosystems and the species they contain will respond, what have we done to constrain those responses (e.g., widespread fragmentation of habitat restricts range shifts), and what can we do to ameliorate the impacts of global climate change on the biota? It is in answering these questions that `applied ecology' complements climate change studies by meteorologists, geographers, and geologists in other disciplines more focused on studying the direct impacts of climate change on human society.

Land clearing for forestry, pastoralism, and agriculture and aquatic habitat destruction through land reclamation and water resource development are arguably the most serious threats to biodiversity today. The long-term consequences of such activity is often not realized at the time it is undertaken, and there is no good appreciation of how far the system can be pushed in meeting production goals before both ecological and economic sustainability are compromised. When land use and water resource development have overshot sustainable levels for production and for other land-use values such as biodiversity, what can be done to restore those values (restoration) or bring about change leading to an acceptable and sustainable condition (rehabilitation)? Both restoration and rehabilitation are important components of `applied ecology'.

Protected areas such as reserves and national parks make an important contribution to biodiversity conservation (**Fig. 1**), but are they adequate to sustain biodiversity in the long term? The overall goals are to conserve species, their genetic variability and potential to respond to environmental change, and the natural ecosystem processes that provide the ecological context in which they have evolved and continue to evolve. Protected area management, the inventory of values and selection of reserves, their design, and the management of threats to their values such as feral animals and weeds, fire management, impacts of human visitation are all topics addressed in part by `applied ecology'.

Globalized trade and associated movement of people and products leads inevitably to unwanted introduction of exotic species, some of which become established in the wild well outside their natural range. This is of major concern because feral populations can be reservoirs for disease that impacts on agricultural production. They can wreak havoc on native species through predation (stoats in New Zealand and foxes in Australia), competition (rabbits in Australia), or interference (zebra mussels in North America). Can we predict which species are most likely to establish, which are likely to cause the greatest impact, model the spread of exotic species when they arrive, and control their spread, distribution, and abundance in order to manage their impacts once they are established?

 doi:10.1016/B978-0-444-63768-0.00848-9

Fig. 1 Less than 1% of native temperate lowland grasslands of Australia remain intact, and that which remains is fragmented and under continual threat from agriculture, pastoralism and, in the Australian Capital Territory, urban expansion. Inset: The striped legless lizard (*Delma impas*), one of the many endangered species that rely on native grasslands. Photos: Sarah Sharp and Will Osborne.

These are examples of the broader societal context in which `applied ecology' does its work. The discipline is generally seen to add value to restoration ecology, habitat management and rehabilitation, management of invasive species (both native and exotic), conservation biology, wildlife utilization, protected area management, and agroecosystem management. The discipline also makes important contributions to environmental forensics, landscape architecture, ecotourism, and fisheries.

Foundation in the Fundamentals

The diversity of concepts drawn from ecology and applied in management of our natural resources is vast and stems from the multidisciplinary nature of natural resource management generally. In dealing with the impacts of climate change on the biota, for example, we need to know of the habitat requirements of species or `niche breadth', the extent of suitable habitat and connectivity that provides scope for `invasion' of new areas as the climate shifts. Coupled with this is the need to know of the limitations to their `physiological tolerances', their `dispersal capabilities' and the `demographic attributes' that will govern the speed of their response through range shifts. Many reptiles have temperature-dependent sex determination, and would appear appallingly vulnerable to climate change. What scope do they have to respond to climatic change, through `natural selection', which in part will depend on `genetic diversity' in the traits determining their `evolutionary responses' to changing climate. Will an evolutionary response be rapid enough? What scope do species have to respond through `phenotypic plasticity' rather than a direct evolutionary response. **Table 1** provides a link between fundamental ecological concepts, principles, and ideas, and the broad areas of application in `applied ecology'.

What Do Applied Ecologists Do?

Applied ecologists engage in their profession at a broader level than commonly recognized. On the spectrum of esoteric research (of no identifiable immediate relevance), through strategic research (of broad relevance) to tactical research (of immediate relevance), applied ecologists vary in their level of engagement. Some are practitioners at the coalface of application undertaking research in the immediate context of management problems, and addressing the immediate concerns of management. Their work is typically funded directly by resource management agencies or industry.

Others address research questions of more fundamental strategic value, in areas where improved knowledge, understanding, and techniques are likely to be of service in addressing contemporary problems as well as problems of the future, many of which are currently unforeseen. Their work is typically funded by research and development (R&D) organizations or by government agencies such as the US National Science Foundation, the Australian Research Council, the UK Natural Environment Research Council, or the NZ Marsden Scheme.

Application often draws support from unexpected quarters, and an important element of the development of the discipline of `applied ecology' is the need to provide tertiary education and research funding in a broad strategic context. There must not be too great a focus on immediate needs in funding applied ecological research, lest we risk passing by many opportunities to build the knowledge base from which solutions for the future can be drawn. At an individual level, it can be argued that to be a good applied ecologist, one must be a good ecologist with a broad research agenda, but also with a keen eye out for application and a willingness to engage in those applications when opportunities arise.

Table 1 Topics in `applied ecology' and concepts, ideas, and topics in ecology that are used in applied ecology

Topics in applied ecology	*Relavant ecological concepts, ideas, and topics*
Restoration ecology	Niche, succession, community dynamics, resilience
Habitat management and rehabilitation	Habitat selection, niche, community dynamics
Management of invasive species	Population dynamics, predator–prey relationships, competition, disease–host interactions, natural selection.
Conservation biology	Population dynamics, population genetics, population viability, biodiversity
Wildlife utilization	Population dynamics, sustained yield
Protected area management	Island biogeography, population viability, biodiversity, ecotones
Agroecosystem management	Competition, biodiversity, natural selection
Forensic sciences	Genetics, taxonomy
Landscape architecture	Connectivity, fragmentation, movements, metapopulations
Ecotourism	Population dynamics, thresholds, resilience
Fisheries	Population dynamics, sustained yield, food webs
Forestry	Population dynamics, sustained yield, demography
Urban development	Habitat, corridors
Ecosystem services	Nutrient cycling, biodiversity
Climate change	Niche, population dynamics
Pollution	Niche, assimilation, bioaccumulation, ecotoxicology
Energy generation and carbon management	Nutrient cycling, bioaccumulation
Water management	Niche, biodiversity assessment

Applied ecologists use one or more of the following approaches in conducting their science – observation, experimentation, and modeling. Any one study or topic may be studied and resolved using combinations of the approaches. For example, conservation of large kangaroos in Australia involves observational studies of kangaroo ecology – knowledge of reproductive cycles, diet, and behavior are all important to managing kangaroo populations. Experiments may be undertaken to explore causal relationships, perhaps involving exclosures and population manipulation to determine responses of vegetation, or to fine-tune survey and monitoring approaches. Modeling may be applied outside the scope of feasible experimentation to investigate the combined effects of environmental changes and human intervention on kangaroo populations as a tool to guide decision making. Some topics, such as large-scale climate change, can initially be studied by observation to quantify the changes that are or not occurring. Field experiments may be impossible, especially at large spatial scales, but small plot or laboratory experiments can provide useful information. Modeling provides a framework for integrating these observations and results of the limited experimentation that is possible to estimate likely changes in environmental conditions and responses by organisms to such changes. Future observations can be used to evaluate the accuracy of predictions of the modeling.

The mix of approaches that are used by applied ecologists is determined by their experience with each, the advantages and disadvantages of each including the costs, practicality, and the quality of data and hence the strength of conclusions obtained by each approach. For example, on the latter point, observations allow clear conclusions to be made about patterns in ecology. However experiments allow clearer conclusions about cause and effect in ecology; that is, about what causes changes in distribution and abundance of organisms compared with what changes have occurred. Modeling allows a great range of possible management actions or scenarios to be examined and a greater range than that can be examined by experiments. However the modeling results are hypothetical and require evaluation of their practical relevance.

Success through Communication and Engagement

Applied ecology measures its success in part by adoption of what it has to offer management. Successful adoption demands communication of results in a form that can be readily comprehended by resource managers and effectively brought to the table in policy setting and decision making (**Box 1**). There are a number of challenges to bring about effective communication.

The first challenge arises from the different cultural perspectives of scientist and manager. The core objective of a natural resource manager is to bring all available knowledge and understanding, scientific and otherwise, to bear on setting policy and making and implementing a decision. At the end of the process, the outcome is evaluated, and the decision confirmed as appropriate or not. For an ecologist, as a scientist, learning that the knowledge and understanding brought to the decision-making process was confirmed as appropriate is satisfying, but from the perspective of his/her discipline, it is potentially pedestrian. Science advances through failure, focuses on the causes of that failure, reevaluation of concepts and principles, collection of new data, and re-application. Managers want the problem solved – they get excited when it all goes well; scientists want to learn something new – they get excited when something unexpected happens. Lack of appreciation, and lack of reciprocal respect, for these differing perspectives can lead to breakdown in trust and with it, loss of communication.

Box 1 Melding ecological principles with urban planning

At the time of the first European settlement in Australia, lowland areas of southeastern Australia had one of the largest areas of native temperate grassland in the world. These grasslands are now among the most endangered natural communities in Australia (Fig. 1). The Australian Capital Territory (ACT) contains about 5% of the high-quality primary native grassland that occurred in the ACT prior to European settlement, home to a number of threatened animal species, including the legless lizard *Delma impar*, the mouthless moth *Synemon plana*, and the matchstick grasshopper *Keyacris scurra*. The expanding Australian capital city, Canberra, is placing continual and increasing pressure on these grasslands and presents city planners with the very great challenge of melding grassland conservation with the relentless expansion of suburban and rural urban development.

Planning for suburban development is a complex process, and planning decisions are made throughout the construction phase. Ecological theory is not in a form that can be used by urban planners, who continually need to assess the costs versus the benefits of planning decisions. Too often the cost–benefit analysis is driven entirely by financial considerations.

Applied ecologists were given the challenge of devising a set of principles that would govern the type and quality of ecological information brought to the planning process and that would enable planners to assess alternatives in the context of both financial and ecological considerations. The principles they devised are as follows.

1. Both regional and local objectives are required for conservation planning on the local scale.
2. Both species and functional communities need to be considered.
3. Knowledge of key life-history properties of species and dynamic processes within the ecological communities is essential for sound conservation planning.
4. Spatial scale is important when assessing the value of published knowledge of species and communities.
5. Common as well as rare species have a bearing on conservation planning.
6. The quality of available data and therefore its value to conservation planning, varies depending on its taxonomic and spatial resolution, seasonal biases, and temporal representation.
7. Areas considered for conservation should be those of the highest value for meeting local, regional, and national objectives.
8. Conservation value includes concepts of size (viability), diversity, representativeness, distinctiveness (rarity), and naturalness.
9. *Diversity*. Conservation areas that possess greater heterogeneity of environmental attributes (floristics, vegetation structure, abiotic components), within the bounds of those conditions known to support lowland grassland communities, are better than those that are largely homogeneous.
10. *Size*. Larger contiguous conservation zones are superior to smaller zones, or zones of equivalent size that are fragmented, all other considerations being equal.
11. *Shape*. Conservation zones that have a large area to perimeter ratio are better than those that are irregular in shape, elongated, or whose boundaries project into suboptimal habitat.
12. Replication of conservation areas in fragmented habitats is necessary as a hedge against catastrophic or stochastic local extinction.
13. Regional conservation planning based on remnants must consider the constraints and opportunities provided by the present and future land-use patterns.
14. Rehabilitation of fragmented habitats should be considered as a means of increasing overall size, buffering, and interconnection.
15. Integration of smaller systems within broader conservation systems increases their conservation value.
16. Consider alternative reserve structures in the light of constraints and opportunities provided by planned development.
17. Conservation zones are not isolated from external influences and careful consideration needs to be given to compatible adjacent land uses, and moderation of their impacts.
18. Include research-based management, monitoring and community participation.

Application of these principles led to the establishment of a series of outstanding urban native grassland reserves in the ACT, reserves that were established as an integral part of the planning and development of the new Gungahlin suburbs. For the applied ecologist, the exercise was communication of ecological principles in a form that could be readily adopted in the planning process, and engagement with planners in bringing about solutions to the challenges of conservation in an urban setting.

Adaptive management, that is, adopting an experimental approach to management intervention, provides a good framework in which scientists and natural managers can work together to achieve solutions to both management problems and advances in knowledge. Under this framework, management intervention is conducted in a rigorous experimental framework where the intervention is implemented as a scientific experiment. Due attention is paid to the fundamental tenets of experimental design and sampling – the use of temporal and spatial controls against which the effects of interventions can be measured, proper replication of experimental treatments, proper attention to sample unit selection and sample sizes. The management intervention occurs in the

context of a solid scientific foundation for the monitoring and evaluation that follows. The benefits of an experimental approach to management intervention are that the ecologists and natural resource managers are working together at all stages of the design and implementation of the intervention, the evaluation of the efficacy of the intervention is on a solid scientific footing and so the intervention can be recast in the light of the outcomes with confidence and, perhaps most importantly, knowledge is advanced both when the intervention is successful and when it is a failure. Adaptive management of natural resources is `applied ecology' at its best.

A second challenge faced in applying ecological knowledge to natural resource management is ensuring that all important information is available to management at the time of setting policy, making decisions, and putting policy into practice. Traditionally, communication of the results of ecological studies occurs in the presentation at learned conferences and by publication as scientific papers in leading journals such as the *Journal of Applied Ecology*, *Ecological Applications*, or *Biological Conservation*. While there have been efforts to better integrate scientists and natural resource managers into professional societies, the primary audience for these channels of communication remain ecologists and other scientists. The audience for refereed publications in journals is primarily comprised of applied ecologists and other scientists.

Many organizations responsible for natural resource management have limited in-house ecological capacity for accessing, evaluating, and adopting the results of research presented through formal scientific channels. This in turn can limit the information available to them at the time of making important decisions. Often, decisions are made on a very small base of available information and a limited network of trusted advisers. Many of the larger research organizations address the issue of broadening the base of information available to managers through the appointment of knowledge brokers – individuals employed and often placed within the natural resource agency whose sole responsibility is to broker exchange of management needs in one direction and ecological information in the other direction between managers and scientists, and to assist in providing that information in a useful form. Knowledge brokers and professional science communicators are also engaged to communicate the outcomes of science to the broader public through the media (television, radio, newspapers), community meetings, and websites of ecological associations. Knowledge brokers must have both scientific understanding and communication skills.

A third challenge is to bring ecologists, industry, and management together to build relationships, identify synergies, and achieve broad and lasting ownership over solutions to environmental problems. This is being addressed by governments in many developed countries by providing monetary incentives for science and industry to work together, placing conditions on industry and community participation in government-funded research, and establishing substantial cooperative research entities that bring industry, community groups, and researchers together in well-funded joint ventures. This has changed the face of `applied ecology', providing many more opportunities for ecologists to engage in research and application of immediate relevance to the economy and society.

Summary

In summary, `applied ecology' draws its strength from the commitment of ecologists to engage in the application of their science to natural resource management. The discipline relies upon a balance that maintains a strong commitment to broad enquiry going beyond the need for solutions to immediate problems at hand. Information important for solving the environmental challenges of the future will emerge from a broad base of fundamental ecological knowledge and understanding. The discipline also relies on effective communication between the diverse sectors responsible for bringing about effective action on the environment. Applied ecologists do not make policy or make decisions about how to manage the environment. Industry, government, and resource managers do that, and it is up to them to take or reject advice. Ecological knowledge and understanding must be brought to the table in a form that can be readily understood and adopted by industry, government, and management. The major challenge is for ecologists to recognize the contribution they can make to the triple bottom line of industry, and to decision making in government and nongovernment resource management agencies. Ecologists need to become and remain engaged in informing the process of policy formulation, decision making, and implementation by bringing the best-available science to the table. In a world where environmental challenges are increasing dramatically, responsible ecologists need to have a keen eye out for applications of their work and a commitment to engage with natural resource managers when opportunities to add value arise. This is applied ecology's *raison d'etre*.

Glossary

Biodiversity offsets Measurable conservation outcomes resulting from actions designed to compensate for adverse impacts arising from project development.
Endemism The ecological state of being unique to a particular geographic location.
Genetic diversity The variation in the amount of genetic information within and among individuals of a population, a species, an assemblage, or a community.
Intrinsic value The inherent worth of something, independent of its value to anyone or anything else.
Species diversity Biodiversity at the species level, often combining aspects of species richness, their relative abundance, and their dissimilarity.
Species richness The number of species within a given sample, community, or area.

Introduction

This standard definition of biodiversity implies a logical functional link between the three levels it comprises and could be articulated, qualitatively, as follows: the organisms that make up a population of a given species behave and respond to their environment as they do as a result of the features determined by their genetic constitution; the contingent of such individuals in a population or group of populations constitutes a species, and the collection of species in a given region are constituents of communities that, together with their physical environment, form the ecosystems, landscapes, and, ultimately, the biomes of the Earth.

Beyond the intraspecific, interspecific, and ecosystem diversity levels, the biodiversity of a given region can be manifested by these additional facets: (1) morphofunctional diversity, represented by the variety of life forms among plants or, its rough zoological equivalent, the diversity of functional groups among animals; (2) the concentration of endemic organisms, that is the cooccurrence of taxa (species, genera, families) with a restricted geographic distribution; and (3) the agrobiodiversity, best reflected by the variety of domesticated and cultivated plants and animals and their wild relatives. Next, we briefly review each of these biodiversity facets.

Morphofunctional diversity is seldom recognized as an important facet of biodiversity, although its relevance is ecologically and evolutionarily crucial, for it represents the amazing variety of responses organisms have evolved to deal with the environmental pressures of their habitats. The examples of Figs. 1 and 2 highlight this facet of biodiversity. The panel of plants (Fig. 1) includes a diversity of life forms depicting a selected variety of ways in which plants from desert ecosystems deal with the crucial limiting factor, water. Thus the panel includes (clockwise arrangement): cacti of several types (e.g., a sahuaro and an opuntia), shrubs with tiny or absent leaves (e.g., ocotillo and creosote bush), succulent rosette-like shrubs and treelets (e.g., agaves), arborescent palm-like plants (e.g., yuccas), and ephemeral annual plants (e.g., dahlia). Such life-form diversity can be astonishing. For example, a description of the floristic diversity of Mexican desert ecosystems included 32 readily distinguishable life forms. The animal example of Fig. 2 shows the diversity of morphofunctional groups among one single group of mammals, bats, depicting the variety of evolutionary routes these animals have developed to solve the challenge of finding and using their food resources, including, clockwise in the diagram, fruit-feeding (e.g., *Artibeus*), nectar-feeding (e.g., *Choeroniscus*), blood-feeding (e.g., *Desmodus*), and insect-feeding (e.g., *Lonchorrhina*) bats. The diversity of adaptations to such variety of feeding habits is dramatically displayed in Fig. 2 by the variations in the animals' heads.

☆*Change History:* March 2018. H. R. Pethybridge included glossary, keywords, extended text and updated references.

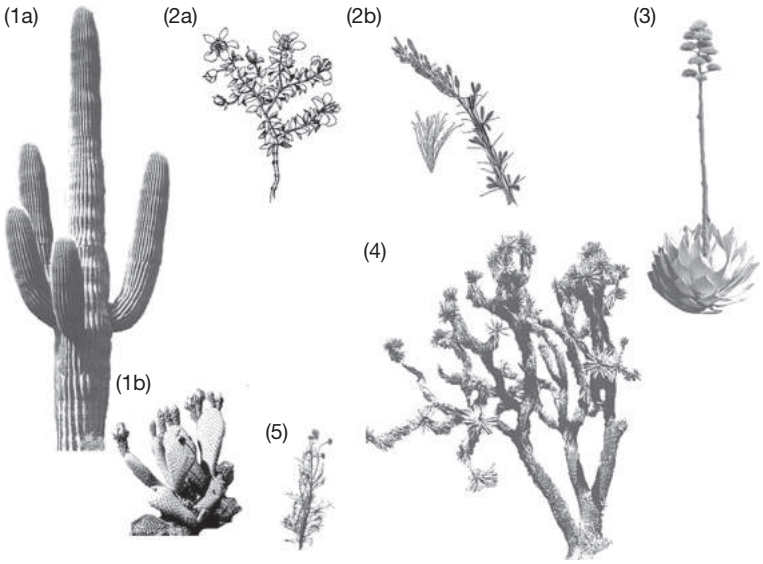

Fig. 1 Biodiversity expressed as the variety of plant life forms that can be found in a desert. Life forms include: (1A) columnar and (1B) prickly pear cacti; (2A) creosote bush and (2B) ocotillo shrub; (3) succulent rosette-like agave (with reproductive structure); (4) palm-like yucca (Joshua tree); and (5) annual herb (dahlia).

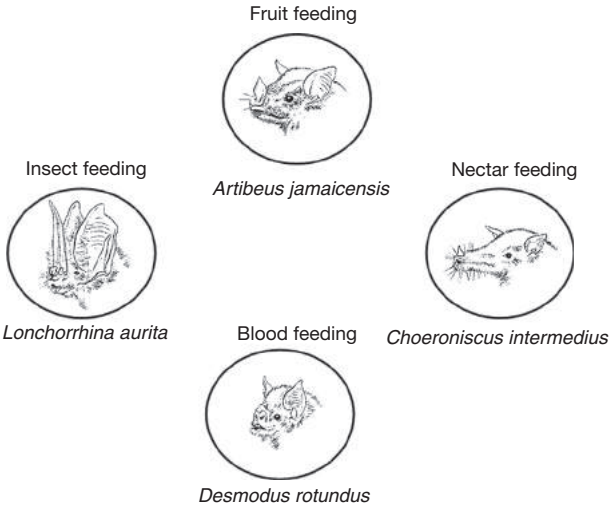

Fig. 2 Diversity of bat feeding habits. Head characteristics reflect functional attributes required to exploit specific feeding sources. For example, the very large ears and nose-leaf of Lonchorrhina aurita are associated to sensorial capacity needed to prey on flying insects. In *Choeroniscus intermedius*, the long snout and a long tongue allow reaching nectar at the base of flower tubes.

The concentration of taxa in a given geographical region, evolved and found nowhere else on the planet, that is, the concentration of endemisms, is an important facet of biodiversity, not only from the biogeographical (the geographic distribution of taxa) and evolutionary (the fact that they frequently represent evolutionary novelties) points of view, but also because regions of high levels of endemism become a priority in biodiversity conservation. This is because the alteration or destruction of regions with high concentrations of endemism (the so-called hot spots), would bring about the irreplaceable loss of unique products of evolution. Endemism can be expressed at different levels: species, genera, families, orders, or even phyla can be endemic to a given region. In Fig. 3, we show the restricted distribution of a pair of pine species (*Pinus* spp.) endemic to Mexico. These species, restricted to temperate forests of that region, evolved in situ and have not been found in other temperate forests of the globe, apart from those shown in the map. Furthermore, both species contrast in its range of distribution within the country. Populations of *Pinus herrerae* can be found along the mountains of western Sierra Madre and the Trans-Mexican Volcanic Belt, while *P. nelsonii* is restricted to a small arid area in north-east Mexico.

Agrobiodiversity is represented by the cultivated and domesticated plants and animals present in a given region; this facet includes as well the wild relatives from which traditional indigenous cultures have selected the forms adapted to the environments

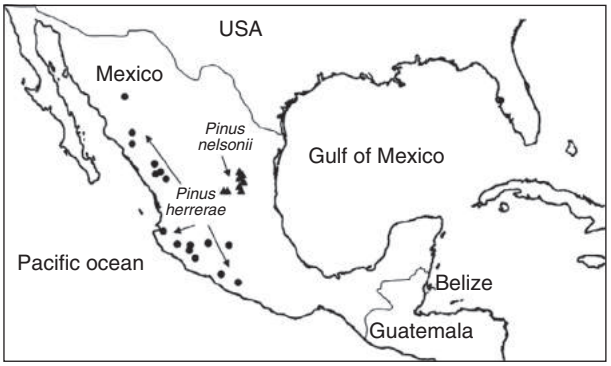

Fig. 3 Two contrasting levels of endemism illustrated by species in the genus *Pinus* within the territory of Mexico. While *P. herrerae* is distributed on the mountains of the western Sierra Madre and the Trans-Mexican Volcanic Belt, but cannot be found in any other country, *P. nelsonii* is restricted to an area of a few square kilometers in the arid lands of northwestern Mexico.

in which they are cultivated or propagated to satisfy diverse human needs. Although this facet of biodiversity represents a minor fraction of the global contingent of species of plants and animals, its importance is crucial, as it represents the vast majority of the food we consume. Agrobiodiversity emerges from the combination of two factors: availability of biodiversity in terms of the wild relatives, and the application of traditional management and knowledge leading to domestication. (Thus this facet of biodiversity includes also cultural diversity and traditional knowledge.) In the case of plants, this has determined the existence of a few regions of the world, popularly known as the Vavilovian domestication centers, or agrobiodiversity centers (Fig. 4). This handful of centers of origin and domestication of plant crops has contributed significantly to human development and wellbeing and, in addition, such centers are areas of great concern from the biodiversity conservation perspective. Among the roughly 2500 crop species, just 103 supply over 90% of the calories humans consume, directly or indirectly, and just three grasses (cereals), rice, wheat, and maize, supply about 60% of the total. In addition, some 15 plants are cultivated as sources of fiber, and thousands more are used as ornamentals or sources of medicines. Agrobiodiversity also illustrates intraspecific or genetic diversity. We do know that most crops are genetically diverse, including many land races that exist in the major cereals and crops such as bananas, cassava, potatoes, and tomatoes. Likewise, cabbage, cauliflowers, broccoli, kohlrabi, brussels sprouts, calabrese, and kale are all selected variants of *Brassica oleracea*. In the case of animals, from the approximately 50,000 described vertebrate species, 30–40 species of birds and mammals have been domesticated; a few of them have a global distribution (except for the Antarctic) and are extremely abundant: cattle (1300 million), sheep (1200 million), pigs (850 million), and chickens (10 billion). Again, the degree of intraspecific variation in animals is impressive, including about 800 distinct breeds each of cattle and sheep.

In summary, biodiversity is a very inclusive concept, involving several facets and levels of organization. Nevertheless, the level of species is the one that has received the greatest attention. Yet, as we describe in the next sections, even at this level our global knowledge is still limited.

Metrics of Biodiversity

The most commonly used method to describe the biodiversity occurring in a particular locality is based on the enumeration of the species present therein. This metric is known as species richness (S). The enumeration of the total number of species present in most habitats is a formidable task. For example, it has been suggested by a team of British ecologists that recording the total number of species in a single hectare of tropical forest would require employing up to 20% of the 7000 systematics active worldwide. Even when aimed at more specific groups (e.g., plants or insects), quantification of species richness might still be problematic if the group under inspection is particularly speciose, its taxonomy is poorly known, or is hard to survey in the field. Therefore, most of the characterizations of S are based on sampling protocols and the inferences that can be drawn from them. Here we provide an example of sampling to assess S.

An increasingly popular analytical procedure is that of species accumulation curves. These curves depict how species richness accumulate with increased sampling effort, as shown in Fig. 5, based on plant species recorded in ten 50 m 2 m transects established in the understory of a rain forest site in southeast Mexico. The survey included only woody plants of <1.5 m height, to assess the forest's regeneration potential, and was performed in homogeneous habitat (i.e., not including microtopographic variations such as ravines, river beds, or flooded areas; this would likely bring about different sets of species). Species richness associated with any given number of transects (sampling effort: two, three, up to ten) is represented as a mean value that was calculated using, in a random sequence, the entire set of the ten transects. Thus a sampling effort of two transects shows the mean of all possible combinations of two transects, and so on, up to a predetermined limit of 100 combinations. In this example, S was calculated applying an estimator that takes into account the relative representation of rare species, that is those represented by a single individual ("singletons"), and those represented by at least two individuals ("double-tons"). The ratio of singletons and doubletons will determine to what extent the observed number of species needs to be increased to estimate S. When such a ratio is zero, the

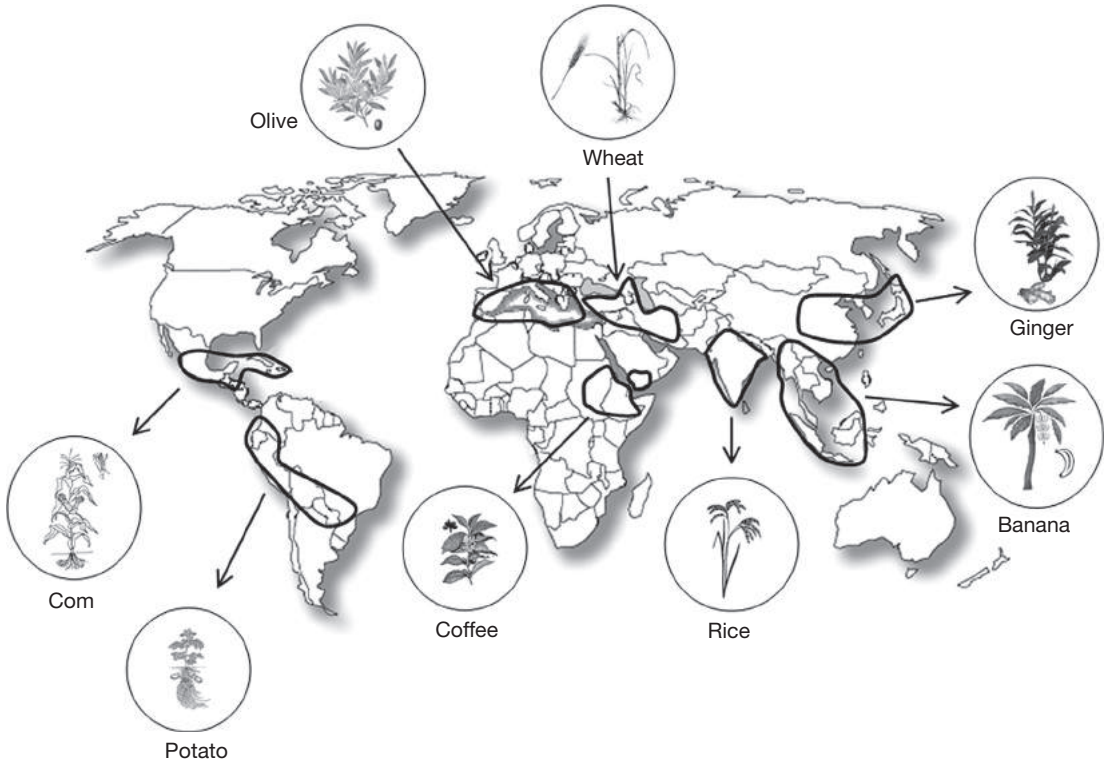

Fig. 4 The Vavilovian centers where traditional knowledge and human intervention on wild plants led to the origin of some of the most important crops.

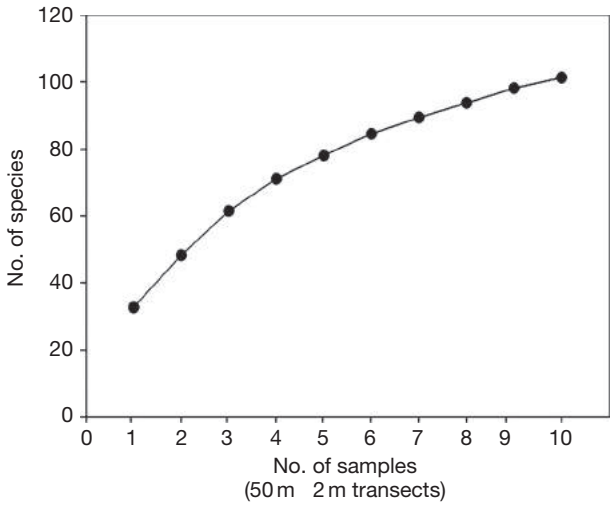

Fig. 5 Species accumulation curve derived from plant species sampled in ten independent transects established in rainforest understory in southeast Mexico. Each point is an estimate of the number of species expected for a given sampling effort (i.e., number of transects). As sampling effort increases, the slope of the curve becomes shallower, indicating that species inventory is approaching completeness (i.e., lesser new species are being added).

number of observed species can be considered to represent a complete inventory of species. The graph shows that at this site the estimated number of plant species in the understory habitat of the rainforest, based on the sampling effort of ten transects, is close to 110 and the rate of accumulation of additional species, as sampling effort increases, is very low. This approach, in addition to providing a trend of species accumulation (S), gives an idea of the completeness of the species inventory, whereby the shallower the slope of the curve at its right extreme, the lower the number of new species expected to be added with additional sampling. In this particular case, the known number of species in the understory microhabitat in this forest is close to the estimated value.

When information on species relative abundance is also available, more revealing descriptions of diversity can be undertaken by considering the distribution of individuals among species. One example of a common approach is the use of rank–abundance plots, also known as dominance–diversity curves (Fig. 6). In this type of plot, species are plotted in an increasing ranking sequence, from

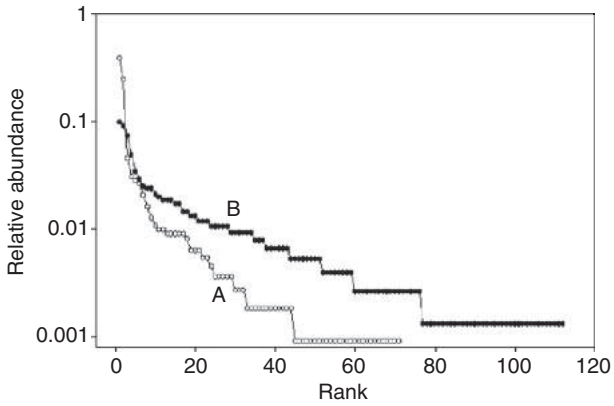

Fig. 6 Dominance–diversity curve comparing species richness and abundance of plant species sampled in two rainforest sites in southeast Mexico. Each species (represented by one circle) is ranked according to its abundance from more abundant (left) to less abundant (right) along the *x*-axis. Site B presents a more diverse species assemblage than Site A both in term of richness and in terms of the equitability in which individuals are distributed among species.

left to right on the *x*-axis, according to their abundance (far left the most abundant, far right the rarest). Proportional abundance is displayed on the *y*-axis using $\log_{10}$ scale, so that the resulting curve reflects the hierarchical distribution of abundances across species. Therefore, dominance/abundance plots readily display species equitability and comparisons among species assemblages with different species richness and equitabilities are easily accomplished. Fig. 6 shows the dominance/diversity curves for two tropical rainforest understory sites, A with 71 species, and B with 112 species (each species represented by open and closed circles, respectively). The plot highlights that while in Site A only a few species are clearly abundant, monopolizing a considerable proportion of the dominance (biologically interpreted as monopolization of the available resources), in Site B species are more evenly distributed. The contrast between Sites A and B shows that, in addition to the difference in the number of species, those of Site A are less equitably distributed than in Site B. Ecologists embrace the notion of equitability and use a metric to define it, evenness, with the implication that, complementary to species richness, the greater the evenness of a site, the greater its ecological diversity. The underlying idea is that if one (or few) species dominate the species assemblage, the community is not very diverse ("too much of the same"), whereas if no species dominate, the community is probably more diverse. Imagine these species represent prey of a predator looking for diversity of food resources in these two communities. Clearly the latter would appear as more diverse than the former to the predator.

The interest of having a synthetic measure of diversity based on the combination of two of its most distinctive attributes, species richness and species relative abundance, has favored the development of a wide variety of so-called diversity indices. These indices are sensitive to the number of species recorded but also to how contrasting their abundances are. Different indices are more or less sensitive to the characteristics of the data used for their calculation. For example, some indices are sensitive to variations in sample size while others are not. In addition, some diversity indices give greater weight to species richness (e.g., the Shannon–Wiener index) and others to the dominance of the commonest species (e.g., the Simpson index). Simpson's index assesses the probability that any two individuals taken at random from a community will belong to different species. It is easy to imagine how such probability would be high in a tropical forest in which tree species diversity is very high, compared to a low probability in a boreal forest where most trees belong to the same species.

In order to illustrate the importance of evenness, Box 1 shows the procedure to calculate the Simpson index ($1/D$) to compare the diversity of two hypothetical bird communities. The first step is to multiply the number of individuals in each species (n_i) by its frequency minus one ($n_i - 1$). The resulting products ($n_i\,(n_i - 1)$) are then divided by the product of the total number of individuals recorded (N) by $N - 1$. Finally, the resulting ratios ($n_i\,(n_i - 1)/N\,(N - 1)$) are added up over all the species to calculate D. The Simpson index is expressed as the inverse of D (i.e., $1/D$), in order to obtain increasing values of the index with increasing diversity. In the example presented in Box 1, Site 1 is about two times more diverse than Site 2, despite the fact that both sites have the same species richness ($S¼\ 8$). Differences in the relative abundance of species can be further examined by calculating the associated evenness index ($E_{1/D}$) that results from dividing the observed index by the maximum diversity, that is, when all species are represented by the same number of individuals. The $E_{1/D}$ values show that the bird assemblage of Site 1 is considerably more "even" that that of Site 2. This is consistent with the fact that the most abundant species of Site 2 accounts for 59% of all individuals in the assemblage (high dominance), while the most abundant species of Site 1 only represents 20% of the total.

The development of new methods to analyze and characterize diversity is a very active field of research. Environmental DNA (or DNA metabarcoding) in particular is an emerging tool for detection of animal species, and thus in monitoring past and present biodiversity. Recent approaches try to combine taxonomic and functional species traits with traditional information on species richness and abundance to generate more comprehensive descriptions of diversity. This may allow distinguishing between localities, even when they have the same number of species and similar species–abundance distributions. For example, if species in one locality belong to a few genera and species in a second locality span over a more ample variety of genera, the latter would be

Box 1

A hypothetical example showing how the distribution of individuals among species changes the diversity of bird assemblages occurring in two sites. Although the two sites have the same number of species, the more even distribution of individuals among species at Site 1 leads to a higher Simpson diversity index and evenness than at Site 2 (see text for details).

considered as more diverse. A similar situation would occur if species in one locality show a greater variety of functional roles (e.g., animal feeding guilds or plant life forms) than the species in the other locality. In sum, the ample variety of ways biodiversity manifests itself, calls for a diversity of criteria to characterize it.

Spatial Scales of Diversity

An essential aspect of biodiversity is that species contingents vary in their spatial distribution, sometimes abruptly, making it necessary to explicitly consider the spatial scale at which diversity is being analyzed. Fig. 7 depicts a simple representation of the different levels of spatial scale at which diversity can be analyzed, portraying a nested scheme of distribution of diversity, scaling up from homogeneous habitats (that we will refer to as localities in this exercise), nested within regions, which in turn are nested within a larger biogeographic region or province. In this scheme, the most basic, local measure of diversity is alpha diversity, which consists of the number of species recorded within a given locality.

In the four localities depicted in Fig. 7, diversity is the same: each locality contains three different species. However, the identity of each of the species in each of the contingents varies from locality to locality. That is, there is a high turnover of species as we move from one locality to another. Ecologists and conservation biologists use the term beta diversity to refer to species turnover. At the larger spatial scale of the region, we observe that the high turnover of species within each region determines a high level of regional diversity, corresponding to a high gamma diversity. Finally, given the high species turnover between regions, the overall biogeographic region exhibits a high delta diversity. It is worth noticing that the specific definitions of locality, region, or biogeographic region are somewhat subjective and vary with the investigator. In any case, the importance of the spatial scales of distribution of diversity for conservation can hardly be overemphasized: if a country, region, or biome is composed of a mosaic of localities of high diversity with a high species turnover (diversity), the protection of the country's biodiversity will demand the establishment of many preserves probably of different types, rather than a few or a single one, even of relatively large size.

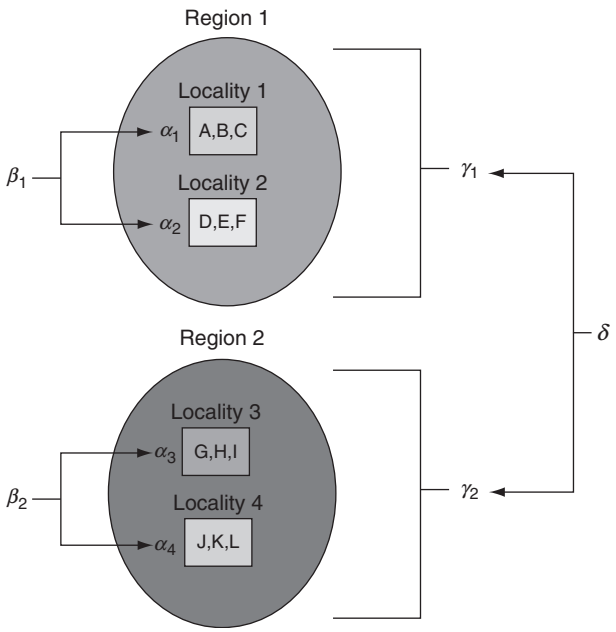

Fig. 7 Schematic representation of the different spatial scales at which diversity can be analyzed. The identity of the species found at each locality (diversity) changes (i.e., species turnover) across localities (diversity). The combination of and diversity makes up the diversity found at the regional level (diversity). Similarly, when moving between regions, a turnover in the species identity occurs (diversity).

Time Course of Biodiversity Through Geological Time

Our knowledge of the patterns of change of biological diversity through geologic time is mainly based on the information contained in the fossil record. The available fossil evidence suggests that the diversity of families of multicellular marine organisms (Fig. 8) rose steadily through the Cambrian and Ordovician period, attaining a plateau about 440 million years ago and then was punctuated by a great wave of extinction in the Permian (290–245 million years ago). After this, it steadily increased to the present.

Terrestrial organisms first appeared about 440 million years ago, with the invasion of the land by the ancestors of plants, fungi, vertebrate animals, and arthropods. In this period, each group increased rapidly in diversity from that time onward. At the species level, terrestrial vascular plants began to diversify markedly around 400 million years ago and declined during the worldwide Permian extinction event that also affected marine organisms profoundly. After this, similar to marine organisms, plants began to diversify around the Mid-Cretaceous Period, some 100 million years ago, with the flowering plants (angiosperms) becoming an extremely diverse and dominant group up to the present.

Thus the fossil records of both marine and terrestrial multicellular eukaryotes indicate maximum diversity at more likely than old rocks to be well preserved, and thus the most recent occurrences of species are more likely to be found than the older occurrences. On the other hand, a considerable fraction of the recent marine faunas are known from a few, restricted localities. Although paleontologists have amassed an impressive amount of information and analyzed it with sophisticated statistical methods, the patterns emerging from these analyses, although exciting and compelling, are still in need of further confirmatory work.

Global Magnitude of Biodiversity

Our understanding of the global magnitude of biodiversity, even considering the level for which we have the best information, species, is still very limited. Complete catalogs of the described, valid species exist for only a few groups of organisms, and the total can only be estimated. This figure is estimated to be around 1.5 million and includes exclusively eukaryotic organisms (basically

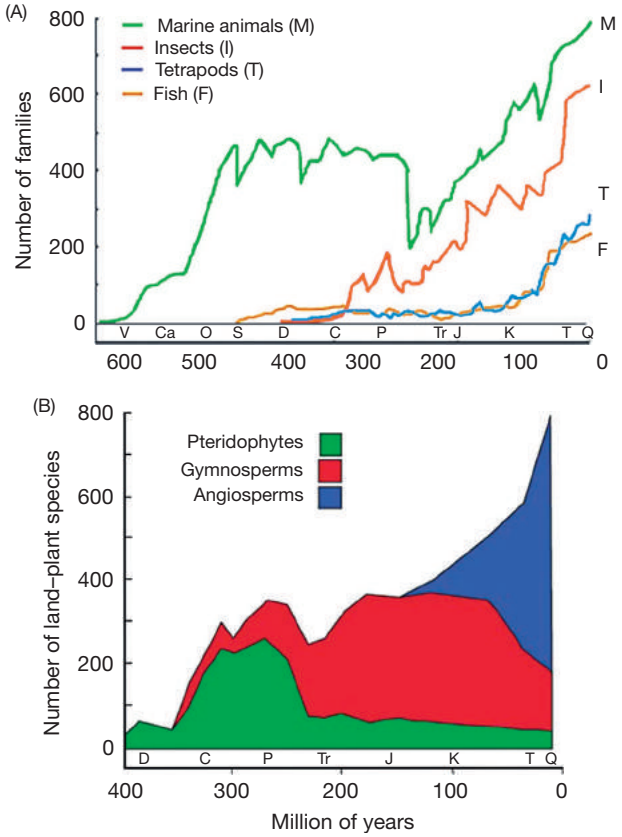

Fig. 8 Time course of (A) the number of families of marine animals, insects, tetrapods, and fish through the last 600 million years and (B) the number of land–plant fossil species in three major groups (angiosperms, gymnosperms, and pteridophytes) through the last 400 million years. *V*, Vendian; *Ca*, Cambrian; *O*, Ordovician; *S*, Silurian; *D*, Devonian; *C*, Carboniferous; *P*, Permian; *Tr*, Triassic; *J*, Jurassic; *K*, Cretaceous; *T*, Tertiary; and *Q*, Quaternary. plants, some groups of animals, and some fungi). The number and definition of prokaryotic species and viruses are still very limited. It is not surprising, therefore, that current estimates of the total number of species in the world span over 2 orders of magnitude (10^6–10^8). Methods employed to estimate global diversity can be classified in three broad categories: (1) ratios of known to unknown groups, (2) extrapolation from samples, and expert opinions by scientists who understand the level of diversity in a particular group of organisms well, or combinations thereof. An example of the first approach is the estimation carried out by ecologists Nigel Stork and Kevin Gaston in 1990. They first noted that the ratio of the number of species of butterflies to all species of insects on the well-known British fauna is 67:22,000. Assuming that such a relationship was robust overall, and based on an estimate of 15,000–20,000 species of butterflies world-wide, they scaled up to a total figure between 4.9 and 6.6 million species of insects. The second approach is illustrated by the study carried out by entomologist Terry Erwin at a rainforest site in Panama. Erwin performed a systematic sampling using a fogging protocol targeted on the beetle fauna living in the canopy of the tree *Luehea seemannii*. Based on the magnitude of the fauna collected and using a series of assumed relationships involving the ratio between beetles and other types of arthropod species, the degree of host specificity of arthropods, and the expected number of tree species to be found in the Tropics, Erwin came up with the astounding estimate of 30 million species of tropical arthropods. Robert May attempted an estimate based on the known relationship between body-size category and number of species of animals. Assuming that such relationship holds for individuals as small as 0.2 mm, May calculated that there might be about 10 million species of animals. All these estimations are based on a series of assumptions that await confirmation. However, there is some level of agreement that the plausible number of global species falls within a range of 5–15 million and a recent review suggests a best guess of around 7 million species.

Yet, new species are continuously described sometimes as a consequence of refinements in the taxonomic classifications but commonly as the result of real discoveries from surveys in nature. Current rates of publication of new species are significant, including some 13,000 animal species per year. This makes it evident that the task of describing the total number of species on Earth will not be completed for many decades, even assuming they can all be collected and analyzed by the appropriate experts before they go extinct due to anthropogenic impact. These discoveries are not restricted to small-sized organisms but also include species of large mammals such as monkeys and deer. Even more, exploration of remote areas sometimes results in the discovery of organisms that generate a biodiversity revolution because of their degree of biological novelty. Examples of this are the plant *Lacandonia schismatica*, found two decades ago in southeast Mexico. This plant was found to belong into an entirely new taxonomic family (Lacandonianceae), due to its spectacular characteristics, including that it presents its reproductive organs with a spatial disposition the other way around from any other known flowering plant: male structures toward the center of the flowers and female structures at the periphery! Equally spectacular as taxonomic novelty is the discovery, a few years ago, of an insect in Africa that combines characteristics of a cricket and a stick insect, so different to any other insect that it required the creation of a new taxonomic order (Mantophasmatodea). All these discoveries underscore the level of uncertainty we have about the magnitude of biodiversity. This uncertainty becomes more striking when we take into consideration that species richness is only one facet of biodiversity, as discussed earlier.

Geographic Distribution of Biodiversity

Among the many trends known about the geographic distributional patterns of biodiversity, the most evident is that of the increase in species diversity with latitude. This trend is consistent across many groups of organisms that have been well analyzed. Among insects this pattern is spectacular. For example, the number of species of ants in local regions increases from about 10 at latitude of 60 N, to some 2000 at latitudes near the equator. Fig. 9 highlights the case of plants and a representative group of vertebrates, birds. In both cases, the upper bound limit of species richness shows a dramatic peak at lower latitudes. In the case of plants, different analyses (e.g., local or regional floras, species density comparisons, standardized diversity samples, etc.) show a very consistent gradient of decrease in plant species diversity with latitude. In broad geographic terms, species densities range from over 5000 species/10,000 km^2 in tropical regions, to <100 in the highest latitudes. In terms of local species diversity, values range from an average of 270 species per 0.1 ha in Colombia to *c*. 15 near the United States–Canada border. Breeding birds increase from about 56 species in Greenland, to 105 in New York, to 1010 in Mexico, to 1395 in Colombia.

Another increasingly evident pattern of geographic variation in diversity has to do with intercontinental variation, specifically the patterns comparing the Neotropics (i.e., the tropics of the New World) with the Paleotropics. Data indicate that about 90,000 species of plants, approximately twice as many as in Africa, south of the Sahara, occur in the Neotropics and that the comparable area of Asia is roughly intermediate in this respect. Fogging sampling techniques using standardized protocols to compare data for canopy beetles (e.g., in terms of species per cubic meter) show the same tendency, although the values are even more contrasting than in the case of plants: 1.17 in Panama and 1.15 in Peru >0.29 in New Guinea >0.02 in Australia and Sulawesi. Similar trends have been observed in numerous other groups, including butterflies (Neotropics > Southeast Asia > Africa), frogs (Neotropics > Africa/Asia > Papua/Australia), and birds (Neotropics > Africa > Asia/Pacific > Australo-papuan). In mammals, the number depends on the particular group; specious groups such as bats are considerably more diverse in the Neotropics than in the Old World, while some groups with relatively few species in general, such as primates, show the opposite trend: Old World > New World.

Fig. 9 Gradients of latitudinal variation in species richness for birds (left) and plants (right). For both groups, species concentrates toward the Tropics peaking around the equator. The data for plants correspond to the number of species per 0.1 ha in different localities of the Western Hemisphere. The number of bird species is standardized per unit of sampling effort in different localities of the world.

Valuation of Biodiversity

The value of biodiversity has been considered from several points of view which can be classified in the following three broad categories: (1) esthetic, (2) ethical, and (3) economic. The esthetic point of view posits the idea that biodiversity includes a wealth of expressions of beauty equivalent to those found in the most esteemed collections of art work. Such an array of beauties ranges from vividly colored beetles and butterflies to whales and ancient forests. Moreover, these expressions of beauty are the result of very long evolutionary processes that exceed by far the age of the most ancient artwork.

The ethical point of view rests on the idea that biodiversity, by itself, has an intrinsic value. This point of view has its roots in philosophical beliefs and considerations that give other forms of life the same rights to exist and meet their needs as humans. This idea is complemented by the notion that *Homo sapiens*, the species currently monopolizing a large share of the energy and resources that support life on Earth, has the ethical responsibility to secure the preservation of other forms of life.

Economics criteria argue that biodiversity provides humanity with monetary revenues directly and indirectly. A classic example of a direct profit coming from biodiversity is illustrated by the variety of chemical compounds obtained from plants, animals, and microorganisms that function as a base for the active ingredients used in a large proportion of the available prescription drugs (e.g., digitalis, morphine, quinine, and antibiotics). In comparison, the notion of indirect profits of biodiversity rests in the realization that several organisms maintain and regulate processes that impact the quality of human life. For example, organisms inhabiting soil (e.g., earthworms and insects) are crucial for maintaining fertility and henceforth allow the growth of crops and forests. Another example is the case of plant pollinators. An important number of crops depend on the "service" provided by wild pollinators. Efforts have been focused to estimate the economical cost that the loss of such ecological services might involve. In the case of pollination by native insects in the United States, a study estimated that the ecological service they provide is worth $3.07 billion per year.

Recent interest in biodiversity valuation has increased in response to the threats it is facing. In this regard, the different criteria we presented have more or less potential to play a role in increasing the awareness about the relevance of conserving biodiversity. Esthetic appreciation of biodiversity has the caveat that it is, in some sense, biased toward the small subset of species that are considered "charismatic" such as whales or birds. Ethical considerations offer the most comprehensive valuation of biodiversity; however, it seems difficult that this type of philosophy will become internalized by a significant proportion of the humanity in the short term. Finally, the economic arguments are compelling and constitute a more tractable argument within the framework of formal markets. However, there are still a reduced number of cases where it has been possible to document with detail the economical value of the services provided by biodiversity. In the end, it is worth keeping in mind that the level of interrelatedness biological systems usually show, determines that the existence of charismatic, economical, or functionally valuable species depends on the maintenance of an unknown number of associated species and ecological processes.

An appealing approach, related to the three arguments referred to above, is that formulated by the Millennium Ecosystem Assessment (MEA). As a large coalition of international conservation and development organizations, governments, and a significant representation of the scientific international community, the MEA has compiled the most thorough assessment of the state of the planet's ecosystems, emphasizing the goods and services they provide, and the likely effects of potential pathways of human economic development on the provisioning of such goods and services (scenarios) and the interrelations thereof with human well-being. We can summarize the logic of the relationships articulated by the MEA, in brief, as follows: biodiversity, represented by the genes, populations, species communities, and biomes, generates a series of supporting services resulting from

ecosystem functioning. Such services, including primary production, nutrient cycling, and soil formation, are the basis for all other ecosystem services. The latter services belong to three major categories: (1) provisioning services, that is, products obtained from ecosystems, including food, fresh water, fuel wood, fiber, biochemical compounds, and a plethora of other genetic resources; (2) regulating services, those that produce benefits obtained from the regulation of ecosystem processes (e.g., climatic regulation, disease regulation, water regulation, air purification, pollination services, biological control); and (3) cultural services, the nonmaterial benefits obtained from ecosystems. These include the esthetic, inspirational, religious, and spiritual values offered by nature, recreation and tourism, educational services, and cultural heritages. The provisioning of such services impinges on human well-being in terms of affording basic materials for a dignified life, health, security, and good social relations. It is hoped that the framework of and the information summarized in the MEA, together with the formulation of future scenarios depending on different routes of economic development, will be used to guide policy regionally and globally. From a more ecological point of view, another interesting derivation of the MEA is that it can provide the framework to focus on the relevant research addressing the connections between biodiversity conservation and ecosystem services, and the influence of biodiversity on human well-being and vice versa.

Biomass

RA Houghton, Woods Hole Research Center, Falmouth, MA, USA

Definition

Biomass refers to the mass of living organisms, including plants, animals, and microorganisms, or, from a biochemical perspective, cellulose, lignin, sugars, fats, and proteins. Biomass includes both the above- and belowground tissues of plants, for example, leaves, twigs, branches, boles, as well as roots of trees and rhizomes of grasses. Biomass is often reported as a mass per unit area ($g\,m^{-2}$ or $Mg\,ha^{-1}$) and usually as dry weight (water removed by drying). Unless otherwise specified, biomass usually includes only living material. For example, neither deadwood nor the organic matter of soils is considered biomass, although soils do contain biomass in the form of bacteria, fungi, and meiofauna. Generally, the biomass of soils (living and dead microbes) is $<5\%$ of soil organic matter.

This article deals almost exclusively with terrestrial biomass and particularly with the biomass of plants. Forests account for 70%–90% of terrestrial biomass, most of this biomass in trees. The distribution of terrestrial biomass among producers, consumers, and microbes is *c.* 0.90%, 0.001%, and 0.10%, globally, with considerable variation among ecosystems. Producers and microbes, for example, may account for similar fractions of biomass in some nonforest ecosystems. The estimates given here refer to the biomass of plants, or producers, only.

Importance

The biomass of plants is of interest for at least three reasons: ecosystem structure, timber, and carbon stocks. Biomass determines the structure of ecosystems. Terrestrial ecosystems generally have more biomass than aquatic ecosystems (compare trees with phytoplankton), and forests have a higher biomass than other types of ecosystems. As a result of the greater physical complexity in the distribution of this biomass, forests also provide a greater diversity of habitats.

The biomass of forests is particularly important as a source of wood for timber and pulp, and forests are managed to optimize production of wood. It is worth noting that the `production' of wood is not the same as the standing stock or amount of wood. Mature forests, for example, have high stocks of wood (high biomass), but `woody grasses' (e.g., sugar cane, bamboo, switchgrass) may be more productive of biomass and thus are receiving attention as potential biomass fuels.

A third reason for interest in biomass is that on a dry weight basis it is 50% carbon. Reductions in biomass through the clearing of forests for croplands, for example, release carbon (as CO_2) to the atmosphere, and reforestation withdraws carbon from the atmosphere. Reducing deforestation and increasing biomass (carbon sequestration – both terrestrial and oceanic) are both options important for managing carbon, and, thereby, the rate of climatic disruption.

Quantities of Biomass

The quantity of biomass per unit area varies spatially and temporally. Living biomass ranges over 2–3 orders of magnitude, from averages of $\sim 400\,Mg\,ha^{-1}$ in tropical forests to averages of less than $10\,Mg\,ha^{-1}$ in treeless grasslands, croplands, and deserts (**Table 1**). Biomass also varies considerably within ecosystem types. Some tropical forests and forests of the Pacific Northwest in North America may attain values in excess of $600\,Mg\,ha^{-1}$. In part this variability results from differences in environment (e.g., soil nutrients or the seasonal distribution of precipitation), and in part it results from disturbance and recovery. A recently burned forest has a living biomass of nearly zero, and as it recovers it reaccumulates carbon (**Fig. 1**). Forests do not accumulate biomass indefinitely, however, because stand-replacing disturbances keep turning old forests into young ones.

Most of the biomass in forests is in the stems, or boles, of trees, with branches, roots, and foliage accounting for lesser fractions. The fractions vary with growth, however. As forests grow larger, a greater and greater fraction of total biomass occurs in boles.

The estimation of forest biomass depends, in part, on spatial scale. At the level of a forest stand, biomass varies through time as a result of disturbances (and recovery). At the landscape scale, biomass varies through space because the ages (since the last disturbance) of patches vary across the landscape. **Fig. 2** shows the ages of forest stands in a $\sim 450\,km^2$ area in the province of Krasnoyarsk, Russia. The remarkable feature of this landscape is the degree to which the forest is a mosaic of different aged stands. The spatial variability in biomass is much greater than it appears from observations of the canopy from the air or from space and suggests that most forests are in the process of recovering from natural or human-induced disturbances.

The estimates of biomass shown in **Table 1** suggest a global total of ~ 1300 Mg, and forests account for more than 80% of that total. But the uncertainty is high. Another estimate suggests a global terrestrial biomass of only 770 Mg (see below).

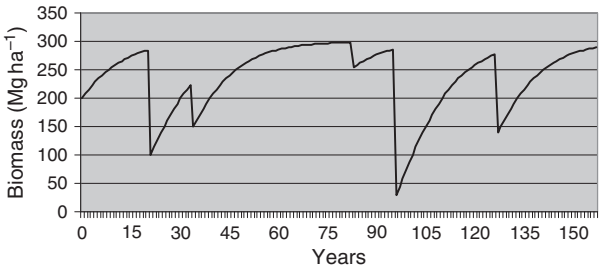

Fig. 1 Changes in the living biomass of a forest (Mg ha^{-1}) in response to disturbances (e.g., fire or logging) and recovery. Each disturbance removes living biomass, which subsequently reaccumulates as a consequence of growth.

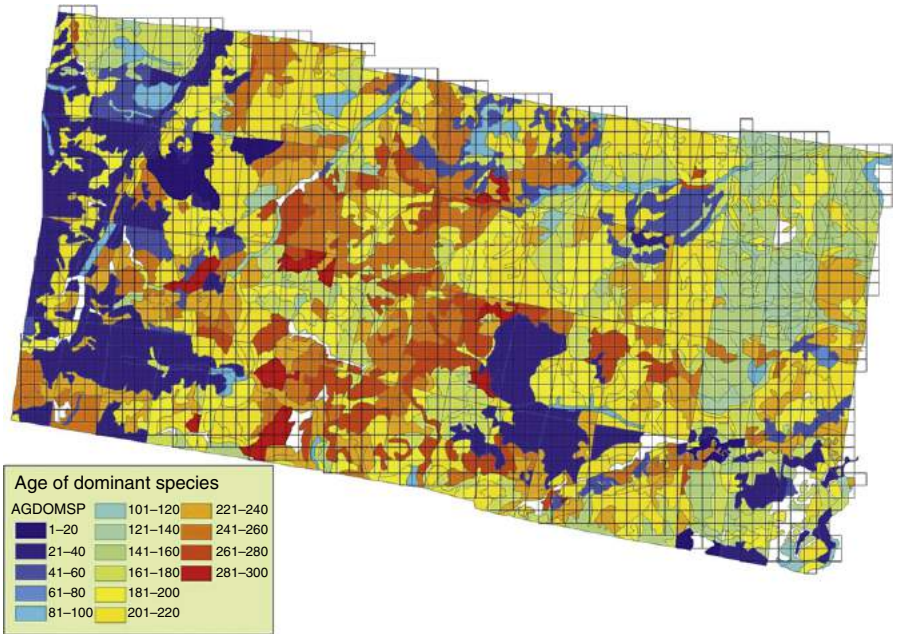

Fig. 2 Forest stands of different age in eastern Krasnoyarsk, central Siberia. Each cell is 500 m $\times$ 500 m.

Measurement of Biomass

There are two aspects to quantifying biomass: measurements at specific sites and methods for extrapolating the results from such sites to large areas. Measurement at a site is, in principle, straightforward. It involves harvesting all plant material within a defined area, drying it to a constant weight, and weighing it. In practice, this type of destructive measurement becomes more difficult if the belowground portions are included and if the vegetation includes large trees. Sorting roots from the soil–root matrix is difficult. The size of the plot is also important: small plots will either over- or underestimate the average biomass if they include or exclude large trees, respectively. Perhaps, more importantly, selection of sites is critical. Sites need to be representative of existing forests, not representative of some idealized notion of a forest. Sampling a large number of sites may help minimize biased selection.

Because destructive sampling is time consuming (expensive), foresters and ecologists have developed indirect methods for estimating biomass. The most common approach uses allometric equations that allow the estimation of tree biomass from more easily measured properties, such as diameter at breast height (dbh), height, and wood density. Systematic sampling (forest inventories) with such measurements and equations allow the biomass (or commercial wood volumes) to be obtained over large areas.

Because temperate zone and boreal forests have been inventoried more than once, their biomass is reasonably well known (Table 2). Accuracies vary among regions and countries but they are generally high for wood volumes. In the Southeastern US, for example, the error calculated for the total volume of growing stock was within 1.1%. On the other hand, `changes' in the stock had an error of $\pm 40\%$. The much larger error associated with change results from magnitude of the change relative to the magnitude of the stocks. Small differences between large numbers are difficult to determine precisely.

Table 1 Mean living biomass, area, and total living biomass of the world's major terrestrial ecosystems

Ecosystem type	*Area (10^6 ha)*	*Total biomass (Pg)*	*Mean biomass (Mg ha^{-1})*

Table 3 Areas and average biomass of natural forests in tropical regions[a]

Region	*Forest area (10^6 ha)*	*Total biomass*[b]	*Average biomass*[b] (Mg ha^{-1})
Asia	264	37	140
Africa	636	85	134
America	952	225	236
Total	1852	348	188

[a]In Africa, three nontropical countries, Lesotho, South Africa, and Swaziland, are included, while the six countries of northern Africa are not. In Latin America, three nontropical countries, Argentina, Chile, and Uruguay, are included.
[b]Values of aboveground biomass were increased by a factor of 1.2 to include belowground biomass.
Adapted from FAO (2001) *Global Forest Resources Assessment 2000*. Rome: Food and Agriculture Organization of the United Nations.

Although forest inventories have been carried out in some tropical forests, large areas have rarely been inventoried. Nevertheless, estimates of the average tropical forest biomass exist (**Table 3**), based on one of three approaches: (1) dividing the forests into different classes (each type corresponding to an average biomass), (2) calculating biomass as a function of environmental parameters (e.g., mean annual temperature and the seasonal distribution of precipitation), and (3) `direct' measurement from remote sensing data. A comparison of seven estimates for the Brazilian Amazon revealed not only a wide range (greater than a factor of 2 between the lowest and highest estimates of total biomass), but also no agreement as to where the forests with the highest and lowest biomass existed (**Fig. 3**). More recent investigations with radar and lidar show much more consistent results, and satellites to measure aboveground biomass directly are being designed by space agencies in Japan, Canada, Europe, and the United States.

Such satellites, in concert with field measurements, are urgently needed. A comparison of **Tables 2** and **3** with **Table 1** suggests an uncertainty in biomass that is a factor of 2, especially if the differences for forests apply to other ecosystems. **Table 1** is a recent compilation of site-specific measurements in different types of ecosystems. In contrast, **Tables 2** and **3** are based on forest

inventories with a much larger number of measurements, presumably more representative of existing forests. Although some of the differences may be the result of changes wrought by human activity (natural forests degraded through use), most of them are probably the result of a biased selection of sites for **Table 1**.

Table 4 shows an alternative estimate of global biomass, where the estimates for forests are derived from **Tables 2** and **3** and the estimates for other ecosystems are the same as in **Table 1**. Although the areas of forests (and land ecosystems) are similar in **Tables 1** and **4**, global biomass from this new compilation is approximately half of that in **Table 1** (770 as against 1300 Pg). That is, global biomass is not known to even one significant figure. Similarly, estimates of the average biomass of forests vary by more than a factor of 2, a fact that is remarkable given that wood volumes are determined to within 1%–2% in national forest inventories. Some fraction of the discrepancy results from scaling wood volumes to total biomass, including not only roots, leaves, and branches, but also understory vegetation, noncommercial species, and trees smaller than those generally inventoried. Much of the difference between estimates, however, is probably the result of site selection.

Changes in Biomass

Biomass (dry weight) is approximately 50% carbon, and the amount of carbon in terrestrial biomass (385–650 PgC) is of the same order of magnitude as the amount of carbon in the atmosphere (~780 PgC) and in the surface layers of the ocean (~700 PgC). Thus, changes in terrestrial biomass have a significant effect on the concentration of CO_2 in the atmosphere.

The carbon released to the atmosphere as a result of deforestation and degradation of tropical forests (1–2 PgC yr^{-1}) is thought to account for 10–20% of anthropogenic emissions (8.4 PgC yr^{-1} were released in 2006 from fossil fuel combustion). In contrast, temperate zone and boreal forests are believed to account for a significant carbon sink in northern mid-latitudes ($\sim$2 PgC yr^{-1}).

Knowing `changes' in biomass is crucial for determining terrestrial sources and sinks of carbon. However, the carbon sink in northern mid-latitude forests calculated on the basis of data from forest inventories (0.65 PgC yr^{-1}) is smaller than the carbon sink inferred from the top-down approaches to evaluating carbon sources and sinks from atmospheric data and models ($\sim$2 PgC yr^{-1}). The difference might be explained by errors (both estimates have wide ranges of uncertainty), by ecosystems other than forests that are not systematically inventoried, or by the accumulation of carbon belowground (roots and soil carbon are not measured by forest inventories).

If the northern mid-latitude sink of $\sim$2.0 PgC yr^{-1} were evenly distributed over the forests of the region, the average annual increase in forest biomass would be 1.2 MgC ha^{-1} yr^{-1}, or 2.7%. Such a change would be difficult to observe with an error of $\pm$40%. However, the sink is not evenly distributed in space. Forest inventories indicate that Canadian and Russian forests lost living biomass $\sim$1990 (0.08 PgC), while forests in the US, Europe, China, and other northern regions gained it (a total of 0.28 PgC). The spatial variability raises the possibility that the major terrestrial sources and sinks of carbon may be much larger than the average sink. What if, for example, 90% of the net terrestrial flux of carbon occurs on lands where the annual changes are large, 12 MgC ha^{-1} yr^{-1}, instead of 1.2 MgC ha^{-1} yr^{-1}? At present, we do not know what fraction of the northern forests is growing and what fraction is already `grown´ (**Fig. 2**). We do not know whether the terrestrial carbon sink is distributed over very large areas (with small annual changes) or limited to areas characterized by rapid rates of change.

In the tropics, the general lack of repeated forest inventories makes it impossible to estimate the sources and sinks of carbon directly from observation. Rather, changes in land use have been used, together with the changes in biomass known to be associated with land-use change, to calculate sources and sinks of carbon. The calculated emissions from tropical deforestation and degradation vary between 1 and 2 PgC yr^{-1}. Uncertainties in biomass contribute about as much to this variability as uncertainties in rates of deforestation. Moreover, estimates of average biomass are insufficient for accurate estimates of carbon emissions. Regional averages, even if accurate, do not necessarily correspond to the biomass of the forests actually deforested.

Carbon emissions determined from deforestation and degradation in the tropics are consistent with the net source of carbon inferred from top-down analyses based on atmospheric data and models. On the other hand, repeated measurements of biomass on small plots of undisturbed forests throughout the tropics indicate an increase in the biomass of (undisturbed) Amazonian forests (although not in tropical Africa or Asia). If the increase applies over large areas of Amazonia, it represents a significant carbon sink. The reasons for the increase in Amazonian biomass are unclear. Are the forests recovering from earlier disturbances, or are they responding to a changing environment (e.g., higher concentrations of CO_2 in the atmosphere or less cloudiness)? Answering this question is important for understanding whether the accumulation of carbon in biomass is part of a steady-state system or a new carbon sink, and, if it is new, whether it can be expected to continue.

Carrying Capacity

MA Hixon, Oregon State University, Corvallis, OR, USA

Carrying capacity is typically defined as the maximum population size that can be supported indefinitely by a given environment. The simplicity of this definition belies the complexity of the concept and its application. There are at least four closely related but nonetheless different uses of the term in basic ecology, and at least half a dozen additional definitions in applied ecology.

Basic Ecology

Carrying capacity is most often presented in ecology textbooks as the constant K in the logistic population growth equation, derived and named by Pierre Verhulst in 1838, and rediscovered and published independently by Raymond Pearl and Lowell Reed in 1920:

$$N_t = \frac{K}{1 + e^{a-rt}} \text{(integral form)}$$

$$\frac{dN}{dt} = rN\left(\frac{K-N}{K}\right) \text{(differential form)}$$

where N is the population size or density, r is the intrinsic rate of natural increase (i.e., the maximum per capita growth rate in the absence of competition), t is time, and a is a constant of integration defining the position of the curve relative to the origin. The expression in brackets in the differential form is the density-dependent unused growth potential, which approaches 1 at low values of N, where logistic growth approaches exponential growth, and equals 0 when $N = K$, where population growth ceases. That is, the unused growth potential lowers the effective value of r (i.e., the per capita birth rate minus the per capita death rate) until the per capita growth rate equals zero (i.e., births = deaths) at K. The result is a sigmoid population growth curve (**Fig. 1**). Despite its use in ecological models, including basic fisheries and wildlife yield models, the logistic equation is highly simplistic and much more of heuristic than practical value; very few populations undergo logistic growth. Nonetheless, ecological models often include K to impose an upper limit on the size of hypothetical populations, thereby enhancing mathematical stability.

Of historical interest is that neither Verhulst nor Pearl and Reed used 'carrying capacity' to describe what they called the maximum population, upper limit, or asymptote of the logistic curve. In reality, the term 'carrying capacity' first appeared in range management literature of the late 1890s, quite independent of the development of theoretical ecology (see below). Carrying capacity was not explicitly associated with K of the logistic model until Eugene Odum published his classic textbook *Fundamentals of Ecology* in 1953.

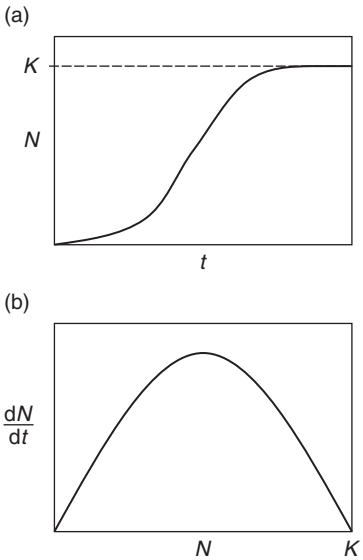

Fig. 1 The definition of carrying capacity most frequently used in basic ecology textbooks. (a) Logistic population growth model, showing how population size (N) eventually levels off at a fixed carrying capacity (K) through time (t). (b) Logistic population growth rate (dN/dt) as a function of population size. Note that the growth rate peaks at 0.5 K and equals zero at K.

 doi:10.1016/B978-0-444-63768-0.00468-6

The second use in basic ecology is broader than the logistic model and simply defines carrying capacity as the equilibrial population size or density where the birth rate equals the death rate due to directly density-dependent processes.

The third and even more general definition is that of a long-term average population size that is stable through time. In this case, the birth and death rates are not always equal, and there may be both immigration and emigration (unlike the logistic equation), yet despite population fluctuations, the long-term population trajectory through time has a slope of zero.

The fourth use is to define carrying capacity in terms of Justus Liebig's 1855 law of the minimum that population size is constrained by whatever resource is in the shortest supply. This concept is particularly difficult to apply to natural populations due to its simplifying assumptions of independent limiting factors and population size being directly proportional to whatever factor is most limiting. Moreover, unlike the other three definitions, the law of the minimum does not necessarily imply population regulation.

Note that none of these definitions from basic ecology explicitly acknowledges the fact that the population size of any species is affected by interactions with other species, including predators, parasites, diseases, competitors, mutualists, etc. Given that the biotic environment afforded by all other species in the ecosystem typically varies, as does the abiotic environment, the notion of carrying capacity as a fixed population size or density is highly unrealistic. Additionally, these definitions of carrying capacity ignore evolutionary change in species that may also affect population size within any particular environment.

Applied Ecology

The term carrying capacity may have first appeared in an 1898 publication by H. L. Bentley of the United States Department of Agriculture, with an original focus on maximizing production of domestic cattle on rangelands of the US southwest. The first use in wildlife management was apparently associated with classic studies of deer populations on the Kaibab Plateau in northern Arizona in the 1920s. The concept was popularized in wildlife ecology by Aldo Leopold and Paul Errington in the 1930s.

There have been four typical uses of carrying capacity in applied ecology, illustrated in Fig. 2: (1) the maximal steady-state number or biomass of animals an area can support in the absence of exploitation (the original use of carrying capacity, K); (2) the maximal sustainable yield (MSY) of biomass of animals an area can produce for exploitation, which equals $0.5K$ in the simplest form of the logistic model; (3) the maximal sustainable economic yield (MEY) of animals an area can produce for exploitation, which equals the maximum difference between yield value and cost of exploitation; and (4) the open-access equilibrium (OAE), where the value of the yield equals the cost of exploitation, which is the upper economic limit of exploitation in the absence of economic subsidies and restrictive management regulations. Note that open access, typical of historical marine fisheries, often leads to severe overexploitation because the population is reduced to sizes far below the other types of carrying capacity. Indeed, even the application of maximum sustainable yield in single-species fisheries management has proven elusive and often disastrous, as evidenced by the poor state of most marine fishery stocks so managed.

Two additional uses of carrying capacity in applied ecology focus on optimal stocking of rangeland with cattle, sheep, etc. The Society for Range Management defines the term as the maximum stocking rate possible which is consistent with maintaining or improving vegetation or related resources. A more general definition is the optimum stocking level to achieve specific objectives given specified management options. These practical definitions implicitly acknowledge that carrying capacity is not a constant, but rather is affected by a variety of environmental factors.

The elusive applied goal has been to determine number of animal-unit-days per unit area that produces a desired objective. A typical simplistic formulation follows:

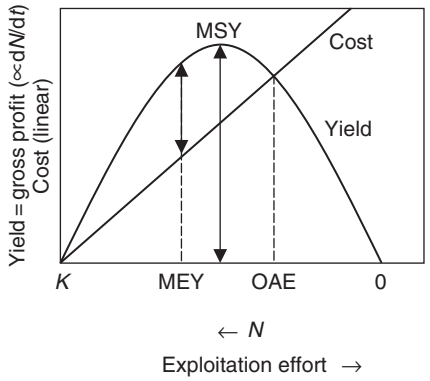

Fig. 2 Four definitions of carrying capacity used in applied ecology. Yield (or so-called surplus production, which directly translates to gross profit and which varies directly with the growth rate of the exploited population) initially increases and eventually decreases as exploitation effort increases, whereas the cost of exploitation presumably increases linearly with effort. The conventional carrying capacity (K) occurs in the absence of exploitation (i.e., zero effort). MSY occurs where total yield peaks (i.e., 0.5 K in the logistic model). MEY occurs where net profit (i.e., gross profit minus cost) is maximal (i.e., where the slopes of the cost and yield curves are identical). The OAE occurs where gross profit equals cost. Typically, as illustrated, $K > \text{MEY} > \text{MSY} > \text{OAE}$.

$$A = (B \times C)/D$$

where A is the number of animal-unit-days an area can support ($(\# \times d)$ per square kilometer), B is biomass of food in the area (kg km^{-2}), C is the metabolizable energy of that food (J kg^{-1}), and D is the metabolizable food energy required per animal unit per day (J/$(\# \times d)$). Obviously, such formulas ignore the reality of environmental variation, species interactions, etc.

A classic field study of wildlife carrying capacity was published by David Klein in 1968. In 1944, some two dozen reindeer were released on St. Matthew Island in the Bering Sea, where previously there had been none. Lichens were plentiful and the population increased at an average rate of 32% per year for the next 19 years, reaching a peak of about 6000 in 1963. During the severe winter of 1963–64, nearly all the animals died, leaving a wretched herd of 41 females and 1 male, all probably sterile. It was not so much the inclement weather that devastated the herd as it was a deficiency in food resources caused by overgrazing. After careful study, Klein concluded that 5 reindeer per square kilometer would have been the carrying capacity of an unspoiled St. Matthew Island. An animal census taken in 1957 gave 4 animals per square kilometer. A further 32% increase during the ensuing year brought the population to 5.3 per square kilometer, in excess of the predicted carrying capacity and a prelude to the eventual population crash.

Conclusions

Overall, the many and varied definitions of carrying capacity, typically stated in rather vague and ambiguous terms, render the concept to be most useful in theoretical ecology. Efforts to parametrize and measure carrying capacity in the field have proven problematic, such that the practical utility of the concept is questionable. This dilemma is especially true when considering the worldwide carrying capacity of humans, which seems better approached by the concept of ecological footprint. Nonetheless, the carrying capacity concept is clearly of heuristic value given the fundamental truth that no population can grow without limit, and especially given the fact that many human societies have behaved as if no limits exist.

Communication☆

Peter K McGregor, Cornwall College, Newquay, United Kingdom

Introduction

Communication is a social behavior that mediates fundamental aspects of animals' lives. It is important during reproduction—playing a role in attracting another individual of the same species and coordinating mating, and extending to aspects of parental care. It is also important in many aspects of survival—from being alerted to the presence of predators by warning calls, through signaling prey defenses, to indicating food sources and defending them. Communication is also often conspicuous to the extent of being spectacular; examples are choruses of songbirds, cicadas, and frogs, and the coordinated displays of fireflies.

Communication is generally thought of as a characteristic of animals, but there are instances in which plants share features of animal communication. For example, the response of some plants to airborne chemicals indicating that a neighbor has been attacked has features in common with the warning or alarm calls of animals. However, as most information on communication comes from the animal kingdom, this article deals with animal communication. The article will begin by introducing key concepts in communication; it will then proceed to discuss the influence of physical and social environments on communication behavior, and it will end by looking at current issues linking behavior and ecology and will touch upon a role in applied ecology.

What Is Communication?

As we shall see below, defining communication is not straightforward and has been the subject of considerable debate. However, there are three readily identifiable components of communication: (1) the signal, (2) the signaler, and (3) the receiver.

Signal

The signal is the information carrier and is often categorized by the sense used to detect the signal (signal modality, see below). For example, a frog's call is an acoustic signal and the flash of a firefly is a visual signal.

Signaler

The signaler is the animal producing a signal, for example, a calling frog, or flashing firefly. Signalers are also referred to as senders, generators, and actors.

Receiver

The receiver is any animal picking up the signal, for example, another frog, or firefly, and they do not have to be the same species as the signaler. Receivers are also referred to as detectors or reactors.

The Relationship Between the Three Components

The relationship between these components is usually portrayed as the signaler produces the signal that is received by the receiver. This is the simplest possible form of communication, but this simple form probably only occurs rarely in natural communication systems. An important complexity of natural systems is that several individuals can be involved in communication, resulting in a communication network (Fig. 1), rather than a dyad of one signaler and one receiver. A second aspect of the complexity of natural systems is that an individual can change dynamically between the roles of signaler and receiver, and may be capable of simultaneous signaling and reception.

☆*Change History*: November 2015. PK McGregor updated this article. A new paragraph on anthropogenic effects was added to the "Towards a definition" section and the "Further Reading section was updated".

This is an update of P.K. McGregor, Communication, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 683–689.

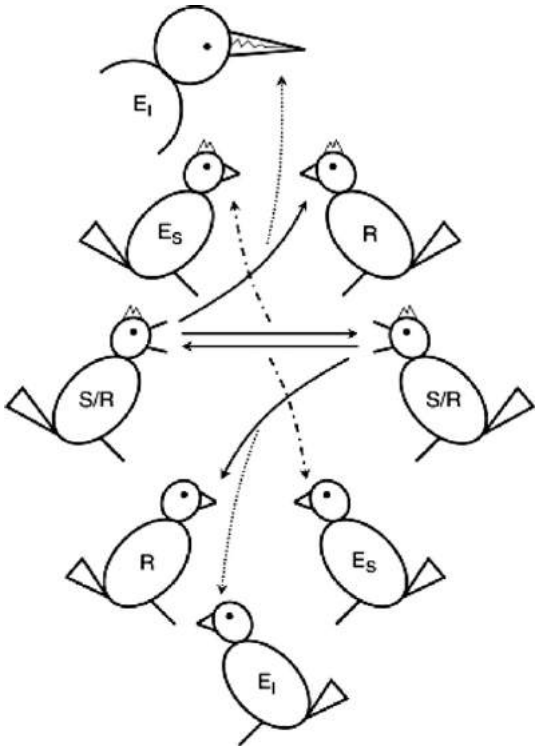

Fig. 1 A schematic representation of some possible patterns of signaling and receiving in a communication network. In the center of the figure, two males (distinguished from females by crest and longer tails) are involved in a signaling interaction (paired *arrowed lines*), that is, have signaling and receiving roles (S/R). The male on the right is also signaling to a female receiver (R, toward bottom left of figure) and another female (center bottom) is intercepting (*dotted line*) this signal (interceptive eavesdropping, E_I). A third female (toward bottom right) is social eavesdropping (E_S) on the interaction between the central males (*dot and dash line*), as is a male (toward top left). The central male on the left is also signaling to a male receiver (toward top right) and a predatory species (top left) is intercepting the signal.

Terms Commonly Used in Communication

The technical terms used when discussing the ecology of communication often originated in different subject areas, such as physics and applied mathematics, and the original meaning of some terms has altered. The meanings of terms listed below reflect their current use.

Transmission Medium

The transmission medium conveys the signal from the signaler to the receiver and, depending on the specific signal, can be air, water, or solid objects. For example, the transmission medium for frog calls and firefly flashes is air, whereas for whale song it is water.

Signal Modality

The signal modality (or channel) refers to the sense used to detect the signal. We are most familiar with senses of hearing, vision, and smell/taste. Three less common modalities use the vibration detection sense, the sense of touch, and the electrical sense. Some signals are referred to as multimodal because more than one sense is required to receive them.

Visual signals most commonly utilize reflected light, as few species are capable of generating light for signaling. Movement is often a feature of visual signals, for example, the claw waving display of fiddler crabs. Acoustic signals encode information in pressure differences of the transmission medium (i.e., air or water) and at extremely close range by displacement of the medium itself. Chemical signals use the sense of smell/taste and differ from other modalities in that they can persist in the absence of the signaler (e.g., scent-marked vegetation).

Seismic (vibration) signals transmit information through the substrate; an example is the foot-stamping signal used by rabbits. Tactile (touch) signals require the signaler and receiver to be in physical contact. Electrical signals are used by two taxonomic groups of freshwater fishes with a well-developed ability to detect electric fields and also organs specialized to generate electricity.

Each of these six modalities differs in transmission speed, persistence, inherent directionality, and the effect obstacles have on them. These differences strongly influence the form of signals used in different contexts and also how the environment affects signals during transmission.

We tend to consider humans good receivers of visual and acoustic signals; however, some animal signals in these modalities are outside of our perceptual range. Acoustic examples include the infrasonic rumbles of elephants and ultrasonic calls of bats; visual examples include the ultraviolet coloration of butterflies and the flashes of infrared light produced by some deep-sea fish.

Information

Information is a fundamental concept to communication because all communication involves information (however, not everything involving information is communication). Confusingly, information is used in two senses in the communication literature. In the everyday sense it means knowledge, but in a technical sense (derived from information theory) it means the reduction in a receiver's uncertainty following reception of a signal. (Uncertainty, H, is calculated by the Shannon–Weaver (or Shannon–Weiner) function: $H = -\sum pi \log_2 pi$ where i is the number of possible behavior patterns and pi is the probability that the ith will occur.) Often authors fail to mention which of the two meanings of information they are using. Where they do, information in the everyday sense is sometimes referred to as semantic information and information meaning reduction in uncertainty is referred to as statistical information. Information will be used in the everyday sense in this article.

Semiotics

Semiotics is the study of signs and symbols, with communication often considered under the heading of biosemiotics; it is dealt with elsewhere in this encyclopedia.

Toward a Definition of Communication

Communication is surprisingly hard to define. Part of the difficulty stems from the wide variety of contexts in which animals communicate and to some extent from the diversity of signals employed. Such diversity means that there can be important exceptions to each of the many definitions of communication. For example, one common definition is mutually beneficial information transfer; however, there are several instances where information transfer is not mutually beneficial (e.g., mimicry by edible species of inedible species, which is a deception to the receiver's detriment). Another aspect of the difficulty of definition is that communication is only a subset of information transfer; a mouse moving through fallen leaves and a tree bending in the breeze both transmit information (on location and wind direction, respectively) but would not be thought of as communication.

One approach is to focus on the role of signals in communication, that is, communication can be defined as behavior involving signals, where signals are defined as adaptations to transmit information. Therefore the call of a frog is an adaptation, for example, to attract females for mating, and likely contains information on species identity in order to function effectively. The rustling mouse generates information on location as an incidental by-product of movement; the rustling sound is probably maladaptive because it is likely to attract a predator.

Communication and the Environment

Communication is only one behavior in an animal's repertoire and whether or not to communicate at any instant is influenced by many factors outside the scope of this article. However, once the decision to communicate has been made, we would expect communication behavior to be as effective as possible. Both the physical environment and the social environment can have major influences on the effectiveness of communication; these are manifested as decisions concerning when and where a signal is broadcast and in the structure of the signal. A complication is that both types of environment change over a range of timescales and often vary cyclically. For example, vegetation changes over an annual cycle in temperate terrestrial habitats whereas the activities of other signalers can change from signal to signal. A limitation on our understanding of such matters is that signaling is a much more conspicuous behavior than receiving, and therefore most of the information on when and where to communicate relates to signaling behavior.

A further complication is the effect of anthropogenic noise; such noise is loud and virtually ubiquitous in all environments as a consequence of human activity, yet it is relatively recent on an evolutionary timescale. There are well-documented effects of anthropogenic noise on signal structure and communication behavior in both terrestrial and aquatic habitats. For example, urban bird song is generally high pitched and loud to reduce the interfering effects of traffic noise and whales show similar effects in the presence of ship sonar. The fitness consequences of such noise-induced changes have yet to be established.

In this section, we will consider the physical environment first because generally its effects are less complex and change less frequently than the effects of the social environment. However, it is important to remember that both physical and social environment contribute to the variation in communication behavior and signal structure that we observe.

Effects of the Physical Environment on Signal Form

All habitats modify signals during transmission. Signals are both attenuated and degraded, that is, signal energy is absorbed and signal details are distorted by the environment. Often degradation will limit the effective range of a signal before attenuation—it is a common personal experience to know that someone at a distance has said something, but to be unable to understand the words; the signal has been detected but the detailed information it contains cannot be discerned. Habitats can be thought of as imposing selection pressures on the form of signals and as a result most signals are adapted to some degree to their transmission environment. For example, birds found in open habitats (e.g., grassland) tend to sing songs with rapid temporal patterning (the songs contain more trills than whistles) and with a wide frequency range. By contrast, woodland bird songs tend to have more low frequency whistles than high frequency trills. This difference contributes to minimizing the effect of the habitat on signals during transmission; trills suffer less degradation from the irregular changes in air temperature and wind speed characteristic of open habitat, while low frequency whistles suffer less degradation induced by reflections from leaves and trunks in woodland.

Transmission conditions also change within a habitat on daily and seasonal timescales; for example, the effects on visual and acoustic signals of a deciduous forest in winter are very different from those in the same forest in summer. Such changes often affect to a greater extent when and where signals are produced than they affect signal structure.

Effects of the Physical Environment on When and Where to Communicate

The most effective time to signal is often related to cyclical changes in the physical environment. An example on a seasonal timescale is communication underlying breeding behavior; breeding is seasonal (e.g., spring in temperate zones and the rainy season in equatorial regions) and so are the long-range mate attraction and territory defense signals such as birdsong and the choruses of frogs and insects. Cycles occurring over shorter timescales are also accompanied by appropriate signaling behavior. Circalunar and tidal cycles are common in marine or intertidal environments and animals such as fiddler crabs produce their claw-waving visual signal at low tide. Daily (circadian) cycles give rise to choruses of bird song at dawn and of frogs and fireflies at dusk. It seems reasonable to expect cycles of receiver activity to coincide with those of signalers. However, it is possible that the amount of information available during periods of very high signaling activity (e.g., intense chorusing) could exceed receivers' processing abilities, with the result that receivers may avoid such periods.

The most effective place to signal from is affected by several factors including transmission conditions and the area to be encompassed by the signal. Environmental factors affecting signal transmission often vary from location to location within habitats. For example, studies that broadcast bird song and record it at different locations to investigate location effects on transmission have shown that the best perch height for maximizing song transmission (i.e., where signalers should be found) is lower than that which favors sound reception (where receivers should be found). As many visual signals rely on reflected light (see above), it is not surprising that signaler location is strongly affected by the incident light regimes in terrestrial and aquatic environments. Some species take things further and alter the properties of the signaling location to enhance signal transmission. For example, mole crickets excavate a calling burrow in an exponential horn shape to amplify their call and some tree crickets create acoustic baffles from leaves to modify the spreading pattern of their call. Signaling from a single location can be less effective than signaling from several locations, often because the signal does not encompass the required area. When several signaling locations are used, the signaler faces a series of decisions including how to apportion effort between locations and the interval before returning to each location. Often solutions to these issues based on a priori considerations will be overridden by the activity of adjacent signalers and receivers, that is, the social environment can modify and often override effects of the physical environment.

Effects of the Social Environment on Signal Form

The most noticeable effects of the social environment on signal form occur when other signalers and receivers have adverse influences that cannot be avoided by ceasing signaling or signaling from another location. One example involves the species specificity or species distinctiveness of signals and is a form of character displacement. If the signal characteristics of sympatric species overlap then we would expect selection for the signals to diverge because communicating with the appropriate species is important in many contexts. Character displacement is commonly assumed to be the cause of a lack of overlap of signal characteristics between species in sympatry when compared with the same species in allopatry.

A common influence of the social environment is an aspect of communication networks, that is, the presence of receivers in addition to the intended receivers (**Fig. 1**). These additional receivers can intercept signals intended for others, usually at a cost to the signaler. Often such interceptive eavesdroppers are predators or parasites that use broadcast signals to locate prey and hosts. Examples are predatory bats that feed on calling male frogs and flies that use calls to locate frog hosts for their parasitic larvae. Signalers rarely call in the presence of such eavesdroppers (i.e., eavesdroppers affect decisions on when and where to communicate; see below), but there are examples in which the form of the signal reduces the opportunity for interceptive eavesdropping. The clearest examples are signals that warn of predators because such warning calls must be given in a predator's presence and could be intercepted by the predator. For example, the warning call (seeet) given by some northern temperate species to an aerial predator has a frequency of about 8 kHz, to which the calling species is more sensitive than the eavesdropping predator.

Interceptive eavesdroppers may also be the same species as the signaler and therefore potential competitors and rivals of the signaler. For example, a male fiddler crab reacts by producing courtship waving signals when he intercepts the courtship signals produced by a male neighbor in response to the female, even though he cannot see an approaching female, and in doing so he becomes a competing suitor. During close-range, high-intensity courtship or aggressive interactions, some song birds change from a far-carrying advertising song to a form of song that carries less far as a consequence of its lower amplitude and greater high-frequency content. Such a change in signal form should restrict the potential for eavesdropping at times when the signaler can suffer high costs.

Effects of the Social Environment on When and Where to Communicate

The most readily observed effect of the social environment on communication is the avoidance of adverse influences (e.g., risk of predation, interference from other signalers) by ceasing signaling or signaling from another location. Interference from other signalers of the same species is particularly severe in high-density communication networks (e.g., breeding colonies, chorus aggregations) and can result in changes in communication behavior. For example, chorusing male frogs have less success attracting a female when another calling male is close by. In response to such interference males may vary the timing of their calls both in relation to close neighbors and the overall synchrony of the chorus. As males may fight to displace others calling from close by and as the larger male usually wins, small males often move away when a large male begins calling near them. It is likely that similar considerations apply to receivers.

Signaling interactions between others are one aspect of the social environment in which eavesdropping would be favored because information on relative aspects of the signalers is readily available from such interactions. In such social eavesdropping (cf. interceptive eavesdropping, above), the eavesdropper does not take part in the signaling interaction (Fig. 1). Social eavesdropping by both sexes has been demonstrated in laboratory experiments on fish using visual signals and in field experiments with territorial songbirds: males and females eavesdropped on aggressive signaling interactions between other males, and females eavesdropped on male–female courtship interactions. There are indications that receivers position themselves in space and time to facilitate social eavesdropping. The specific circumstances of an interaction and the individuals involved will determine whether the signalers involved will gain or lose from the presence of social eavesdroppers (e.g., the winner of an aggressive interaction may gain while the loser may not) and therefore how the eavesdroppers will affect when and where the interaction occurs.

Origin of Communication Behavior

The evolutionary origin of communication behavior is usually considered solely as a question of how signals originate, that is, how they evolved to become specialized to carry information. Two evolutionary origins for signals have been suggested; they differ in "who benefits from the information in the signal." If both signaler and receiver benefit from the communication, it is likely that signals originate as a consequence of selection for increasing efficiency of information transfer. This is usually termed ritualization, and it generates a signal by the simplification, exaggeration, repetition, and increased stereotypy of the signal precursor. Signal precursors are behaviors that incidentally contain some relevant information such as intention movements, displacement activities, and autonomic responses. A second evolutionary route for the origin of signals is usually referred to as sensory exploitation. Signals are selected to exploit "preexisting sensory biases" built into receivers. For example, male spiders use signals for mate attraction that stimulate females' prey-detection receptors.

If the evolutionary origin of communication is considered in a wider network context, a third possibility emerges. Information networks include communication networks (in which information transfer occurs via signals as described above), but also networks of information based on potential signal precursors. Semiochemicals (e.g., alarm pheromones) are examples of such potential signal precursors and receivers gathering information from them are said to be spying. Chemical signals could evolve from semiochemicals through spying (as production of the semiochemical by the signaler becomes specialized). In an analogous manner, communication networks could evolve from spying networks, reversing the presumed order of communication appearing before eavesdropping.

Current Issues and an Application

Honesty and Handicaps in Communication

Much of the recent research on communication in behavioral ecology has addressed the issue of whether signals are honest in the context of mate choice, resource defense, and predator–prey interactions. There are examples of communication involving deceit (such as the mimicry example mentioned above), but the wider issue is the selection pressures signalers and receivers exert on one another. When signalers and receivers have conflicting interests, the result is likely to be a coevolutionary arms race. Two such instances are potential prey signaling to deter predators from attacking and females using male signals to choose the best mate. Selection should favor signals that best achieve signalers' interests, even at the expense of receivers; therefore signals are unlikely to be honest. However, selection should also favor receivers adept at gathering information in their best interests. Such a co-evolutionary arms race seems likely to result in signals that are "honest on average."

One way it is thought that signal honesty can be ensured is if signals are costly. This idea is usually referred to as the handicap principle, where handicap means the conspicuous cost of the signal, that is, resources used for the signal that might otherwise have increased signaler fitness. A hypothetical example would be the energy used to produce a call indicating a larger than actual body

size—energy that could otherwise have been used to grow a larger body. The debate about the role of handicaps in communications is outside the scope of this article.

Persistence and Payoff Asymmetries

The persistence of communication even when signalers differ from receivers in benefits (i.e., there is a large payoff asymmetry) is a topic of current interest in behavioral ecology. Two factors that allow communication to persist despite payoff asymmetries are the rarity of the signal and the genetic relatedness of signaler and receiver.

Extreme payoff asymmetries are found when the signal is rare and communication occurs between species. For example, edible mimics are thought to gain protection from predators by resembling inedible or dangerous prey (models) only when mimics are rare relative to models.

Extremes of relatedness often characterize striking examples of cooperation and its associated signaling. For example, individuals of the same species sometimes cooperate in locating distant food sources through signals such as the dance language of honeybees and the pheromone trails of ants. Often such social insects are very close genetic relatives. Other examples of cooperation include foregoing reproduction to help a close relative reproduce (e.g., social insects, naked mole rats). The details of the signaling underlying such cooperation are still under study, but are likely to be important to the functioning of cooperation. When the signaler is a different species from the receiver, the lack of genetic relatedness may be the factor favoring cooperation and the associated signaling. Examples include the cleaner fish found on reefs that closely approach other, generally much larger species (clients) quite capable of eating the cleaner. However, the cleaner only approaches a client closely after an exchange of signals to indicate that the larger species is a client and not a predator. Recent research suggests that the signals also allow the client to minimize the risk that a cleaner will bite rather than clean.

Conservation and Communication

The long-range advertising signals in most signal modalities contain information on species identity. Such information is valuable to conservation efforts because such signals and signaling activity allow species to be identified and their abundance to be estimated. This application is particularly well developed for birds, allowing species to be identified, and counted even at night or when they are hidden by dense vegetation. If birds can be individually identified, then detailed information on survival, habitat use, and immigration rates can be collected. Most bird vocalizations are naturally individually distinctive and techniques have been developed to gather such information as a noninvasive alternative to catching and marking.

Summary

Communication is behavior involving signals. Signals are adaptations that transmit information and in this way are distinguishable from other aspects of the environment that incidentally contain information. Much communication occurs in a social environment of a network of several signalers and receivers. Signals are diverse, with several signal modalities (e.g., vision, hearing, smell) used for communication, some of which cannot be detected unaided by humans (e.g., ultraviolet color patterns of butterflies and the ultrasonic calls of bats).

The effectiveness of communication depends on conditions of both the physical and the social environment. These affect when and where communication occurs and the structure of the signal. The effects can occur over a range of timescales, from seconds to years, and often vary cyclically.

Signals can evolve through ritualization (of behaviors that are precursors of signals), through the use of preexisting sensory biases of receivers, and through information gathering in networks.

Communication has featured in two areas of current interest in behavioral ecology: whether signals are honest and how communication persists when there are large differences in the benefits between signalers and receivers. Animal signals also have a role as a census and monitoring tool in conservation.

Community

AJ Underwood, University of Sydney, NSW, Australia

The Concept of a Community

Despite the widespread use of the term 'community', there has been remarkably little detailed ecological discussion of what it means. This remains a strange omission, given that communities are supposedly the actual units of study for many ecologists. There seem to be two, very different ways of viewing a community. One is that species exist in integrated communities that have persistent features through time (e.g., composition of species or structure of food webs) and are repeated in different places. Thus, the ecological community of species is organized, structured, and integrated. The species in the community are interdependently interactive and, often, it is presumed that the interactions are, at least in part, responsible for maintaining the entity.

The alternative view is much less about the structure of a community. It holds that communities are simply a human invention. The term community is used to describe the collection of organisms that are found in the same place at the same time. They may (or may not) exhibit interdependencies. They may or may not interact. They coexist because they have similar physiological responses to physical components of the environment and/or they have similar needs for resources of food and shelter. Alternatively, some of them may be present because they need others as prey (or as some other resource).

There is no doubt that these two views are very different and lead to very different forms of ecological study. If the former view is correct, the community is, indeed, a valid and necessary object of study. It will only be possible to understand the ecology of the component species, if their interactions and interdependencies are understood. There could be no argument that the populations (and, in fact, the individuals in the populations) that make up the community are not the only valid units to investigate and explain. The community, itself, has ecological features and properties.

In contrast, if the latter, more descriptive and less structured view is correct, then the community *per se* has no structured existence and is simply a collection of entities – the populations of the species present. These populations and the interactions among them are the important units to study.

Throughout the history of ecology, there have been periods when one or other view has been (or has been considered to be) dominant. There does not ever seem to be a time when one definition looks likely to prevail over the other. As a result, there is no particularly successful or acceptable definition of community that will satisfy all – or even most – ecologists. The most extreme views are a very tightly coevolved and integrated community versus a random collection of species that happen to co-occur. Neither view is particularly likely to be sufficient or even correct.

The reality is probably somewhere in between. Some components of a community may, in fact, be highly interdependent and coevolved. Others are not. At the same time, coevolved traits can almost certainly be caused or maintained even in the loosest co-occurring set of species. For example, it is not a necessary condition that coevolved features of inferior competitors for food must be caused by consistent interaction with the same dominantly competitive species. Such features could well result from consistent competition for resources by a range of different and changing superior competitors. The intensity of and responses to competition can be ongoing and progressive, even though the superior competitors change from one generation to the next (or faster) for inferior competitors. Competition can be extensive, but caused by different species in varying mixes from one part of a habitat to another.

To avoid some (but sadly not all) of the confusion associated with the term community, the two ecological approaches will here be referred to using the term 'community' for tightly knit, consistent sets of species. 'Assemblage' will be used for the more loosely associated set of co-occurring species, where the whole set of species is not a repeatable, identifiable set.

Community as a Superorganism

One of the consequences of considering a community to be structured has been the notion that the set of species making up the community were tightly interacting and coevolving. Plant ecologists had identified numerous different types of associations of various species of plants. Some of these associations, the communities, came to be considered as a completely integrated unit – a kind of superorganism.

In its most extreme form, the description of communities began to prevail that coexisting species occurred together because they have similar needs for resources and similar responses to environmental stresses. The community developed because of deterministic pathways of succession, leading to a stable climax. The analogy was that a community develops by processes like ontogenetic development of an individual animal or plant. It is predetermined from conception, that is, from the early establishment of species in the habitat in which the community develops. Interactions affecting each component species are evolved responses to the presence, abundances, and activities of the other species in the community. Such interactions lead to homeostatic development of an equilibrium in the climax community and therefore to predictable patterns of structure.

 doi:10.1016/B978-0-444-63768-0.00473-X

Another property of superorganismic communities is that wherever they come into contact with each other, there is only very limited possibility of overlap. Thus, where two plant communities, for example, a forest and an open grassland, exist side by side, their boundary is a fairly narrow ecotone. Sometimes, ecotones contain species not found in either adjacent community, but there cannot be broad existence of mixtures of species from the two communities because the species are closely adapted to the community where they 'belong'. Species from one community should therefore be unable to thrive in the absence of some members of that community or in the presence of species that do not belong with them.

Assemblages

The concept of communities as superorganisms received considerable criticism in the US and Russia. Much of this criticism was apparently ignored or otherwise had little impact. There were compelling reasons to maintain a body of theory about integrated communities. For example, without a widespread use of communities as objects to study, there was no compelling need for theories about the ecology of communities (such as some of the theories about deterministic processes and patterns in natural succession). Ecologists might apparently have had less work to do.

There were, nevertheless, important features of developing ecology that made it inevitable that concepts about communities would be questioned. One of these was undoubtedly that animal ecologists in the early decades of the 1900s were finding some difficulties not shared by plant ecologists. Animals, at least many of them, were actually more difficult to observe (they ran or flew away, they actively hid when disturbed, etc.). As a result, the passive, motionless structures of sets of plants (i.e., communities) were not so evident for sets of animals. Seeing apparent patterns was not such a preoccupation for ecologists studying animals.

A second area of developing ecology had this problem in a more severe form. Early marine ecologists could not actually see the animals under the water and were, willy-nilly, forced to examine them in dredges and grabs that would bring pieces of substratum, with attached or embedded animals to the surface. Any structure or relationship of species into groupings had to be inferred from these samples. Furthermore, early marine biologists were compelled to recognize that their units of study were not natural (nor even contrived descriptions of) communities. Instead, they were studying species in artificial and arbitrarily designed sampling units – dredges and grabs. This did not stop them describing an equilibrial type of community – a biocenosis. This term was used to describe the collection of organisms found together in an oyster bed. It was, however, important that the unit of study was clearly a sample or representation of reality and not a naturally defined collection of species. It took some years before the sample unit became the standard unit of terrestrial ecological study.

Inevitably, quantitative sampling pervaded more and more of terrestrial (and plant) ecology. Objectively sampled data along environmental gradients provided data that did not fit easily into a structure of defined plant communities. This was often resolved by designating the anomalous samples as transitional or atypical or as identifying 'mixed stands' of plants. The latter is a somewhat obscure way of dealing with anomalous results, given that the tightly integrated community cannot realistically be considered to be mixed with another community.

Eventually, sufficient evidence accumulated to indicate that evidence for communities was outweighed by contrary evidence. Whittaker's sampling of vegetation up the environmental gradient of height in the Great Smoky Mountains is a deserved classical study to demonstrate this. Instead of accepting the evidence of communities of species of plants, as was the widely held view, he sampled at intervals up the mountains, to determine which species were present and their vertical distribution. As a result, he found that most, if not all, species were distributed independently up the gradient. There were not tightly knit, coherent communities.

The result was definitely not the anticipated outcome. Communities up a mountainside should have consisted of a set of species which have (or, of which, most have) upper limits to distribution at about the same height. They should have reasonably coincident lower limits to distribution. Otherwise, there can be no organized community of co-occurring species. Instead, Whittaker in 1956 found that upper boundaries and lower boundaries were scattered, without any obvious order, up the mountain (see later, **Fig. 1**).

The interpretation of this result was difficult because the concept of communities as integrated units was so widespread that Whittaker had to resurrect the term 'individualistic concept' to describe the independent patterns of distribution of species.

Many subsequent analyses of assemblages of species, particularly across gradients, have described species being distributed according to their physiological tolerances. The distributions are, however, modified (usually, their extent or range is reduced) by interactions with other species (such as pathogens, competitors, and predators). Assemblages of such species intergrade along a gradient and do not display the abrupt, ecotonal changes supposedly identifying communities. Such analyses do not require *ad hoc* argumentation about the intergrading or missing or partial nature of communities.

So during the 1960s, work casting doubt on the superorganismic communities that had been popular with plant ecologists was being published. It is ironic that, at the same time, animal ecologists were developing new rationales for integrating the ecologies of species into integrated communities. A very sophisticated theory was beginning to be developed about coevolution and diversity of species in communities. 'Assembly rules' that were supposed to maintain the structure of communities began to appear.

A new unit of study – the ecosystem – was popularized. This was based not just on a set of integrated species being a community, but on a more holistic ecosystem, which included the biota and all the physical and chemical components of habitat within which they interact.

The definition of an ecosystem can be difficult if not impossible. It is supposedly a community, but not just consisting of an interactive, integrated set of species. Instead, an ecosystem is a set of species interacting intimately with all the inputs and outputs of resources and energy. Given that, for most assemblages, vital resources of food are autotrophs which require sunlight, the connection of use of solar energy must extend to all organisms on the planet that are dependent on solar energy. Thus, in an attempt to use a rational definition, all of life on Earth, except for chemotrophs (e.g., organisms around deep-sea vents of hot water), should be considered to be in a single ecosystem. In its most extreme form, the world as a single ecosystem has achieved considerable impetus from the well-publicized concept of Gaia. This is the Earth conceived to be responding to change as though it were a single entity. Despite this concept, it is, however, not clear that the whole planet has yet been demonstrated to be a necessary, nor useful unit of study for ecologists.

Why Are Communities Found in Nature?

One of the reasons for there being so many observations of communities in nature seems to be intimately related to receive wisdom (paradigms) about units of study. If an ecologist strongly believes that plants and/or animals are in communities, with few species overlapping from one community to another and with fairly abrupt boundaries, there can be problems for designing objective sampling. Suppose it is thought, or it has been described, that there are, say, three communities along some environmental gradient. Each of these communities is associated with particular dominant or abundant species (A and B; C; D and E; respectively). A study in some new area may well involve searching along the gradient until A and B are numerous together. This purportedly identifies the presence of the first community. The second community is identified to be where C are numerous, and the third where D and E are numerous together. Now, sampling around the three areas which have been already designated to be containing different communities will, inevitably, reveal great differences in the species making up the communities and in the densities or relative abundances of species in each community. Similarly, if two areas are defined to contain the same community, because they each have an abundance of the species that dominate that community, sampling in the two areas will inevitably reveal quite a lot of similarity.

Instead, sampling along the gradient should be at random or regular intervals, depending on the nature of the study and the hypotheses being tested. Then, at least, there is no prior dogma defining where to sample. Data about the identities or abundances of species at each point sampled can then be analyzed to test hypotheses.

Sampling without unquestioned acceptance of the existence of communities is, however, also fraught with difficulties, as illustrated in **Fig. 1**. In the first case (**Fig. 1a**), there are three very well-defined communities along an environmental gradient. Very few species transcend these structures. Sampling at the sites indicated will reveal different sets of species, with very little overlap. The data would reveal that communities exist because sample points contain quite different sets of species.

Unfortunately, if the species are entirely independently distributed along the gradient, this type of sampling will not be useful. Sampling at intervals along a gradient (as in **Fig. 1b**), where species have independent distributions, would also reveal apparent communities. There would be different sets of species at each place sampled. The data would be very similar whether or not communities really exist.

Independence of distributions is essentially the null hypothesis against which to test the hypothesis that species are clumped as communities, with nonrandom commonality of boundaries. There is, of course, a third alternative that species have boundaries that are more regularly spaced than is the case for randomly distributed species. This is, however, irrelevant to any attempt to identify the existence of communities.

This has led to the realization that identification of nonrandom patterns in arrangements of species along environmental gradients requires data about the actual distributions, rather than sampling of organisms at intervals across the habitat. One methodology uses contiguous quadrats across the gradient. The numbers of species that have a boundary in each quadrat are recorded (as in **Figs. 1c** and **1d**). So, transects of quadrats up a mountainside would be examined. As one progresses from the bottom upward, the first occurrence of a member of a particular species indicates its lower boundary. The number of these lower boundaries is recorded for each quadrat. Similarly, the quadrat in which the last member of a species is encountered denotes its upper boundary.

This is illustrated for the two distributions, each with 18 species, in **Fig. 1**. For the species in **Fig. 1a**, the numbers of lower and upper boundaries per quadrat are shown (**Fig. 1c**). The same data are shown for the distribution in **Fig. 1b**; there are clear differences. The clumped species have more boundaries in some quadrats (i.e., more 2's and 3's) than shown by the randomly scattered species. The former also have more and larger gaps between quadrats with boundaries.

Methods to analyze such data began to appear in ecological papers in the mid-1970s. Note that it is therefore a recent phenomenon to have statistical techniques to use in tests of hypotheses about the existence of communities where these are defined in terms of nonrandom coincidences of their boundaries. Prior to the last 30 years, it was very difficult to use the sorts of data collected by community ecologists to distinguish between communities (i.e., with clumped boundaries), random and regular patterns of distributions of species.

Collective Properties of Assemblages

One reason that it matters whether or not species coexist in structured communities is because of so-called 'emergent properties' of associations of species. Thus, communities were long thought to have properties, or characteristics, that were not discernible, nor

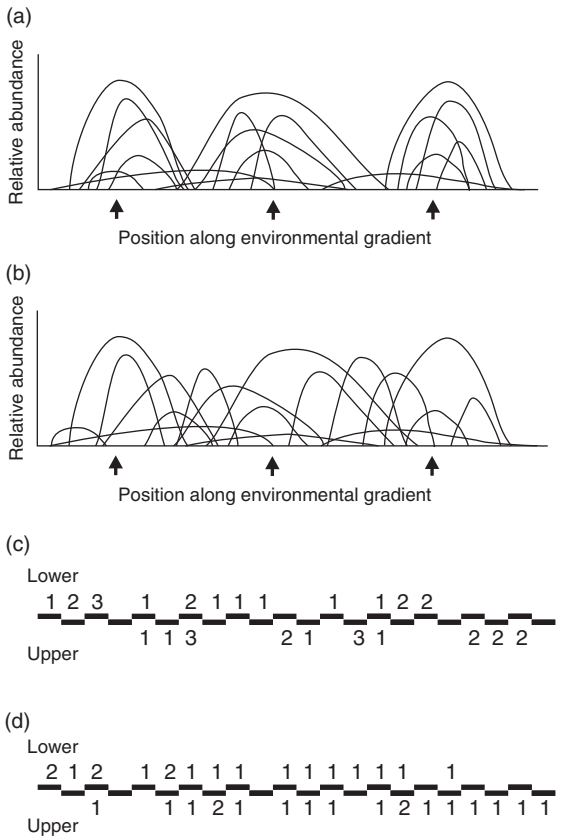

Fig. 1 Sampling along an environmental gradient (e.g., distance from a river, height up a mountain) to detect communities of species. (a) Most species are arranged in discrete communities, with very few occurring across boundaries of communities. Edges of distribution of the species in one community are coincident and there is little overlap with an adjacent community. (b) Species are arranged independent of each other and there are no communities. Sampling at intervals along the gradient (at the positions shown by arrows) would reveal different assemblages of species whether or not they were actually structured into communities. (c) and (d) The numbers of lower and upper boundaries per quadrat of the 18 species are shown for (a) and (b), respectively. The black bars represent the quadrats used along the gradient. Boundaries appear more clumped in (c) than in (d) (there are more boundaries in some quadrats in (c) than in (d); see text for details), identifying the difference between the two sets of distributions of species.

predictable, from knowledge of the species as individual entities. The properties of a set of species interacting with each other in a community were emergent in the sense that one had to study the community to know about, understand, or explain them. These characteristics of species 'emerged' from the community as the unit of study.

There has been widespread discussion of the concept of emergent properties in ecological investigations. Some of this discussion is, to say the least, confusing. For example, some properties of a set of species are simply collective properties due to grouping them into a set (whether or not such grouping is appropriate). Often, the diversity of species in a community is considered to be an emergent property, because it cannot exist for the individual species. In fact, this is a collective property that can be determined from the properties of the component species. An analogy is the average size of individuals of a population of deer. This is not a property of the individual deer, but can be calculated from their individual sizes. It does not 'require' study of the population as an entity.

Emergent properties may exist. For example, natural selection may operate on individuals because of their interactions with (and only with) other members of a community. If this were the case, clearly the community would have to be studied as a unit; the process (the property) could not be found (would not emerge) from study of only the component species.

As with other issues about communities, the concept of emergent properties is confusing, because the term means various and different things. To some, it means properties that become apparent when the scale of observation is changed, but this does not apply in the context of communities. The observations that are interpreted to be indicating the evidence of a community are at a particular scale; it makes no sense to change the scale.

To others, emergent properties are those that are unexpected to find in an assemblage because not enough information was available about its components. Using this definition, emergent properties are those that are found by studying communities, but that were not known from information about the component species. Ignorance about components does not make a more holistic study the best option – the community would still have to be understood in terms of its components for that ignorance to be dispelled. Apart from that, any such property could only possibly 'emerge' once. Once the property is known for one assemblage, it

can be predicted for another assemblage from similar knowledge about the components of that assemblage. This scarcely defines emergent properties of communities in a useful manner.

The third and, probably, philosophically most useful meaning of emergent properties is that they exist in a community, but cannot possibly be derived from knowledge of components of the community. Thus, reductionist studies of ecology will fail to provide understanding of communities because studying the components will not lead to understanding of the community as a whole.

So, for communities to be appropriate units of study, not only must they have some definable structure (as above), but also they must have emergent properties, so that subcomponents (i.e., the populations of different species) and their interactions are not appropriate units. This makes the practical usefulness of the concept of a community very difficult to demonstrate. Whether or not trying to demonstrate that existence of emergent properties is useful is a moot point, because it can distract from the real task of understanding the ecology of the observed assemblage.

A final comment on emergent properties is that many ecologists have holistic views about the way organisms operate, based on patterns of energy flow through ecosystems. Properties of ecosystems that make them appropriate units for study presumably include emergence. This makes the use of ecosystems even more problematic than the definitional problems briefly discussed earlier.

Do Ecologists Study Communities?

Apart from ecologists who have not been consistent in using any definition of a community, there are many who have attempted to define community and, perhaps, have attempted to demonstrate that what they study actually fits the definition. Searching the ecological literature for studies of communities is, however, revealing about the nature of community ecology. It is surprising to discover that many studies are, in fact, only about components of a community. The most common type of study is actually about a group of species that are closely related taxonomically, for examples, the warblers in a forest, or all the birds in a watershed, or all the beetles on a farm. Apart from being in different habitats, these three examples would usually involve increasing numbers of species. But, does this sort of study actually have anything to do with a community, where this has been defined in a useful or meaningful way?

The assemblage of fish on a patch-reef, or birds in a patch of forest, could only represent a community if no other species were interacting with them. Each group is generally interactive with other animals and plants as sources of food (and for other things). Such groupings are sometimes and should more generally be described as 'taxocoenes', that is, species that are related taxonomically and are found together in the same area.

Other ecologists study a 'guild', defined as an assemblage of species of similar or quite different taxonomic affinity that are found together and that use the same resources (for food, or shelter, etc.). For these, the term 'guild' is more informative than community (unless the definition of community is the same as guild, which makes the former redundant). An example would be to study, in some area, the set of birds, mammals, and ants that feed on seeds of the same species of plants.

So, most community ecologists do not actually study communities! There are, nevertheless, some cases where the unit of study is a community, where this means tightly coevolved species of different kinds of animals, living in close association, in the same arrangements at many times, in many places.

The classical examples are communities of host–parasite or host–pathogen relationships. The parasites are generally considered to persist because they adapt, immunologically, behaviorally, etc., to the host, despite the host's attempts to get rid of the parasites. Thus, nematodes and tapeworms are well adapted to their host's morphology, behavior, physiology, biochemistry, etc. If they were not so tightly integrated with the host, they might be likely to kill the host or to prevent it from reproducing. Both host and parasite would go extinct. Alternatively, the host would adapt to be able to rid itself of infestation and the parasite would not persist. Close coadaptation is therefore essential for the various species involved in a host–parasite community.

It is thus the case that some specialist communities do exist, can be objectively defined, and can be demonstrated to fit the definition. These are then the cases of communities which deserve the term as a description that identifies their usefulness as units of study. Caution is, however, still required. Not all cases of host–parasite (and similar) assemblages are so tightly structured. Many parasites have a complex life cycle, involving several quite different types of hosts (snails and sheep for some cestodes; invertebrates, birds, and fish for others). Under these circumstances, understanding the ecology of the assemblage of host and parasites requires understanding the direct and indirect trophic and competitive interactions between the hosts and other species that interact with them, but which are not involved with the parasites. This immediately creates all the problems of definition that were involved for any other apparent community.

Conbiota

Brian D Fath, Towson University, Towson, MD, United States and International Institute for Applied Systems Analysis, Laxenburg, Austria
Felix Müller, Christian-Albrechts-University, Kiel, Germany

Introduction

Textbooks described *Ecology* as the study of how organisms relate to other organisms and with their physical environment. More basically, this means the interactions of the living and nonliving aspects of the environment, or simply a study of the biotic and abiotic interactions in space and time. The breakthrough in this clarification, first proposed by German biologist, Ernst Haeckel in 1866 was the recognition and inclusion of the interactions and feedbacks of two broad scientific domains that previously were rarely considered in unison. The field of ecology has developed well over the past 150 years with little change in this basic direction or understanding.

However, this foundational insight raises some important questions. Just as biology addresses the fundamental question of "What is life?," we must also ask ourselves "What is nonlife?" The notion that we can distinguish between biota and abiota is perhaps a fallacy that should be explored more deeply.

By definition, abiota means without biota, or expressly, without life. Such conditions are easy enough to imagine in areas devoid of life, such as on the moon or other celestial surfaces known to be lifeless. However, any planet, such as earth that has life, it is clear that there is a constant and profound interplay between life and nonlife. The life actively selects elements from its environment and rearranges the chemical and physical conditions of that environment. Therefore, our contention is that it is inaccurate to refer to most nonliving aspects of the environment as abiotic. We introduce a new term, *conbiota*, to convey the sense that these environmental factors are not independent from life, but have coevolved *with life*. We provide several examples of this phenomenon and encourage readers to further explore and develop this concept of interdependence.

Global Examples of Coevolution Between Life and Environment

A useful perspective of the environment is to envision four interacting spheres: atmosphere, hydrosphere, lithosphere, and biosphere. The chemical composition of these four spheres is shown in **Table 1**. The current atmospheric balance, with a high concentration of reactive oxygen, is thermodynamically far from equilibrium, which is maintained by the renewal processes of the photosynthesis in the biosphere. This is evident in James Lovelock's famous insight that one way to detect if life is on a planet is to investigate the chemical composition of its atmosphere. In other words, basic atmospheric chemistry has evolved with life. The presence of oxygen not only was a requirement for the evolution of aerobic respiration, but also the precursor to the formation of the stratospheric ozone layer that provides protection from the sun's ultraviolet radiation. This has direct impact on the form of the lithosphere, and through indirect feedbacks, impact on the biosphere itself. Before the protective ozone layer was established, life was confined to water and near shore mudflats, which also provides some diffusive shield from the radiation. Thus, stratospheric ozone was a necessary step for the colonization of land by plants and animals. Before the advent of land plants, circa 600 million years ago, orogenic uplift activities would erode back to the sea "relatively" quickly, on a geological time scale of a few hundred million years. With the establishment of land plants, erosion rates were greatly reduced by the deep root action maintaining soil structure. Therefore, the lithosphere also is influenced, not only in composition but in form. The current topography of the planet is not an abiotic geological artifact but the coevolutionary result of life—nonlife interactions. **Fig. 1** shows possible pathways of exchange between the spheres. Note that while even a lifeless environment could experience exchanges, life is the active integrator of these spheres: the main drivers of transformation originate with life.

Local Examples of Coadaptation Between Life and Environment

At a local scale, scientists measure abiotic factors such as wind, light, temperature, humidity, runoff, soil chemistry, etc. It is clear to anyone that has walked through a forest that these factors are not independent of life. Quite the contrary, the measurements are highly adapted to the presence of living organisms. For example, under the canopy of a closed forest, the air is still, the temperature cool, the light subdued, the humidity high, and the rainfall largely intercepted. In an open field, one experiences more directly the sun, wind, rain, etc. Data from two experimental sites in Germany show explicitly the impact that biota can have on previously assumed abiotic factors.

The respective research sites are situated in the Bornhöved Lakes district and they have been investigated in an ecosystem research project for several years by several cooperating working groups. The detailed framework conditions and related results can be found a summarized form in Fränzle *et al.* (2008).

The first example (Fig. 2A) demonstrates that organisms are manipulating the temperature regimes in their habitat, showing temperature regulations and buffer capacities related to microclimatic conditions. The figure includes a comparison of a beech forest ecosystem and the directly neighboring arable land ecosystem at the Bornhöved research area during one day in the summertime (June 11th). The measured temperatures in the air (0 to 36 m) and the soil (0 to −1 m) are depicted as hourly temperature gradients. The highest temperatures in the air appear at the 18:00 curve, the lowest at 5:00 in the beech forest. The grassland conditions are similar concerning the timing, but rather different concerning the amplitudes: 8–35°C in the air of the grassland, while the structure of the beech forests limits the span width to 10–24°C. In the soil, similar relations can be seen, whereby the average temperature of the grassland is much higher than in the beech forest, which shows an amplitude of about 2°C while 10°C are reached in the grassland.

The winter conditions are visible in Fig. 2B. Here the buffering capacity of the forest canopy is reduced strongly, therefore also the temperature amplitudes are high in beech forest. Also, the sequence of time steps is similar in both cases but the soils differ very much. While the winter temperature buffering capacity of beech forest is very high, higher frost challenges appear in the case of the grassland.

Similar to the temperature climate, ecosystems are also modifying their hydrological conditions on the base of living processes or living process products, such as soil organic matter or substrate heterogeneity. The plants are producing heterogeneity of hydrological pathways, for example, by stem flow or through fall distributions, and they are also strongly determining the seepage dynamics, the evapotranspiration and—by these factors—the whole water budget. Fig. 3 is demonstrating these conditions with reference to the two compared ecosystems "arable land" and "beech forest," which have also been analyzed in the temperature figures. The two ecosystems were both used as agricultural fields until 100 years ago when the forest was planted. Thus, all distinctions have been emerging due to different land use structures—and different conbiotic relations—for 100 years. Here, we can see interesting differences with respect to the pathways of water loss: while in the agricultural fields the seepage is dominating,

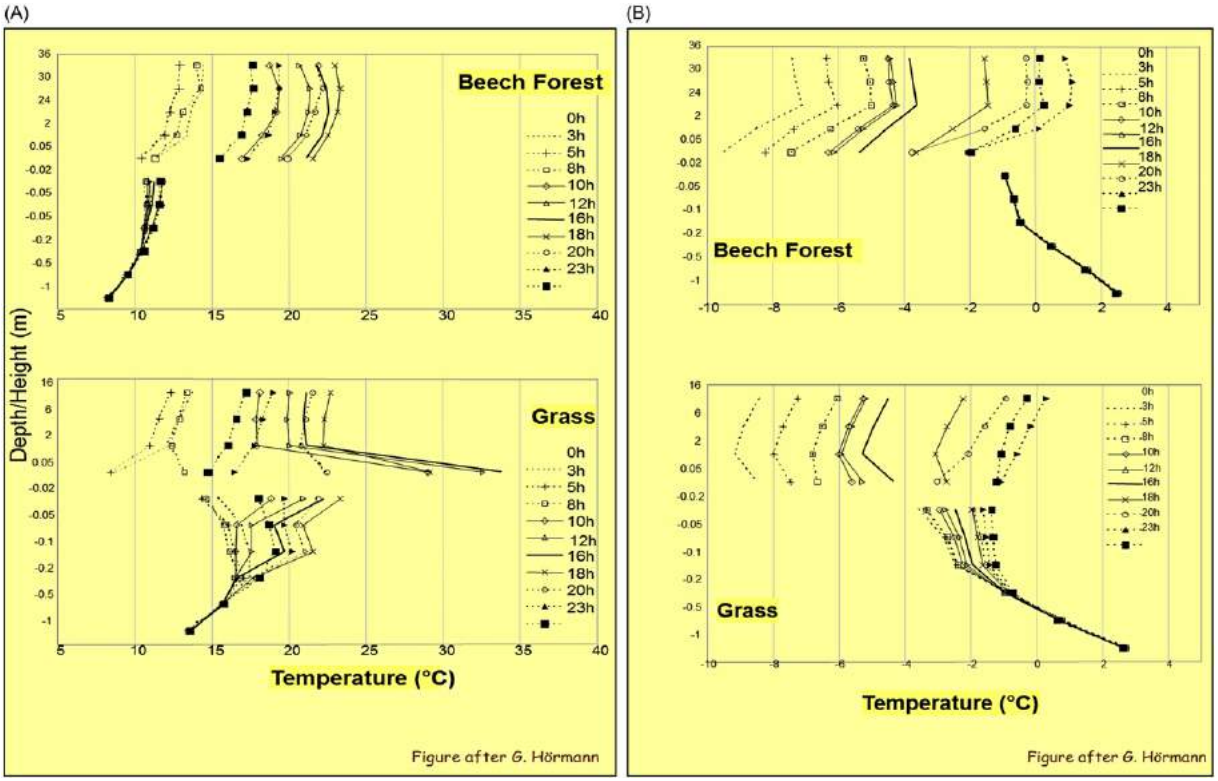

Fig. 2 (A) Temperature profiles of a beech forest ecosystem and the directly neighboring arable land ecosystem (planted with grass) at the Bornhöved research area in the summertime (June 11th). The measured temperatures in the air (0 to 36 m) and the soil (0 to −1 m) are linked as hourly temperature gradients. Measurements and data compilation were done by Hörmann and colleagues. (B) Temperature profiles of a beech forest ecosystem and the directly neighboring arable land ecosystem (planted with grass) at the Bornhöved research area in the winter (December 29th). The measured temperatures in the air (0 to 36 m) and the soil (0 to −1 m) are linked as hourly temperature gradients. Measurements and data compilation were done by Hörmann and colleagues.

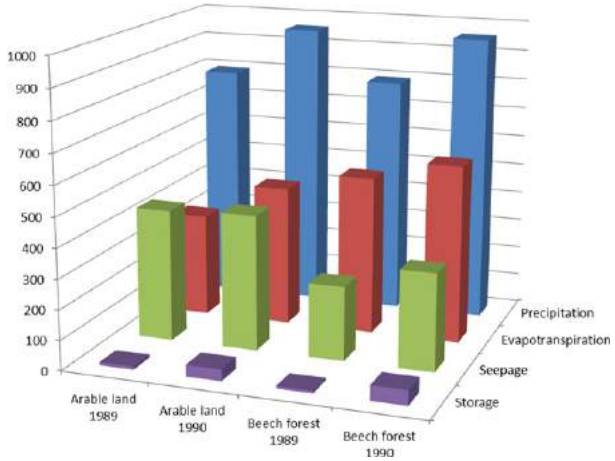

Fig. 3 Elements of the soil water balance of the two ecosystems "beech forest" and "arable land" in the Bornhöved Lakes area in mm/a, following Bornhöft (1993, p. 91).

producing a flow toward the groundwater layer, the forest flows are dominated by evapotranspiration flows, whereby the transpiration is the most important process.

In Fig. 4, the soil water balance of the arable land ecosystem is depicted as a gradient scheme from 1989 to 1998. Each row shows the development of the volumetric soil water content within 1 year (number of days at *x*-axis), and the colors are related to the percentage; deep blue demonstrates a high water content, while it is low in the case of the red colors. Obviously, at the measured field, the lower soil compartments are much dryer than the upper ones; around 50 cm depth, the plowing inputs have

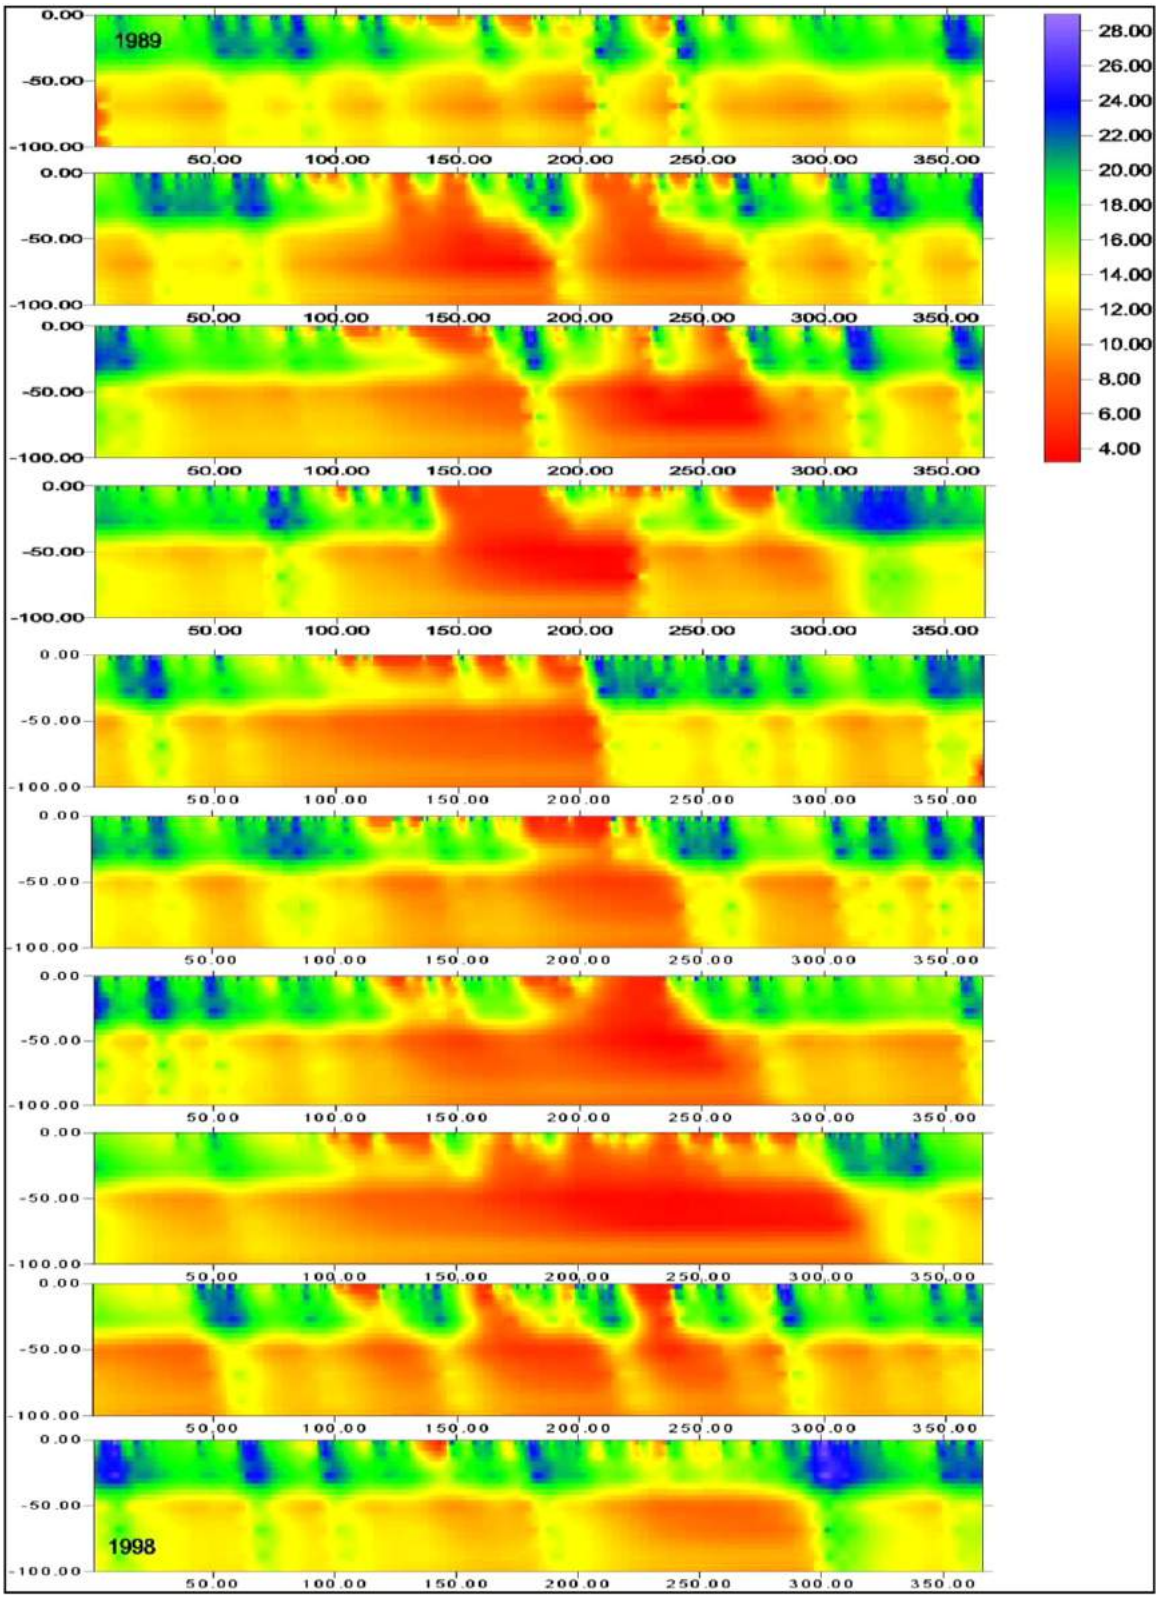

Fig. 4 Dynamics of volumetric soil moisture gradients (vol%) at the arable land site of the Bornhöved research area between 1989 and 1998. Data compilation and measurements by G. Hörmann and colleagues (see Fränzle *et al.*, 2008).

produced a strong gradient. This evidence of a plow pan can be found in all cases. The abiotic conditions are here regulating the water flows, which only in a few cases (blue intrusions) show rapid drainage phases, thus the "living space" with active plant roots

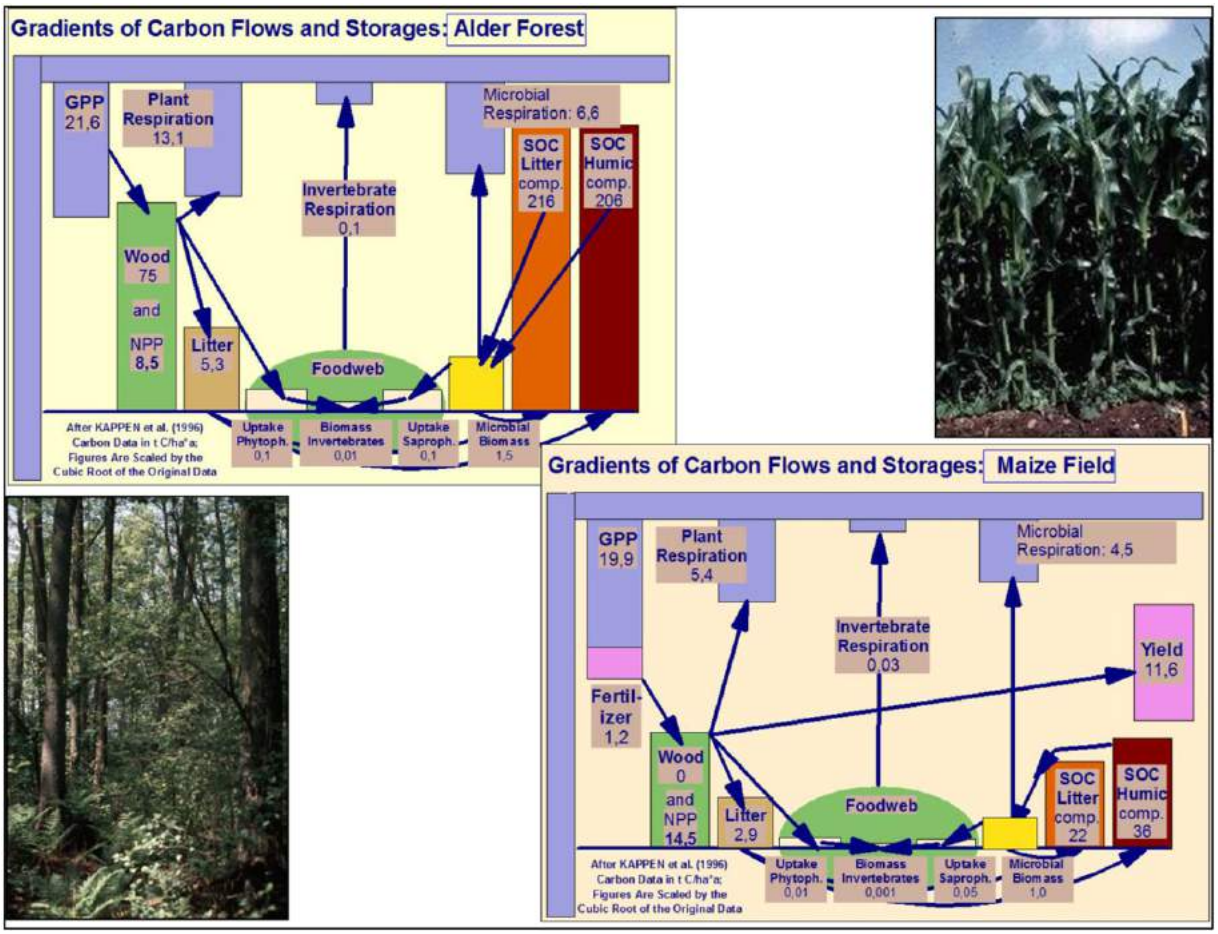

Fig. 5 Elements of the carbon budget of the alder forest ecosystem in comparison with the arable land test site at the Bornhöved research area. For original data and detailed descriptions see Fränzle *et al.* (2008).

is separated from the dry soil body in the deeper compartments. In this case, the biotic interference of the "abiotic" soil conditions was human use of the ecosystem for agriculture.

Another interesting observation can be related to the climate dynamics throughout the years of measuring activity: the summer drying period is steadily increasing in length and intensity between 1992 and 1996.

Fig. 5 also shows us how biotic and abiotic elements are cooperating and how the factors are mutually influenced. The flows of carbon are assessed for two ecosystems, the alder forest of the Bornhöved main research area and the neighboring maize field, which is the (meanwhile well-known) arable land ecosystem. While in this system, through agriculture, there are annual measures that reorganize it to a pioneer stage, the alder forest has had about 60 years to develop on the base of former wetlands. Thus, we can find extreme distinctions, for example, concerning the organic carbon contents in the soils, which are distinguished here into litter (easily decomposable) and humic compounds (hardly decomposable). Both fractions provide minimal values at the field ecosystem, which are not given the chance to store detritus as soil organic carbon in a higher intensity. These abiotic items are underlined by the water conditions: while the field is representing a rather dry state, the alder forest provides a steadily wet soil, which additionally is influenced by N fixing bacteria of the Frankia type. Furthermore, the forest has been enabled to build up a self-organized structure with many micro habitats which are missing on the field. Finally, the architecture of the forest is providing a well-buffered microclimate. In the end these "abiotic" factors which have been mainly achieved due to biotic activities, are providing habitat conditions for several species, thus the biomass of the fauna is 10 times higher than the biomass of the field ecosystem.

Finally, the biotic and abiotic conditions are summarized in **Fig. 6**, where integrity indicators are depicted in a comparison of the beech forest and the neighboring arable land ecosystem. The assessment of integrity has been based on the orientor approach (Müller and Leupelt, 1998) and ecosystem concepts, which try to synthesize ecosystem structures and functions, representing the ecosystem energy, water, and matter balances. Thus, we find a holistic representation of the degree and the capacity for complexifying ecological processes on the base of an accessible number of indicators. They also represent the basic trends of ecosystem development; thus, they show the developmental stage of an ecosystem or a landscape. They are totally based upon the conbiotic idea: biotic and abiotic elements are forming a mutual system of interactions with increasing interrelations as the developing sequence of succession continues. In this sequence, the system is optimizing the following indicators: biodiversity, abiotic heterogeneity, exergy capture, entropy export, storage capacity, reduction of nutrient loss, biotic water flows, and metabolic

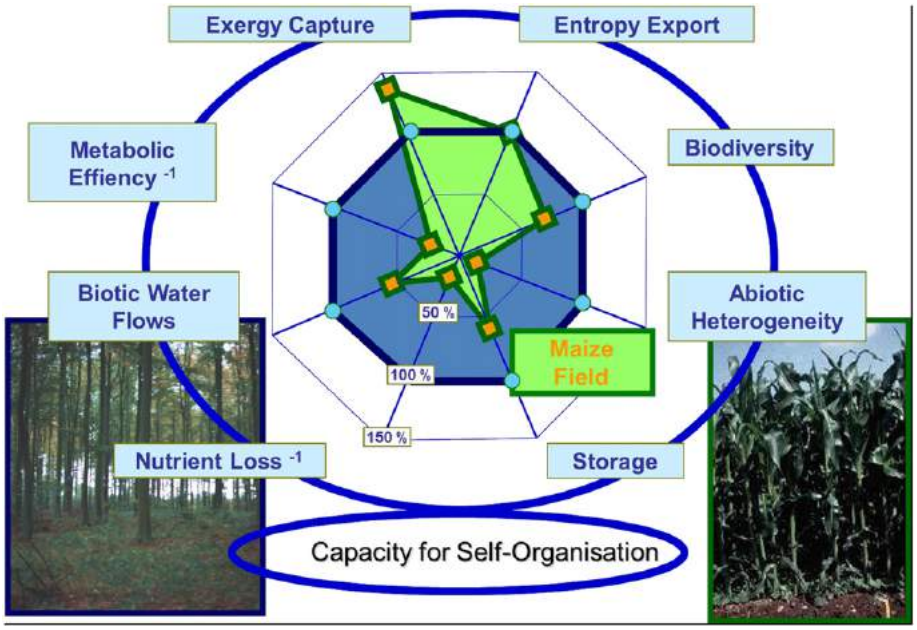

Fig. 6 Comparison of indicator values for ecosystem integrity referring to two ecosystems in Bornhöved Lakes research area. After Müller, F. (2005). Indicating ecosystem and landscape organization. *Ecological Indicators* **5**(4), 280–294.

efficiency. All of them are produced as outcomes of biotic and abiotic activities, thus the basic features of ecological systems in fact are founded on conbiotic structures and functions.

Conbiota through a successional lens also leads to the recognition that environments are in varying stages of integration and development. The degree to which life modifies and shapes that environment is along the continuum from early states of succession to later stages of succession. Much emphasis is placed in succession theory on the traits of the "r-selected" species and "K-selected" species. The former are fast-growing, short-lived, with effective dispersal mechanisms such as wind borne seeds. They often employ vegetative or asexual reproduction, do not compete well with other species, and their numbers fluctuate widely, being strongly influenced of density-independent factors. The latter are slow-growing, long-lived, with low reproductive rates and dispersal rates. Populations are more stable due to diversion of production to defense and parental investment. These two characters present end points for idealized species to occupy a role. However, just as important as the species itself is the environment in which it inhabits. There are "r-selecting" environments and "K-selecting" environments. The former are more extreme, ephemeral, unpredictable (Fig. 7A), and the latter are more stable, homeostatic, and predictable (Fig. 7B). Furthermore,

they are that way precisely because the interactions between life and the environment. This is additional evidence that the earth is a self-regulating, feedback-driven system such that life creates conditions that are conducive to life.

Summary and Conclusion

The idea that life and environment are deeply intertwined is not new. However, language matters, and the current vocabulary that employs biota and abiota as strict opposites does not accurately reflect the reality of the situation. Therefore, here we suggest introducing the term *conbiota* to explicitly and formally recognize the coevolutionary and coadaptive ways in which life alters and shapes its environment. This term is a broad brush that acknowledges the role of life, but we assume that there is a gradient of influence of life on environment. Further refinement of this concept could lead to new classes of properties that measure the degree to which life plays an active role. This might spark a discussion not only into the question we posed earlier, "What is life?," but also into its counterpart "What is environment?"

Cooperation☆

Raghavendra Gadagkar, Indian Institute of Science, Bangalore, India

Background

Not surprisingly, humans have displayed an absorbing fascination for examples of cooperation in the animal world, long before the evolutionary puzzle associated with them became evident. Indeed, freedom from evolutionary thinking accommodated all manner of untenable theories about cooperation, in the past. While T.H. Huxley believed that cooperation and altruism were only possible among close kin and P. Kropotkin saw "mutual aid" everywhere he looked, unconnected with any sort of kinship, both W.C. Allee and V.C. Wynne Edwards succumbed to a naive form of group selection, the notion that cooperation and self-sacrifice existed because they were good for the group and the species—never mind that they were harmful to the individuals displaying them.

Kin Selection

Modern evolutionary thinking by people such as J.B.S. Haldane, W.D. Hamilton, R.L. Trivers, J.M. Smith, and E.O. Wilson, which kept in mind the critical problem of the potential for a few cheaters to wreck any cooperative group, has given us our current theories of cooperation. These modern advances have depended in part of clear-cut demarcation and definition of different kinds of interactions possible among animals (see **Fig. 1**). The most significant advance in explaining the evolution of cooperation came from Hamilton's inclusive fitness theory. Not only does this theory provide a logical explanation for why cooperation evolves more easily among kin, it also shows why close kinship is not always essential. Kin selection or, more precisely, Hamilton's rule has three parameters, namely, cost to the actor, benefit to the recipient, and the coefficient of relatedness between actor and recipient. Given appropriately skewed cost/benefit ratios, it is easy to see that even rather low levels of relatedness can satisfy Hamilton's rule. Unfortunately, an excessive and often exclusive focus on measurement of relatedness and the neglect of the cost and benefit terms in empirical studies, has sometimes given the false impression that kin selection fails to explain cooperation.

When the cost and benefit terms have been adequately measured, Hamilton's rule has proved to be a powerful theoretical framework for understanding the evolution of cooperation and altruism in a wide variety of organisms from bacteria to man. To cite just two examples, studies on the white-fronted bee-eater in Kenya have shown that not only the presence of helpers at the nest but also the bizarre behavior of the father's harassing their sons to return and act as helpers, is consistent with the predictions of Hamilton's rule. Computation of the costs, benefits, and relatedness involved in different strategies shows that by harassing their sons and bringing them back to help rear additional offspring, fathers gain a substantial fitness advantage. In contrast, sons reap about the same fitness benefit whether they resist their father's harassment and carry on with their own family life or whether they succumb to the harassment and return to act as helpers. And in the primitively eusocial wasp *Ropalidia marginata*, Hamilton's rule correctly predicts that only about 5% of the individuals should opt for solitary life while the remaining should opt for altruistic, sterile worker roles.

In any case, kin selection is indeed inadequate when cooperation is directed toward nonrelatives, as it often is in human societies. Those who study humans use a somewhat more liberal use the word cooperation using it not only when there is cooperation, that is, both actor and recipient benefit from an interaction but also when there is altruism, that is, when the actor pays a cost and only the recipient benefits, cost and benefit being measured of course in terms of Darwinian fitness. To help explain the evolution of cooperation by natural selection in the absence of close genetic relatedness between actor and recipient, at least four additional potential mechanism of evolution have been suggested, in addition to kin selection (see **Fig. 2**). The first of these additional mechanisms is Direct Reciprocity, originally proposed by Robert Trivers as "Reciprocal Altruism." The idea here is that if a cost incurred now is retrieved at a later point in time, then both actor and recipient will benefit on the long run. As might be expected, such reciprocity will require individual recognition, long-term memory, and well developed cognitive abilities. For these reasons direct reciprocity is more likely in humans than in animals for which it was first proposed. And once we allow cognitive abilities involving recognition and memory, other more sophisticated and more subtle mechanisms can be imagined. For example, one can postulate that there is no need for the same individual who received help to reciprocate. As long as the helper received help in the future from someone, the same effect is achieved. This is possible if the act of helping someone by a helper is noticed by others in the population and the helper builds up a reputation for being a helper. Then others who may

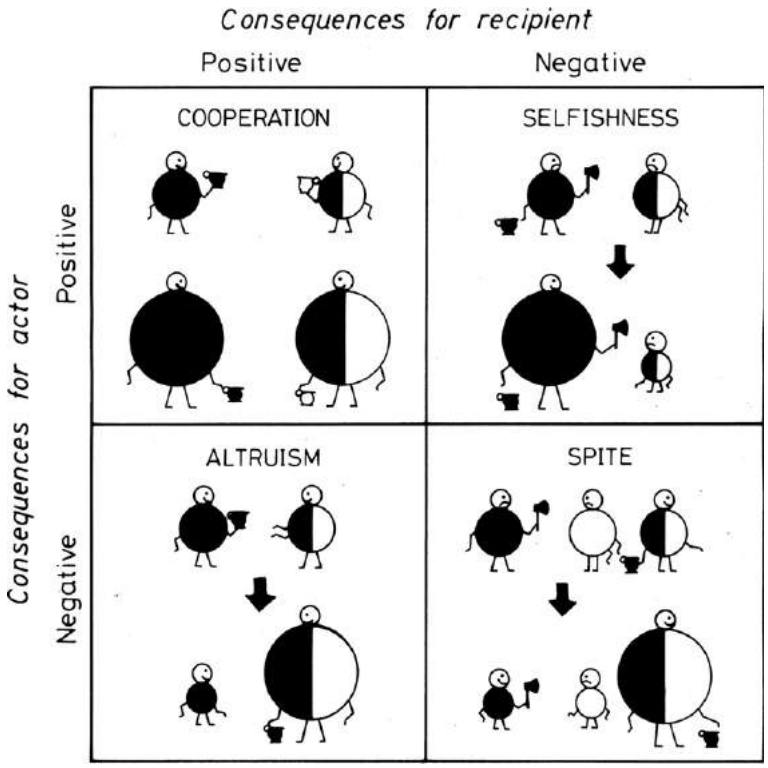

Fig. 1 The consequences of interaction between animals. The recipient here is the actor's brother and therefore shares 50% of his genes, as is indicated by the shading. Help of any kind (the offering of food or shelter, easing access to a mate, and so on) is indicated by a vessel, and harmful behavior by an ax. *Cooperation*: Both individuals benefit and such behavior will therefore evolve easily. *Altruism*: The altruist diminishes his own genetic fitness but raises his brother's fitness to the extent that the shared genes are actually increased in the next generation. *Selfishness*: The selfish individual reduces his brother's fitness but increases his own to an extent that more than equals the brother's loss. *Spite*: The spiteful individual lowers the fitness of an unrelated competitor (the unshaded figure) while reducing that of his own or at least not improving it; but the act increases the fitness of the brother to a degree that more than compensates for the actor's loss. Reproduced from Gadagkar, R. (1997). Survival strategies—Cooperation and conflict in animal societies. Cambridge, MA: Harvard University Press.

not necessarily have received help directly from this helper will also be likely to help her because she is a known helper. This kind of mechanism labeled as Indirect Reciprocity is postulated to explain why for example, people donate to charities. A more sophisticated form of indirect reciprocity may involve cooperators for spatially defined networks to keep cheaters at bay. This is labeled as Network Reciprocity and has been shown mathematically to help cooperation to evolve in populations of potentially selfish individuals. Finally there is Group Selection, a refined version that is cognizant of the problem of cheaters and postulates that although selfish individuals outcompete cooperative or altruistic individuals within groups, groups of cooperators outcompete groups of selfish individuals and the net effect depends on how fast the selfish individuals drive cooperators within group to extinction relative to how fast groups of cooperators drive to extinction groups of selfish individuals. Despite their apparent diversity, these five mechanisms for the evolution of cooperation have a rather beautiful mathematical unity (see Nowak, 2006).

Perhaps the most fascinating recent advance in the study of cooperation and altruism in humans has been due to the collaboration of evolutionary biologists, psychologists, and economists and the use of "games," such as the ultimatum game and the public goods game, to uncover patterns of human behavior. The main results of such studies are that people by and large do not behave and expect others to behave, in apparently rational, selfish ways traditionally predicted by theoretical economists. Instead, people behave in a fair manner and expect others to do the same. Even more interestingly, people appear to have an innate dislike for cheaters and are often willing to incur as cost to themselves to punish cheaters even if it yields them no direct benefit. The prevalence of such "altruistic punishment" is now thought to be the evolutionary force that maintains cooperation and altruism in human societies.

It must be mentioned that even in the context of evolution of sociality and cooperation in animals and insect societies such as those of ants, bees and wasps, kin selection itself has recently come under severe criticism. Claiming that kin selection, also known often as inclusive fitness theory or Hamilton's rule, is not sufficiently general and robust, some prominent researchers have turned back to a combination of individual and group selection to explain the evolution of cooperation, altruism, and

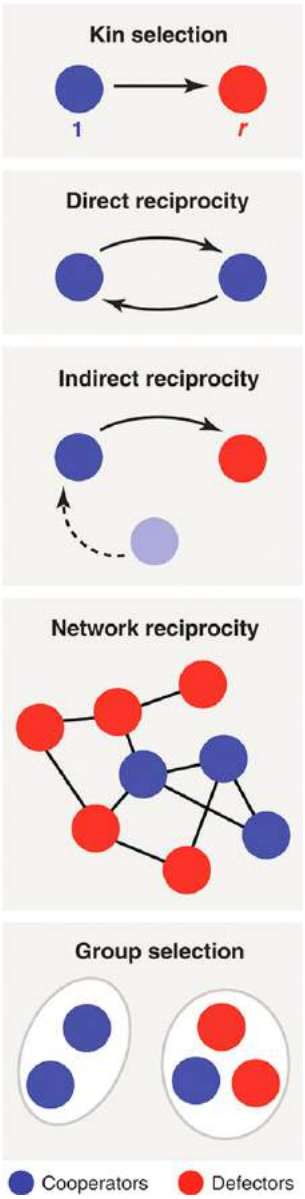

Fig. 2 Five mechanisms for the evolution of cooperation. Kin selection operates when the donor and the recipient of an altruistic act are genetic relatives. Direct reciprocity requires repeated encounters between the same two individuals. Indirect reciprocity is based on reputation; a helpful individual is more likely to receive help. Network reciprocity means that clusters of cooperators outcompete defectors. Group selection is the idea that competition is not only between individuals but also between groups. Reproduced from Nowak, M. A. (2006). Five rules for the evolution of cooperation. *Science* **314**, 1560–1563.

sociality in the animal kingdom as a whole. This effort is sometimes referred to as multilevel selection. While the defenders of kin selection have dismissed these criticism as unjustified and a rather fierce debate has ensued and deeply divided the disciple, it appears to me that the scientific study of cooperation in animals and humans is poised for even more exciting new developments, whichever way the debate for and against kin selection goes. This optimism is rooted in the current realization among biologists that although natural selection is rooted in competition it is cooperation among competing actors that is central to every major evolutionary innovation, every major transition in evolution, whether it was the origin of cells, of eukaryotes, of insect and other animal societies, or of language.

Demography

B-E Sæther, Centre for Conservation Biology, Norwegian University of Science and Technology, Trondheim, Norway

Introduction

Generation time, that is, the mean age of mothers of newborn individuals when stable age distribution is achieved, summarizes many key demographic features of a species. Long generation times occur when the survival rate is large and when the population growth rate or the net reproductive rate is small. Here we shall show that variation in generation time can explain many basic relationships between demography and population dynamical characteristics and life history.

Definition of Generation Time

The famous Euler–Lotka polynomial equation,

$$\sum_{x=1}^{\omega} \lambda^{-x} l_x m_x = 1$$

allows us to calculate the asymptotic population growth rate λ if the survival function l_x, which gives the probability of being alive from age 1 to age x, as well as the fecundity rate at age x, m_x, are known. This equation has ω roots, that is, equal to the maximum number of age classes, which can be obtained numerically. The generation time is then given by

$$T = \sum_{x=1}^{\omega} x\lambda^{-x} l_x m_x$$

Many species have demographic rates that are almost constant or independent of age. If α is the age of first reproduction, and assuming $\omega = \infty$, we get a simplified expression for the generation time $T = \alpha + s/(\lambda - s)$, where s is the adult survival rate. We see that in general, T decreases with λ and increases with the net reproductive rate.

The `Slow–Fast' Continuum of Life-History Variation

Comparative analyses of many taxonomic groups have shown a strong covariation among different life-history traits. At one end of this `slow–fast' continuum of life-history variation, we find species that mature early and have large litter sizes, but short life expectancy. At the other end of this continuum, species are located that start to reproduce first after several years, have a small litter size (often just a single offspring), but have high adult survival rates, which may exceed 95%.

The sensitivity of λ to a small change in a demographic trait can be derived by implicit differentiation of the Euler–Lotka equation trait, giving

$$\frac{\partial \lambda}{\partial m_x} = \frac{\lambda^{-x+1} l_x}{T} \text{ and } \frac{\partial \lambda}{\partial s_x} = \frac{\lambda^{-x} l_x v_{x+1}}{T}$$

where v_x is the reproductive value:

$$v_x = \frac{\lambda^x}{l_x} \sum_{u=x}^{\omega} l_u m_u \lambda^{-u}$$

Similarly, the elasticity of ln λ to a change in the logarithm of a life-history parameter is

$$e_p = \frac{\partial \ln \lambda}{\partial \ln p} = \frac{p}{\lambda} \frac{\partial \lambda}{\partial p}$$

The elasticity index can be used to compare the relative contribution of the trait to the population growth rate λ because elasticities sum up to 1. We can then examine how the same relative change in a trait, for example, in adult survival, will affect λ when we move along the `slow–fast' continuum of life-history variation.

In birds, some clear patterns appear in the interspecific distribution of elasticities. (1) The mean elasticity across species of adult survival rate was significantly larger than the mean elasticity of fecundity rate. (2) The distribution of the elasticities of fecundity rate was skewed against small values, whereas the elasticities of adult survival rate values were approximately normally distributed around the mean (Fig. 1). (3) The elasticity of adult survival increased with adult survival rate (Fig. 2a) and decreased with clutch size (Fig. 2c). In contrast, the elasticity of fecundity rate decreased strongly with adult survival rate (Fig. 2b), and hence age at maturity, but increased with clutch size (Fig. 2d). Thus, relative changes in adult survival of birds have larger impact on the

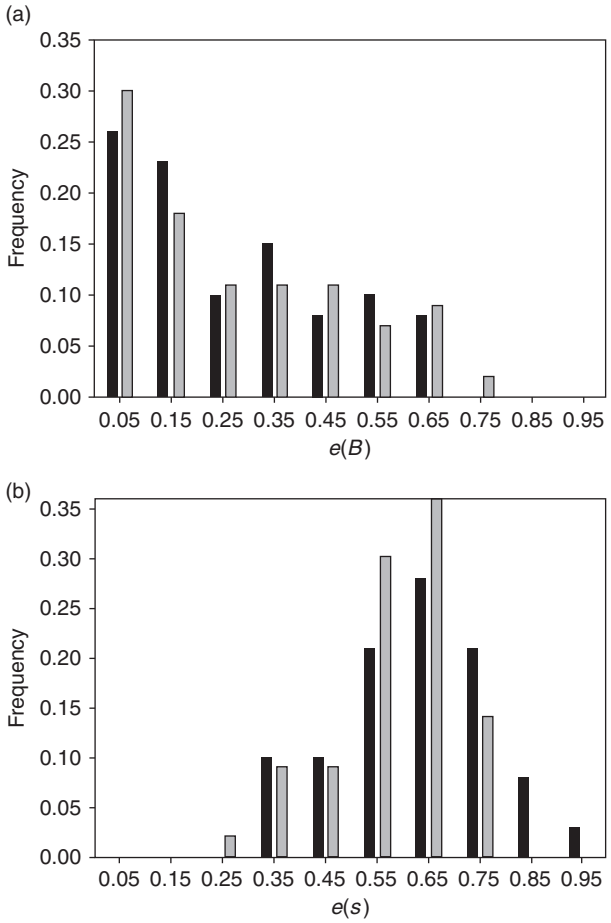

Fig. 1 The distribution of the elasticities of the (a) fecundity rate $e(B)$ and (b) adult survival rate $e(s)$ calculated for the asymptotic population growth rate λ estimated from the Leslie-matrix (solid columns) and when the juvenile survival rate s_{juv} is chosen to give $\lambda = 1$ (shaded columns).

population growth rate than changes in fecundity rate. Furthermore, the growth rate of species at the slow end of the `slow–fast' continuum of life-history variation is more sensitive to changes in adult survival rate than high-reproductive species. Similar patterns also seem to be present in other vertebrate taxa as well.

Decomposing Population Dynamics

Analyses of time series of population fluctuations show large interspecific differences in population dynamics. As a first step, it is convenient to classify them into time series that show a long-term increase or decrease, and time series that show fluctuations around some mean population size. In the first group, there is no density dependence, and the changes from one year to another are determined by the population growth rate and stochastic variation in the growth rate. In the second group, density dependence is also present, which produces a characteristic return time to equilibrium.

Stochastic variation in the population growth rate is due to demographic and environmental stochasticity. Demographic stochasticity is caused by random variation among individuals in fitness contributions due to independent chance events of individual survival and reproduction. This produces random fluctuations in population size, with variance proportional to σ_d^2/N. Environmental stochasticity affects the age-specific demographic rates of all individuals in the population similarly, producing a constant variance among years in the population growth rate σ_e^2, independent of population size. Thus, environmental stochasticity affects the population at all sizes, whereas demographic stochasticity most strongly influences the dynamics at smaller population sizes.

To understand the effects of generation time we must examine how it affects each of the components in the population dynamics.

Life-History Correlates of Demographic Stochasticity in Birds

Based on individual demographic data, the demographic variance σ_d^2 can be estimated from data on individual variation among females in their fitness contributions to the following generations. The total contribution of a female i in year t (R_i) is the `number of female offspring born during the year that survive for at least 1 year' plus 1 if the female survives to the next year. The

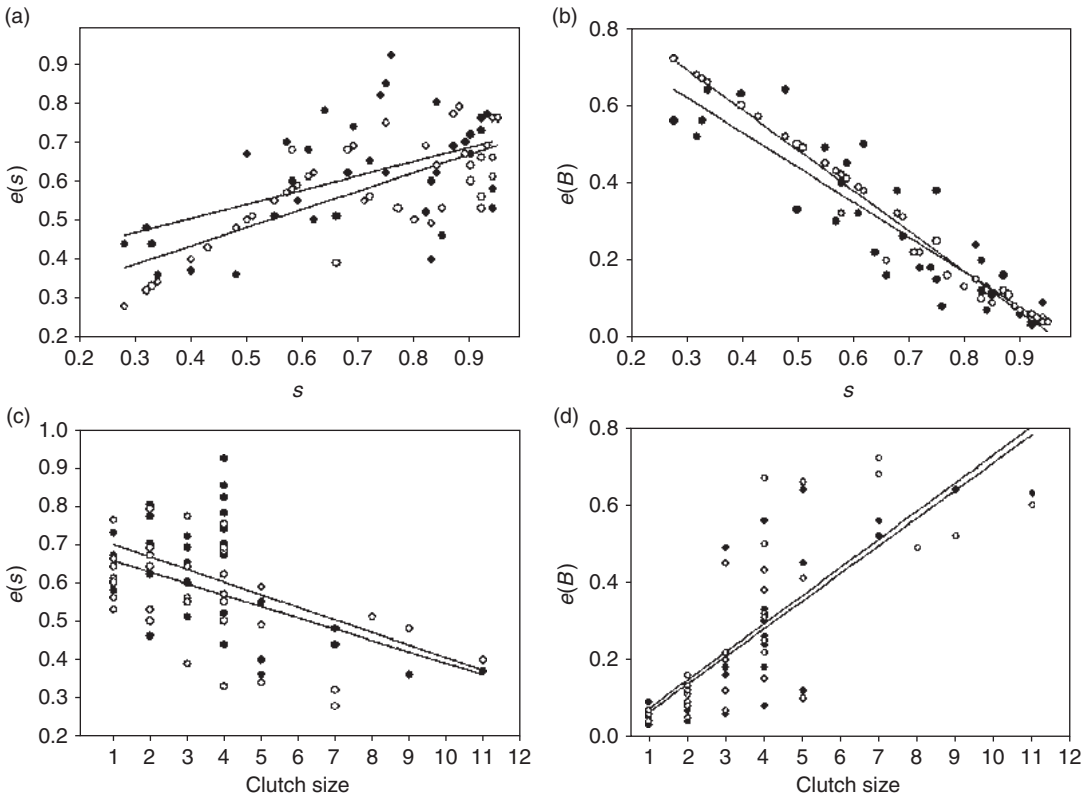

Fig. 2 The elasticity of adult survival rate $e(s)$ and fecundity rate $e(B)$ of birds in relation to adult survival rate s and clutch size, calculated for the actual asymptotic population growth rate λ (circles) and when the juvenile survival rate s_{juv} is chosen to give $\lambda = 1$ (squares).

demographic variance can then be estimated as the weighted mean across years of

$$\sigma_d^2(t) = E\frac{1}{a-1}\sum (R_i - \overline{R})^2$$

where $\bar{R}$ is the mean contribution of the females, a is the number of recorded contributions in year t, and E denotes the expectation. We can further partition σ_d^2 into components due to variation in fecundity, survival, and interaction between fecundity and survival. Writing B for the number of offspring produced, $I = 1$ if the mother survives and $I = 0$ if she dies, the demographic variance is the mean over years of the within-year variance of $R = B + I$. This can be split into its components $\mathrm{var}(R) = \mathrm{var}(B) + \mathrm{var}(I) + 2\mathrm{cov}(B, I)$ that can be estimated separately by simple sum of squares. In long-lived species, stochastic variation in age structure constitutes an important component of demographic stochasticity and for species with a mean age of maturity older than 3 years we must base our estimates on contributions (B_{jt}, I_{jt}) for the different age classes i in year t. We then calculate the demographic stochasticity from the projection matrix and separate this into components that are generated by demographic stochasticity in each vital rate.

It is obvious that such detailed demographic data are rarely available. However, in birds we can compute demographic variance of several species and relate the estimates to the position of the species along the `slow–fast' continuum of life-history variation. According to one hypothesis, σ_d^2 is expected to increase with adult survival rate (and hence to decrease with clutch size) because very few offspring recruit in short-lived species with a high first-year mortality. Alternatively, σ_d^2 can be expected to decrease with adult survival rate because life-history constraints (small reproductive rates, high life expectancy) generate small variability in fitness among individuals in long-lived species.

In birds, the two components of the demographic variance due to stochastic variation in fecundity and survival were positively correlated. As expected from this relationship, interspecific differences in demographic variance were closely related to the size of both the fecundity component and the survival component. Interspecific differences in demographic stochasticity were well explained by life-history variation. Larger values of σ_d^2 were found in species at the fast end of the avian life-history continuum, that is, in species with large clutch sizes (**Fig. 3a**), short life expectancy (**Fig. 3b**), early age at maturity, (**Fig. 3c**) and short generation times (**Fig. 3d**). This supports the hypothesis that the level of demographic stochasticity in avian population dynamics is subject to life-history constraints on the possible range of variation in fecundity or survival, resulting in small values of σ_d^2 in long-lived species with small reproductive rates.

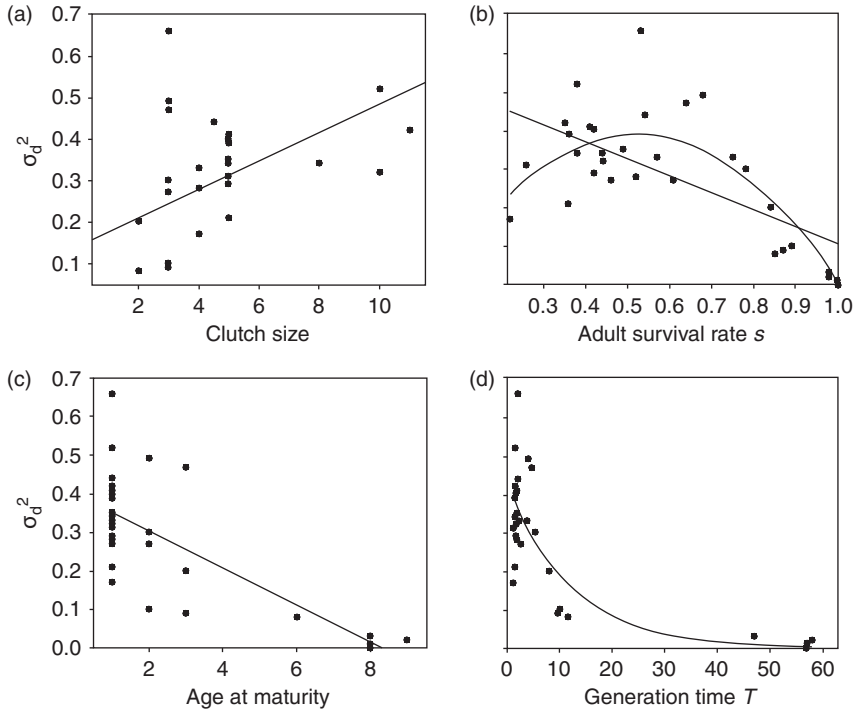

Fig. 3 The mean value across bird species of the demographic variance σ_d^2 in relation to (a) clutch size, (b) adult survival rate s, (c) age at maturity, and (d) generation time T.

A General Definition of Density Dependence of Age-Structured Populations

To analyze the effects of density dependence on the population dynamics, let us first consider a simplified life history in which individuals mature at age 1 year with adults having age-independent fecundity and survival. We can then write the dynamics $N(t) = \lambda[N(t-1)]N(t-1)$, where $N(t)$ is the population size in year t and $\lambda[N(t-1)]$ is the density-dependent finite rate of increase. The strength of density dependence γ in such a model can be defined as the negative elasticity of the population growth rate λ with respect to changes in population size N, evaluated at the carrying capacity $K : \gamma = -\left(\partial \ln\lambda / \partial \ln N\right)_K$. This approach can be extended to an age-structured density-dependent life history in which the total density dependence in the life history, D, should be defined as the negative elasticity of the population growth rate per generation, λ^T, with respect to the change in the size of the adult population when fluctuating around the carrying capacity, so that

$$D = -\left(T\frac{\partial\ \ln\lambda}{\partial\ \ln N}\right)K \qquad [1]$$

where T is the generation time. Thus, the annual rate of return to equilibrium then becomes $\gamma = D/T$.

Population Dynamics of Birds in Relation to Generation Time

This general definition of density dependence (eqn [1]) facilitates comparison of population dynamics across species with different types of life history. Here the author illustrates this approach by comparing the stochastic density-dependent population dynamics of different bird species. We assume that the expected adult annual survival and fecundity rates are independent of age, that density dependence is exerted by the adult fraction of the population on any combination of juvenile and adult vital rates, and, finally, that deviations of the adult population at time t from equilibrium $x(t) = N(t) - K$ are expected to be small or moderate. Based on these assumptions, we obtain a linearized autoregressive model with time delays from 1 to α years:

$$x(t) = \sum_{i=1}^{\alpha} b_i x(t-i) + \omega(t) \qquad [2]$$

where b_i is the autoregressive coefficient for time lag i, $\omega(t)$ is a noise term with mean zero and variance σ_ω^2, describing environmental stochasticity, including transient fluctuations in age structure and autocorrelations due to long-term fluctuations in the biotic or abiotic environment.

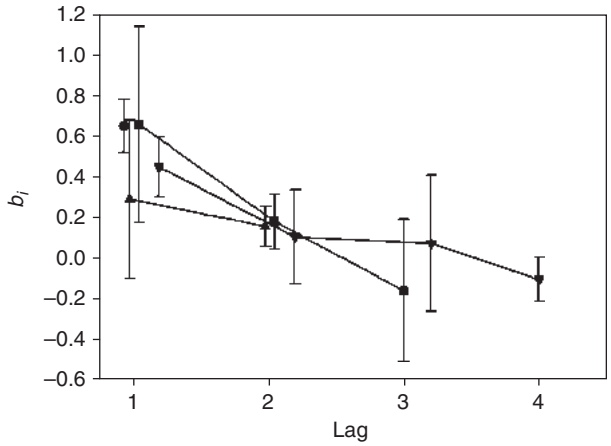

Fig. 4 Mean values (±SD) of the autoregression coefficients b_i for different lags in the population dynamics of birds in relation to variation in age at maturity of birds. Circles represent species that mature at 1 year, triangles age at maturity at 2 years, squares age at maturity at 3 years, and reversed triangles species that mature at 4 years or older.

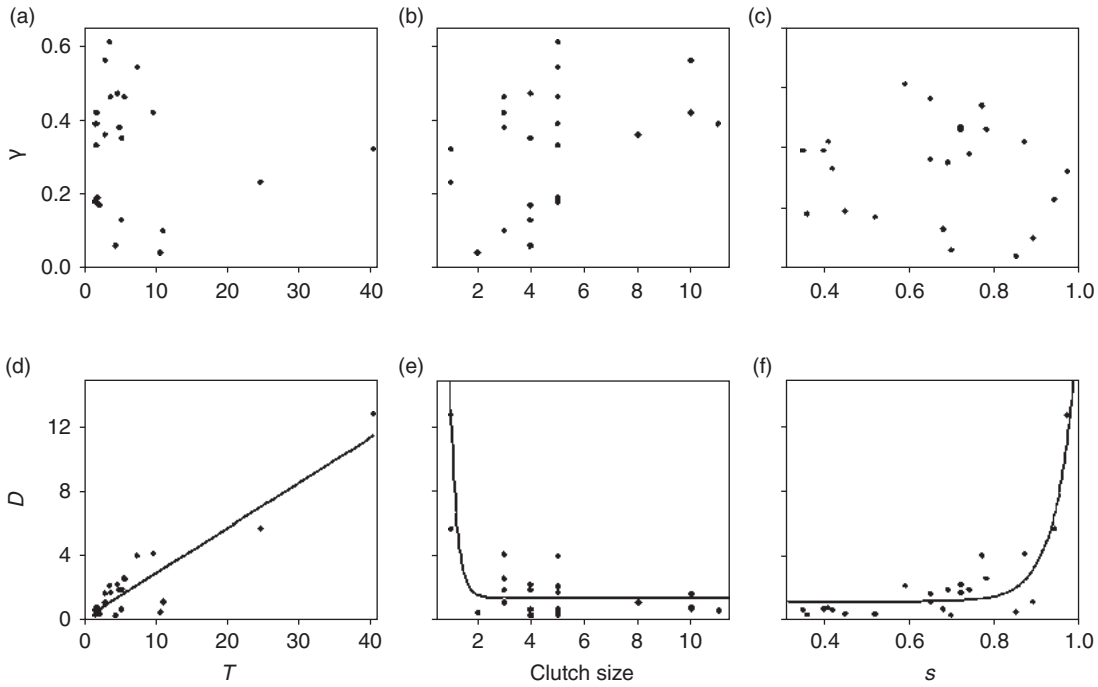

Fig. 5 The strength of density dependence in annual population fluctuations γ and in the total life history D in relation to (a), (d) generation time T; (b), (e) clutch size; and (c), (f) adult survival rate s of birds.

The autoregression coefficients b_i for species with age at maturity $\alpha \geq 2$ decreased with time lag (**Fig. 4**), indicating that the effects of the previous years' population sizes on current population size decreased with time. These autoregression coefficients b_i do not directly reveal the strength of delayed density dependence because they depend on life-history parameters as well as density dependence in the vital rates. In a species with $\alpha > 1$ with no density dependence in subadult or adult survival rates, b_1 equals the adult annual survival rate, s. Similarly, in a species that matures at 1 year, if $b_1 = 0$ the population autocorrelations for all time lags will be zero, corresponding to a white noise process for the population size $N(t)$ that indicates strong density dependence.

Again using the general definition of density dependence (eqn [1]), it is evident that there is a relationship between total density dependence in the life history and the autoregression coefficients

$$(1 - s)D = 1 - \sum_{i=1}^{\alpha} b_i \qquad [3]$$

In our data set from birds, the density-dependent effects at annual scale were independent of life history, including generation time (Fig. 5a) as well as clutch size (Fig. 5b) and adult survival rate (Fig. 5c). As a consequence, the stationary variance in the time series σ_N^2 was also independent of life history.

We have previously shown that many avian demographic traits such as clutch size and age at maturity scale closely with adult lifespan. Accordingly, we find that several features of population dynamics measured on a timescale of generations can be predicted from life-history characteristics. The strength of total density dependence in the life history D increased with generation time T (Fig. 5d) and adult survival rate (Fig. 5f) but decreased with clutch size (Fig. 5e). This implies that the effect on the population growth rate per generation of a change in population size was larger for long-lived than for short-lived species. Consequently, the rate of return to equilibrium measured in generations decreases with generation time T (correlation coefficient of $\log_{10}$-transformed values $= -0.73$, $P < 0.001$, $n = 23$).

To compare the residual variation in the population process, we must account for interspecific variation in age at maturity that will cause differences in the lag structure of the population dynamics. We first estimate the variance in the stationary distribution of the population sizes σ_N^2 in our model (eqn [2]) and then calculate the variance in the noise of a first-order process with a single time lag of 1 year, σ_ϵ^2, that will give the same stationary variance in population size as in the full model. Theoretical analyses show that variance for this white noise process for species with age at maturity larger than 1 year should be approximately equal to the environmental variance. In our bird data set, $\log_{10} \sigma_\varepsilon^2$ was independent of $\log_{10} T$ (Fig. 6a). In contrast, there was a highly significant linear increase in $\log_{10}(\sigma_\varepsilon^2 T)$ (Fig. 6b). Furthermore, the environmental variance for this process per generation ($\sigma_\varepsilon^2 T$) was closely related to life-history characters, that is, $\sigma_\varepsilon^2 T$ decreased with clutch size, but increased with adult survival rate. This suggests that environmental stochasticity per generation is greater for long-lived species than for species with short life expectancies. In contrast, interspecific differences in avian demographic stochasticity per generation are independent of life-history variation.

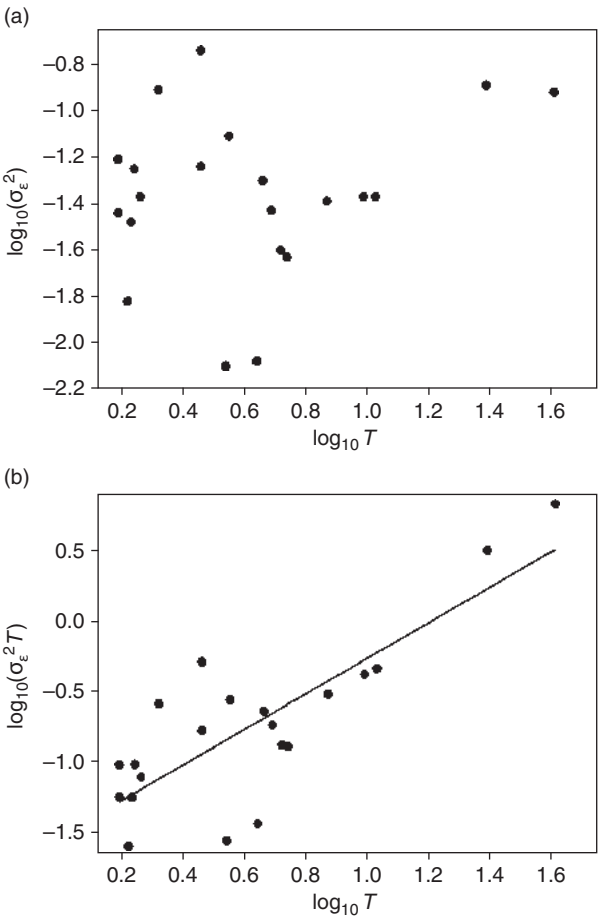

Fig. 6 (a) The residual variance in a first-order process, σ_ϵ^2, describing environmental stochasticity transient fluctuations in age structure as well as long-term autocorrelations in the environment and (b) in the total residual variance over a period of one generation $\sigma_\epsilon^2 T$, in relation to generation time T of birds.

Conclusion

Life-history traits show in most taxa a strong pattern of covariation. In many cases, species distribute them along a `slow–fast' continuum of life-history variation, for which generation time is a useful proxy. These analyses demonstrate clearly how many population dynamical patterns can be explained by the species' location along this continuum.

Detritus☆

Martin Zimmer, Leibniz Centre for Tropical Marine Research, Bremen, Germany and University of Bremen, Bremen, Germany

Glossary

Detritus Particulate dead organic matter of plant, animal or microbial origin.

Degradation Chemical breakdown of chemically diverse detrital compounds through, e.g., light (photo-degradation), microbial activity, or digestive processes of detritivores.

Decay Physico–chemical and microbial processing of detrital matter, such as leaching or microbial degradation.

Decomposition Entire process of detrital breakdown through decay, promotion by detritivores and direct contributions of detritivore, such as feeding and digestion, and mineralization.

Detritivore Animal that feeds on detritus (mostly used in aquatic ecology).

Decomposer Microbial contributor to decomposition.

Mineralization Final step of decomposition: transformation of organic matter into inorganic compounds.

Saprophage Animal that feeds on detritus (mostly used in terrestrial ecology for an animal that feeds on leaf litter).

Spatial subsidy (Organic) Matter, e.g., detritus, that is transported passively or actively from one (donor) habitat to another (recipient) habitat where it serves as resource to consumers in the recipient habitat; spatial subsidies are allochthonous material, contrasting autochthonous material that is derived from the same habitat.

Detritus

The term detritus summarizes nonliving organic matter, be it of animal, plant, or microbial (protist, fungal, bacterial, archeal) origin. For decades, it remained an ongoing debate as to whether or not "detritus" includes living microorganisms that colonize and nutritionally utilize the organic matter or inorganic components incorporated in detrital pellets. However, detritus sensu *strictu* consists of particulate organic matter (POM) that is to be degraded and does not include the agents of detritus degradation nor inorganic compounds that cannot be degraded. In aquatic ecology, dissolved organic matter (DOM) is sometimes considered a significant portion of detrital matter (together with POM). Part of DOM is derived from POM through initial steps of decay (see below), and remarkable amounts of DOM are exuded from living organisms. Hence, DOM is, strictly speaking, not to-be-degraded dead organic matter but either a product of detrital leaching (see below, for distinction between detritus and its leachate) or, similar to fecal matter (see below), derived from living organisms rather than the result of a death event. On the other hand, detrital matter is essentially always microbially colonized, and hence, a distinction of detritus and the living microbial biomass might not be reasonable from an ecological point of view.

Herein, the focus will be on dead plant material, not including microbial or inorganic components, since this is the most significant contributor to detritus in most terrestrial and aquatic systems. This view coincides largely with what is called "litter" in terrestrial ecology, whereas "POM" in aquatic ecology, and "wrack" in marine ecology, may also include organic matter of animal origin. Thus, it is obvious that a definition of the term detritus that is commonly agreed upon beyond ecological disciplines can hardly be provided.

Origin

As is obvious from the above, the origin of detritus is manifold. Because of its overwhelming importance in terms of both quantity and significance for nutrient cycling, mostly plant litter (i.e., detritus of vegetal origin) will be considered here. Detritus of animal origin (necromass) should be named carcass or carrion, and animals feeding on such organic matter are necrophagous (rather than saprophagous or detritivorous); this and other potential contributors to the total detrital mass will be briefly discussed below.

Two sources of plant detritus, namely vascular plants and macroalgae, that can be subdivided further, will be considered here. Besides photosynthetically active tissue, be it leaves, needles or stems, some vascular plants produce woody tissue (i.e., twigs, branches and logs). Dead roots contribute to the belowground pool of detrital matter and may decompose into mineral nutrients quickly (fine roots) or remain particulate over months and years (woody coarse roots; see woody detritus).

Although terrestrial by origin, vascular plants grow in, and produce detritus into, the terrestrial and both the freshwater (freshwater macrophytes and spatial subsidy from land plants) and the marine environment (seagrasses, saltmarsh vegetation, and mangroves). Macroalgae solely occur in the marine environment, but some of their detritus is exported into the semiterrestrial environment of the littoral and supralittoral coastal area, along with marine macrophyte detritus. Under particular conditions,

☆*Change History*: November 2017. M Zimmer is the sole author involved. The entire text has been slightly modified and updated. All figures where transferred in color figures.

This is an update of M. Zimmer, Detritus, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 903–911.

 doi:10.1016/B978-0-12-409548-9.10918-2

such as in floodplain forests, initially terrestrial detritus that has been deposited in freshwaters may, along with small amounts of detritus of aquatic origin (i.e., algae), occasionally be relocated into the terrestrial system (e.g., upon seasonal inundation or, as in the case of the marine-terrestrial transition zone, upon extreme tide events). On the other hand, inundation of flood plains may import additional terrestrial material from the terrestrial into the aquatic system.

Thus, detritus plays an important ecological role both as autochthonous source of nutrients (see **Table 1**) and as spatial subsidy (**Fig. 1**), i.e., as allochthonous resource that is passed from a donor in one habitat to a recipient in a second habitat. Detritus of terrestrial origin is also the major energy source to many lentic freshwaters and low-order streams in forested areas, making up several hundreds of grams per meter square per year. This subsidy of terrestrial detritus to freshwaters is mostly significant during winter (i.e., after autumnal leaf fall and under conditions of low productivity of planktonic or benthic aquatic plants). Huge amounts of up to several kilograms (dry mass) of detrital marine macrophyte wrack are deposited per km shoreline at the upper margin of the intertidal zone of rocky shores and soft sediment beaches with each incoming high tide, summing up to hundreds of tons per kilometer shoreline per year. Owing to the strong influence of tidal water movements and coastal winds as well as fast decomposition rates of some but not all marine detritus, the resulting high-intertidal wrack line is subject to enormous temporal variability and dynamics in both quantity and quality of detritus. Along the same line, tropical intertidal mangrove forests and temperate intertidal saltmarshes trap allochthonous detrital matter, originating from marine algae and macrophytes, as well as autochthonous detritus

Table 1 Estimated average production of detritus in selected generalized types of ecosystems (based on different sources)

	Production ($g\ m^{-2}\ a^{-1}$)
Freshwater macrophytes	300
Freshwater microalgae	
Phytoplankton	20
Phytobenthos	20
Marine microalgae	
Phytoplankton	20
Phytobenthos	30
Marine macrophytes	
Seagrass beds	500
Marine kelp forests	800
Macroalgae	300
Terrestrial macrophytes	
Saltmarshes	800
Mangrove forests	900
Tropical forests	300
Deciduous forests	100
Boreal forests	50
Grasslands	75
Tundras	25

Note that variation around these averages may be high when comparing, e.g., temperate and tropical systems, or seasonal patterns within a particular system.

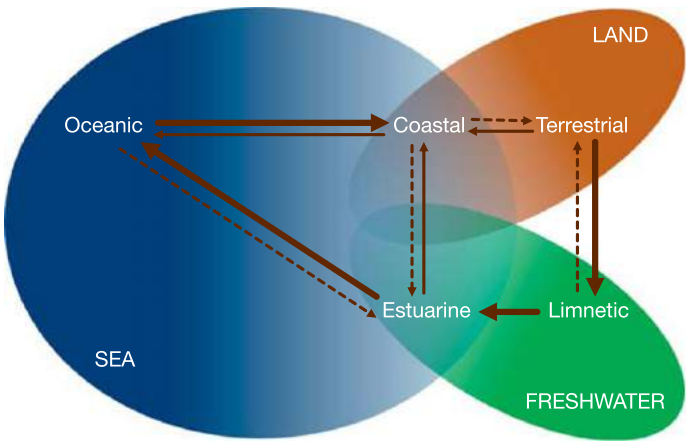

Fig. 1 Pathways of exchange of detritus among, and detrital connectivity of, ecological systems. The strength of an arrow indicates the significance and probability of the depicted connection and its direction.

among their aerial roots and stems. On the other hand, these intertidal ecosystems feed an annual amount of up to 1 t angiosperm detritus per kilometer coastline into estuaries, coastal waters and the open sea, and thus, contribute to the fertility of shelf zone.

In geographical zones with seasonal patterns of climatic conditions, leaf litter input into terrestrial and aquatic (mostly freshwater) systems (i.e., senesced leaves of broad-leaved deciduous trees) peaks during fall. However, some leaves are shed while still green and photosynthetically active, owing to physical disruption, be it through animal action or wind. The needle litter of coniferous trees is shed almost evenly over the year (but see *Larix decidua*, the European larch), but exhibits some rhythmicity of, e.g., 4 (Scots pine, *Pinus sylvestris*) or 7 (Norway spruce, *Picea abies*) years. It is mostly through physical disruption, but also senescence, that twigs and smaller branches of trees fall onto the forest floor or into forested water bodies. By contrast, bigger branches and logs become detritus through anthropogenic action (silviculture and logging) or upon death of the tree (e.g., through storm events or lighting strikes). All these events are more or less evenly distributed seasonally. Many aquatic vascular plants—freshwater macrophytes, marine seagrasses and intertidal saltmarsh vegetation—exhibit strong seasonality with increased release of detritus during fall, in some cases accompanied by a total die-off of above ground biomass. This seasonal pattern gets enforced by storm-driven wave action that predominates in fall and to a lesser extent in spring. Marine macroalgae, finally, show a pattern of detritus production that is similar to, but less marked than in, aquatic macrophytes. In tropical rainforests, the seasonality of litter fall seems to be correlated with rainfall seasonality, exhibiting peak litter fall after the dry season. However, species-specific litter fall dynamics result in a much more evenly distributed production of vegetal detritus. Two of the three predominant tree species in North Brazilian mangrove forests exhibit only little seasonality in litter fall, but *Avicennia germinans* sheds most of its leaves between the end of the rainy season and the start of the dry season.

Composition

The species composition of detritus in different ecosystems reflects the primary production of the respective autochthonous and allochthonous sources. Accordingly, it is necessary to distinguish between (terrestrial) angiosperms, aquatic macrophytes and algae (cf. **Fig. 1**). Terrestrial plant detritus has a substantially wider C:N (and C:nutrient) ratio than most aquatic organic matter, and is thus more difficult to decompose. An even narrower C:N ratio than in aquatic vegetal detritus is characteristic of detritus of animal origin (see below) the significance of which varies temporally and between distinct habitats. Algal detritus contains few and little recalcitrant compounds, such as cellulose, lignins or phenolics. Among terrestrial detrital sources, these parameters vary both among species and within a given species with environmental conditions (**Table 2**). Water-soluble compounds are readily leached off the detritus during early decomposition stages, particularly under moist or submerged conditions. Upon decay, the C:N ratio of the detritus-microbe conglomerate usually significantly drops, owing to the developing dense microbial biomass that accumulates nitrogen from the surrounding environment as well as leaching of carbonic but retention (immobilization) of nitrogenous detrital compounds.

Thus, wrack deposits in the high intertidal can be rich in nitrogen and poor in structural defense compounds, if they mainly consists of macroalgal material and animal necromass, or they are rich in cellulose and lignins but poor in nutrients, if mostly angiosperms, be it subtidal seagrasses, intertidal saltmarsh vegetation, or terrestrial vegetation, contributed to the wrack. Similarly, it is essential to freshwaters whether the detrital source is aquatic macrophytes and planktonic or benthic algae or terrestrial angiosperms. In the terrestrial realm, we distinguish between monocot detritus in grasslands and dicot detritus in forests, the latter, in turn, originating from either shrubs or woody plants, being either deciduous, evergreen or coniferous trees.

Decay and Decomposition

Detritus of whatever origin is decayed through leaching of water-soluble compounds of mostly low molecular mass and the action of microbial decomposers (decay: see Glossary). Feeding by detritivores (mostly in aquatic ecology; Latin: *detrítus*: scree, rock

Table 2 Comparison of terrestrial and aquatic sources of detritus with respect to estimated ranges of contents (%) of significant determinants of detrital quality to decomposing organisms (based on different sources)

	Limnetic		*Marine*		*Terrestrial*
	Angiosperms	*Algae*	*Angiosperms*	*Algae*	*Angiosperms*
Cellulose	10–30	0–25[a]	20–30	0–25[a]	20–50

Nitrogen	1–5	1–5	2–5	1–5	0.1–5

[a]Among algae, it is only green algae (Chlorophyta) that contain cellulose in their cell walls.
[b]Brown (Phaeophyta) and red algae (Rhodophyta) contain alginate, carrageenan or agar, being structurally and functionally similar to hemicelluloses, in concentrations of up to 30 %, but hemicelluloses are restricted to angiosperms.
[c]Some green algae (i.e., Charaphyceae) contain lignin-like precursors, but lignins are restricted to angiosperms.

debris; *voráre*: to gobble, to gulp) and saprophages (mostly in terrestrial ecology; Greek: *saprós*: rotten, foul; *phageïn*: to feed) directly and indirectly contributes to the mass loss and chemical degradation of detrital matter and results in decomposition (see Glossary). Besides the purely physical process of leaching, biochemical—degradation by microbes and digestion by detritivores—and biological processes—dislocation, fragmentation and numerous animal-microbe interactions—play major roles in the mass loss of detritus (Fig. 2). Thus, decomposition dynamics can mathematically be described through exponential decay:

$$M_t = M_0 e^{-kt}$$

$$-k = \frac{\ln\left(\frac{M_t}{M_0}\right)}{t}$$

with M_t: mass of detritus at time t; M_0: initial mass of detritus (at time 0); t: time (in days); $-k$: decay rate. Decay rates are usually expressed per day (d^{-1}), but may also be given per year. Wood decay (see below) depends on the diameter of the twig, branch or stem, and is usually measured by means of tissue toughness or density.

Because of having received most of scientific interest in decomposition processes, leaf litter (i.e., annually shed leaves of deciduous trees) will be used as a model herein to exemplify decomposition processes. While the outline presented here can be generalized in first approximation, decomposition of other types of detritus may differ in detail to varying degree. Mass loss rates, usually used as a measure of decomposition rates, not only depend upon the type of detritus (see Table 3), but also on numerous environmental factors, such as moisture (in terrestrial habitats), temperature or the presence and activity of detritivorous animals. Accordingly, detritus can be classified as decomposing fast ($-k > 0.01$; $>1\%\ d^{-1}$), medium ($0.001 < -k < 0.005$; 0.1%–0.5% d^{-1}) or slowly ($-k < 0.005$; $< 0.1\%\ d^{-1}$) (see Table 3).

Ecological significance

It was only during the last couple decades that we began to understand or even appropriately acknowledge the essential role of detritus for within- and between-ecosystem cycles of matter and energy. Through the release of nutrients upon decomposition, detritus plays a major role in ecosystem processes by serving as the source for nutrient cycling and provision to primary producers in all biotopes. In many systems, as different as marine kelp forests, subtidal seagrass meadows, intertidal saltmarshes or mangroves, and deciduous or tropical forests, 80% or more of the annually produced plant biomass is recycled through the detritus pathway rather than consumed by herbivores. In terrestrial habitats, organisms involved in detritus decomposition are responsible for more than 95% of the total community metabolism. In freshwaters, detrital matter, be it dissolved or particulate (see above), greatly exceeds the organic matter present in living microorganisms, plants or animals.

Leaf litter

When freshly fallen plant litter is exposed to rain or dew, water-soluble compounds (e.g., amino acids, simple sugars or phenolics) are rapidly lost through leaching. As long as the leachate remains in contact with the litter as water film, this early-stage leaching accelerates litter degradation through the promotion of microbial activity and increased palatability of the litter to detritivorous

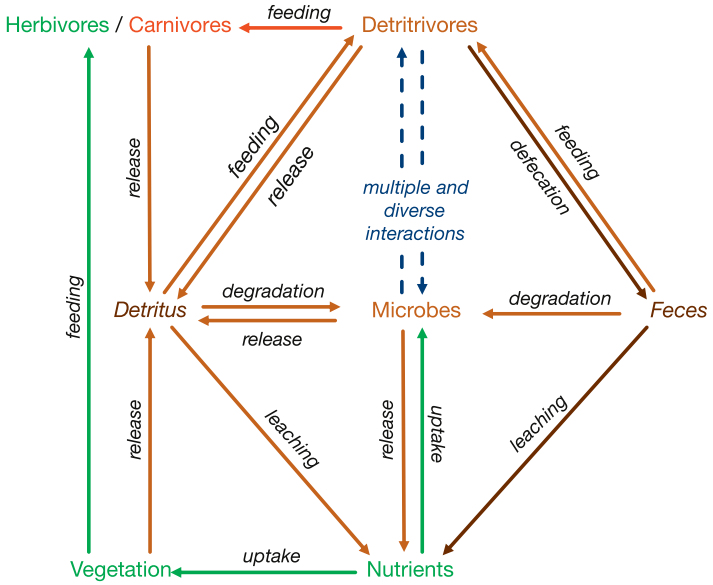

Fig. 2 Fluxes of matter among, and biotic interactions of, different compartments of the detrital subsystem in aquatic and terrestrial habitats. Broken arrows between detritivores and microbiota depict the diverse trophic, symbiotic and synergistic interactions of these central players in decomposition processes.

Table 3 Ranges (based on values reported in the literature) of decay rates ($-k$ d^{-1}) for selected types of detritus decomposing in different habitats

	$-$ k (d^{-1})	*Decomposition habitat*
Freshwater detritus		
Macrophytes	0.01–0.04	Aquatic
Marine detritus		
Macroalgae	0.0–0.07	Subtidal

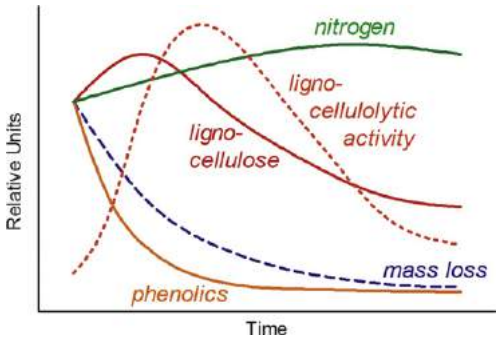

Fig. 3 Simplified scheme of changes upon decomposition in detrital mass (broken blue line) and contents of selected compounds (solid lines) [in % of initial value], as well as microbial activity against lignocellulose (dotted red line) [arbitrary units].

animals. The amount of mass lost through leaching varies according to both the leaf species and environmental conditions such as moisture. Physical disruption, e.g., through frost, drying and re-wetting cycles, sun light (UV), but also fragmentation upon feeding by detritivores, further promotes the loss of water-soluble compounds.

The remaining detritus itself, however, becomes enriched in larger and more recalcitrant compounds, as readily degradable substances are lost. Along the same line, leaching under water results in extensive release of dissolved organic matter (DOM), and differences in the chemical composition ("quality") of detrital sources are leveled out during early decay. Once dissolved in water, be it an aquatic environment or interstitial soil or pore water, DOM is prone to chemical degradation through microbial activity, eventually resulting in the formation of humic substances of varying chemical composition and the release of mineral nutrients. The other significant contributor to humic substances is the degradation of recalcitrant proteins and lignocellulose.

While leaching results in initial mass loss of detritus, the relative content of recalcitrant detrital compounds increases during the initial phase of decomposition (**Fig. 3**). At the same time, rapid microbial colonization leads to both a spatial accumulation and immobilization of nitrogen and increasing degrading activity on the detrital surface. Owing to a successive shift from microbes that utilize easily accessible low-molecular mass compounds to those that degrade lignocellulosic compounds, lignocellulolytic activity peaks after considerable mass loss through leaching and early degradation. Throughout late decomposition stages the formation of diverse humic substances due to the degradation of proteins, cellulose and phenolic compounds (including lignins) stabilizes the remaining detrital mass through inhibiting degradative microbial activity. In soils and sediments, this chemically stabilized organic matter is further decomposed at only very slow rates, particularly under anoxic conditions. Thus, huge stores of organic matter accumulate in sediments below marine seagrass beds or intertidal saltmarshes and mangroves and are essentially prevented from being transformed into climate-active gases, such as CO_2 or N_2O. Anaerobic decay, however, releases methane (CH_4), another potent climate gas, unless high sulfate concentrations inhibit methanogenesis.

The decay and decomposition rate, determining the release of nutrients to be available for growing plants and microorganisms, depends on both physical and chemical detritus characteristics (see **Tables 2** and **3**) and the activity of organisms involved in

decomposition. Accordingly, some types of leaf litter (e.g., alder, elder or chestnut) decompose within a couple months, while others (e.g., oak, beech or eucalypt) may last for years. Needle litter decomposes even more slowly. Microbial colonizers of detritus act in processing their substrate, rendering it an acceptable food source for detritivores. Most of the detrital biomass, particularly recalcitrant compounds such as phenolics and lignocellulosic cell wall compounds, requires (mostly aerobic) microbial activity for its degradation, which is, hence, slowed down under anoxic conditions, such as in (water-logged) soils and sediments. Thus, microbial litter colonizers serve detritivorous animals twofold. They precondition their detrital food sources and they are utilized as readily available source of (partly essential) nutrients. On the other hand, microorganisms are supported in degrading detrital matter through fragmentation by animals (see below), resulting in a significantly increased detrital surface. Further, microbial cells and propagules that survive the passage through a detritivore gut find themselves on a favorable substrate, detritivore feces, spread on a larger scale than microbial propagules themselves could achieve, and re-location of detrital particles by detritivores into favorable microhabitats facilitates microbial activity.

Consumption of detritus by detritivorous animals is the most obvious mode of mass loss. Detritivores of leaf litter belong to numerous diverse taxa, including molluscs, crustaceans, myriapods, insects, mites, nematodes and annelids. There is good evidence for general preferences of detritivores for some species of plant litter over others, and, as it is driven by detrital characteristics, such as the content of nitrogen and calcium, the C:N ratio or leaf thickness and toughness, this patterns seems to hold beyond biogeographical borders. Some consumers meet their decision based on the microbial community that inhabits the litter, but since microorganisms colonize different litter types at different species compositions (and densities), the outcome of this feeding behavior is similar and roughly reflects both microbial colonization and decay patterns. Typically litter of Betulaceae, Ulmaceae, Oleaceae, and Aceraceae is preferred over that of Fagaceae and gymnosperm trees, and litter of dicotyledonous plants over that of monocots. Toughness of plant tissue, and contents of nutrients and repellents, respectively, are probably major reasons for the observed feeding preferences. Generally, high nitrogen contents promote decomposition processes, while phenolics deter feeding by detritivores, impair enzymatic degradation processes, and thus, slow down decomposition. Thus, the loss of phenolics through leaching comprises an important initial step of decomposition that determines subsequent processes, and overwintered litter which is low in phenolics is a preferred food source to detritivores and decomposes faster than fresh litter. Along the same line of argument, terrestrial leaf litter loses deterrence upon submergence in water. These drivers of preferences interact with each other, and decomposition rates cannot be predicted by only one of them. Thus, the leaf litter of the mangrove *Avicennia germinans* in Northern Brazil is tougher than the litter of *Rhizophora mangle* but contains less phenolics—whereas detritivorous crabs prefer *Rhizophora* litter, mass loss of *Avicennia* litter proceeds much faster.

Similarly, most detritivores exhibit a marked preference for litter that carries high microbial biomass, exerting high microbial activity. This may proximately be due to phagostimulating compounds present in the microbial biomass. Further, detritivores obviously gain from feeding on microbially inoculated litter, but the ultimate reasons for this have not been unambiguously identified. Microbial biomass may significantly contribute to nutrition by providing essential nutrients, and some detritivores (e.g., terrestrial isopods) prefer feeding on those microbes that they can readily digest. Ingested microbiota may also assist in digestive processes by releasing digestive enzymes that can even break recalcitrant compounds such as lignocellulose. Alternatively, or in addition, microbial processing of the litter prior to detritivore consumption may be the determinant for this feeding preference.

Feeding by detritivores results in fragmentation of those detrital particles that are not ingested. Fragmentation of detritus increases leaching (see above) but in the midterm reduces nutrient release through immobilizing nutrients in increasingly produced microbial biomass; in the long term, however, fragmentation increases nutrient availability by stimulating microbial activity. Grazing on litter-colonizing microbes by detritivores may be expected to reduce microbial biomass. However, in part due to selective grazing on inactive or senescent cells and inducing nutrient release and compensatory re-growth, microbial activity and thus possibly even microbial biomass are increased in the long run. Since detritus has, on one hand, to be processed by microbes before detritivores feed on it, while, on the other hand, microbes are supported in decomposing the litter through fragmentation by soil animals, the interactions of the soil fauna and microbiota are, at least in part, considered truly mutualistic (**Fig. 2**).

Leaf litter decomposition on land

Early estimates suggested that the soil fauna contributes $<5\%$ to overall decomposition. Thus, indirect contributions to decomposition processes, promoting microbial decay, were assumed to prevail. These estimates, however, were based on respiration data and did not account for the large amounts of fragmented, ingested and digestively utilized litter. Currently, there seems to be common agreement that the contributions of microorganisms and animals are roughly equivalent. On average, soil animal activity increases decomposition by almost 25% through indirect promotion of microbial degradation of detrital compounds. In addition to those interactions of microorganisms and detritivores that are common to all habitats where decomposition is mediated by animals, the saprophagous soil animals control microbial activity during decomposition processes through the creation of favorable conditions for microbial decomposers and dislocation of leaf litter fragments into these conditions, as well as through dispersal of microbial propagules and inoculation of leaf litter.

Mechanical breakdown of lignocellulosic material, remaining in the leaf litter after leaching, by chewing detritivores (shredders in aquatic ecology, macrofauna in terrestrial ecology) facilitates its enzymatic degradation. Fragmentation of detritus positively affects the biomass and/or activity of the detritus-colonizing microbiota. Microbial biomass and activity increases when fragment size drops, but fragmentation may also inhibit fungal growth when particle size drops below a certain level of about 0.3 mm. Thus, the ratio of detritus-colonizing bacteria and fungi, and hence further decomposition processes, may in part be determined by particle size. In turn, both a detritivore's ability to fragment litter and the fragment size resulting from fragmentation strongly depend on the litter type.

Upon decomposition and subsequent mineralization brought about by microbial activity, nutrients derived from the decaying and disintegrating leaf litter material are eventually incorporated into the soil, where they are either taken up by the vegetation and soil microorganisms or may be incorporated as humic substances into clay-humic complexes that are recalcitrant towards further degradation and hence act as long-term nutrient store. Anoxic conditions contribute to the long-term stability of organic matter. In floodplains and water-logged sediments of the intertidal, leachates from litter remnants and nutrients released from detritivore feces or microbial cells that are dissolved in the porewater may eventually reach the hyporheic zone of the adjacent freshwater or the coastal waters upon submarine porewater discharge, providing input to the aquatic pool of dissolved organic matter (DOM). It is already during these fluxes that degradation of DOM proceeds.

Leaf litter decomposition in water

Except for the fact that leaching of water-soluble compounds proceeds much faster in water than on land, the basic processes of decay and decomposition are considered similar. Extensive leaching during early decay diminishes differences among detrital sources in terms of quality as resource for microbes and detritivores. Thus, decay rates of different detrital sources are more similar than on land.

While forested freshwaters, shaded by canopies, are fed by the energy input from terrestrial plant litter, open water bodies without (or with little) shoreline canopy exhibit a higher significance of autochthonous primary production by phytoplankton, macrophytes and their attached algae. In these systems, the significance of allochthonous detritus for nutrient cycles is mainly during winter, when in situ primary production is negligible. Overall, however, freshwaters must be considered heterotrophic (i.e., they are fueled from outside). By contrast, marine systems may be net producers or net consumers, depending on both adjacent habitat types (and the corresponding amounts and types of detritus) and the prevailing water currents. For intertidal saltmarshes and mangroves the question of whether they are sinks or sources of organic matter is still being discussed controversially. Common agreement seems to exist that being sink or source depends on the environmental setting and may change over time. Thus, the pneumatophores of the mangrove *Avicennia* seem to capture drifting leaf litter more efficiently than the prop roots of *Rhizophora*, but only when the tidal level does not exceed the length of the pneumatophores in which case floating leaves of high buoyancy would drift away above the roots.

Owing to water movements, in contrast to the situation in the terrestrial environment with mostly negligible effects of wind, detritus accumulates at sites with little or no flow, e.g., among stems of saltmarsh plants, roots of mangrove trees, or during slack high tide, rendering the in situ detritus distribution patchy (see above). While these trapped accumulations provide valuable shelters and refugia for benthic animals, detritus accumulation at large scales may result in temporal creation of anoxic conditions underneath the patches that, in turn, will reduce decomposition processes, because many of these are oxygen-dependent, especially those that involve animal activity.

In aquatic habitats, particularly in freshwaters, it is mostly fungi (aquatic hyphomycetes) that are involved in the breakdown of POM, but benthic shredders interact with them in similar manners to how terrestrial detritivores interact with microbes. Considering DOM a contributor to detrital matter (see above) that makes up 10–25-times the annual amount of POM, planktonic bacteria are just as important in decomposition as benthic microorganisms acting on POM are. Thus, the dominance of fungi that prevail the benthic decomposition of angiosperm detritus diminishes when suspended detritus of algal or microbial origin, being mostly decomposed by pelagic bacteria, is considered. Such suspended detrital matter in the water column has been coined "marine snow," and its dynamics have been increasingly studied recently, after we started appreciating its potential importance for matter fluxes in the marine realm. Upon eventual sedimentation of suspended POM, both pelagic bacteria, sedimenting along with the POM they colonize, and benthic bacteria and fungi act together.

In both cases, it is essentially only DOM (and some fine-POM) that can be transported to, and enter, adjacent habitats. Via this transport, up to 10^9 t C of terrestrial detritus reach the open sea annually worldwide. By contrast, POM sediments and is decomposed by benthic organisms. Upon seasonal flood events, part of the benthic detritus may be relocated into terrestrial flood plains or intertidal saltmarshes and mangroves, but the major portion of detritus is eventually incorporated into sediments and the pore water (the hyporheic interstitial), where oxygen consumption through aerobic degradation processes may result in anoxic conditions.

Vegetal detritus

World-wide, the annual plant biomass production exceeds animal biomass production by a factor of about 10. Thus, plant detritus is much more important in terms of amount and availability for nutrient release through the action of microorganisms and animals (decomposition: see above) than animal detritus. Accordingly, the ecological significance of vegetal matter decomposition has received a great deal of attention, but the decomposition of animal products (see below) has received relatively little. Among plant detritus, leaf litter may be the most prominent type of detritus in most ecosystems (see above), but depending on the biotope considered needle litter (in boreal forests), monocot litter (in grasslands and wetlands), or algal and angiosperm wrack (in coastal areas) may comprise the detrital pool predominantly or even entirely. The belowground compartment of terrestrial habitats and angiosperm-vegetated soft sediments is partly fueled by root detritus that decays in place unless being transferred to the oxic surface by bioturbation or human action.

Plant litter of whatever origin (see above) serves as substratum and food source for diverse microorganisms, be it bacteria, archeae, yeasts and fungi, microalgae or protists. Along with the plant litter itself, being of relatively low nutritive value (see above), these microorganisms are ingested by detritus-feeding animals and utilized as readily available and digestible

(supplementary) food source (see above). Thus, the digestion of both plant litter and microbial biomass eventually releases nutrients that can be utilized by the vegetation as soon as they are excreted, egested along with fecal masses, or set free upon the death and subsequent decomposition of the detritivore.

Macrophyte detritus

Macroalgae are considered nutrient sinks in coastal waters, but when they become detritus, they turn to being a nutrient source upon decomposition. Owing to reduced water flows in stands of macrophytes (including seagrass meadows and the intertidal vegetation of saltmarshes and mangroves), remarkable amounts of detritus may accumulate between blades, fronds, stems or aerial roots. Similarly, the stagnant water body at slack high tide deposits drifting wrack of little buoyancy along the high tide mark (until the wrack will be resuspended and removed from the wrack line by the next higher high tide). Once deposited, it is utilized as food by various invertebrates, such as sea urchins, molluscs and crustaceans, and fish that feed on large detrital particles, but also by filter feeders that ingested suspended remnants of detritus fragmentation. Once the wrack is worked into the soft sediment by wave action or bioturbation, the infauna, such as annelids and nematodes, contributes significantly to its decomposition, just like the micro- and mesofauna does in terrestrial habitats.

Primary production in near-shore macrophyte beds can also be exported to, and utilized by, other marine and nonmarine systems. Energy transfer from coastal to inland systems is brought about by terrestrial consumers that enter the intertidal area to feed upon, and fuel terrestrial food chains with, marine food sources that have been deposited ashore by tidal currents. The very same tidal currents may remove detritus of marine and intertidal origin from the intertidal and coastal subtidal zones into estuaries or the open sea (cf. **Fig. 1**) where it is subject to decomposition under submerged conditions. For instance, 15% of the CO_2 globally fixed in plant biomass, enters the open sea as seagrass detritus, while seagrasses make up less than 1% of the marine plant biomass. Thus, detrital spatial subsidies that are transported beyond habitat borders, where they serve as resources, play a significant role in fueling both terrestrial and aquatic ecosystems.

Woody detritus

Woody debris, be it small twigs, branches or whole stems, contribute significantly to the detrital biomass in forests, freshwaters and coastal marine areas. These inputs derive from both natural and anthropogenic activities including senescing trees, natural disturbance (e.g., windfall and slope failure), silviculture and forest management. In temperate forests, the input of woody debris amounts to roughly 1 t ha^{-1} a^{-1}. Generally, wood decomposition is slow, but small twigs in the litter layer may decompose at almost the same rate as leaf litter. By contrast, the decomposition of logs and trunks roughly equals the life time of the tree. Infestation of the wood by wood-boring and -inhabiting invertebrate, e.g., molluscan shipworms or crustaceans in the marine and intertidal environment, or beetle larvae and termites in the temperate and tropical, respectively, terrestrial realm, may accelerate wood decay by enlarging the surface area and promoting microbial activity, or may contribute to decomposition through digestive processes.

Particularly coarse woody debris adds long-lasting unique habitat structure and resources to both terrestrial and aquatic habitats, by being an important source of energy and nutrients for microorganisms and detritivores, trapping sediments, offering protection against harsh environmental conditions, and serving as refugium from predation to both consumers and inhabitants of decomposing wood. Coarse woody debris increases the diversity of biological communities in aquatic and terrestrial habitats. Certain species of fish depend on wood in streams to survive and to spawn. Logs, trunks and rootmats still attached to fallen trees are a key structural component in streams that deflects flows in ways that scour stream pools and induce meanders, but also anchors streambanks against high flows and floods by fixing the sediment, thus, reducing erosion and sedimentation downstream. Woody debris also serves as food source (albeit of low quality, owing to low nutrient and high lignocellulose contents) to xylophagous detritivores. Even more important, the surface of woody debris is densely colonized by microbial biofilms that, in turn, are grazed upon by various different animals. Along this line, the density and species composition of the microbial biofilm drives the settlement of potential animal colonizers on the wood surface. As the development of the biofilm, in turn, partly depends on wood exudates, chemical compounds that are leached off the woody detritus, the chemical composition of the wood indirectly mediates its colonization by invertebrates.

In contrast to most other types of detritus, dead wood in forests is not necessarily in contact with the forest floor—standing dead trees are also subject to decomposition, but the position of the trunk (along with the tree species, the composition of the forest community, soil characteristics and environmental conditions) determines the processes of decomposition. Even more than for angiosperm litter of photosynthetic tissue, the degradation, or at least modification, of lignin is a prerequisite for wood decomposition. Thus, it is essentially fungi (albeit of various taxonomic affiliations) that drive wood decay, being limited by the extremely wide C:N ratio of roughly 300–1000 (cf. **Table 2**). While soft- and brown-rotting fungi hydrolytically degrade cellulosic and hemicellulosic moieties of the cell walls, leaving brownish lignin remains, white-rot fungi oxidatively degrade lignins, but concomitantly also hydrolyze cellulose and hemicellulose—the main goal of lignin degradation is not the nutritive utilization of aromatic carbohydrates, but the removal of an embedding matrix to gain access to fiber polysaccharides. Fungal attack of freshly dead wood is facilitated by insects that actively intrude the wood by burrowing holes and galleries. Xylophagous insects are by more than 90% Coleoptera, at later stages of wood decomposition being accompanied by Collembola and noninsects, such as millipedes, isopods and lumbricids. In the tropics, it is mainly termites that destroy rotting wood. Most of these invertebrates are by now known to either bear endogenous (genes for) cellulases, or they rely on microbial symbionts to provide the enzymes needed to breakdown lignocellulose. Wood-boring shipworms (Bivalvia: Teredinidae), colonizing submerged woody debris,

harbor bacterial symbionts in their gills that produce lignocellulose-degrading enzymes, whereas crustaceans (isopods and amphipods, e.g., *Limnoria* and *Chelura*) that share the same lifestyle produce endogenous cellulases.

While the role of (coarse) woody debris is well-studied in forests and freshwaters, there is a dearth of information on its importance in marine coastal ecosystems. In high-intertidal tidepools with little algal cover, woody debris increases habitat complexity and heterogeneity and is readily colonized by motile invertebrate in search for shelter from harsh environmental conditions and predation. In low-intertidal pools and the open coast, the complex habitat structure of algal communities increases the relative significance of woody debris and its microbial biofilm as supplementary food source at the expense of its role as habitat structure.

While leaf and needle litter in grass- and woodlands is more or less evenly distributed, albeit with patchily scattered hot spots of high substrate quality and decomposing activity, the distribution of woody debris in a given habitat is rather heterogeneous, resulting in patches of refugia and supplementary food sources by means of biofilms. Similarly, coastal detritus, be it macroalgae or angiosperms, accumulate in patches, either at the upper margin of the intertidal zone (wrack line or drift line), in areas of little water movement beneath stems, roots, shoots or thalli of macrophytes, or aggregated in drift mats floating subtidally (see above). In either case, the patchy nature of these types of detritus provide habitat heterogeneity, although the effects on the community of animals making use of these patches may differ substantially, being either favorable (see above) or detrimental in terms of reducing the oxygen availability and producing hypoxic or even anoxic microhabitats underneath and within these patches.

Roots

Living roots shape their immediate environment, the rhizosphere, by exuding water-soluble organic compounds into the pore-water and by aerating the soil (or sediment in the case of seagrass, mangroves or saltmarsh plants). Upon death, root material is prone to belowground decomposition. This particular environment is characterized by relatively stable temperature and moisture conditions (as compared to conditions above ground). Except for very slow decay in boreal or permafrost soils, the climatic settings of the aboveground environment prove to be much less significant as drivers of root decay rates than root chemistry. However, the belowground environment may be prone to developing hypoxic or even anoxic conditions (especially when submerged, e.g., in floodplains or the intertidal), and even small-scale scarcity of oxygen may hamper root decomposition.

The detritus of coarse roots that are lignified resembles woody debris, and their decay is similar to the decay of wooden structures. Fine roots, however, essentially lack the structural compounds of wood and are relatively rich in nutrients and water-soluble compounds. Thus, fine roots can decay at rates similar to those of leaf litter, but, interestingly, difference in fine root decomposition rates do not seem to mirror those of leaf litter of different species. Fine root decay rates are mediated mostly by root chemistry, i.e., C:N ratio and calcium content. It is mostly the endogeic micro- and mesofauna (infauna of sediments) that contributes to fine root decomposition.

Animal detritus

Carrion

In comparison to plant litter, carrion (i.e., remnants of dead animals) is characterized by significantly higher nitrogen contents (i.e., a narrower C:N ratio) and fewer recalcitrant or deterrent compounds. Thus, unlike plant litter, animal necromass provides spatially and temporally rare detritus patches of high quality. Large carcasses are usually skeletonized after 1–3 years, but, depending on climate, complete decomposition of small carrion may be achieved within 1–2 months. However, relatively little is known about how carrion decomposition affects ecosystem functioning, how the size of the carrion patch controls decomposition and nutrient release, or how the huge amounts of carrion derived from catastrophic die-offs influence the respective ecosystem. From what is known, it can be concluded that the contribution to nutrient cycling from the decomposition of animal remnants can be substantial and, in such cases, should be considered in the formulation of nutrient budgets, even beyond habitat borders (e.g., in the case of terrestrial carnivores catching fish and leaving the carcass prone to decomposition in their terrestrial environment). For instance, dead whales (or other large marine vertebrates, such as sharks or sea elephants) that sink to the deep sea floor can provide allochthonous nutrient input to a variety of (scavenging) deep-sea organisms, such as crustaceans, sea cucumbers, annelids, slime eels or sharks, for decades. Owing to the particular environmental conditions of the deep sea (low temperature, high pressure) and the scarcity of scavengers, decay and decomposition of these carcasses is slowed down remarkably.

In contrast to detritivores, feeding on vegetal detritus, most of which are invertebrates, necrophagous consumers of carrion are represented by a high number of both invertebrate and vertebrate species. Necrophagous invertebrates mostly belong to the insect orders Diptera and Coleoptera. Invertebrate necrophages colonize and utilize animal necromass in waves of occurrence that are typical for a given habitat and climate. By contrast, the species of the dead animal has little influence on the process of carrion decomposition. After several stages that differ in the prevailing biochemical processes and the involved necrophages, the last steps result in mummification and subsequent sceletonization. The sequence of waves of invertebrate necrophages may, however, at any point be interrupted by scavenging vertebrates that feed upon carrion at any stage of decomposition.

Fecal detritus

Some authors consider feces of detritivores part of the detrital pool, but this point of view does not account for the particular role of feces as an intermediate step in decomposition processes. Detritivore feces—animal-processed material of initially vegetal origin, and hence considered animal detritus here—are usually characterized by a narrower C:N ratio than the detritus they derived from. Besides almost unchanged detrital fragments, detritivore feces contain considerable amounts of amorphous material, being

the result of digestive processes, with about 30%–50% of the ingested detritus complexed in humic substances. This amorphous feces fraction can subsequently be rapidly lost during feces disintegration. However, the peritrophic envelop that surrounds the feces of many detrivores may counteract disintegration and slow down fecal decay in some cases.

Fecal pellets of detritivores are often more readily decomposed through microbial action and coprophagous animals than the original detritus. Consequently, their C:N ratio rapidly drops during aging. Coprophagy, being promoted by the suitability of feces as environment for microbial decomposers, results in a further mechanical breakdown of already fragmented organic matter, and thus, directly contributes to decomposition processes. Owing to the digestion of litter-colonizing microorganisms during the gut passage, freshly dropped feces of detritivores usually contain less active microbiota than the leaf litter they are derived from. Further, possibly through both particle fragmentation and differential proliferation potential for bacteria and fungi in gut lumen of detritivores, the bacteria:fungi ratio is in favor of bacteria in the feces of many detritivores. Further changes in the microbial community occur during feces aging and decomposition. Reasons for fast microbial colonization of feces are the high initial content in viable microbial cells and propagules, the favorable surface:volume ratio, and the high content in easily accessible nutrients of a predigested substrate.

Most features of detritivore feces also apply to another particular type of detritus, namely dung (i.e., fecal masses derived from large herbivores, frugivores, carnivores and scavengers on carrion). Among these, fecal masses of herbivorous mammals (e.g., cattle) attract a particularly rich fauna of coprophages. Vegetal (algal) material that survives, and is still active after, gut passage is not detritus sensu *strictu*, as detritus is, *per definitionem*, dead. Other characteristics, such as distribution and dynamics in space and time, rather resemble carrion. Alike rotting fruits and dead animals, dung is characterized primarily by its spatial and temporal concentration in discrete and ephemeral patches of high energy and nutrient content. These patches provide home and food to diverse and highly dynamic communities of consumers making short-term use of this transient energy source. Coprophagous animals are found among dipteran, coelopteran and micro-lepidopteran insects, as well as oligochaete annelids. The sequence of coprophagous and coprophilous animals that appear on and in dung and the processes they initiate are highly predictable, but in detail depend on the habitat and climate under investigation. Specialized coprophilous fungi, similarly, exhibit a clear sequence of utilization of their habitat, spores of early stages already being present in the dung when it is deposited by the herbivore. Apparently, users of dung are highly specialized, and their community is significantly different from what usually is referred to as decomposers or detritivores. Depending on climatic conditions, dung patches may become completely decomposed in few months but may also last for several years. Thus, as for most types of detritus, nutrient release is not sudden but extended over a longer time interval, so that detritus provides a long-term store and source of nutrients at the basis of ecosystems.

Dominance☆

Helmut Hillebrand, University of Cologne, Cologne, Germany

Introduction

The coexistence of species in ecological communities is almost always asymmetrical such that some species are dominant, but most are rare. This inequality of species contribution is reflected by the degree of dominance in species composition and the identity of the dominant species. The analysis of dominance has been a cornerstone in general ecology, tightly linked to questions of community structure and diversity. Understanding the degree of dominance and the identity of the dominant species is implicit in studies on community assembly and organization, on causes and consequences of diversity, and on evolutionary and macroecological constraints of regional species pools.

Dominance in a local community can be highly obvious as one species monopolizes the use of space and visually characterizes the structure of the assemblage (**Fig. 1**). Such striking dominance of single or few species can be seen in many terrestrial and aquatic communities. However, even in communities with seemingly lower dominance, only a few species contribute the majority of the biomass or the count of individuals.

The degree of dominance can be characterized by the maximum proportion of individuals (or biomass) contributed by a single species in an assemblage (dominance ratio). The dominance ratio can fluctuate between 0 and 1, but values >0.5 are very common, both for individuals and for biomass (**Fig. 2**). Another way of addressing dominance is represented by rank–abundance curves, where species are ordered in ranks according to their proportional contribution. All classical rank–abundance models—broken-stick, log series, or neutral models—predict the numerical dominance of just a few species out of all species present. Similar relationships can be derived between rank and biomass instead of abundance. The shape of the rank–abundance curve is a strong visualization of dominance (**Fig. 2**A) and a readily assessable way of analyzing the effects of ecological interactions and abiotic drivers on species dominance.

The complementary term to dominance is evenness, which describes the equality of the distribution of proportions across species. Communities with less well pronounced dominance have a higher evenness (a higher degree of equality in the distribution of abundance or biomass on different species). Consequently, the correlation between dominance (as maximum proportion of one species) and evenness is negative (**Fig. 2**B).

Patterns of Dominance

Across all types of realms and habitat types, the number of individuals and the total amount of biomass are almost inevitably dominated by one or few species, whereas most species are rare. However, the proportion of numbers or of biomass made up by the most dominant species differs strongly even in closely related assemblages or spatially adjacent communities (**Fig. 1**). Published dominance ratios range from 0.2 to almost 1 for abundance as well as biomass. The proportion contributed by the three most dominant species consistently exceeds 50% and very often 75%. The degree of dominance differs highly with the exact way dominance is measured, but also across spatial and temporal gradients. In order to understand the mechanisms driving dominance within communities and in regional scales, it is important to identify some of this variation in dominance ratios.

Measure-Based Patterns

The dominance ratios calculated for biomass often differ strongly from dominance ratios calculated for abundance, which is mainly due to the fact that the identity of the species dominating abundance differs from the species dominating biomass. As a consequence, the rank of any species within a community according to the proportion of abundance and the proportion of biomass tend to be negatively correlated. Therefore, the maximum dominance found for abundance is often uncorrelated to dominance assessed by biomass (**Fig. 2**C).

As a consequence of these different outcomes, ecologists have to define whether dominance in abundance or dominance in biomass has to be the main target of their study. The answer to this question is mainly driven by the ecological processes focused on. Number-driven processes such as dispersal and intra- or interspecific encounters are best reflected by abundance dominance, whereas other processes such as competition for resources or energy flux are mainly affected by dominance in biomass.

The degree of dominance is largely independent of the number of species present in a local assemblage, as becomes evident by the lack of correlation between taxonomic richness and dominance ratios (Fig. 2D). This pattern is corroborated by the repeatedly found lack of correlation between evenness and taxonomic richness in many community types. This uncoupling is mainly due to the fact that the overall species number is a consequence of the number of rare species, which have negligible influence on the share of dominant species in a community. In other words, a species can be highly dominant independent of the length of the tail of rare species in the assemblage.

Spatial and Temporal Patterns

The most ubiquitous spatial gradient in diversity is the latitudinal decline of species richness from the Tropics to the poles. This richness gradient is assumed to be accompanied by a gradient in evenness, where single species gain more dominance in temperate

or boreal areas compared to tropical ones. However, systematic evidence is rare for this pattern or similar changes along altitudinal gradients. Many macroecological studies on range–abundance relationships have shown that widespread species have higher local densities, but the mechanisms for these patterns are still widely discussed and comprise purely statistical reasons, population dynamics, or resource use.

In addition to geographical gradients, dominance also varies along environmental conditions. Dominance tends to be high under harsh environmental conditions, such that entire organism guilds are represented by single species. An example are saltmarshes, where the most stressful marine side of the marsh is often inhabited by few species (e.g., *Salicornia*, *Spartina*), whereas, more landward (and less affected by salt), the number of species increases and the dominance of a single species decreases. Also in freshwater–terrestrial contact zones, the aquatic side of the gradient is often dominated by single terrestrial species adapted to the stressful conditions such as reed. The reason for this pattern is the strong selection for certain adaptations in the harsh environments, which favors only few specialized species.

Also gradients in productivity are often related to dominance patterns. Dominance tends to be high under high productivity, whereas habitats of low to intermediate productivity seem to be less probable to be dominated strongly by a single species. Fertilization studies often enhance the dominance ratio (cf. **Fig. 2**A). Many studies concur on a decrease in evenness with increasing community biomass, which then translates into an increase of dominance with increasing biomass production.

Dominance varies not only over spatial gradients but also in time. This can be strongly seen not only in chronosequences of succession, but also in many paleoecological investigations. In early primary succession, the habitat tends to be harsh and few species dominate early seral stages. Later on, dominance ratios might decline when more species contribute more evenly to community biomass. When the chronosequence remains undisturbed, late successional stages may exhibit increasing dominance ratios again, as highly competitive species displace other organisms. Also in secondary succession, dominance is also most pronounced in early developing species guilds (colonizers) and in late stages (competitors), whereas mid-stages show lower dominance levels.

Paleoecological analyses of pollen or of diatom community composition nicely show the shifts in dominance ratios over time. Sequences of strong single species dominance are often interrupted by phases of more even abundance distribution. These shifts are often related to alterations of the abiotic environment on local (changes in nutrient input or water chemistry) or regional (climate) scales.

For all these temporal and spatial gradients, it should be noted that not only the degree of dominance changes but also the identity of the dominant species. Species dominating early and late successional stages differ as do species between the extremes of environmental or spatial gradients. Both the dominance ratio and the identity of species have strong consequences for the functioning of ecosystems.

Mechanisms of Dominance

The primary questions for the understanding of dominance is: what keeps most species rare and makes few species dominant? Even in neutral communities consisting of ecologically equivalent species, overall biomass or abundance are dominated by few species. Neutral theory predicts that even in the absence of any trait differences between species, stochastic events will create dominance for some and rarity of many species. The identity of the dominant species and the degree of dominance follows not from any ecological interactions or environmental conditions, but depends on ecological drift, dispersal success, and timing of colonization. However, most realized communities deviate from neutrality and the primary question posed above requires mechanistic answers. These answers will strongly differ with the scale of the analysis, for example, on the local scale of interacting populations (i.e., communities) and on the regional scale of species pools. Within communities, the main mechanisms creating dominance are interactions within and between species as well as the abiotic factors constraining these interactions. Between communities, dispersal and spatial niche differentiation are strong forces regulating how the regional species pool transfers into local community structure. Addressing the regional species pool itself, the evolution and descent of certain lineages is the major driver of regional dominance.

Local Communities

Competition

Interspecific competition generally leads to a reduction of the contribution of poor competitors to the community, whereas superior competitors are able to gain dominance. Thus, competition is a process strongly increasing dominance. The degree of competitive dominance depends on two factors: (1) on the asymmetry of the competition and (2) the time for superior species to develop their dominance (see further below). The former aspect depends on the distribution of traits in an assemblage of competing species. If traits are similar, and thus competitive advantage of a certain trait low, dominance will be low. On the other hand, strong dominance can be expected if traits are skewed and competitive advantage of a certain trait is large (**Fig. 3**). Competition of terrestrial plants for light is a lucid example for such an asymmetric competition for a unidirectional resource, as

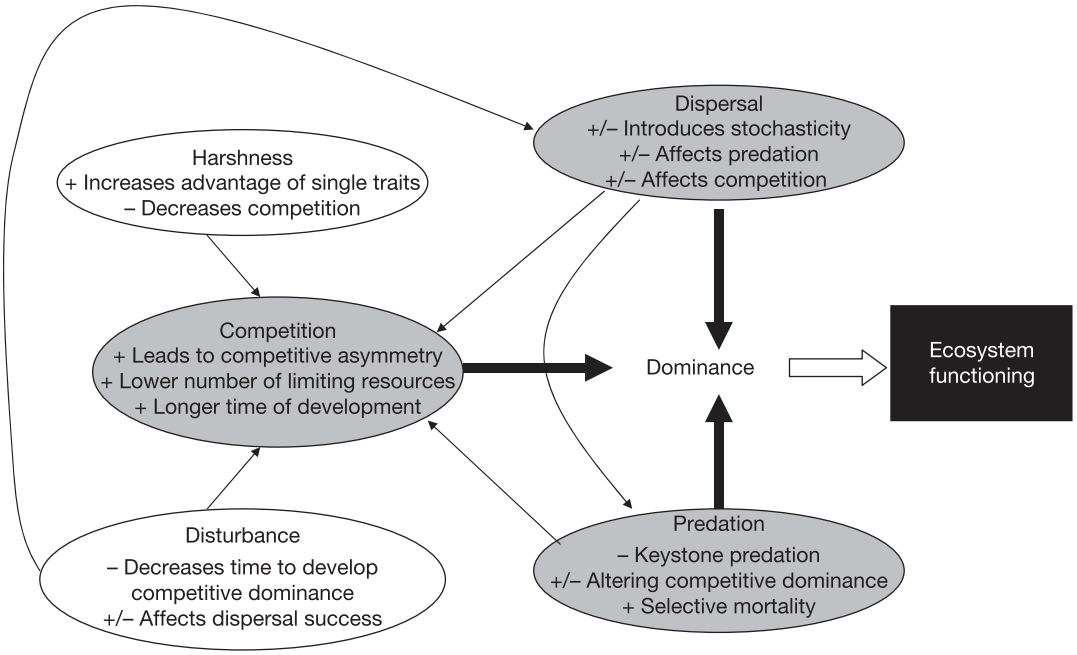

Fig. 3 Conceptual depiction of processes affecting dominance. *Gray ovals* comprise biotic processes, *white ovals* abiotic constraints. Direct effects are represented by *bold arrows*, indirect effects by *thin arrows*. '+' and '−' characterize processes or traits increasing or decreasing dominance, respectively.

competitive success mainly depends on one single trait (plant height), and species growing higher are able to strongly dominate communities. Similarly, filamentous species highly dominate many undisturbed assemblages of benthic algae (periphyton) as they are able to compete successfully for light and water column nutrients.

The skewed distribution of successful traits is also the reason why anthropogenic input of fertilizers often leads to enhance dominance (**Fig. 2**A). Fertilization of terrestrial or aquatic environments (eutrophication) generally enhances the availability of one or few resources, but not of others. Thereby, the array of traits leading to competitive success narrows. A typical example is represented by the addition of phosphorus (P) to lakes, which often leads to the dominance of cyanobacteria species which need a lot of P but are able to fix atmospheric nitrogen (N).

More generally speaking, dominance increases when the number of potentially limiting nutrients decreases (**Fig. 3**). It has been shown that the evenness of lake phytoplankton increases with increasing number of limiting nutrients. Similarly, the evenness of plant assemblages peaks at intermediate ratios of available N:P, but is low at low or high N:P ratios, respectively. Thus, a strong imbalance of N and P, which leads to limitation by either only N or only P, leads to greater dominance of single species. Similarly, gradients in productivity implicitly are also gradients in the number of limiting resources. Very unproductive terrestrial ecosystems often are systems with strong water shortage and dominated by species most successful in accessing water. Very productive terrestrial ecosystems tend to be limited only by light and again single species with certain traits will dominate. Therefore, dominance is least pronounced in mid-productive ecosystems.

Environmental harshness has often been supposed to reduce competition, which however has been falsified in recent years. Instead harsh conditions often require certain adaptations and the array of traits leading to survival and competitive success are also highly narrowed for organisms in extraordinarily harsh conditions. Thus dominance of single species is the general case in these environments.

The second aspect, time of development, describes whether the competitive advantage of a species can fully develop (**Fig. 3**). The gain of competitive dominance takes time, while the extent of time strongly depends on the generation time of the organisms and the already-mentioned asymmetry in competitive advantage. A highly superior fast-growing species will gain dominance more rapidly than a slow-growing species which has only a marginal competitive advantage compared to the cooccurring species. Competitive dominance in competing microalgae can arise within days or weeks, whereas it may last years in long-lived trees or in ecological similar moss species in a bog.

Because the gain of competitive dominance takes time, spatial as well as temporal heterogeneity may stop or even reverse this process. Spatial heterogeneity can be provided by patchiness in resource supply or by biotic or abiotic architecture affecting competitive success. Patchy resource supply creates a mosaic of resource ratios and competitively advantageous strategies. Architecture often opens up refuges or represents the basis for the success of other life-forms (such as epiphytes). Temporal heterogeneity is often investigated in the form of fluctuations in resource availability, which also reduces competitive dominance or reverses competitive ranks of the interacting species.

Disturbances, defined as an irregular mortality-inducing event, has been proposed as a univariate explanation of dominance and diversity patterns, most prominently by the intermediate disturbance hypothesis (IDH), which predicts highest species

richness at disturbance regimes of intermediate frequency and intensity. Similarly, it predicts that low-disturbance ecosystems are dominated by competitively superior species, whereas high disturbance creates dominance by species able to cope with the extreme mortality in these systems. Dominance is thus expected to be low in mid-disturbance regimes, where dominance opens niche opportunities for species by creating patchiness of environmental conditions allowing species to differentially express life-history tradeoffs. Strong evidence has accumulated that how disturbance (and also consumption as a biotic mortality agent) affects community structure is coupled to the productivity of the system, which affects the rate of biomass accrual and dispersal and thus the speed of competitive displacement in a community (see below).

Consumption

Consumers can act as a mortality agent keeping competitively superior species from gaining dominance. Consumption in this meaning comprises all kinds of consumer–prey interactions including herbivory, predation, and pathogens. Dominance can be enhanced or reduced by consumer presence, and the sign of the effect often is mediated by changing competitive interactions between prey species. Consumers can enhance dominance when they favor competitive success of well-defended or less-preferred prey species. More often, however, consumption reduces dominance if the superior competitor is especially prone to consumption.

The generality or selectivity of the consumer is highly important for their effect on dominance in prey communities. Selective consumers increase dominance if they favor species with a certain trait but they can reduce dominance if they are specialized on competitively superior species. The latter interaction is known in the ecological literature as keystone predation, which describes the preferential consumption of a competitively dominant species and thus the fostering of subdominant species. Keystone predation generally decreases dominance ratios and has been observed in many ecosystems strongly structured by competition.

Generalist consumers are also able to reduce dominance, mainly in situations where dominance is fostered by strong competition and fast competitive displacement. In highly productive ecosystems, dominance by single species is generally high, but these dominant species are often highly prone to consumption. Especially plants allocate less resources to defense (structural or chemical) with increasing ecosystem productivity (aka the growth rate hypothesis of defense). Therefore, plants adapted to dominate at high resource supply tend to be highly vulnerable to grazing and grazer presence reduces dominance. Thus, productivity is a key factor to understand the degree of consumer control on diversity and dominance. Several meta-analyses concurred on a dominance-reducing effect of consumers in highly productive ecosystems characterized by strong dominance of fast-growing species, which is strongly reduced by the presence of consumers. At low productivity, consumer effects on diversity are mainly negative, which translates to an increase in dominance.

Many trophic interactions are able to propagate through the food web and may change dominance indirectly on the next trophic level (trophic cascades). Predators can alter the dominance ratio and the identity of dominance species in plant assemblages via the reduction in herbivore density or activity. Other indirect effects in food webs have also been identified as altering and regulating the dominance in community structure. Apparent competition and associational resistance are two pathways mediating the contribution of different prey species to the entire prey assemblage. Also nutrient regeneration may change competitive advantages in communities where recycled nutrients play a major role in primary production. The presence of a P-rich consumer may enhance N-regeneration compared to P-regeneration and thus shift the available N:P elemental ratio and therewith competitive success of different prey taxa.

Facilitation

The role of positive interactions for community structure and dominance has only recently become a focus of ecological studies. The importance of mutualistic interactions is especially seen in the dominance of life-forms with long-evolved symbioses in certain ecosystems. The dependence of trees dominating boreal forests on mycorrhiza and the dependence of corals on symbiotic zooxanthellae are vivid examples highlighting the effects of positive interactions in community structure. Also nitrogen fixation via rhizobia can foster the dominance of certain plant groups such as the Fabaceae in terrestrial ecosystems with high light but poor N-availability.

Additionally, facilitation clearly plays a role in temporal gradients of dominance, as the presence of a certain pioneer species often is necessary in order to allow the dominance of late successional species. Facilitation can thus create dominance by the favored species, but it also can reduce dominance by allowing coexistence of species which would not be able to thrive without the presence of a facilitative species.

Dominance in Metacommunities

Ecological communities are not isolated, but connected via dispersal, which links local communities into metacommunities. Metacommunities provide a framework to understand the scale dependence of dominance and to highlight important controlling factors of dominance such as ecological interactions, dispersal, and species sorting. Regional and local dominance can strongly differ as do the processes leading to regional versus local dominance. Most locally dominant species are competitively superior species. However, depending on the frequency of disturbance, the overall probability of dispersal and the presence of source sink

dynamics, regionally dominant species may be either superior competitors or superior dispersers. The degree of regional (and local) dominance further depends on the spatial heterogeneity in environmental conditions across the local patches.

The effect of dispersal on dominance is clearly rate dependent (Fig. 3). At very low dispersal rates, neither competitive nor consumer–prey interactions are affected and the impact of dispersal is low. The identity of the competitive dominant species may strongly differ between the local communities, as each community will have a different species composition. At highest dispersal, all species are able to reach each of the local communities, and competitive dominance still plays the most important role, but now one species, the superior competitor in the regional species pool, will dominate all local communities. At intermediate dispersal frequencies, the dominance of the best competitor will be disturbed by frequent invasion of good colonizers as long as colonization–competition tradeoffs persist. The dominance can also be reduced in source–sink metacommunities, where local populations in harsh local (sink) patches are maintained by substantial dispersal from benign (source) patches.

The frequency of disturbances (or other sources of mortality) in the local patches determines how important different dispersal regimes can be. With no opening of space, dispersal cannot rescue colonizers from being excluded by competitors. However, with disturbance space is opened for colonizers to persist and the importance of colonization traits compared to competitive traits increases with disturbance frequency and intensity.

The identity of the dominant species can be highly dissimilar between local patches in a metacommunity, depending on dispersal rate (see above) and the environmental and geographical distance between the local patches. Higher geographical distance enhances the probability of dispersal limitation and higher environmental distance allows for species sorting. Beta-diversity, which measures the turnover in species composition between local patches, increases with increasing spatial distance and with decreasing environmental similarity.

Including metacommunity dynamics and community assembly into the analysis of dominance also allows addressing the effect of stochasticity and assembly sequence on dominance ratio and the identity of dominance species. As exemplified in Fig. 1, nearby habitats of similar abiotic conditions can have different species setup and can be highly dominated by one species, which is almost missing in the other system. These differences can occur due to founding effects, which stress the importance of colonization sequence. Overall dominance can be enhanced by a species colonizing an enemy-free space and growing into a size refuge (which is the mechanism probably leading to the dominance of green algae in the right rock pool Fig. 1) or by a species arriving able to monopolize and defend space (which is congruent with inhibition mechanisms in succession, see temporal patterns above).

Dominance in Regional Species Pools

From a global perspective, dominance became evident to the first exploring naturalists, who already described the changing vegetation on Earth by large units such as biomes. These biomes are not necessarily defined by the dominance of single species, but often by the dominance of certain phylogenetic lineages and life-forms. Thus, regional species pools tend to be dominated by higher taxonomic or evolutionary units. As the regional species pool is highly important for the species being able to colonize local communities (and metacommunities), the historical processes leading to regional dominance will also affect dominance patterns in local communities. Especially models focusing on neutrality of species traits or assuming strong stochastic dispersal effects but weak local interactions propose a strong regional imprint on local community structure. The importance of these processes including speciation–extinction dynamics or range expansions for local community patterns is still strongly debated and will probably be different in different biomes.

Consequences of Dominance

The degree and identity of dominance strongly differ between ecosystems, but does this variation matter for the functioning of ecosystems? Obviously the processes in ecosystems (such as productivity, respiration, energy transfer, resource retention) are mainly driven by the dominant species. The traits of dominant species thus have a higher importance for ecosystem functioning than the traits of rare species. The consequences of dominance are separate from the consequences of keystone species (sensu Payne) and foundation species (sensu Dayton). Whereas keystone species are species affecting ecosystem processes by having very high per capita impacts (e.g., top predators) and foundation species comprise species which have strong impact on ecosystem structure by enabling community structure (e.g., trees), the importance of dominance is based on the relative fraction of matter and energy flow canalized through one species. However, most foundation species are locally dominant, whereas most keystone species are not.

The question becomes highly important in the face of strong alterations of global diversity and of dominance patterns by human actions such as habitat destruction, species homogenization, and fertilization. Recent theory and experiments suggest that local species richness can affect local ecosystem processes. In many of these experiments, the identity of the species had a major effect on the outcome. The identity of the dominant species consistently affects primary production, decomposition rates, consumption rates, and overall community respiration. Species identity effects have in many studies been more important than the effects of species richness per se.

Few studies have manipulated not only the number of traits present but also their distribution. Studies looking for effects of evenness on ecosystem processes such as productivity are few to date, but one emerging pattern is that higher evenness in plants tends to reduce primary productivity. This can easily be explained by the fact that high evenness prevents the community from being dominated by the most productive species. Thus, important ecosystem processes tend to be best performed in communities characterized by strong dominance.

This primacy of dominant species in ecosystem functioning does not necessarily mean that rare species are unimportant. Many ecologists have proposed that the importance of subdominant species is an insurance against spatial or temporal fluctuations in abiotic conditions. Thus, rare species represent an insurance as they may be able to perform major ecosystems processes under different environmental constraints. More evenly structured communities may perform such shifts more easily than communities characterized by a strongly dominating species. However, this evenness insurance effect has not been analyzed theoretically or experimentally yet.

Dormancy☆

Philip Withers, University of Western Australia, Crawley, WA, Australia
Christine E Cooper, Curtin University of Technology, Perth, WA, Australia

Introduction

Dormancy is a widely recognized behavioral and physiological state of both animals and plants that generally involves inactivity and reduced metabolic rate (Fig. 1). Torpor is a similar term to dormancy, meaning inactivity or lethargy. Dormancy or torpor can involve very different physiological states, in response to a variety of different stimuli, including low temperature, high temperature, lack of water, or lack of food. It can be a short-term event (<24 h), can occur for a few consecutive days, or may last an entire season or even many years. Dormancy can also involve a developmental arrest (diapause). Cryptobiosis, which literally means "hidden life," is a more extreme state than dormancy, with almost no detectable activity or metabolism. It is most prevalent in lower vertebrates, and is often a seasonal survival strategy to cold or desiccation.

Cryptobiosis

This state of "suspended animation" has been observed for a variety of invertebrate animals and plants during extreme environmental conditions. It was first described for invertebrate animals that survived an absence of water by becoming inactive and allowing their tissues to become desiccated (anhydrobiosis, e.g., rotifers). Two other forms of cryptobiosis also involve an altered state of cellular water, freezing temperatures (cryobiosis, e.g., a frozen insect), and high osmotic concentration (osmobiosis, e.g., brine shrimp eggs in a salt lake). Another form of cryptobiosis is survival of a lack of oxygen (anoxybiosis, e.g., killifish eggs sealed inside their egg capsule). The best-known example of cryptobiotic animals is probably the eggs of brine shrimp (*Artemia*), which can survive extended periods of complete desiccation, high salt concentration, or anoxia; their desiccated eggs are also remarkably resistant to extremes of temperature. Various "resurrection" plants are well-known examples of cryptobiotic plants, being able to recover from desiccation for extended periods. Seeds of some plants are also spectacularly resistant to desiccation, sometimes for very long periods of time (e.g., seeds more than 1000 years old of the Indian lotus from an ancient lake bed in China).

All of these forms of cryptobiosis involve complete inactivity. Ecological advantages of cryobiosis include survival of harsh environmental conditions, and dispersal of highly resistant life stages. However, the physiological adaptations required by these animals and plants to survive extreme conditions at no detectable metabolic rate are generally complex and specialized.

Diapause and Quiescence

Diapause is an ecological strategy for the avoidance of harsh conditions that involves the cessation of development of a subadult life stage. It is essentially a time-delaying tactic to synchronize further stages of the life cycle with appropriate environmental conditions. Diapause is especially common in insects but is also observed in a wide variety of other invertebrate animals (e.g., brine shrimp embryos) and vertebrate animals (e.g., annual killifish embryos), as well as many plants (e.g., buds, bulbs, rhizomes, and seeds). Some plant seeds require drying out before they can develop, ensuring that adverse dry seasons pass before the embryo starts to develop. Diapause is also a reproductive strategy in a variety of mammals for the delayed implantation and development of embryos (e.g., macropod marsupials, mustelids, and deer). Quiescence is a period of inactivity, similar to diapause, but is a facultative response to an immediate change in environmental conditions that is terminated simply by the resumption of more favorable environmental conditions, rather than a programmed and obligate response. It may be a response to harsh environmental conditions such as low or high temperature, or drought. Many invertebrates and plants (particularly their seeds) become quiescent.

Hibernation (Winter Dormancy)

Hibernation is when an organism spends the winter in a state of dormancy; it is long-term multiday torpor. Many plants survive extended periods of cold and desiccation, either as aboveground trees or shrubs, or as underground structures. Protective scales around stem tips allow buds of aboveground plants to endure winter conditions without damage. The aboveground structures of other plants die back in unfavorable conditions, leaving dormant underground bulbs, rhizomes, tubers or corms, for which the

soil buffers environmental extremes. Many plants accumulate solutes in their fluids to prevent freezing during winter, while others can tolerate freezing of water in their xylem and other extracellular water pools. For ectothermic animals, hibernation is primarily a behavioral state with reduced body temperature, hence activity and metabolic rate. Some use supercooling or antifreeze solutes to avoid freezing, or tolerate freezing of their extracellular fluids (e.g., weta crickets and wood frogs). Many endothermic mammals also hibernate (Table 1). Mammalian hibernators typically use multiday torpor for weeks or even months (e.g., Fig. 2), and attain very low body temperatures (T_b's) (e.g., 0 to -5°C). Only one bird, the poorwill, is known to hibernate, although many other birds (and mammals) readily use single-day torpor during winter.

Estivation (Summer Dormancy)

Estivation is summer dormancy, that is, long-term torpor during summer for survival of hot and dry periods. Many desert plants survive extended periods of high temperature and low rainfall. Some survive as desiccated seeds (5%–10% water content), particularly annual species, but some survive desiccation as adults. These "resurrection" plants, such as the Rose of Jericho (*Selaginella*), can desiccate to about 5% water content during dry periods, but survive and "come back to life" after rain. Pincushion lilies similarly re-activate by regenerating from buds after rain.

(1978) Energetic and field aspects of mammalian torpor: The Richardson's ground squirrel. In: Wang, L.C.H. and Hudson, J.W. (eds.) Strategies in Cold. Natural Torpidity and Thermogenesis, pp. 109–145. New York: Academic Press.

Fig. 3 Estivating frog (*Cyclorana cultripes*) in a cocoon of shed skin. Photograph by G. Thompson and P. Withers.

Amongst invertebrates (e.g., earthworms and insects) estivation usually involves an inactive stage with a water-resistant covering. For example, estivating earthworms form a mucus cocoon to resist desiccation, and many insect pupae are remarkably resistant to water loss. Amongst vertebrates, fishes, amphibians, and reptiles enter a similar estivation state. Fishes and amphibians often form a cocoon of dried mucus (e.g., African lungfishes) or shed epidermal layers (e.g., some desert frogs; **Fig. 3**) to resist epidermal water loss; the cocoon covers the entire body surface except for the nostrils. Reptiles have a relatively water-impermeable epidermis and do not need to form a cocoon to reduce evaporative water loss. Estivating ectotherms typically have an intrinsic metabolic depression for energy conservation.

Some mammals also estivate (**Table 1**). For example, desert ground squirrels enter a long-term estivation state that is physiologically similar to hibernation except for the higher ambient temperature (T_a) and T_b. Other mammals such as cactus mice and kangaroo mice use single-day torpor cycles during summer.

Thermal and Energetic Physiology of Torpor

Torpor involves a number of physiological changes, especially related to body temperature, metabolism, and water balance. These physiological changes are interrelated insofar as body temperature influences energetics, and water balance is related to both body temperature and metabolism. However, the detail of the physiological consequences of torpor differs between organisms.

Ectothermic Animals and Plants

For ectotherms, T_b is essentially equal to T_a during hibernation/estivation. This means that any decrease in T_a during hibernation or estivation is accompanied by a decrease in T_b, which in turn is accompanied by an exponential decline in metabolic rate (MR) as described by the Q_{10} relationship, that is,

$$Q_{10} = (\mathrm{MR}_{T_{b2}}/\mathrm{MR}_{T_{b1}})^{10/(T_{b2}-T_{b1})} \text{ or}$$
$$\mathrm{MR}_{T_{b2}} = \mathrm{MR}_{T_{b1}} Q_{10}^{(T_{b2}-T_{b1})/10} \quad (1)$$

where $\mathrm{MR}_{T_{b2}}$ is the metabolic rate at T_{b2} and $\mathrm{MR}_{T_{b1}}$ is MR at T_{b1}. For most physiological variables, Q_{10} is generally about 2.5. This decrease in MR results in substantial energy savings and thus a prolonged survival period in the cold.

For some ectotherms there is an unequivocal intrinsic metabolic depression during estivation that occurs without any change in T_b (e.g., snails, fishes, and amphibians). Some plant seeds during dormancy are also hypometabolic or even ametabolic. This

intrinsic metabolic depression, which is often a decrease in MR to about 20% of normal, occurs in the absence of any T_b, ionic, osmotic, or any other discernable physiological perturbation. The cue for intrinsic metabolic depression would appear to be a change in environmental conditions that indicates impending potential for desiccation. Intrinsic metabolic depression is not a short-term (e.g., daily) event; it often takes about 2–4 weeks for metabolic depression to become fully developed. It is probably more important for estivation, which has a lesser hypometabolism by lowered T_b than hibernation. The molecular or biochemical mechanisms for this intrinsic metabolic depression are not well understood; however its physiological significance is clearly extension of the hibernation/estivation period that can be survived by conserving energy.

Endothermic Animals

Endothermic vertebrate animals have a fundamentally different relationship between T_a and T_b than ectothermic animals and plants as a consequence of thermoregulatory thermogenesis. Thermal and energetic consequences of torpor are therefore more complex for endotherms because at low T_a their MR is normally increased above basal (BMR) by metabolic thermogenesis that maintains T_b constant (normothermia). During torpor, there is a profound decrease in MR, typically to 1% or even less of normothermic MR, and a concomitant decrease in T_b often close to T_a (**Fig. 4**). Entry into torpor appears to be a controlled physiological process, not simply an inability to thermoregulate. During torpor at moderate to high T_a's, T_b declines to nearly T_a and MR declines exponentially with T_b. This is the same pattern as for ectotherms, and indicates a state of nonthermoregulation. However, if T_b decreases below a species-specific set point at lowered T_a, then T_b is regulated at that set point by the onset of thermogenesis; this is the same as the normothermic thermoregulatory response except that the T_b set point is lower than for normothermia. For many single-day torpidators the torpor set point is about 20°C, but it is generally much lower for hibernators (about 0–5°C, but as low as −5°C for arctic ground squirrels).

Two mechanisms contribute to the marked decline in MR of endotherms during torpor. Defense of normal body temperature is relaxed and so the thermogenic increment in MR above BMR is eliminated. As a consequence, heat production is less than heat loss and T_b declines to close to T_a and so there is a further decline in MR due to the Q_{10} effect. However, if T_a decreases below the torpor set point where T_b is again defended, then MR increases for thermogenesis. For most endotherms, the decline in MR during torpor is accounted for by the elimination of the thermogenic MR increment and the decline in T_b and MR with a typical Q_{10} ($\approx$2.5).

Intrinsic metabolic depression is a third possible mechanism contributing to MR reduction during torpor. However, the contributions of the elimination of thermogenic MR increment and the decline in T_b and Q_{10} effect are so great that the contribution of intrinsic metabolic depression, should it occur in an endotherm, would be a relatively minor absolute energy saving.

Arousal from torpor is typically a physiologically driven event requiring considerable thermogenesis by shivering (skeletal muscle thermogenesis) or metabolism of specialized brown adipose tissue (in placental mammals but not marsupials or birds). There is also increasing evidence that many species use passive rewarming (e.g., basking) to arouse, since it greatly reduces the metabolic cost of arousal. Long-term hibernation by mammals is not necessarily a continuous period of prolonged inactivity. It is

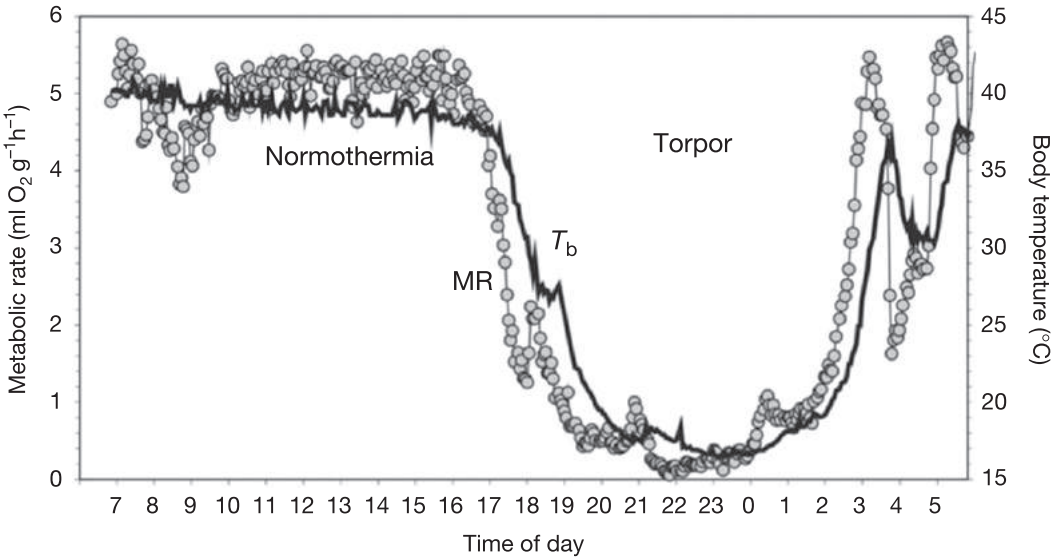

Fig. 4 A daily torpor cycle in a typical single-day torpidator, the dunnart *Sminthopsis macroura*, showing the decline in T_b and MR during entry into torpor, a short period of sustained torpor, and then the increase in T_b and MR during arousal from torpor. Data from F. Geiser, unpublished data.

periodically broken by a short period of arousal, then re-entry into hibernation (e.g., Fig. 2). The reason for these periods of arousal and re-entry is not clear. There appears to be some physiological "need" to periodically arouse. It has been suggested that perhaps some accumulated metabolite needs to be eliminated by urination, which only occurs if the animal is normothermic.

The beneficial energy savings of torpor are clearly evident from the difference between the high normothermic MR and the greatly reduced torpid MR, even after accounting for the metabolic cost of arousal. For daily torpor, the energy saving depends on the length of the torpor bout and the depth of torpor; for a dunnart, the daily energy saving is about 36% for 13 h of torpor (e.g., Fig. 4). For hibernation, the daily energy saving is greater because metabolic rate is low for typically 24 h per day; for a hibernating ground squirrel, the energy saving is about 85% over 6 months.

There is a complex pattern of single-day torpor, multiday hibernation, and multiday estivation amongst mammals and birds (Table 1) that partly reflects phylogeny but also body mass. Torpor is more advantageous for small than large species. Small species have a higher mass-specific metabolic rate and therefore benefit more from the energetic saving associated with torpor. The rate of entry into and arousal from torpor is strongly dependent on body mass. Small species enter torpor quicker because of their higher thermal conductance (higher surface-to-volume ratio) and they also arouse quicker because of their higher mass-specific MR and lower thermal inertia. In contrast, larger species cool and rewarm slower, so the energy savings are less, especially for daily torpor.

Cues for Dormancy

Many plants respond to the climatic cycle of their habitat. In particular, photoperiod, temperature, and rainfall are important cues for the commencement and also cessation of dormancy. Some species respond to long-term climatic cycles, while others undergo more immediate facultative responses to ambient temperature or water availability. For animals, single-day torpor can occur rapidly in response to short-term environmental changes, such as inclement weather. It generally occurs on a circadian cycle, corresponding to the normal period of activity/inactivity. Onset of hibernation or estivation, being seasonal long-term periods of dormancy, is a more prolonged and sometimes programmed response to an impending change in environmental conditions. For example, desert frogs initiate estivation if conditions become dry, by burrowing, forming a cocoon, and initiating intrinsic metabolic depression; this can take 3–4 weeks, but occurs independent of time of year. In contrast, hibernation by some mammals such as ground squirrels is obligate and only occurs at a specific time of the year after a period of preparation (e.g., seeking out or constructing suitable hibernation sites, increased activity and feeding, deposition of energy stores, and changes in body fluid solutes). This pattern of obligate hibernation is controlled on a circannual cycle by cues that include shortening photoperiod and decreasing air temperature. Reduced water availability and high T_a are primary cues for estivation.

Ecological Consequences of Dormancy

The general roles of torpor, hibernation, and estivation are avoidance of unfavorable short-term or long-term (seasonal) climatic conditions and conservation of energy during this period of inactivity. Seasonal dormancy also has obvious ecological benefits. It allows species to exploit ephemeral environments. Hibernation and estivation enable species to colonize habitats that would otherwise be unsuitable for growth or survival at certain times of the year due to harsh environmental conditions. Timing of active life stages or generations can be optimized. Seasonal dormancy therefore contributes to the fitness of individuals and species.

There would also appear to be costs associated with torpor. Many species do not use or survive torpor, and species capable of torpor do not necessarily use it on a routine basis. There is a fundamental physiological advantage (at least for endotherms and even for many ectotherms) of maintaining a high and stable body temperature, for example, growth, digestion, muscle contractility and immunological defense. There is also a physiological danger of thermal death or being unable to arouse if the T_a becomes too low (e.g., freezing), or death if energy reserves become insufficient for arousal. Ecological costs of torpor could include vulnerability to predation, competition from conspecifics that do manage to successfully forage, reduced reproductive success, and lower rates of essential activities such as cell division and digestion. There are also similar and additional costs of seasonal dormancy. It can delay reproduction and development, diminish posthibernal reproduction, require that short-lived species survive for longer, and result in sex-biased populations if there is differential survival based on gender. For multiday torpor by endotherms, there appears to be a necessity for periodic arousal, suggesting some physiological requirement for an occasional return to a high T_b (see above).

Ecological Effects of Acidic Deposition☆

Charles T Driscoll, Syracuse University, Syracuse, NY, United States
Irene Martins, University of Coimbra, Coimbra, Portugal

Introduction

Detailed studies by a large community of scientists for more than four decades have provided considerable insight into the ways in which atmospheric deposition alters ecosystems. When it was first identified, acidic deposition, or acid rain as it is commonly called, was viewed as a simple problem that was limited in scope. Scientists know now that acids and acidifying compounds enter ecosystems largely from atmospheric deposition and are transported through soil, vegetation, and surface waters, resulting in a range of adverse ecosystem effects. Controls on emissions of air pollutants, which were initiated in North America and Europe in the 1970s, have resulted in some recovery of ecosystems from the adverse effects of historical acidic deposition. In this article, information on patterns of acidic deposition, the effects of atmospheric deposition of sulfur and nitrogen on sensitive forest and freshwater resources, and the recovery that has resulted from controls on emissions of air pollutants is synthesized.

Acidic Deposition

Acidic deposition largely comprises sulfuric and nitric acid derived from sulfur dioxide and nitrogen oxides, respectively, and ammonium resulting from emissions of ammonia. Sulfur dioxide and nitrogen oxides, originating from human activities, are emitted into the atmosphere largely by the burning of fossil fuels, while ammonia is largely the result of agricultural activities. Once such compounds enter an ecosystem, they can acidify soil and surface waters, bringing about a series of ecological changes. The term " acidic deposition" encompasses all the forms of these compounds that are transported from the atmosphere to Earth, including gases, particles, rain, snow, clouds, and fog. Acidic deposition can occur as wet deposition, in the form of rain, snow, sleet, or hail; as dry deposition, in the form of particles or vapor; or as cloud or fog deposition, which is more common at high elevations and in coastal areas. Wet deposition is fairly well characterized by monitoring at approximately 200 National Atmospheric Deposition Programs (http://nadp.sws.uiuc.edu/) in the United States. In contrast, dry deposition is highly dependent on metrological conditions and vegetation characteristics, which can vary markedly over short distances in complex terrains. As a result, dry deposition is poorly characterized and highly uncertain. Dry deposition is characterized through the Clean Air Status and Trends Network (http://www.epa.gov/castnet/), which includes about 80 sites in the United States.

Sulfuric and nitric acids lower the pH of rain, snow, soil, lakes, and streams. Areas experiencing elevated acidic deposition include eastern North America (**Figs. 1** and **2**), the western United States, Europe, and Asia. In 2010–12, wet deposition (i.e., deposition from forms of precipitation such as rain, snow, sleet, and hail) in acid-sensitive regions of the eastern United States had average pH values of 4.1–5.0, which is about 2–10 times more acidic than background conditions.

Acidic deposition trends in the eastern United States and Europe mirror emission trends in the atmospheric source area or airshed for these regions. Long-term data from across the eastern United States and Europe show declining concentrations of sulfate in wet deposition since the mid-1970s (**Fig. 1**), coincident with decreases in sulfur dioxide emissions. In the United States, decreases in emissions of sulfur dioxide have occurred as a result of emission control programs largely for electric utilities associated with the 1970 and 1990 Amendments of the Clean Air Act. Based on these long-term data, a strong positive correlation exists between sulfur dioxide emissions in the source area and sulfate concentrations in wet deposition. It is expected that the sulfate concentration of wet deposition will decrease (or increase) in a direct linear response to the decrease (or increase) of sulfur dioxide emissions in the atmospheric source area. These observations strongly suggest a cause and effect relationship between emissions of sulfur dioxide and deposition of sulfate in sensitive regions. A similar relationship has started to become evident between emissions of nitrogen oxides and wet deposition of nitrate. In the United States, controls on nitrogen oxide emissions from electric utilities have occurred largely through the US Environmental Protection Agency Nitrogen Budget Program. This relationship for nitrate is not as strong as the relationship for sulfur because emissions of nitrogen oxides in the United States have substantially decreased only since the early 2000s. However, it appears that recent decreases in emissions of nitrogen oxides from electric utilities are starting to result in decreases in atmospheric deposition of nitrate (**Fig. 2**). Atmospheric ammonium deposition has not changed in recent decades, but is becoming an increasingly important consideration in air quality management and acidic and nitrogen deposition, with the decreases in nitrogen oxide emissions and nitrate deposition.

Effects of Acidic Deposition on Forest Ecosystems

In acid-sensitive regions, acidic deposition alters soils, stresses forest vegetation, acidifies lakes and streams, and harms fish and other aquatic life. These effects can interfere with important ecosystem functions and services such as forest diversity and

productivity, and water quality. Years of acidic deposition have also made many ecosystems more sensitive to continuing air pollution. Moreover, the same pollutants that cause acidic deposition contribute to a wide array of other important environmental issues at local, regional, and global scales (see **Table 1**).

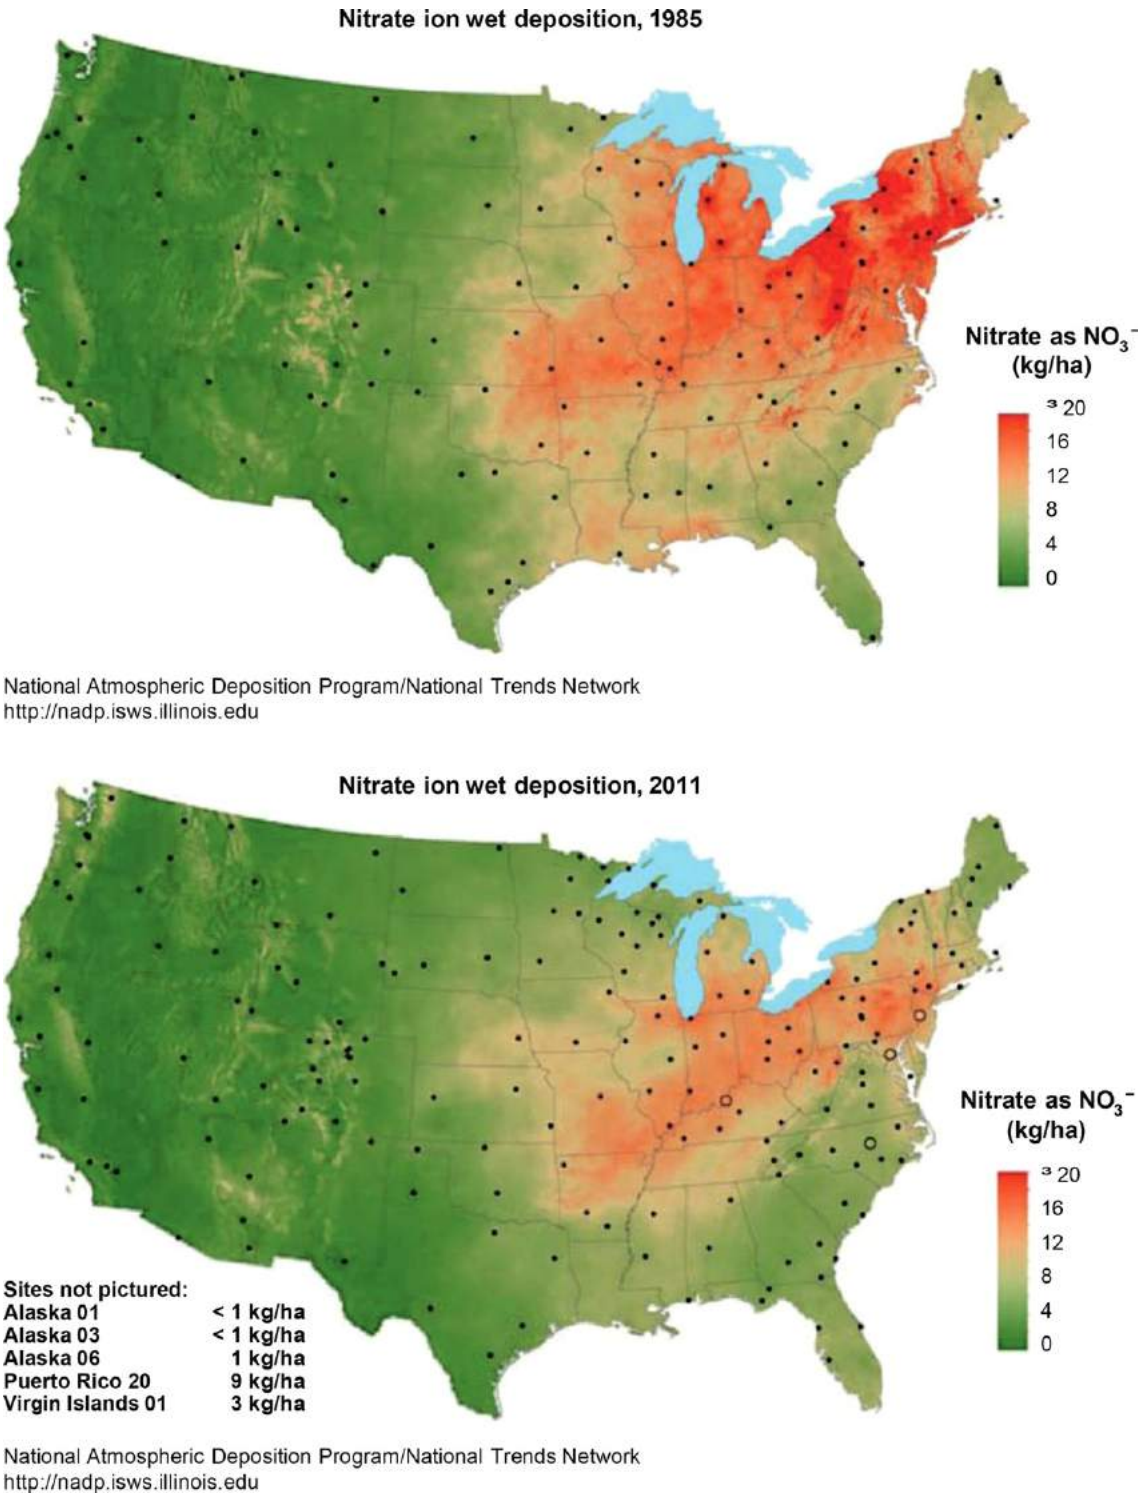

Fig. 2 Map of wet nitrate deposition for the United States for 1985 and 2011. Data are from the National Atmospheric Deposition Program (NADP) network.

Effects of Acidic Deposition on Forest Soils

Research has shown that acidic deposition has chemically altered soils with serious consequences for acid-sensitive ecosystems. Soils compromised by acidic deposition lose their ability to neutralize continuing inputs of strong acids, provide poorer growing conditions for plants, and extend the time needed for ecosystems to recover from acidic deposition. Acidic deposition has altered,

Table 1 The links between sulfur dioxide and nitrogen oxide emissions, acidic deposition, and other important environmental issues

Problem	*Linkage to acid deposition*
Coastal eutrophication	Atmospheric deposition adds nitrogen to coastal waters
Mercury	Surface water acidification increases mercury accumulation in fish
Visibility	Sulfate aerosols diminish visibility and view
Tropospheric ozone	Emissions of nitrogen oxides contribute to the formation of ozone

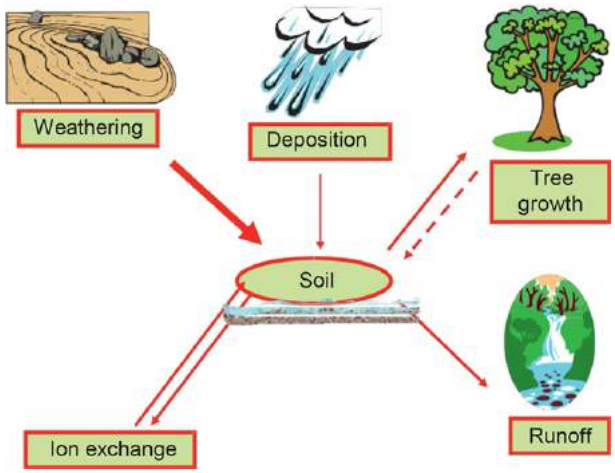

Fig. 3 Conceptual diagram illustrating the inputs and losses of calcium and other nutrient cations for forest ecosystems. Ecosystems with low weathering rates have low supplies of calcium and other nutrient cations available to soil and trees. High inputs of acidic deposition increase the leaching of calcium and other nutrient cations from soil. In acid-sensitive regions with low weathering rates, this can deplete soil pools of available calcium and other nutrient cations and limit the quantity available for tree growth.

and continues to alter, soils in sensitive regions in three important ways. Acidic deposition depletes available calcium and other nutrient cations from exchange sites in soil; facilitates the mobilization of dissolved inorganic aluminum into soil water; and increases the accumulation of sulfur and nitrogen in soil.

Loss of Calcium and Other Nutrient Cations

The cycling of calcium and other nutrient cations in forest ecosystems involves the inputs and losses of these materials (Fig. 3). For most forest ecosystems, the supply of calcium and other nutrient cations occurs largely by weathering (i.e., the breakdown of rocks and minerals in soil). Calcium and other nutrient cations may also enter forests by atmospheric deposition, although this pathway is generally much smaller than that of weathering. Losses occur largely by vegetation uptake and drainage waters. An important pool of ecosystem calcium and nutrient cations is the soil available pool or the soil cation exchange complex. Plants are generally able to utilize this source of nutrients. Forest ecosystems that are naturally sensitive to acidic deposition are generally characterized by low rates of weathering and generally low quantities of available nutrient cations. Under conditions of elevated inputs of acidic deposition and subsequent transport of sulfate and nitrate in drainage waters, nutrient cations will be displaced from available pools and leached from soil. This condition is not problematic for areas with high weathering rates and high pools of available nutrient cations. However, in acid-sensitive areas typically at higher elevation and with shallow soils, which contain minerals that are resistant to weathering, the enhanced loss of calcium and other nutrient cations can result in a depletion of available soil pools.

Over the last century, acidic deposition has accelerated the loss of large amounts of available calcium from acid-sensitive soil in acid-sensitive areas. Depletion occurs when nutrient cations are displaced from the soil by acidic deposition at a rate faster than they can be replenished by the slow breakdown of rocks or the deposition of nutrient cations from the atmosphere. This depletion of nutrient cations fundamentally alters soil processes, compromises the nutrition of some trees, and hinders the capacity for acid-sensitive soils to recover. For example, more than half of the available calcium has been lost from soil at the Hubbard Brook Experimental Forest, New Hampshire, over the past 60 years. Note that while acidic deposition to acid-sensitive areas is decreasing and there is some associated recovery of the acid-neutralizing capacity (ANC) of surface waters (see Surface Water Acidification section), in many regions the levels of acidic deposition remain high enough to continue to deplete exchangeable nutrient cations from soil. Moreover because soil weathering is a slow process, the depletion of cations from soil may limit the recovery of acid-impacted ecosystems over the long term.

Mobilization of Aluminum

Aluminum is often released from soil to soil water, lakes, and streams in forested regions receiving high acidic deposition, low stores of available calcium, and high soil acidity. One of the most significant ecological effects of acidic deposition is the mobilization of aluminum from soil and a shift in the form of aluminum in water from nontoxic organic forms to highly toxic inorganic forms. Concentrations of aluminum increase markedly with decreases in pH, particularly the toxic inorganic forms of aluminum. It is evident that concentrations of aluminum increase exponentially when surface water pH decreases below 6. Aluminum concentrations are thought to be ecologically significant when they increase to values above 2 mmol L^{-1}. This condition occurs below pH 6.0.

High concentrations of dissolved inorganic aluminum can be toxic to plants, fish, and other organisms. Concentrations of dissolved inorganic aluminum in streams in eastern North America and areas of Europe are often above levels considered toxic to fish and much greater than concentrations observed in forest watersheds that receive low inputs of acidic deposition.

Accumulation of Sulfur and Nitrogen in Soil

Elevated inputs of sulfur and nitrogen deposition also result in enhanced accumulation of these elements in soil. This response is generally not thought to have adverse effects on forest ecosystems. Indeed, elevated nitrogen deposition has the benefit of increasing the sequestration of carbon in soil, which offsets, to some extent, emissions of carbon dioxide to the atmosphere. Negative consequences of the accumulation of sulfur and nitrogen in soil will be realized only if these materials are mobilized to surface waters in response to decreases in inputs from atmospheric deposition. In the case of nitrogen, ecosystem accumulation of this growth-limiting nutrient can occur until it becomes no longer growth limiting. High inputs of nitrogen can result in a condition referred to as "nitrogen saturation," which coincides with increases in the leaching of nitrate to surface waters and the associated soil and water acidification. In the case of sulfate, it is unclear if soil sulfur is mobilized following decreases in atmospheric sulfur deposition or the associated eutrophication of ecosystems.

Effects of Acidic Deposition on Trees

Acidic deposition has contributed to the decline of red spruce and sugar maple trees in the eastern United States (Fig. 4). Symptoms of tree decline include poor condition of the canopy, reduced growth, and unusually high levels of mortality. The

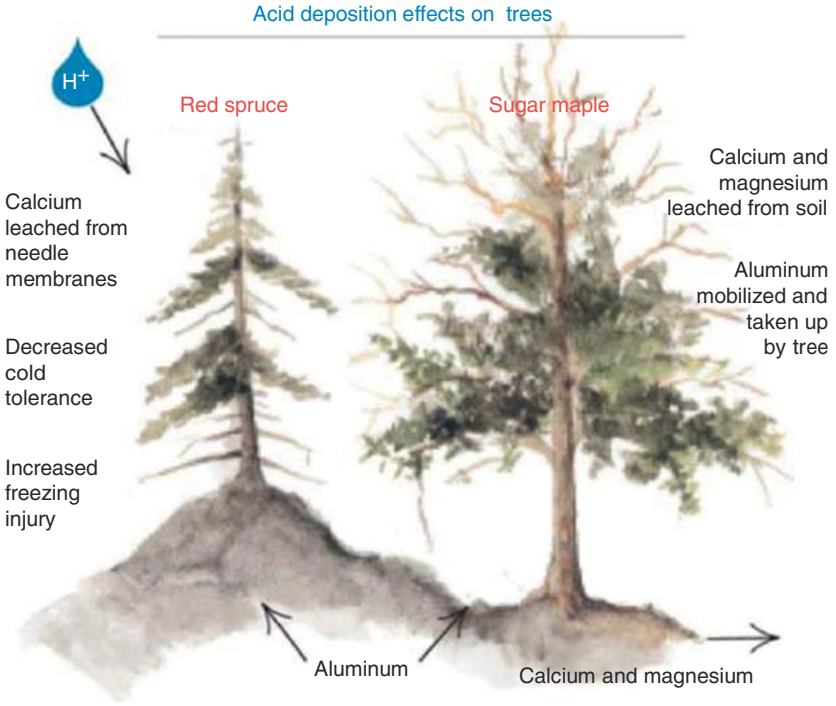

Fig. 4 Conceptual diagram illustrating the mechanisms by which acidic deposition impacts red spruce and sugar maple. Acidic deposition impacts red spruce through loss of membrane calcium due to direct leaching from foliage or reduced uptake of calcium from soil. The loss of membrane calcium makes red spruce more susceptible to winter injury. Acidic deposition results in loss of soil available calcium and magnesium and less uptake by sugar maple. This condition may make sugar maple more susceptible to insect or drought stress.

decline of red spruce and sugar maple in the northeastern United States has occurred over the last four decades. Factors associated with the decline of both species have been studied and include important links to acidic deposition.

Red Spruce

Acidic deposition is the major cause of red spruce decline at high elevations in the northeast. Many large canopy red spruce in the Adirondack Mountains of New York, the Green Mountains of Vermont, and the White Mountains of New Hampshire have died since the 1960s. Significant growth declines and winter injury to red spruce have been observed throughout its range.

Red spruce decline occurs by both direct and indirect effects of acidic deposition. Direct effects include the leaching of calcium from leaves and needles of trees (i.e., foliage), whereas indirect effects refer to acidification of the underlying soil chemistry.

The decline of red spruce is linked to the leaching of calcium from cell membranes in spruce needles by acid mist or fog. The loss of calcium renders the needles more susceptible to freezing damage, thereby reducing the tolerance of trees to low temperatures and increasing the occurrence of winter injury and subsequent tree damage or death. In addition, elevated aluminum concentrations in the soil may limit the ability of red spruce to take up water and nutrients through its roots. Water and nutrient deficiencies can lower the tolerance of trees to other environmental stresses and cause decline.

Sugar Maple

The decline of sugar maple has been studied in the eastern United States since the 1950s. Extensive mortality among sugar maples appears to have resulted from low levels of nutrient cations, coupled with other stresses such as insect defoliation or drought. The probability of decreases in the vigor of the sugar maple canopy or incidence of tree death increased on sites where the supply of calcium and magnesium to soil and foliage is lowest and stress from insect defoliation and/or drought is high. Low levels of nutrient cations can cause a nutrient imbalance and reduce the ability of a tree to respond to stresses such as insect infestation and drought.

Nitrogen Impacts

Inputs of nitrogen are generally considered to benefit forest ecosystems, because nitrogen is generally the growth-limiting element. However, recent research in the eastern United States has demonstrated a varied response to elevated nitrogen inputs, with many tree species apparently benefiting from this condition, but at the same time the health of some declining, such as red spruce, red pine, and white cedar. It appears that there are "winners and losers" as ecosystems respond to changes in the "chemical climate."

Effects of Acidic Deposition on Freshwater Aquatic Ecosystems

Surface Water Acidification

Acidic deposition degrades surface water quality by lowering pH (i.e., increasing acidity); decreasing ANC; and increasing dissolved inorganic aluminum concentrations. While sulfate concentrations in lakes and streams have decreased in eastern North America and Europe over the last 30 years, they remain high compared to background conditions (e.g., approximately 20 meq L^{-1}). Many lakes and streams in acid-impacted regions have shown some chemical recovery in response to emission controls, but have not achieved full recovery.

Acidification of surface waters due to elevated inputs of acidic deposition has been reported in many acid-sensitive areas receiving elevated inputs of acidic deposition, including Great Britain; Nordic countries; Northern, Central, and Eastern Europe; southwestern China; southeastern Canada; the northeastern United States; the Upper Midwest; and the Appalachian mountain region of the United States. Large portions of the high-elevation western United States are also potentially sensitive to acidic deposition; however, atmospheric deposition to this region is relatively low. Concern over effects of acidic deposition in the mountainous regions of the western United States may be overshadowed by the potential effects of elevated nitrogen deposition, including eutrophication of naturally nitrogen-limited lakes.

To illustrate the regional impacts of acidic deposition, a comprehensive survey of lakes greater than 0.2 ha in surface area in the Adirondack region of New York was conducted to obtain detailed information on the acid–base status of waters in this region. Of the 1469 lakes surveyed, 24% had summer pH values below 5.0. Also, 27% of the lakes surveyed were chronically acidic (i.e., ANC less than 0 meq L^{-1}) and an additional 21% were susceptible to episodic acidification (i.e., ANC between 0 and 50 meq L^{-1}). An analysis of the anion content of these lakes illustrates that these lakes have been acidified predominantly by atmospheric deposition of sulfate.

Seasonal acidification is the periodic increase in acidity and the corresponding decrease in pH and ANC in streams and lakes, which generally occurs during the higher flow fall, winter, and spring periods. Episodic acidification is caused by the sudden pulse of acids and a dilution of acid-neutralizing base cations (e.g., calcium, magnesium, sodium, potassium) during spring snowmelt and large rain events in the spring and fall. Increases in nitrate are often important to the occurrence of acid episodes. These conditions tend to occur when trees are dormant and, therefore, retaining less nitrogen. At some sites, short-term increases in

sulfate and organic acids can also contribute to episodic acidification. Episodic acidification often coincides with pulsed increases in concentrations of dissolved inorganic aluminum. Short-term increases in acid inputs to surface waters can reach levels that are lethal to fish and other aquatic organisms. All the acid-sensitive and acid-impacted regions discussed in this article have documented effects associated with episodic acidification.

Trends in surface water chemistry in Europe and eastern North America indicate that recovery of aquatic ecosystems impacted by acidic deposition has been occurring over a large geographic scale since the early 1980s. Some regions are showing rather marked recovery, while others exhibit low or nonexistent increases in ANC. Based on long-term monitoring, virtually all surface waters impacted by acidic deposition in Europe and eastern North America exhibit decreases in sulfate concentrations. This pattern is consistent with decreases in emissions of sulfur dioxide and atmospheric sulfate deposition. The exception to this pattern is streams in unglaciated regions, such as the central and southern Appalachian Mountains. Watersheds in this region and other portions of the southeastern United States exhibit strong adsorption of atmospheric sulfate deposition by highly weathered soils, and only some are exhibiting modest recovery from decreases in acidic deposition. In Europe, the most marked decreases in surface water sulfate have occurred in the Czech Republic and Slovakia, regions that historically experienced very high rates of atmospheric sulfate deposition. More than half of the surface waters monitored in Europe are showing increases in ANC. The rate of ANC increase in Europe is relatively high. This pattern is, in part, due to the relatively high rates of sulfate decreases. In the United States, some regions are showing statistically significant increases in ANC, including lakes in the Adirondacks, New England, and Upper Midwest, and streams in the Northern Appalachian Plateau.

Three factors limit the chemical recovery of the water quality of acid-impacted surface waters, despite the decreased deposition of sulfate. First, levels of acid-neutralizing base cations in streams have decreased markedly due to a loss of base cations from the soil and, to a lesser extent, a reduction in atmospheric inputs of base cations. Second, inputs of nitric acid have acidified surface waters and elevated their concentration of nitrate in many acid-impacted regions. Finally, sulfur that has accumulated in the soil, particularly in the southeastern United States, may be released to surface water as sulfate, even though sulfate deposition has decreased. It appears that the best approach to accelerate the recovery of acid-impacted lakes is to make additional cuts in emissions of sulfur dioxide and nitrogen oxides.

The decreases in sulfate and nitrate concentrations and increases in pH and ANC exhibited in some surface waters is an encouraging sign that impacted ecosystems are responding to emission controls and moving toward chemical recovery. Nevertheless, the magnitude of these changes is small compared to the magnitude of increases in sulfate and nitrate and decreases in ANC and pH that have occurred in acid-impacted areas following historical increases in acidic deposition. However, as discussed earlier, in many acid-sensitive regions, soils continue to acidify despite decreases in acidic deposition. Moreover, many acid-impacted watersheds in northern North America and Europe are showing increases in concentrations of dissolved organic carbon in response to decreases in acidic deposition. Dissolved organic carbon is indicative of the release of naturally occurring organic acids from soil. It is thought that acid deposition limited the transport of these naturally occurring organic acids to surface waters. Now with recovery, this process is being restored. However, as organic acids are acids, increased concentrations will limit the extent of pH and ANC increases in recovering ecosystems.

Response of Aquatic Biota to Acidification of Surface Waters by Acidic Deposition

Decreases in pH and elevated concentrations of dissolved inorganic aluminum have resulted in physiological changes to organisms and direct mortality of sensitive life-history stages, and reduced the species diversity and abundance of aquatic life in many streams and lakes in acid-impacted areas. Fish have received the most attention to date, but entire food webs are often adversely affected.

Decreases in pH and increases in aluminum concentrations have diminished the species diversity and abundance of plankton, invertebrates, and fish in acid-impacted surface waters. A detailed summary of the response of aquatic biota to the acidification of surface waters is provided in **Table 2**.

In the Adirondacks, a significant positive relationship exists between the pH and ANC levels in lakes and the number of fish species present in those lakes (**Fig. 5**). Surveys of 1469 Adirondack lakes conducted in 1984 and 1987 show that 24% of lakes (i.e., 346) in this region do not support fish. These lakes had consistently lower pH and ANC, and higher concentrations of aluminum than lakes that contained one or more species of fish. Experimental studies and field observations demonstrate that even acid-tolerant fish species such as brook trout have been eliminated from some waters in New York.

Similar relationships are evident in surface waters in acid-impacted regions throughout the world. Studies demonstrate the effects of acidic deposition on fish at three ecosystem levels:

- Effects on single organisms (condition factor—the relationship between the weight and the length of a fish). Fish condition factor is related to several chemical indicators of acid–base status, including minimum pH. This analysis suggests that fish in acidic streams use more energy to maintain internal chemistry than would otherwise be used for growth.
- Population-level effects (increased mortality). Bioassay experiments show greater mortality in chronically acidic streams than in high ANC streams. Egg and fry are sensitive life-history stages for fish.
- Community-level effects (reduced species richness). The species richness of fish and other aquatic organisms decreases with decreasing ANC and pH.

Table 2 Biological effects of surface water acidification in North America

pH decrease	*General biological effects*
6.5–6.0	Small decrease in species richness of phytoplankton, zooplankton, and benthic invertebrate communities resulting from the loss of a few highly acid-sensitive species, but no measurable change in total community abundance or production
	Some adverse effects (decreased reproductive success) may occur in highly acid-sensitive species (e.g., fathead minnow, striped bass)
6.0–5.5	Loss of sensitive species of minnow and dace, such as blacknose dace and fathead minnow; in some waters decreased reproductive success of lake trout and walleye, which are important sport fish species in some areas
	Visual accumulations of filamentous green algae in the littoral zone of many lakes, and in some streams
	Distinct decrease in the species richness and change in species composition of the phytoplankton, zooplankton, and benthic invertebrate communities, although little, if any, change in total community biomass or production
5.5–5.0	Loss of several important sport fish species, including lake trout, walleye, rainbow trout, and smallmouth bass; as well as additional nongame species such as creek chub
	Further increase in the extent and abundance of filamentous green algae in lake littoral areas and streams
	Continued shift in the species composition and decline in species richness of the phytoplankton, periphyton, zooplankton, and benthic invertebrate communities; decrease in the total abundance and biomass of benthic invertebrates and zooplankton may occur in some waters
	Loss of several additional invertebrate species common in oligotrophic waters, including *Daphnia galeata mendotae*, *Diaphanosoma leuchtenbergianum*, *Asplanchna priodonta*; all snails, most species of clams, and many species of mayflies, stoneflies, and other benthic invertebrates
	Inhibition of nitrification
5.04.5	Loss of most fish species, including the most important sport fish species such as brook trout and Atlantic salmon; few fish species able to survive and reproduce below pH 4.5 (e.g., central mudminnow, yellow perch, and in some waters, largemouth bass)
	Measurable decline in the whole-system rates of decomposition of some forms of organic matter, potentially resulting in decreased rates of nutrient cycling
	Substantial decrease in the number of species of zooplankton and benthic invertebrates and further decline in the species richness of the phytoplankton and periphyton communities; measurable decrease in the total community biomass of zooplankton and benthic invertebrates in most waters
	Loss of zooplankton species such as *Tropocyclops prasinus mexicanus*, *Leptodora kindtii*, and *Conochilus unicornis*; and benthic invertebrate species, including all clams and many insects and crustaceans
	Reproductive failure of some acid-sensitive species of amphibians such as spotted salamanders, Jefferson salamanders, and the leopard frog

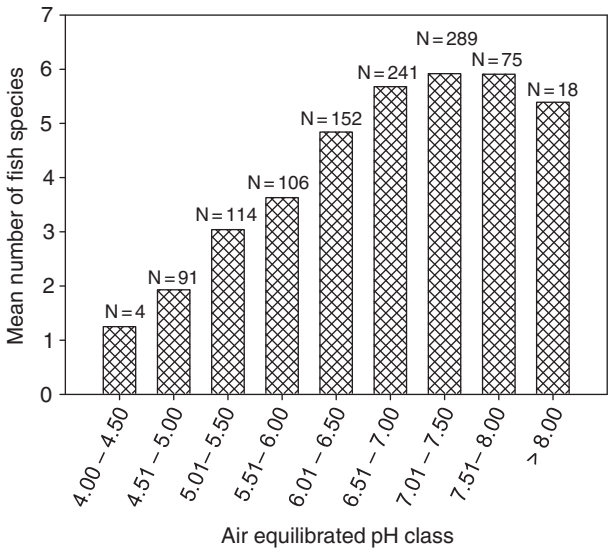

Fig. 5 Distribution of the mean number of fish species for ranges of pH from 4.0 to 8.0 in lakes of the Adirondack region of New York. *N* represents the number of lakes in each pH category.

Although chronically high acid levels stress aquatic life, acid episodes are particularly harmful because abrupt, large changes in water chemistry allow fish few areas of refuge. High concentrations of dissolved inorganic aluminum are directly toxic to fish and pulses of aluminum during acid episodes are a primary cause of fish mortality. High acidity and aluminum levels disrupt the salt and water balance of blood in a fish, causing red blood cells to rupture and blood viscosity to increase. Studies show that the viscous blood strains the heart of a fish, resulting in a lethal heart attack.

While most acid-impacted regions have monitoring programs that document the chemical recovery from acidic deposition, there are far fewer programs that track biological recovery. The limited studies that have been conducted generally show limited and delayed biological recovery in response to chemical recovery. Moreover, the endpoint of biological recovery is unlikely to be that which existed prior to the advent of acidic deposition, because of changes that have occurred to ecosystems in the intervening decades.

Effects of Acidic Deposition on Marine Ecosystems

Due to increased carbon dioxide emissions resulting from anthropogenic activities, hydrogen ion concentrations in surface oceans are predicted to increase 150% by 2100, which may pose threats for diverse marine organisms, particularly, shell-forming and calcifying organisms.

In the case of some commercially exploited filter-feeders, such as oysters, it is likely that the physiological impacts related to reductions in calcium carbonate availability affect ecosystem functioning and the provision of ecosystem services provided by these organisms. Nonetheless, the effects of other stressors (e.g. warming, eutrophication, metal contamination) cannot be discarded and are difficult to evaluate.

On the other hand, infaunal marine organisms, such as the clam *Mya arenaria*, which were considered to be relatively robust to changes in seawater pH and carbonate geochemistry, seem to suffer from several order impacts caused by sediment acidification, such as shell dissolution, behavioural alterations, more lesions, increased mortality.

Ecosystem-level analysis suggest that food web consequences of ocean acidification can extend beyond groups thought most vulnerable and affect fishery yield and ecosystem structure, yet, the indirect effects of ocean acidification on calcifying organisms are uncertain and can be counterintuitive. For example, primary productivity has been found higher at natural CO_2 vents with near-future CO_2 levels, compared to control sites with present-day CO_2 levels, which counterintuitively drove, via provision of more habitat and food, to a greater abundance of herbivorous gastropods.

Other works suggest that, while lower pH impairs the senses of reef fishes and reduces their survival, cephalopods and crustaceans will remain largely unscathed. In the same way, it is projected that habitat changes promoted by ocean acidification reduce seafood production from coral reefs, but increase production from seagrass and seaweed. Thus, the overall effects of ocean acidification on primary production and, hence, on food webs will result in hard-to-predict winners and losers. In fact, results from some experimental and numerical analyses propose that marine biota may be more resistant to ocean acidification than expected. In some cases, ocean acidification will enhance growth of marine autotrophs and reduce fertility and metabolic rates, but effects are likely to be minor along the range of pCO2 predicted for the 21st century, and feedbacks between positive responses of autotrophs and pH may further buffer the impacts.

Ecosystem Response to Air Quality Management

As discussed earlier, aquatic ecosystems have responded in North America and Europe to emission control programs. In Europe and Canada emission control programs have been specifically established to protect ecosystems from the effects of air pollution and acidic deposition. In contrast, in the United States, air quality management has been driven by human health concerns, and ecosystem recovery has been a cobenefit of these initiatives. However, as has historically been the case in Europe and Canada, the United States is starting to recognize the benefits of services associated with healthy ecosystems. This has led to interest in the concept of "Critical Loads" and "Target Loads," an approach that has been used in Europe for decades. A critical load is the loading of an air pollutant to an ecosystem below which harmful ecological effects have not been documented. A critical load is governed by the inherent biophysical characteristics of an ecosystem, such as rates of chemical weathering and soil characteristics. A target load is a political decision and maybe higher or lower than the critical load depending on political and economic considerations. In the United States, the US Forest Service, the National Park Service, and the US Environmental Protection Agency are starting to use critical loads to guide management in protecting ecosystems from air pollution effects. Calculations of critical loads of acidity and nitrogen have been conducted for regions of the US and the entire country. Those regions showing exceedances in critical loads are similar to those discussed above as experiencing surface water acidification (see Surface Water Acidification section).

In some regions, the recovery of ecosystems from acidic deposition has not been fast enough to protect impacted resources. Under these conditions, basic material, such as limestone or calcium carbonate, has been added as a management approach to mitigate the adverse effects of acidic deposition. Addition of basic materials has been successful in the protection of ecosystems from the impacts of acidic deposition. National programs have been implemented in Germany and Sweden. There have been no negative effects of liming in the treatment of acid-impacted watersheds or surface waters.

Ecological Efficiency☆

Lawrence B Slobodkin, SUNY, Stony Brook, NY, United States

Glossary

Ecosystem processes An intrinsic characteristic whereby an ecosystem maintains its integrity. Processes include decomposition, production, nutrient cycling, and fluxes of nutrients and energy.

Energy transfer The conversion of one form of energy into another, or the movement of energy from one place to another.

Entropy Is a measure of evenness of a distribution of energy between parts of a system.

Steady-state systems Matter entering the system is equivalent to the matter exiting the system.

Trophic level The position an organism occupies in the food chain.

Introduction

Historically, studies of multispecies assemblages have often focused on "energy." There were three general reasons for this:

1. Units of energy relate to all biological activity.
2. There was, for many years, the hope that a focus on energy would somehow bring ecology under the purview of thermodynamics.
3. Finally, once it had become customary to use energy units, there was no strong reason to change.

Concern with energy began as part of an attempt to extend the formal rigor of thermodynamics to biology. Lotka developed a diagram of an abstract ecological system at steady state. At the suggestion of Hutchinson, Lindeman used the notation of Lotka to describe the passage of energy through a lake.

In this trophic dynamic scheme, ecosystems are represented as a set of trophic levels. All the photosynthesizers (green plants, algae, and many kinds of colored bacteria) can be labeled as trophic level 0, the herbivores as level 1, carnivores feeding on herbivores as level 2, carnivores feeding on them as level 3, etc.

Ecological efficiency was rigorously defined by Lindeman as the fraction of the energy that is consumed by organisms on one trophic level that serves as nourishment for organisms on the next higher trophic level (**Fig. 1**). Any definable portion of a community has an ecological efficiency if, and only if, it is possible to measure the energy per unit time taken from it by predators and the energy that it consumed from its prey or food organisms or, in the case of photosynthetic organisms, from solar radiation.

The trophic dynamic diagram of Lindeman was not perfect. There are omnivores that consume both flesh and vegetation, thereby feeding on several trophic levels. There are multiple tropic levels among the decomposers. There are also cannibals and organisms that change their trophic level as they mature. These considerations complicate assignment of particular species to particular trophic levels.

With the exception of some deep sea and hot spring bacteria, that use chemical energy in the absence of light, photosynthesis directly, or indirectly, provides the energy for all organisms. Photosynthetic organisms gain radiant energy from sunlight and transform it into potential or chemical energy. Some of the chemical energy in plants is passed on to herbivores whence energy may be passed on either to higher-order carnivores or parasites or detritivores. The chemical energy consumed by herbivores is dissipated as heat, stored, or passed further up the food chain. In addition, all trophic levels contribute energy in the form of dead organisms and excreta to decomposer organisms, like bacteria, and molds.

The energy income to plants has been variously defined as the energy of the sunlight impinging on the plants or as the energy actually fixed by photosynthesis. This makes an enormous difference in the estimated value of ecological efficiency for the plants but does not matter for the ecological efficiency estimates of higher trophic levels.

Measuring Ecological Efficiency

To say that a particular population or trophic level has a particular ecological efficiency is an assertion about the ratio of energy received by that population or trophic level and the energy consumed from that population or trophic level by a predator or a next higher trophic level, during the same time interval. It is not measurable from a single population or a single trophic level.

☆*Change History*: March 2018. H Pethybridge included glossary, keywords, minor text edits, added Fig. 1, and updated references.

This is an update of L.B. Slobodkin, Ecological Efficiency, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1019–1024.

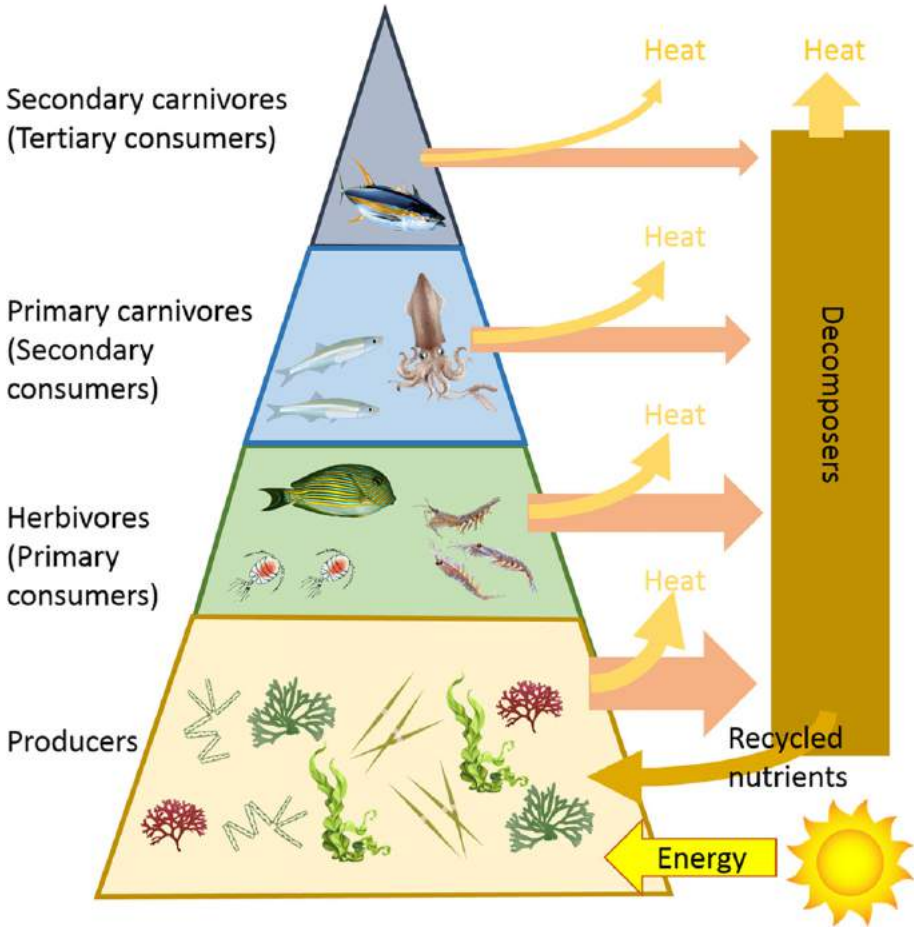

Fig. 1 The amount of energy transferred as biomass from one trophic level to the next (ecological efficiency).

Early efficiency estimates used surrogates for energy (biomass, population counts, total protein, etc.), but for the last 45 years direct energy measurements have been more common. Actual measurements of energy can be made of heat production by living organisms in a calorimeter or by combustion of whole organisms or their parts in a bomb calorimeter.

The caloric content per ash free gram of whole organisms varies between approximately 4500 calories per gram, found in carbohydrates and many whole plants, to 8000–9000 calories per gram found in pure fats. Most animals usually are around 5600, the value for protein mixed with a little fat. Efficiency of particular energy consumption processes can also be evaluated by considering biochemical equations directly, but ecologists do not often do this.

When circumstances permit, all organisms can reproduce and grow far more than is needed for their own replacement, however death rates will exceed the rates of growth and reproduction when circumstances change. Periods of low energy income and high mortality are interspersed with periods of high-energy availability and high growth and reproductive rate.

Ecological efficiency varies seasonally. In very small organisms, growth and multiplication can be very rapid—basically keeping up with energy income. In larger organisms, there are typically periods during which energy income exceeds the possibilities for enhanced growth and reproduction and periods of food shortage when organisms can only rely on stored energy. Higher values for ash-free total calorie concentration in animals are found either when food is particularly abundant or when energy is being stored in advance of some process that will make higher energy demands than can be met immediately by feeding. Large seeds, yolky eggs, prehibernating mammals, and premigratory birds have high caloric density.

In very small aquatic organisms, like in diatoms and copepods, oil droplets may serve for flotation as well as energy storage. In large animals like walrus, whales, and bears, fat may also serve as thermal insulation.

The Relation Between Population Maintenance and Ecological Efficiency

Generally, prey convert energy from an inedible form, which the predators cannot use as a food supply, to a more digestible and convenient form. Plants turn sunlight into food for animals. Also, a population of mice can transform inedible grain

into food for cats so that a steady-state population of mice can be considered to have an ecological efficiency from the standpoint of a steady-state population of cats. The ecological efficiency of the mice is defined as calories of mouse eaten per unit time by the cat population divided by calories of cat-inedible food, say grain, eaten per unit time by the mouse population.

How we choose to measure ecological efficiency of any population or trophic level will determine the value observed and will affect the usefulness of the measurement. We might measure the loss of the mouse population to all predators rather than to cats alone. This would also permit a measurement of the ecological efficiency of the mice but it would have a different, legitimate, meaning from that in which only cats were considered.

Both plants and animals that confront seasonality in growth and reproductive conditions have evolved energy storage mechanisms. In motile organisms and in plant seeds adapted for transportation or penetration of the soil, energy storage is usually in the form of fats and oils, which are maximally compact and least disturbing to the external shape of the organisms.

Lower caloric concentration in stored energy is found in organisms in which shape is not as important. Potatoes and other roots and some mollusks enclosed in shells store energy as starch or glycogen rather than fats or oils as do sedentary polychaetes, for example, lugworms. The transition of energy from one trophic layer to the next occurs when organisms are eaten but the process is always accompanied by production of heat, carbon dioxide, and indigestible material. At every trophic level, exudates, detritus, and dead organisms support detritivores, including bacteria and molds. This stepwise transformation of potential energy digestion results in increasingly recalcitrant residual material that finally may be added to sediments.

A steady-state stipulation may be important. If house-cats become excessively competent at catching mice, they may get a large temporary yield of mouse meat at the cost of destroying the mouse population completely. This is generally analogous to any problem of overexploitation of the kind that is encountered in fishing or hunting situations. Some predators may exploit their prey in a way that minimizes the danger to the persistence of the prey population. This is termed "prudent predation" and there was, at one time, a concern that this involved "group selection." The problem disappeared when it was shown that the focus of individual selection was on the escape and survival capacity of the prey and not on actual "prudence."

Unless the focus population (the one whose ecological efficiency is being measured) is a population of plants, it consumes energy from some other population, the food or prey population. Other organisms in the consumer, or predator, populations may eat energy-rich material from the focus population. The remainder of material produced by the focus population may be thought of as related to maintenance.

A population can have higher ecological efficiency if minimal energy is used for its own population maintenance. "Maintenance" costs are the activities of, and products from, the focus population that would occur even in the absence of predators or herbivores. Some of the products of maintenance are still energy rich and supply energy income to decomposer organisms—ranging from molds and bacteria to detritivorous animals. These materials include dead bodies or body parts and exudates, for example, dead leaves, fallen logs, molted skin, skin fragments, and mucous, fecal material, and loose scales. Maintenance requires oxygen consumption, produces carbon dioxide, and degrades some organic materials.

In moist and oxygenated situations, molds and bacteria and detritivores decompose organic wastes relatively quickly. Energy-rich compounds that are not consumed become humic stains in sediments, peat, coal, or oil and may eventually be burned as fossil fuels.

Farmers Are Not Predators

Focal populations may be "farmed" rather than preyed upon. Cows turn hay and feed into meat and milk, of interest to the farmer who maintains the animals in such a way as to minimize energy expenditure in exercise and aggression. Placid cows are more efficient but the entire situation in which humans do part of the work of maintenance of the population is highly unnatural.

In a farming situation, the consumption and the yield from a focal population can be measured in units of money and time. The ratio of price of produce to cost of husbandry is important, but since it is not defined in energetic terms it is not an ecological efficiency. Recall that part of the motivation of Lotka, Lindeman, and Hutchinson was to make theoretical contact with thermodynamics.

Ecological efficiencies in the sense of Lindeman, used in most ecological literature, do not have any meaningful definition for entire communities or entire ecosystems. There is a tendency to confuse the ideas of efficiency and effectiveness.

Geese can eat grass off golf courses, birds may eat noxious insects, and bacteria can help digest organic matter in sewage effluent. These valuable processes are only remotely connected to ecological efficiency. Advocates for vegetarianism quite correctly note that the amount of resources—sunlight, water, and fertilizers needed to grow animal flesh—is several times larger than that needed to produce an amount of vegetable food of equivalent or superior nutritional quality.

Ecosystems or communities can be managed for particular purposes, for example, maximum steady-state yields of fish, seaweed, grass, elephant tusks, or game. Management can increase these yields, but this is deeply different from ecological efficiency, which cannot be measured for an entire system. Animals and plants can be more or less effective at performing desired functions. Effectiveness at particular processes is of immediate intuitive value. It is less obvious why ecological efficiency matters for any practical purpose.

A high ecological efficiency does not imply a large amount of material being maintained at any trophic level.

Efficiency, Yield, and Stability

In many circumstances, ecological efficiency can be increased by more intensive predation, but only at the cost of reducing the availability of energy for population maintenance and probably lowering the total yield from that population. For example, if the fishing rate is excessive, a prey population may have a very high ecological efficiency, but also a dangerously low population size.

Whole organisms or parts of organisms in the focus population may be eaten. Feeding on another organism does not automatically infer the death of that organism. Parts of living plants may be eaten without killing the plants as in the feeding of bovines on grasses. Certainly, most macroscopic plants are partially eaten by herbivores as can be confirmed by examining almost any leaf. Almost all leaves have their outline broken by missing portions and their surfaces marked by tunnels, galls, or holes.

Some animals can be eaten in such a way as to not kill them. For example, parrotfish browse on the branches of coral without killing the entire coral. Stone crab claws are commercially harvested by breaking them off the living animals that are then released to presumably regenerate new claws. Clams are often fed upon by fishes in such a way as to leave the animals alive, removing only vulnerable parts of their anatomy—particularly the siphons.

Obviously, there are many procedures by which a focus population may avoid predators or at least minimize the harm from higher trophic levels. Mechanisms range from the flight of small birds before a hawk, the secretion of foul odors by many insects, and digging further into sediments by clams in the wake of crab attacks. Correspondingly, there are an endless variety of ways in which predators attack their prey. All parasites can be considered predators that have evolved ways of feeding that do not immediately kill their prey.

Most of the solar energy impinging on green plants dissipates as heat. The rest drives the photosynthetic process, converting light energy to chemical energy in organic molecules. The photosynthetic organisms usually use most of the sugars and carbohydrates that they produce for growth, reproduction, and repair.

Usually there is not a perfect local balance between photosynthetic energy fixation and energy losses to respiration. Residual material, particularly in oligotrophic situations, is a relatively small fraction of the organic material produced by the photosynthesizers in that ecosystem. This residual material may be washed away and used by some distant organisms, or buried, joining sediment or adding to fossil fuel or to the brown color of soil. The existence and condition of organic material in sediments depends broadly on the availability of water and oxygen for decomposer bacteria and molds.

The relative quantities of consumed energy that are dissipated as heat, used in growth and reproduction, stored as fats or oils, or passed on to higher trophic levels, vary among organisms, and vary with different times and circumstances. However, heat and buried or dissolved carbon compounds are the universal ends of all energy that enters an ecosystem.

Because some potential energy is converted to heat at each trophic level, the total energy per unit time that flows through the system must decrease with trophic level. If the maintenance cost per gram of live standing crop tissue is approximately independent of trophic level, a pyramid of standing crop abundance is generated, the classical "Eltonian pyramid."

When growth and metabolic rates (per calorie-day maintained) are very high in the lower trophic levels, and relatively low in organisms at higher trophic levels, the trophic pyramid can be inverted—with small standing crops of plants and herbivores turning over rapidly at the bottom while maintaining large populations at higher trophic levels. Examples include some aquatic systems that are based on phytoplankton.

Those organisms that are not food for any other organisms in the system have by definition ecological efficiency equal to zero. While the ecological efficiency of a top predator population is usually considered to be zero, but parasites on or in these predators can be taken as an even higher trophic.

In fact, there is probably no animal or plant population that actually has ecological efficiency of zero. Occasionally, even elephants, wolves, and tigers, if they are very young or very old, fall to predators or carry parasites, and even the driest and most toxic of vegetation usually shows obvious signs of having been partially consumed by some herbivore or mold.

In addition to feeding predators, energy is used in processes of growth and reproduction. Plants and animals both do work in moving internal fluids and intracellular parts. Animals are more mobile than plants, and a correspondingly larger portion of their ingested energy is expended as movement against external forces and friction.

In a growing population, the rate of energy consumption is greater than the rate at which energy is discharged from the population. At its upper limit, ecological efficiency is greatest when a population is rapidly growing and such a short time interval is considered that no deaths or losses of potential energy from individuals have occurred. At the lower limit, ecological efficiency of the focus population goes to zero as a starving population approaches extinction or if there are no predators.

In short, ecological efficiency will vary with conditions. Ecological efficiency will approach a steady state only if abundance, age distribution, and size distribution of the organisms in the focal population are not changing and neither are the predation rate and the distribution of age and size of the prey.

Ecological Efficiency and Evolution

The central mechanism of microevolutionary change involves selection among alleles in a single population. Measuring selection is quite different from measuring ecological efficiency. There are many ways of organizing an energy budget but ecological efficiency determination always requires measurements on at least three populations. This is extremely important in the context of how natural selection impinges on ecological efficiency.

There is no way for natural selection to act on ecological efficiency directly, but the interaction between populations of predators and the populations of their prey is inherently unstable in the absence of natural selection. It has long been known that the interaction of predators and prey can be unstable in laboratory experiments and in mathematical models. Typically, the last prey is eaten and the predators then starve to death unless special mechanisms and properties exist that prevent or at least delay this collapse of the system.

Obviously, predators and their prey are both found in nature, as if there were evolutionary mechanisms for stabilizing their coexistence. The actual food webs and food chains we find are the survivors of a massive group selective selection process—all the unstable webs and food chains are gone. In addition, the natural selection on the process of predation and on the escape of prey while not selecting for any particular value of ecological efficiency will tend toward stabilization of the particular predator–prey system involved.

Thermodynamics and Ecological Efficiency

There are many books and papers that use arguments about entropy in ecological systems. While we can focus on particular predators and consider the ecological efficiency of a particular focus population from the standpoint of particular predators, detritivores, etc., the boundary conditions for analyses of entropy and enthalpy in closed systems are certainly not met by ecological systems. 'Closing' an ecological system in the sense of elementary thermodynamics results in almost immediate death of all organisms in the system. They are not at equilibrium, nor is it generally possible to control temperature properly, and certainly they are not at chemical equilibrium. Ecological efficiencies are dimensionless ratios of rates defined in units of energy per time over some interesting area but they have not been measured within the boundary conditions for thermodynamics or steady-state thermodynamics.

Ecological efficiency involves the idea of a population or trophic level being fed upon by a predator or parasite population while feeding on some lower trophic level, but without the benefit of the farmer's attention. This seems to be a basically unstable arrangement. Why does not a higher trophic level completely eat out the lower one, or why cannot the lower trophic level evolve properties that make it immune to predation by the members of the higher tropic level?

Estimates of ecological efficiency vary widely. Some of this variance is due to actual biological differences but some is due to a variety of technical problems. We generally cannot directly measure transfers of energy in the field. Therefore, ecological efficiency measures require that more readily available measures, such as census data, stomach contents analyses, or some measure of biomass, are converted to calories by use of different conversion constants derived from measure of the caloric content of different categories of organisms in the system combined with field census data.

With the possible exception of relatively rare and large organisms in controlled situations, census evaluations in nature have relatively large and sometimes poorly known errors. Typically, there are not replicates available for the situation being examined.

Also, while steady-state conditions are not required for efficiency measurements, the meaning of non-steady-state evaluations is limited.

Ecological efficiency is not a constant across ecological situations, although this was, for a while, a tempting hypothesis. The same systems examined over different timescales may have different ecological efficiencies.

Attempts to circumvent the problem of sampling, repetition, and lack of a steady state can be made by using laboratory populations, in which food to the populations and yield from the populations can both be controlled. Of course, the relevance of these studies to field values remains uncertain.

When ecological efficiency was evaluated in laboratory populations of *Daphnia* and hydra, they approximately agreed with each other and were within the range of values reported from nature. It can be demonstrated that any apparent constancy of ecological efficiency cannot be the result of evolutionary selection. In fact, it is an epiphenomenon.

Ecological efficiency has a curious relation to natural selection, which may shed light on other evolutionary questions. Using the now classical metaphor of the spandrels of San Marco, Gould and Lewontin elegantly underscored the question of whether there exist biological properties that are not in themselves selected for or against by the evolutionary process but are carried along by selection in the process of selection for some other properties. Ever since, there have been arguments about whether or not such properties exist and whether or not there are any properties of the biological world that are ignored by selection.

An elementary tenet of modern evolutionary theory is the natural selection for differences in fitness among members of a population. Sometimes, the fitness advantages of the selected organisms are not obvious. This can generally be resolved by further study or suitable reexamination of details of the process. If necessary, the problem can often be resolved by considering the effects of selection not only on individuals but also on their kin. A mother whose probability of individual survival and longevity is materially reduced by reproduction may be producing a sufficient number and quality of young so that the total fitness of mother and young may be higher than that of some other mother and young, thereby providing raw material for selection.

In order for natural selection for ecological efficiency to achieve any particular value, the selective process must somehow work in a coordinated way on at least three populations within that community. There is no readily describable mechanism for that to occur. Possibly a massive group selection process acting on entire trophic systems might raise or lower the rates and quantities of energy transfer, but what is much more likely is that one or more of the populations in the trophic system will be eliminated or greatly reduced while ecological efficiency continues to be set by multispecies relationships that have no direct selective meaning.

The actual value of ecological efficiency seems to be an epiphenomenon of selection, operating on all of the components of energy transfer in a trophic system, rather than being in any way the direct target of selection. This implies that there is at least one property of ecological systems that is real and measurable but not related in any clear way to natural selection. Ecological efficiency values require coordination among parts of ecological systems, each of which are themselves subject to natural selection without particular coordination between the different selective forces.

Ecological Stoichiometry: Overview

RW Sterner, University of Minnesota, St. Paul, MN, USA
JJ Elser, Arizona State University, Tempe, AZ, USA

Introduction

Most ecological analyses have been constructed from single-currency descriptions, ones based on single dimensions such as biomass, carbon, nitrogen, or energy. For example, the carbon budget of a forest or a lake would include the inputs and outputs and relevant interchanges of C within the ecosystem. This means of analysis has enabled a great deal of progress. However, a multivariate approach that looks simultaneously at multiple dimensions can provide additional insight and predictive power. For example, both carbon and nitrogen can be studied at once and such a description would have to include knowledge of the C:N ratio of different ecosystem components. These multivariate approaches considering multiple currencies are useful because each individual currency interacts with others. Sometimes these interactions are simple, sometimes they are complex. Some pairs of measures are tightly linked in certain locations. For example, the Ca:P ratio in different fish species is almost exactly equal to 2.3, which is the same ratio as Ca:P in bone. Linkages such as these result from the fact that energy and multiple substances do not flow independently through ecosystems. In other cases, element ratios can exhibit a great deal of flexibility with and across species. Understanding these linkages is the goal of ecological stoichiometry.

`Ecological stoichiometry' is a relatively new term, but stoichiometric approaches were used in some of ecology's classic studies. Considerations of limiting factors, as in Liebig's law of the minimum, are inherently stoichiometric. Resource ratio approaches to competition explicitly include ratios of nutrient supply and nutrient content of competitors, making these models stoichiometric. The classical view of the oceans as having N and P in balance with biotic demand, as first articulated by A. C. Redfield in the middle of the twentieth century, is a stoichiometric view. Ecological stoichiometric principles are involved in studies of food quality, nutrition, nutrient recycling, and others, which have long histories of investigation.

To be more explicit, ecological stoichiometry is defined as the study of the balance of energy and multiple chemical elements in ecological interactions. Most will be familiar with the concept of stoichiometry from introductory chemistry classes where it is used to analyze chemical reactions to identify, for example, the reactant that might limit the formation of some specific chemical product in a chemical reaction. In any chemical reaction when reactants combine to form products, mass must balance during these atomic rearrangements. Ecological stoichiometry seeks to apply this same line of reasoning to understand some of the factors regulating ecological processes such as trophic interactions (herbivory, predation, detritivory), competition, energy flow, and biogeochemical cycling. In considering the stoichiometry of a single chemical reaction, knowing the elemental composition of the reactants and products is essential. Similarly, in ecological stoichiometry, one must know the elemental composition of the organisms involved, and their abiotic world.

Consider the familiar example of the enzyme-catalyzed and light-driven reaction of photosynthesis:

$$6CO_2 + 12H_2O \rightarrow C_6H_{12}O_6 + 6H_2O + 6O_2$$

This reaction involving carbon dioxide and water as reactants, and glucose, water, and oxygen as products in actuality is the net outcome of dozens of individual reactions. It summarizes the overall requirements for CO_2 and H_2O needed for the formation of a glucose molecule by this complex, multistep biochemical process. Our concern here is that the fixed chemical structure of glucose firmly establishes the chemical bounds of the system's behavior. If only one carbon dioxide molecule is added to the above, CO_2 will be in excess, and no more glucose molecules can be produced due to limitation by the other reactant, water. Considering the stoichiometry of this reaction calls attention to the powerful ways in which chemistry imposes constraints on biology. All chemical elements on the left side of the reaction must be accounted for on the right, thus explaining a very important outcome of photosynthesis: the production of O_2. Also, the specific chemical formula of the desired product determines what mixture of reactants can be optimally used.

Ecological stoichiometry takes the same approach. However, instead of considering one to perhaps dozens of reaction steps, it summarizes the chemical balance of ecological transactions that are the net outcome not of dozens but perhaps of tens of thousands of reactions that comprise an organism's entire metabolism (its `metabolome'). Despite this leap in reaction number, the law of mass balance for all constituent elements must still be obeyed. Functional organisms cannot be constructed with arbitrary proportions of chemical elements. Thus, stoichiometric constraints impose order on ecological interactions same as they do on individual chemical reactions. Most ecological interactions involve some form of transfer of matter. These fluxes strongly control productivity and community structure both in terms of absolute magnitude (the fertility or richness of the habitat) and in terms of relative abundance (the ratios of limiting resources). Elements such as nitrogen and phosphorus act like limiting reagents in the highly complex set of chemical reactions that take place during organism assimilation, growth, and decay.

Two classical papers in ecological stoichiometry in particular provided groundwork for subsequent studies. The oceanographer A. C. Redfield noted the quantitative similarity in terms of N:P ratios between the mean chemical composition of deep oceanic waters and the chemical composition of active plankton in surface waters. He hypothesized that the similarity was not accidental. This `Redfield ratio' of 16 N:1 P atoms was considered by Redfield to be evidence that the biota exerted a large-scale influence on

the chemical composition of the sea, a new perspective relative to prevailing views that did not assign the biota with a major causative role in global chemical cycling. This stoichiometric process, operating over extremely large spatial and temporal scales, imposes a biotic fingerprint on the chemistry of the abiotic world. The influence of the Redfield ratio on oceanic biogeochemistry is difficult to overestimate but more recent developments have come to place this finding in a broader context.

The terrestrial biogeochemist W. A. Reiners proposed that the study of the chemical signatures of living things (such as their C:N:P ratios) and of their ecological coupling in nature provides a `complementary' perspective on ecosystem dynamics, supplementing understanding derived from the then-dominant single currency bioenergetics perspective. He argued that, at the core of living things, what he called `protoplasmic life', chemical composition was relatively constrained. However, around their protoplasmic core, living things deployed drastically different materials for structural support. These structural materials may have dramatically different elemental composition, for example, C-rich cellulose in plants, Ca-rich shells in mollusks, Si-rich frustules in diatoms, or P-rich bones in vertebrates. The evolution of these major structural adaptations, and the subsequent proliferation of biota bearing them, in turn had major impacts on ecological dynamics and ultimately on large-scale biogeochemical cycling. Reiners's argument highlights the importance of protoplasmic versus structural allocations in determining organismal elemental composition. While indeed this is important, it is also true that even `protoplasmic' life can vary in elemental composition in important ways due to differences in biochemical allocations connected to growth status and life-history strategy (as described below).

Homeostasis and the Constraints of Mass Balance and Chemical Proportions

A key aspect to ecological stoichiometry is the degree of variation of elemental composition of an organism or species. Is elemental composition a fixed trait characteristic of that species, or is it a flexible parameter that largely reflects local resource and environmental conditions? This contrast is captured in a quantitative way in the concept of `stoichiometric homeostasis', the degree to which the elemental composition of an organism maintains a strict chemical composition (like a glucose molecule) despite variation in the chemical composition of resources. Stoichiometric homeostasis can be parametrized in the form of a homeostasis coefficient, H (eta), as:

$$H = m^{-1}$$

where m is the slope of a plot of the elemental composition of the consumer under consideration against the elemental composition of the resource being consumed. Both the x- and y-variables should be log-transformed in this measure. In this approach, if the consumer shows no variation in its elemental composition despite wide variation in its resource supply, then the slope of such a line (m) approaches zero and H approaches infinity (strict homeostasis). On the other hand, if the consumer's elemental composition exactly tracks that of its resource supply, then m takes the value of 1 and H has a value of 1 (no homeostasis, complete plasticity).

Data for real organisms range between these extremes and can depend on the experimental conditions imposed. Strict homeostasis does not appear to be reached in many situations, although strong homeostasis appears to be the rule for many metazoans. For example, in experiments in which the P-content of the algae on which it is raised varies from 1% to 0.05%, the P-content of the crustacean herbivore *Daphnia* varies little (only from 1.5% to 0.9%, corresponding to H of ~ 7, strong but not strict homeostasis). In contrast, the green alga *Scenedesmus*, when grown on inorganic nutrient supplies with N:P ratios ranging from 5 to 80, shows almost a 1:1 correspondence between its biomass N:P ratio and that of its medium. In this case of weak homeostasis, H approaches a value of 1. These examples illustrate a general pattern in which photoautotrophic organisms (cyanobacteria, algae, vascular plants) are generally thought to exhibit great plasticity in elemental composition. In contrast, heterotrophic organisms (including bacteria but especially metazoans) regulate their elemental composition more strictly around particular values. The contrast of these physiological strategies has profound consequences for food web dynamics and energy flow and nutrient cycling in food webs.

The Biology of Elements

Each of the 100+ elements in the periodic table has characteristic chemical and physical features governing properties like the elements it will bond with, how easily it will ionize, etc. These properties arise mostly from the atomic size of each element and the arrangement of electrons within shells surrounding the nucleus. Metals such as Fe or Mo for instance can exist in different oxidation–reduction states, and thus these elements are involved in electron transport in membranes and in other biological locations. Other elements such as C or N are very useful for making highly complex three-dimensional (3-D) shapes. Thirty or more elements are thought to be essential to the growth of at least some organisms. This number and range of reactivities give biological systems a great range of chemical behaviors to choose from in order to organize their activities. The physical and chemical properties of elements have a great bearing on ecological stoichiometry.

As discussed above, differences in organism elemental content between species are very relevant in ecological stoichiometry and ecology in general. Nevertheless, some elements are consistently high in abundance in biological systems while others are consistently rare. For example, the chemical composition for a living human can be written:

$$H_{375000000}O_{132000000}C_{85700000}N_{6430000}Ca_{1500000}P_{1020000}S_{206000}Na_{183000}K_{177000}Cl_{127000}$$
$$Mg_{40000}Si_{38600}Fe_{2680}Zn_{2110}Cu_{76}I_{14}Mn_{13}F_{13}Cr_{7}Se_{4}Mo_{3}Co_{1}$$

This formula combines all the countless different compounds in a human being into a single abstract `molecule'. Ecological stoichiometry asks how far this analogy to a single complex molecule will take us.

Ecological stoichiometric principles should apply to any element, and possibly to some of the less-reactive biochemicals as well. However, stoichiometric analysis has focused most on several elements that make up moderate to large proportions of living biomass and that also may become limiting to organism growth. The four elements considered below relate strongly to ecological dynamics and evolutionary fitness.

Carbon

Carbon (C) is the third or fourth most abundant element in the universe. Though it is not especially abundant on the whole of the Earth, it is a major component element of life. C is a highly mobile element in ecosystems, with common forms in gaseous, liquid, as well as solid phases. C has a valence state of 4 and can form four strong bonds with four other atoms; this allows it to produce virtually limitless arrangements of chains, rings, and other highly complex 3-D shapes. Its importance in biological systems is indicated by the fact that the soft tissue of living organisms is generally 40–55% C by dry mass. This large amount and generally tightly bounded range reflects the constant, ubiquitous, structural role of C throughout living systems.

Most biochemicals fall within a narrow range of C contents. Carbohydrates are similar to many other types of molecules in being almost 50% C. Of all common biological molecules, fats have the highest carbon content, with about 75% of their mass contributed by C. Organic structural matter that may make up large amounts of organism biomass includes the cellulose and lignin of plants and the chitin of arthropod exoskeletons. Even most inorganic structural matter used in living things contains considerable carbon, for example, the calcium carbonate of mollusk shells and the apatite of vertebrate bones both have large amounts of C. An exception is the silicon-containing shells of diatoms; these are nearly carbon free.

Nitrogen

Nitrogen (N) neighbors carbon in the periodic table and has many similarities in terms of biological chemistry. It too is highly abundant in the universe and is similarly abundant as carbon on Earth. It too is a major element of life and is found in all three phases in ecosystems. Its redox reactions include N-fixation, denitrification, and nitrification. With a valence state of 3, it is not quite as capable as C in forming complex 3-D shapes. The soft tissue of living organisms is generally 2–10% N by dry mass. This relatively large value is due to the fact that molecules needed in large quantities in the cell, such as proteins, nucleic acids, and pigments, contain N.

Chief among the important N-contained biomolecules are proteins, which are about 15% N by mass. Proteins themselves can serve a structural role but, as enzymes, they also drive nearly all the biochemical activities of a cell. Nucleic acids also are about 15% N by mass. In the form of DNA, nucleic acids make up the genetic code, though DNA is not a large fraction of cell mass. Even more important to ecological stoichiometry is the more abundant RNA (especially rRNA), which is critically important to cell growth and thus evolutionary fitness. All organisms require abundant proteins and nucleic acids to live and grow. The lowest N-content in living things is generally found in very metabolically inactive creatures.

Phosphorus

Phosphorus (P) has a larger atomic mass than C or N, and it is less abundant in the universe than those two elements. However, it is more abundant on the whole of the Earth than is either C or N. P lacks a significant gaseous phase, imparting very different biogeochemical behaviors to this element compared to C or N. Its abundance in the aqueous phase is strongly controlled by the presence of other elements, most notably oxygen (O) and iron (Fe). Most of the P at Earth's surface is found in the oxidized form of PO_4^{3-} (phosphate). Phosphates can polymerize, and the reaction

$$ATP + H_2O \rightarrow ADP + H_2PO_4^-$$

has a high free energy change but occurs slowly without a catalyst; these characteristics make P a highly suitable element to be involved in transfer of chemical energy around a cell. The soft tissue of living organisms is generally 0.3–2% P by dry mass.

Phosphorus is widespread in biochemistry, being found in relatively high abundance in membranes and being involved in many biochemical reactions throughout a cell. However, P is thought to have two focal roles in whole-organism stoichiometry. First, P alternates with sugars in forming the backbone of nucleic acids. As rRNA, nucleic acid serves a key role in allowing a cell to make proteins. Eukaryotic ribosomes are $\sim$50% rRNA while prokaryotic ribosomes are $\sim$65% rRNA. In this way, we can say that phosphorus is the elemental engine for protein manufacture. Second, P in the form of the mineral apatite is a major component of bone and thus has a major structural role in vertebrates. In small, unicellular heterotrophs such as bacteria and in rapidly growing larvae of insects, generally around 50% and sometimes as much as 90% of total cellular phosphorus may be contained in nucleic acids, especially rRNA. In larger heterotrophs, structural support tissues such as bones take on greater importance in body P-pools and in accounting for differences between species. These interspecific differences can be ancient in evolutionary origin and represent major differences in body plans comparable to taxonomic levels such as family or above.

Iron

Iron is a considerably larger atom than even P. It is as much abundant in the universe as C and N, but it is more abundant than C and N on Earth. It is the first or second most abundant element in the whole of the earth. A majority of the Fe in the Earth's crust is in the form Fe^{2+} (ferrous) but this is quickly oxidized at the oxygen-rich surface to Fe^{3+} (ferric). Though making up 30% of the mass of the whole Earth (a very large fraction), concentrations of Fe in oxic waters can be extremely low due to the low solubility of ferric iron. Low iron concentrations have been shown to limit primary production rates, biomass accumulation, and ecosystem structure in a variety of open-ocean environments, including the equatorial Pacific, the subarctic Pacific, and the Southern Ocean, and even in some coastal areas. Binding of Fe with other molecules is very important to governing its overall solubility. Organically bound Fe may be the dominant chemical form in aqueous solutions.

Iron is chemically versatile. It can coordinate with O, N, or sulfur (S), and it can bind to small molecules. Iron-containing proteins are key features of many energy-transducing biological reactions in processes such as photosynthesis, respiration, and others. Iron serves no major structural role in biological systems. Instead, it is a renewable reaction center. Thus, the soft tissue of living organisms is generally $<1\%$ Fe by dry mass.

Molecules containing Fe include hemoglobin, cytochrome *c*, and ferridoxin.

Contrasting Homeostasis in Plants and Animals

Autotrophs rely on either light or chemical energy to turn CO_2 into organic carbon molecules. Photoautotrophs are photosynthesizing organisms such as algae and higher plants that use light for this process. Heterotrophs, in contrast, obtain their chemical energy from preexisting organic molecules. Examples of heterotrophs include bacteria, which absorb organic substances from their surroundings, and many different animals, which consume and digest other organisms. These two major contrasting nutritional strategies of autotrophy and heterotrophy also contrast in their stoichiometric flexibility. Autotrophs obtain carbon, energy, and nutrients from different, somewhat independent sources, whereas many heterotrophs obtain all of these at once from the same food parcels. This contrasting flexibility in turn has a great bearing on the specifics of how stoichiometry enters into ecology.

Photosynthesis relies on light energy to fix CO_2 into organic molecules such as sugars. From these building blocks many other biochemicals can be made. Carbon:nutrient stoichiometry (C:N or C:P ratios) in individual autotroph species can be quite variable. Biochemicals such as carbohydrates and many lipids, which contain only C, H, and O, are made without incorporation of nutrients such as N or P. An autotroph in the light and with adequate access to CO_2 can make a plentiful supply of these compounds (starches, oils, organic acids, etc.) without investment of other critical resources. It is often observed that autotrophs growing in high-light, low-nutrient environments will possess a great abundance of these molecules, so much so in fact that the C-content of the autotroph will be elevated under those types of conditions. Carbon:nutrient ratios within such plants can be exceedingly high (>1500 C:P, for example). When a slow-growing, nutrient-limited autotroph suddenly is exposed to high nutrient availability, it will take up those nutrients much faster than its growth rate. That is, nutrients are taken up in excess compared to growth requirements and in some extreme cases stored in specialized structures such as vacuoles or in specialized molecules such as polyphosphate. High carbon:nutrient ratios are also characteristic of large autotrophs such as trees, which require substantial investment in wood and ancillary tissues having high C:nutrient ratio. Ecological implications of these stoichiometric responses to light:nutrient ratios are discussed below.

Autotroph nutrient content is related to growth rate (μ, g g^{-1} d^{-1}). A quota (Q) is the mass or molar quantity of nutrients per cell (this discussion assumes a constant cell size). In unicellular autotrophs, the `cell quota' concept relates these two variables. The quota of the element that regulates growth rate will be very tightly related to growth rate by a relationship referred to as the Droop formula:

$$\mu = \mu'(1 - k/Q)$$

where μ' is a theoretical maximum growth, never attained, associated with infinite quota, and k is the minimum quota occurring at zero growth.

Under strongly nutrient limiting conditions where growth rate is low, quota of the limiting nutrient will be low, meaning a low nutrient:C or high C:nutrient ratio (see cellular C:P, **Fig. 1**, top panel). The minimum cell quota (k) is set by the level of nutrient-containing biochemicals necessary for basic metabolism, and nutrient requirements for growth are added to this basal level. A true upper level for nutrient content (less than μ') will be set by some combination of the composition of protoplasm at high growth rate or the ability of an autotroph to store excess quantities of any nutrient not currently needed for growth. In autotrophs, growth involves at least two specific major stoichiometric components, and probably more. The first is N for proteins involved in photosynthesis, especially the enzyme RUBISCO, which can be a major portion of cellular biomass. Metabolism in vascular plants relates more strongly and consistently to N than biomass or C. The second is P for ribosomes, which are needed to manufacture additional proteins.

In addition to these patterns relating content of the limiting nutrient to growth rate, the ratio of nutrient elements in an autotroph varies positively with the ratio of those nutrients in the environment. Soils or water of high N:P ratio will generally support plants or algae with high N:P ratio. This positive relationship derives in part from shifts in species across gradients such as these, with competition favoring species that have similar nutrient ratios as the supply ratio in the environment. It also derives

from intraspecific, physiological shifts associated with differing storage and utilization of the two nutrients similar to those described for quota above. Fig. 1 summarizes these different influences on autotroph nutrient content.

Samplings of whole assemblages of autotroph biomass have been examined in terrestrial, freshwater, and marine ecosystems, and have included microscopic as well as macroscopic species. Terrestrial ecosystems, with their larger, cellulose-rich, and woody plant species have higher and more variable C:P and C:N ratios than aquatic ecosystems. In the aquatic realm, offshore marine environments characteristically have low and less variable C:P and C:N ratios in their suspended matter, which contains a strong signal of autotroph biomass. We saw this relative constancy in the offshore marine realm when we discussed the Redfield ratio above. Redfield described the marine plankton to have a C:N:P ratio of 106:16:1. Today there is continuing interest in the Redfield ratio in the ocean, and it is known that it is not a true constant but rather varies with several factors, including climate. Freshwater ecosystems can be thought of as being intermediate in their stoichiometric patterns of C:N:P between terrestrial ecosystems and offshore marine ecosystems.

Animals and other heterotroph species also vary in their chemical content. Large shifts in C:N or C:P ratios in heterotrophs can follow from storage of large amounts of chemical energy in the form of lipids. Some invertebrates in seasonal environments, for instance, may assimilate and store lipids to the point where they are approximately half of organism mass. When those lipids are subsequently catabolized, dramatic shifts in C:N or C:P result. However, in contrast to the great stoichiometric flexibility often observed in autotrophs, unicellular and multicellular heterotrophs come closer to approaching an idealized, strictly homeostatic, abstract `molecule' of defined chemical composition. Reasons for this contrast between plants and animals are not well understood but might involve lack of specialized storage vacuoles in animal cells and the fact that animals obtain carbon, energy, and nutrients from living or recently living material, which is less chemically variable than the abiotic sources of carbon, energy, and nutrients used by plants.

Metazoan animal species exhibit a wide range of N:P ratios. Small, poorly skeletonized organisms such as tadpole stages of amphibians have N:P of ~ 20 whereas some fish species that are heavily endowed with calcium phosphate apatite mineral both in their internal skeleton and in their scales have N:P of ~ 5. Fish in fact are a highly stoichiometrically variable group. From that

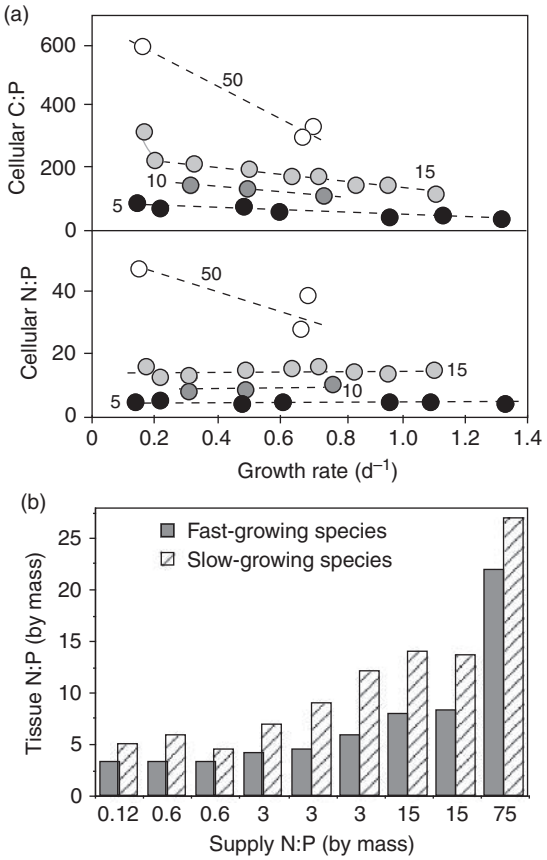

Fig. 1 Autotroph nutrient content as a function of both growth rate and nutrients in the external environment. (a) Experiments with the unicellular alga *Dunaliella tertiolecta*. Symbols refer to different N:P in the growth medium (5–50). (b) Experiments with two species of grasses, one (*Dactylis glomerata*) fast-growing and the other (*Brachypodium pinnatum*) slow-growing. In the upper part of (a), note that cellular C:P declines with increasing growth rate, and is highest at low growth rate and where the environmental N:P is greatest. Similarly, both panels of (a) show that environmental N:P has a positive effect on algal N:P at all growth rates. In panel (b), note again that environmental N:P has a positive influence on tissue N:P. Panel (b) also shows that for any given environmental N:P, the fast-growing species has lower N:P than the slow-growing species.

minimum N:P of about 5, different species of lower structural P content range upward to N:P of 15. Within fish, the Ca:P ratios are highly constrained, indicating that most of the stoichiometric differences in this group result from evolutionary pressures on structure and hardness of the integument.

These inter- and intraspecific patterns of elemental content combine in food webs of many species. Stoichiometric imbalance, where resource and consumer differ radically in their nutrient content, generates interesting ecological dynamics that we will consider next.

Stoichiometry of Limiting Elements

The earliest application of stoichiometric reasoning in ecology probably was that in the work by Justus von Liebig (1803–73), who was concerned with factors influencing crop growth yield. His studies led to what we now call `Liebig's law of the minimum'. One way to phrase Liebig's law is that growth is controlled not by the total of all resources available, but by the one scarcest resource. This is a direct analogy to the concept of a limiting reagent in a chemical reaction producing a stoichiometrically fixed product. `Scarcest' is a relative term and refers to the availability of a resource in the environment relative to biological demand. For example, chemical resources needed in large quantities such as C or N might be `scarce' in this context even if they are at higher concentration than elements such as Fe or Mo needed in much smaller quantities. Liebig's law does not apply to all possible resources. Ones that fit it most precisely are referred to as `nonsubstitutable' resources, ones which organisms cannot trade one for another. Individual elements are largely nonsubstituable with each other whereas many (though not all) organic molecules have substitutable alternatives.

If one knows the stoichiometry of resources and consumers, one can make predictions about which resource will run out and therefore become the `limiting reagent', regulating growth and production. We see this reasoning in such recently studied phenomena as the Southern Ocean, high-nutrient/low-chlorophyll (HNLC) region. This portion of the ocean is notable because of not only a simultaneous occurrence of low algal biomass but also high levels of the nutrient elements N and P. In most marine and freshwaters, one or both of N and P become exhausted and become limiting. However, in the HNLC regions, it is usually Fe that becomes exhausted first. Iron limitation in HNLC regions has been confirmed in small-scale bottle experiments, and in some spectacular, large-scale open-ocean fertilization experiments where Fe was introduced from a ship and the subsequent development and decay of a high algal patch was followed. Fe-limitation has also been described in near-shore oceans and even in lakes.

Liebig's law is most often thought of in terms of plant population dynamics, where individual elements form the set of possible resources. There are, however, also circumstances where Liebig's law has been applied to animal growth. Liebigian dynamics are strongly suggested, for instance, in the section below on stoichiometry and animal growth.

The stoichiometry of limiting factors varies considerably in space and time. Over long timescales associated with soil development during primary succession on a mineral soil, the N:P balance shifts because P is present in the original parent material, but N derives largely from biological processes including N-fixation. Thus, a new mineral soil will contain P but almost no N, and N will be limiting to plants growing on that site. N-fixers are favored. As N in the soil builds up over successive production/decay cycles, N comes into approximate balance with P. Over long timescales, highly weathered soils can have most of their P removed or bound into inaccessible forms, and P can become limiting. Soil development fitting this general pattern has been observed on the Hawaiian islands. Ancient tropical soils are often highly deficient in P, and there is a general pattern of an increased N:P in the foliage of coniferous trees, grasses, herbs, shrubs, and trees as one goes from the poles to the tropics.

When one seeks to apply Liebig's law in any individual case, complications often arise. For example, different species of an assemblage may be limited by different nutrients simultaneously, meaning multiple resources might limit a community. This form of multiple resource limitation is very well studied in theoretical models and has been the foundation of some recent elegant experimental studies as well; theory and experiment together suggest that the number of elements that are simultaneously limiting to different species has a large influence on the biodiversity of a community. Where multiple resources become limiting, biodiversity is higher. In this form of multiple-element limitation, one might potentially see the community as a whole respond to single additions of more than one resource. The largest response is expected where multiple resources are added, because this will stimulate the greatest number of species. In other cases, due to biochemical reasons, availability of one element might aid in the acquisition of another element. For example, the enzyme that allows cells to make use of organically bound P contains Zn; thus, potentially adding or subtracting Zn might be functionally similar to adding or subtracting P. Ecologists today do not have a comprehensive, widely accepted terminology for dealing with cases of multiple-nutrient limitation.

Liebig's law appears today in work referred to as resource competition theory (RCT). RCT provides a predictive, mechanistic framework for studying how community structure relates to resource availability. Good competitors for a resource are defined as those that require relatively small amounts of a resource in order to maintain themselves in a community in the face of mortality losses. Stochiometrically, good competitors often are those that themselves have low nutrient contents or high C:P or C:N ratios. However, both differential resistance to mortality and differing ability to acquire nutrients can also play strong roles in determining competitive ability.

Various tests of this theory have been performed and support for RCT predictions have come from the laboratory and field in experiments involving microorganisms (bacteria, cyanobacteria, algae) and vascular plants and even metazoan animals. For example, resource conditions with high Si:P ratios tend to favor diatoms (which have relatively low P-requirements but require silica), while other algal taxa (which have no Si-requirement) dominate over diatoms when Si:P ratios are low. Coexistence is predicted, and observed, when Si:P ratios are intermediate; in such a situation, the diatoms are limited by Si while its competitor would be limited by P. Similarly, the relative abundance of cyanobacteria (and especially N-fixing cyanobacteria) is often higher

when environmental nutrient supplies occur at low N:P ratios. Recent studies have also shown that the nonlinear resource utilization functions of species allow for multispecies coexistence due to the complex, and perhaps chaotic, dynamics that ensue when multiple resources (light, nutrient elements) can be limiting to multiple species (`coexistence by chaos').

Nutrient limitation by N or P interacts with the carbon cycle in interesting ways. Ecosystems that are strongly nutrient limited are often observed to have primary producers with elevated C:N or C:P ratios. Those nutrient-limited ecosystems can be said to have high nutrient-use efficiency. They make much biomass with each unit of nutrient acquired. As discussed above, in some systems it is the overall availability of light relative to nutrients that controls C:N or C:P ratios. No matter which terminology or thought process is used to study these relationships, the functional outcome is that growth rate and stoichiometry are related in nonhomeostatic organisms such as autotrophs.

Life Histories

Chemical composition is part of an organism's phenotype. It is therefore molded by natural selection and other evolutionary forces like any other aspect of an organism. Thus, the role of the organism in nutrient fluxes in ecosystems is shaped in evolutionary time. As we saw in our discussion of resource competition theory, ecological success or failure, and therefore evolutionary fitness, is tied directly to chemical content. Organism stoichiometry affects fitness. There are also more complex connections between stoichiometry and evolutionary pressures. Because of the distinct stoichiometry of structural matter, evolutionary pressures on body size or major body plans involving structure will have stoichiometric implications. In fact, anywhere organism function has some kind of distinct stoichiometric signature, evolution will be steered by and will in turn alter stoichiometry. Ecological stoichiometry can help us better understand some of the many selective forces on organism function. A good example is in life histories. A life history for a given species is its schedule of vital rates including growth, reproduction, and mortality. Life-history theory typically considers these schedules to be phenotypic traits exposed to selection and shaped by ecological forces. However, these vital schedules, though measurable, do not exist independent of the physical, inorganic world. Because certain vital rates have distinct chemical signature, ecological stoichiometry can illuminate key aspects of life-history evolution.

Growth Rate

The growth rate hypothesis (GRH) links elemental content to biochemistry and in turn links both of those to life history. It concerns the specific growth rate of body mass (μ, g g^{-1} d^{-1}). The GRH comes about because of the almost uniquely low N:P ratio of nucleic acids compared to all other major biochemicals. According to the central dogma of molecular biology, information flows from DNA to proteins by way of several forms of RNA. Protein is a large fraction of cell mass and to achieve high specific growth rates of cell mass, a great deal of ribosomal RNA is needed to manufacture large amounts of protein at high rates. In rapidly growing *Escherichia coli*, RNA makes up approximately 35% of total cell mass, and as much as 90% cellular P is in RNA. Such a large proportion of cell mass in a single biochemical of unusually low N:P generates a distinct stoichiometric signature for the whole organism. Due to this stoichiometric imprint of RNA, the GRH posits positive relationships among three variables: specific biomass growth rate, P-content, and RNA content. Support for the GRH comes from multiple groups of organisms ranging from unicells to small invertebrates such as *Drosophila* and *Daphnia* (Fig. 2).

Applicability of the GRH to larger organisms is still unclear. When organisms are examined over a range of many orders of magnitude in body size, RNA content is observed to decline greatly with body size, as does growth rate. Whole-organism P content, however, does not decline as strongly with body size in such a range. Hence, in considering a range of organisms from microbes to large multicellular animals, there must be a shift in P-containing pools along body-size gradients from RNA to other substances. As we will see in more detail below, in vertebrates bone replaces RNA as a major P-reservoir.

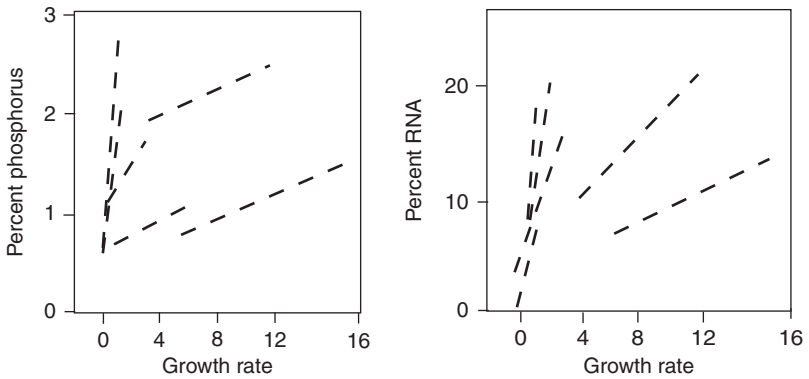

Fig. 2 Positive relationships among specific biomass growth rate (μ, d^{-1}) and both P-content and RNA content. Each dotted line represents a different species. Though species differ from one another, these variables are often linked in a way consistent with the GRH.

There is evidence too that the GRH applies to autotrophs as well as heterotrophs. In a study with the unicellular alga *Selenastrum*, high growth rate was associated with a shift in the boundaries between N- and P-limitation; the N:P of the boundary was lower at high growth rate. This is consistent with a need for larger quantities of low N:P RNA at high growth rate. Similarly, a model of unicellular algal growth was analyzed where cellular investment in two broad classes of biochemical machinery was examined: (1) assembly machinery, for example, ribosomes with low N:P ratios, and (2) resource-acquisition machinery, which is made up mainly of protein containing N but little or no P. Shifts in optimal N:P ratios in the model were associated with growth rate. Low N:P was favored at high growth, whereas high N:P was favored under low growth and strong resource scarcity. These studies of microscopic autotrophs are consistent with the GRH. In one study looking at foliar N and P in more than 100 vascular plants, N:P was lower in species that have higher growth rate. **Fig. 1b** showed one such contrast.

The GRH thus proposes a material basis to a key life-history parameter: growth rate. All else being equal, specific biomass growth rate will be closely coupled to such life-history parameters as age and size at first reproduction, and therefore is directly tied to fitness itself. Because it is especially P among all the elements that is disproportionately required for high growth, we can further hypothesize that high-growth phenotypes might be particularly sensitive to the presence or absence of phosphorus from the environment. A fascinating biomedical example of the GRH in action is in cancerous tumors, which in many cases are high in RNA. P-content of tumors has not often been studied, but evidence for high P-content in tumors has been seen.

Growth–Competition Tradeoffs

The GRH provides an explanation for why an organism might be selected to have high P content. Why then don't all organisms have high P content? As elsewhere in evolutionary biology, the answer lies in understanding key tradeoffs. What disadvantage might there be to having a high-growth, high-P lifestyle? Ecologists have long recognized a general syndrome of life-history characteristics, those that promote rapid-growth, colonist-type, life histories from those that promote success in the face of extreme competition due to presence of many competitors. The former are referred to as *r*-selected species and the latter are referred to as *K*-selected species. Stoichiometry has its own version of $r - K$ selection theory.

We have already seen that high-growth (*r*-selected) life histories require high P. However, it is equally the case that species of low nutrient content will outcompete species of high nutrient content during exploitative competition for resources. Stoichiometry predicts that this tradeoff will be particularly evidenced under conditions of P-limitation, because of the close tie between P and high growth rate. High-growth-rate species are anticipated to be poor competitors. According to stoichiometric theory, this tradeoff results from the material basis of a high-growth-rate lifestyle.

Nutrient Cycling, Flux, and Dynamics

The rate of cycling of potentially limiting elements is a critical feature of ecosystems, determining important aspects of their structure and function. This cycling includes movement of elements between abiotic and biotic pools as well as among living species. Autotrophs take up resources from their environment, and they may also leak some nutrients back into the surrounding soil or water media; they also produce litter which is broken down, and decays and releases nutrients into abiotic pools. Heterotrophic consumers participate in nutrient cycling when they ingest food and release wastes back to the abiotic pool. If we understand the controls on the rate that nutrients are made available or reavailable for living organisms to take up, we will have a powerful tool to understand and predict many features of ecosystems. Stoichiometric approaches to nutrient cycling are based on the conservation of matter and consider patterns among multiple elements.

Under strict homeostasis, we consider individual species to have fixed stoichiometric coefficients in their chemical makeup. Thus, the chemical flexibility needed to balance a reaction where resources are reactants and organism biomass is a product comes from the composition of waste products, another product in the reaction:

$$\text{Resources} \rightarrow \text{Organism biomass} + \text{Wastes}$$

If we know both the chemical content of organisms and the chemical content of their resources, we can use the conservation of matter to calculate the chemical composition of wastes. Note that variation in the chemical content of either resources or organism biomass can influence the chemical content of wastes.

One aspect of stoichiometry is merely the use of a set of tools for balancing chemical reactions involved in nutrient cycling and maintaining appropriate relationships among all the elements. However, stoichiometric homeostasis also has a characteristic and somewhat peculiar effect on nutrient cycling. A homeostatic consumer alters the fraction of ingested nutrients that are retained for growth in response to the chemical content of the food. A homeostatic consumer must generally retain most stringently the scarcest element. For example, when ingesting food of relatively low P-content, a homeostatic consumer must retain P with elevated efficiency. In other words, it must retain that substance which already is in scarce supply in the ecosystem while it resupplies the nonlimiting elements back to abiotic pools (**Fig. 3**). Nutrients that are found in relative excess tend to be recycled back to the environment while nutrients that are scarce in the food relative to a consumer's requirements are retained for growth. Thus, when put into the context of whole ecosystems, interesting dynamics result from homeostatic consumers.

These processes have been measured in many different situations. **Fig. 4** shows the effect of chemical variation of both resources and consumers in one set of aquatic organisms. Because natural ecosystems are composed of numerous species all with their own

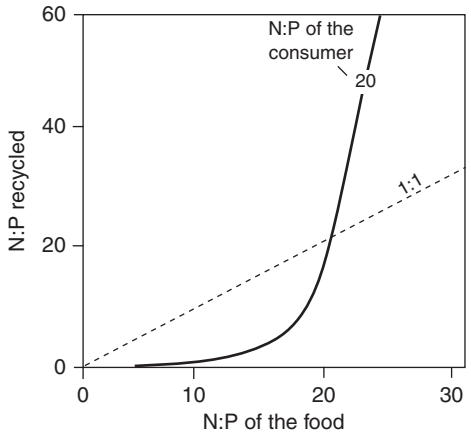

Fig. 3 The ratio of nutrient elements recycling by a feeding homeostatic consumer as a function of the ratios of elements in its food. At low N:P in the food, the homeostatic consumer retains N with high efficiency, recycling excess P, and hence the N:P recycled is very low. In contrast, at high N:P in the food, the homeostatic consumer retains P with high efficiency, releases relatively more N, and thus the N:P recycled is very high. Homeostasis in the consumer causes this relationship to curve and the greater the ability of the consumer to retain the element limiting its own growth, the tighter the bend in the function.

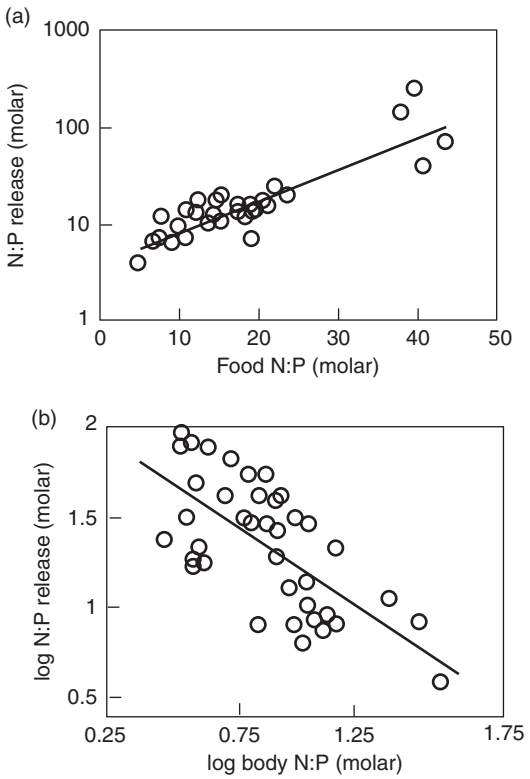

Fig. 4 Two aspects of stoichiometric determination of nutrient cycling, the nutrient content of the resources (a) and the nutrient content of the consumers (b). Both examples consider homeostatic animal consumers feeding upon chemically variable resources. In (a), the N:P ratio of nutrients released by freshwater zooplankton is positively related to the N:P ratio of the food they eat. This example shows that when consuming foods relatively high in either N or P, homeostatic consumers dispose of the excess nutrient and retain the nutrient most limiting to their own needs. Note the log scale of the *y*-axis, meaning a curvilinear function on linear axes. In (b), the stoichiometric variability of different aquatic vertebrate consumers generates a negative relationship between the N:P ratios of nutrients released and the N:P ratio of the consumers themselves. This example shows that consumers with bodies containing either relatively high N or P must retain that element high in their biomass and further that they will dispose of the element relatively scarce in their own biomass.

characteristic stoichiometry, natural food webs consist of many different resource–consumer pairs. Some of these will be stoichiometrically similar while others may be stoichiometrically dissimilar.

We also see a strong stoichiometric control on nutrient recycling in terrestrial systems. Leaves exhibit a wide range in C:N:P ratios, which is largely a function of the species or functional group of the plant, but as we have already seen it also depends on growth conditions and other factors. When leaves die, there is a corresponding wide range in nutrient content of the detritus they form. Due to nutrient resorption prior to leaf abscission, detritus often has a very low N- and P-content, a factor which emphasizes the stoichiometric dissimilarity between resources (detritus) and living consumers (microbial decomposers and detritivorous animals). Ecological stoichiometry is most easily revealed in systems where there is great chemical variability, like in this consideration of detritus and detritivore. Fig. 5 shows how strongly the nutrient content of detritus corresponds to the rate that detritus breaks down, at least at this large, cross-ecosystem scale.

This range in mineralization rate results from the stoichiometric match between the chemical composition of the litter and the needs of the organisms feeding on that litter (microorganisms, detritivores), so it combines stoichiometric food-quality effects, such as will be described below, with stoichiometric nutrient cycling rates. The highly biodiverse soil food web can grow and metabolize more rapidly when supported by high-nutrient litter instead of low-nutrient litter.

Another example of stoichiometric recycling effects involving plants, soils, and decomposers involves Ca-content. In a long-term (30-year) study where 14 different tree species were raised in monoculture, it was found that soil properties came to strongly depend on the Ca-content of the leaves of the tree species growing on that plot. Soil under tree species with high-Ca leaves, roots, and litter (e.g., maples, basswoods) was higher in pH, higher in C, lower in C:N, and higher in exchangeable Ca than was soil under tree species low in Ca (e.g., oaks, pines). Earthworm biomass also was higher under high-Ca tree species. The chemical parameter Ca was better related statistically to these and other similar relationships than was identity of the tree species themselves or the identity of functional groups like angiosperms versus gymnosperms, suggesting that it was indeed the stoichiometry of Ca in the litter that was the key factor involved.

Alteration of Community Composition and Ecosystem Dynamics through the Stoichiometry of Recycling

When we place these specific stoichiometric recycling effects into the context of complete, complex ecosystems, a variety of interesting dynamics result. For example, as we just saw, terrestrial plant species that produce low-nutrient litter will have a depressive effect on mineralization rates in their vicinity. A low mineralization rate will reduce primary productivity, lower plant biomass, and raise light:nutrient ratios. These conditions in turn will favor particular plant species that are good nutrient competitors. Because one factor that can improve a species' competitive ability for a given nutrient is a low content of that nutrient in its leaves, a cycle of positive feedback is favored: with good nutrient competitors altering nutrient cycling in their vicinity in such a way as to improve their chances of success against other species.

Shifts among consumer species differing in stoichiometry can also have ecosystem-level consequences. In freshwater plankton food chains, large-body-size, high-growth-rate *Daphnia* are favored under particular regimes of fish predation, for example, when there are many piscivores that deplete the planktivorous fish populations, releasing *Daphnia* from fish predation. Because *Daphnia* have a characteristic high-P stoichiometric signature, changes in fish predation regime can realign pelagic nutrient pools and fluxes. It has been observed that phytoplankton in the presence of abundant *Daphnia* grazers will be relatively more P- than N-limited and N-fixation will be reduced. These examples illustrate the close connections between community structure and ecosystem nutrient fluxes that are easily understood by consideration of stoichiometric principles.

Animal Growth: Stoichiometry and Food Quality

Ecological theory often incorporates the effects of food supply on consumer growth and reproduction by a hyperbolic functional response between animal growth and reproductive rates and the density of food. This is referred to as a `numerical response'. In

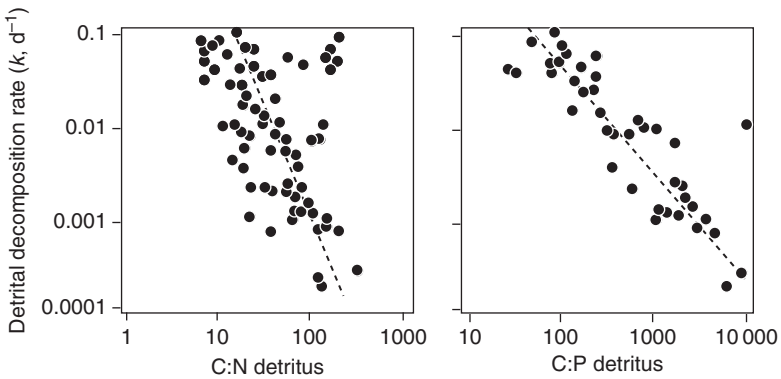

Fig. 5 The rate of breakdown of terrestrial detritus depends strongly on stoichiometry. The higher the C:N or C:P ratio, the slower the leaf litter breaks down (lower rate coefficient, *k*). As a consequence, the rate that nutrients are recycling back into the soil also depends on stoichiometry, with higher mineralization rates for detritus with low C:N or C:P.

addition, in the growth of an individual, a minimal quantity of food, alternatively known as the `threshold food concentration' or the `subsistence food level', is defined as that needed to offset respiratory losses. At the population level, a higher threshold is needed for growth to be sufficient to offset various sources of mortality. These effects of food quantity have been studied for a long time; however, incorporating the effects of the quality of food on consumer performance and dynamics has been much more difficult yet is done where ecological stoichiometry becomes very relevant.

While there are many known aspects of food quality (digestibility, palatability, toxicity, content of nutritive biochemicals such as essential amino acids and fatty acids), ecological stoichiometry measures food quality as the content of potentially important nutrient elements, especially N and P. This measure is in keeping with the extensive literature on the importance of N in affecting consumers in terrestrial and marine environments. It is also consistent with the increasing knowledge of the role of dietary P in freshwaters and perhaps in terrestrial ecosystems as well. In general, the quality of a food item is inversely related to its C:nutrient ratio, where the nutrient can be N or P. This effect can be understood to be an outcome of the fact that the nutrient element is increasingly diluted in the dominant C-biomass, making it difficult for the animal to extract sufficient limiting element from the food.

Stoichiometric theory gauges the onset of such limiting effects via calculation of the threshold elemental ratio (TER). The TER is defined as the food C:nutrient ratio above which the animal's growth becomes limited by nutrient X rather than C (carbon), where X might be N, P, or another element. In the simplest models, the TER is based on only three traits of the consumer: its own C:X ratio and its maximal gross growth efficiencies for C (E_C) and the nutrient (E_X). Gross growth efficiency is defined as the rate at which mass accumulates in production (or new growth) divided by the rate at which mass is ingested by the consumer. The maximum gross growth efficiency for an element is assumed to occur when that element is limiting growth. Assuming strict stoichiometric homeostasis of the consumer, the TER is calculated as

$$\mathrm{TER}_{\mathrm{C:X}} = (E_C/E_X)\mathrm{C} : \mathrm{X}_{\mathrm{consumer}}$$

Noting again that the TER is the C:X ratio in the food above which the consumer's growth should become limited by element X, a consumer with low TER is more likely to be limited by element X than a consumer with a high TER. Thus, an animal becomes less likely to be limited by nutrient X (its TER increases) as the consumer's C:X ratio increases (its nutrient content declines), as its ability to sequester element X increases (E_X increases), or as its carbon-assimilation efficiency decreases (E_C decreases).

The dependence of the TER on net C-growth efficiency implicitly means that the TER increases as food concentration decreases. This is because under such strong food-limited conditions, the respiratory demands of maintenance metabolism dominate the energy or C-balance, and C-growth efficiency is reduced. Thus, TER theory predicts that stoichiometric food quality should be of greatest importance under conditions of high food abundance. **Fig. 6** illustrates this in a general case, in which the line labeled `A' is the minimum TER for the consumer in question, asymptotically achieved at maximum $E_C$ at infinitely high food quantity. The line labeled `B' is the minimum amount of food that the consumer needs in order to maintain a constant body mass.

The effects of stoichiometric food quality have been extensively tested in the laboratory and the field, especially for freshwater zooplankton under conditions of potential P-limitation. For example, *Daphnia* growth commonly declines when food C:P ratio is above ~250. P-assimilation efficiency increases to high values as the TER is approached. Lab experiments involving short-term manipulation of food P-content or direct P-supply to the *Daphnia* have confirmed that this growth decline is at least partially due to a direct P-limitation of the animal. Furthermore, field studies have shown that *Daphnia* abundance is low under lake conditions in which seston C:P ratios are above 250. Further, short-term amendment of seston P-content increases *Daphnia* growth when seston C:P is above the TER, showing that the predictions of stoichiometric theory are confirmed not only in the lab but also under natural conditions. Also consistent with TER theory, animals with low body P-content, such as the crustacean *Bosmina*, appear to be relatively insensitive to food P-content, both in the lab and in lakes. Recent studies outside of the plankton have also provided

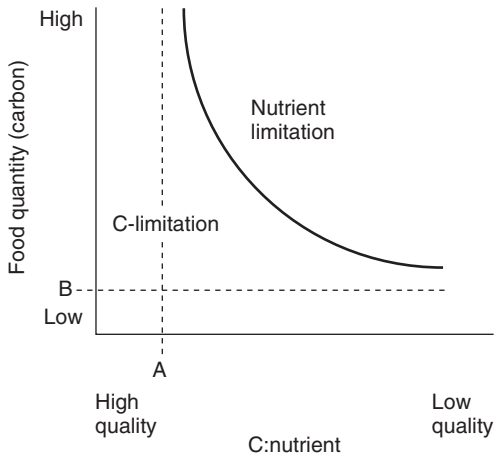

Fig. 6 Boundaries for limitation by food quantity (energy) vs. food quality (stoichiometry) for a homeostatic consumer as a function of food quantity. At high food abundance and high food C:nutrient ratios (low food quality), the consumer should be limited by the nutrients in its food. At low food abundance or low food C:nutrient, the consumer should be limited by total food quantity, or total energy content.

evidence of dietary P-limitation in benthic (stream insects, snails) and terrestrial animals (caterpillars, weevils), adding to previous evidence of dietary N-limitation from diverse habitats.

In sum, these studies show that stoichiometry is an important axis of food quality affecting basal consumers in diverse food webs. Relatively simple physiological processes and species traits can be used to predict their operation and impact.

Complex System Dynamics Driven by Stoichiometry

Theoretical ecology uses mathematical tools to place the nature of interactions into a formal, analytical framework. A goal is to understand features governing population dynamics and species diversity. Special emphasis has been placed on ecological competition and predator–prey dynamics. These studies often focus on the presence or absence of equilibrium points in model solutions, which indicate the possibility of species coexisting with each other over the long term. Moreover, a fundamental difference between stable equilibrium points and unstable equilibrium points is recognized. In the former, dynamics tend to restore the system to its equilibrium point after a small perturbation, whereas in the latter, like a ball rolling off the peak of a hill, small displacements from equilibrium can result in large changes and even be catastrophic to coexistence.

Herbivore Extinction Due to Poor Food Quality

Stoichiometrically implicit predator–prey and especially plant–herbivore interactions have been built and analyzed, providing some clues as to the role of stoichiometry in system dynamics and species diversity. In these models, consumers respond to food quality determined by element ratios, and nutrients are recycled according to stoichiometry and strict homeostasis. Recycling provides a feedback between a herbivore and its algal or plant prey. The herbivore's growth and nutrient release rates decline as the prey's C:nutrient ratio increases above its TER. These analyses involve development of versions of the classic Lotka–Volterra predator–prey models in which the homeostatic regulation of nutrient content varies between predator and prey. When the prey is modeled as a photoautotroph, its nutrient content will be variable and the predatory herbivore will have fixed nutrient.

The effects of introducing stoichiometric constraints to such models of trophic interaction are dramatic (Fig. 7). In classical Lotka–Volterra-type models, the predator can always grow whenever prey abundance is above some finite level. This is seen as a vertical, linear nullcline for the predator; the predator's nullcline is the set of points where the predator's net growth rate is zero. There is thus only one possible equilibrium point of plant and herbivore density for the system. However, in a stoichiometric version of these equations, both prey and predator nullclines are hump shaped. The prey's nullcline intersects the *x*- (prey-) axis due to nutrient limitation. The intersection point is determined by the maximal C:nutrient ratio the prey achieves under nutrient limitation. Stoichiometric models are unusual in that the predator's nullcline also is hump shaped, in this case due to the negative effects of poor food quality when the plant achieves high biomass on a fixed and limited amount of nutrient in the system. At high plant biomass, plants have high C:nutrient ratio, and further additions of biomass (C) can have a depressive effect on herbivore dynamics, a paradoxical result. The herbivore population is inhibited by the addition of bulk food. In fact, the herbivore can shift between positive growth and negative growth by the addition of plant biomass to the system! This counterintuitive aspect of the model has been termed the `paradox of energy enrichment'.

Stoichiometry alters nullclines so that both are nonlinear, meaning they can intersect each other at more than one point. Depending on the parameters used, there is potential for multiple equilibria, limit cycles, and potentially chaotic dynamics when one includes

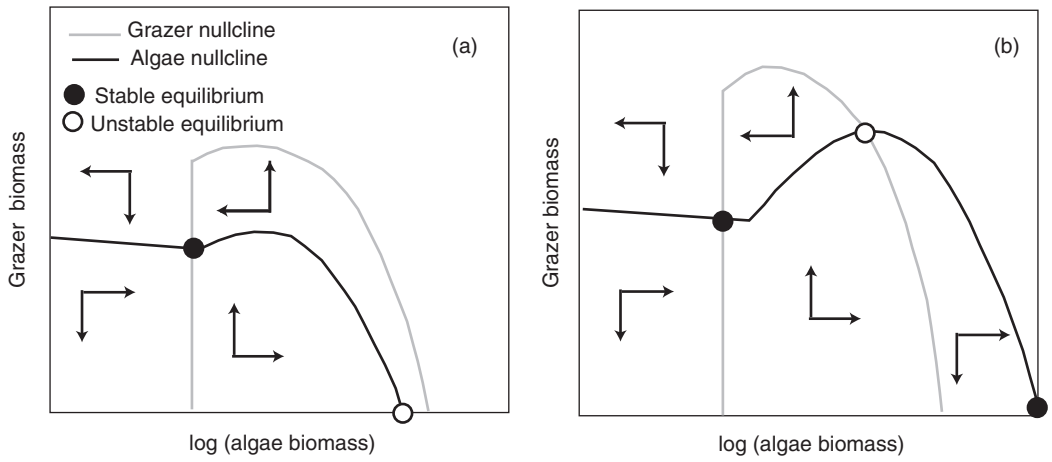

Fig. 7 Predator (grazer) and prey (algae) nullclines in a theoretical model. Panels (a) and (b) use different parameters for the same model. Stoichiometry makes the grazer nullcline hump shaped, which alters predicted dynamics and makes it possible even for a stable equilibrium point at zero grazer biomass.

stoichiometry in such a system. A particularly interesting equilibrium is illustrated in Fig. 7b, in which conditions are such that the prey nullcline intersects the prey axis at a high value, beyond the upper intersection of the predator's nullcline. In this situation, a stable equilibrium exists at the prey's intersection on the *x*-axis, a point where the grazer is extinct and cannot invade from low population levels. This is a grazer extinction point occurring in a `world' of very high food (plant) biomass! In ecophysiological terms, this situation is more likely to occur for grazers with high body nutrient content and for environmental conditions in which autotrophs develop very high biomass C:nutrient ratios. As described earlier, the latter occurs when nutrients are severely limiting and when light intensities and perhaps pCO_2 levels are high. Indeed, the theory predicts that local deterministic extinction of a herbivore can occur with increased light intensity or with any ecological change that induces high C:nutrient ratio in plant biomass.

A similar model has been built and analyzed where the prey is made to be stoichiometrically variable, but the predators are held to be homeostatic. An analogous situation to this would be the case of bacteria (homeostatic) being fed upon by Protozoa (stoichiometrically variable). When we change the point of strict homeostasis from the predator to the prey, the complex dynamics discussed for Fig. 7 disappear. It is both the presence of strict homeostasis and its location within a food web that influences system dynamics.

Increased Primary Production Can Reduce Food Chain Production

The idea that increased food abundance might have negative effects on consumers is a surprising stoichiometric prediction. Numerous lab and field studies have tested predictions of stoichiometric theory for trophic interactions with a special emphasis on examining how light and nutrients can jointly regulate herbivore production. For example, a laboratory study involving *Daphnia* and a green alga showed that growth of *Daphnia* was maximal at intermediate light. At low light, algal biomass was limiting to *Daphnia* growth. At very high light intensities, algal P-content was limiting (Fig. 8). Consistent with stoichiometric theory, the light intensity supporting maximal growth moved to higher light intensities as nutrient content in the system increased. In a longer-term study also involving *Daphnia* and a green alga (Fig. 9), increased light intensity was shown to inhibit *Daphnia* population growth and trophic efficiency but eventually nutrient recycling by the *Daphnia* was able to increase algal nutrient content so that high grazer densities eventually were achieved. In a result that supports the idea that increased light intensity can result in grazer extinction, in this study one replicate vessel received especially high light intensity, which resulted in unusually high algal C:P ratio and a *Daphnia* population that was never able to increase in abundance and was undergoing significant decline at the end of the experimental period.

Several studies involving field mesocosms have also shown that manipulation of light-nutrient balance has a strong effect on secondary production in nutrient-limited ecosystems. For example, a field experiment in a P-limited Canadian lake reduced light intensity to mescosms by more than tenfold. After 30 days, seston C:P ratio had decreased significantly and zooplankton production was increased nearly fivefold. Thus, there is strong evidence that secondary production in food webs is strongly influenced not only by overall rates of ecosystem productivity (`food quantity') but also by the quality of that production as indexed by its nutrient content.

Large-Scale Stoichiometry

Ecological stoichiometry also offers insights into factors regulating the multiple pathways by which energy and multiple chemical elements move or are stored at the scale of ecosystems and above. For example, whole-ecosystem manipulations of food web structure have shown how ecosystem nutrient levels and stoichiometric constraints influence the operation of cascading trophic

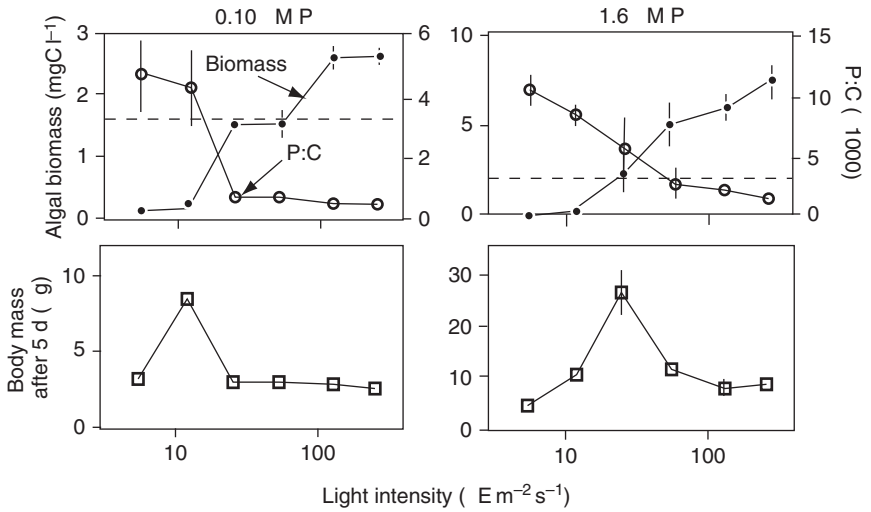

Fig. 8 Algae and grazers in light gradients. As light increases, algal biomass increases and algal P:C decreases, worsening food quality for grazers. Maximal grazer growth (highest mass) occurs at intermediate light levels.

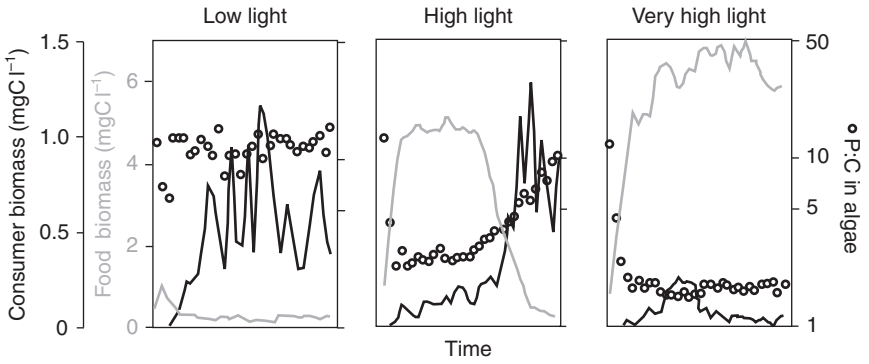

Fig. 9 Algal (food) and grazer (consumer) dynamics over time (>90 days) at three light levels. At low light, algal biomass remained low, P:C in algae was high, and grazers were variable but often abundant. At high light, algal abundance was initially high and P:C was low, but eventually the grazer became abundant and the system resembled the low-light condition. Finally, at very high light, algal abundance remained high, P:C remained low, and grazer abundance remained low.

interactions in which alterations in top trophic levels impinge on ecosystem productivity and nutrient cycling. In an experimentally fertilized, P-rich lake, introduction of a fourth trophic level (piscivorous northern pike, *Esox lucius*) led to strong reductions in planktivorous minnows and thus a major increase in zooplankton biomass and especially *Daphnia*. Consistent with stoichiometric nutrient recycling theory, increased *Daphnia* abundance was associated with increased N:P ratios in nutrient pools and a major reduction in the previously dominant N-fixing cyanobacteria. In a parallel experiment in which pike were introduced to a similar minnow-dominated but unfertilized lake, reduced minnow abundances did not result in increased *Daphnia* abundance. Instead, *Daphnia* abundances declined in parallel with changes in an unmanipulated control lake. Both *Daphnia* declines were associated with major increases in seston C:P ratios, suggesting that the *Daphnia* success in these lakes was strongly controlled by `bottom-up' food-quality constraints and relatively unaffected by `top-down' effects of food web interactions. These observations are consistent with an emerging view that strong trophic cascades may be confined to ecosystems having nutrient-rich autotrophic production at their base, as ecosystems with poor quality, nutrient-limited autotroph biomass may be unable to support high biomasses of herbivores capable of exerting significant grazing pressure.

Comparative studies across multiple ecosystems have suggested that stoichiometric constraints play an important role in regulating the fate of organic matter and the cycling of nutrients at the ecosystem scale. As mentioned earlier (**Fig. 5**), when considered across multiple studies in diverse terrestrial ecosystems, the rate constant of detrital breakdown correlates negatively with detritus C:nutrient ratio, although considerable variation can exist within particular studies. That is, nutrient-rich detritus (low C:nutrient ratio) breaks down rapidly, returning nutrients to available pools for reuptake by plants, while low-nutrient detritus (high C:nutrient ratio) breaks down slowly and may enhance immobilization of soil nutrients by microbiota, slowing the reuse by plants. Other large-scale patterns in the fate of C in ecosystems appear to be tied to autotroph nutrient content. When data for numerous ecosystems across diverse habitats (oceanic, limnetic, terrestrial) were compiled, strong positive correlations are seen between the percentage of primary production consumed by herbivores and plant nutrient content and turnover rate: ecosystems with fast-growing, nutrient–rich plant production support significant populations for herbivores which consume important quantities of that production. In contrast, in ecosystems with slow-growing, low-nutrient plant biomass, significant quantities of primary production escape consumption in the grazing food chain and enter detrital pathways and long-term C storage. Likewise, the release or retention of nitrogen or organic C appears to be a function of stoichiometric balance in watersheds. Several studies have shown that stream NO_3 concentrations or export rates are negatively correlated with average watershed soil C:N ratios, consistent with stoichiometric theory. Conversely, other studies have shown that concentrations or export rates of dissolved organic C from watersheds are positively correlated with watershed soil C:N ratios. Thus, ecophysiological limitations on the processing of organic C and nutrients by soil microorganisms ramify to affect the fluxes of materials at watershed and regional scales.

Stoichiometric constraints also play a role in the regulation of biosphere-scale processes governing oceanic and terrestrial C-cycling, atmospheric CO_2 concentrations, and thus global climate. In the open ocean, biogeochemical processes appear to be closely linked to multiple limitations associated with light intensity (as mediated by water column mixing processes), macronutrients (N, P), and micronutrients (especially iron). In the enormous central Pacific gyre, long-term studies have shown climatic variations associated with El Niño that reduce the intensity of vertical mixing processes and cross-thermocline nutrient transfers that enhance the success of light-limited, N-fixing cyanobacteria. Dominance of these algae, in turn, increases the C:P ratio of primary production and thus increases net carbon sequestration in deep waters. In other parts of the ocean, low iron supplies rather than light may limit primary production and N-fixation and thus stoichiometric coupling of C- and macronutrient cycles can ultimately depend on iron supply, itself regulated by long-term processes associated with delivery of continental dust. Since the production of continental dust is itself closely regulated by climatic conditions (rainfall patterns), a set of complex feedbacks that plays out over tens of thousands of years is established.

These feedbacks have been incorporated into global biogeochemical models that investigate the autoregulatory capability of the biosphere (`Gaia'). In these studies, it has been shown that a self-regulating system at the scale of the biosphere emerges if the organisms driving the Earth's biogeochemical systems operate under functional constraints on their processing of energy and matter. In other words, no higher-level selection at the scale of the biosphere (`Gaia' as organism) is required for planetary self-regulation to operate. Instead, `Gaia' is a complex interactive system with dynamics determined as an emergent property of selection operating primarily on the ecophysiological traits and constraints of individual organisms.

Introduction

This article contains an overview of the scientific discipline broadly defined as ecophysiology. Included is a definition of physiological ecology, a discussion of the relationship of this discipline to the fields of functional morphology and biomechanics, and a commentary regarding the use of the comparative method as a central aspect of the discipline.

What Is Ecophysiology?

Because the external environment is intrinsically variable, living organisms must maintain a separate and distinct internal environment. Physiology is, at its core, the study of the mechanisms organisms use to maintain the internal environment. The maintenance of a constant internal environment is termed homeostasis, and it is achieved through behavioral changes and internal regulation at the system, organ, cellular, and molecular level. The concept of homeostasis was first recognized by Claude Bernard (1813–78), who worked primarily in the field of human physiology. Humans demonstrate exceptionally stable internal environments, in contrast to many other animals and plants, where some aspects of the internal environment are maintained, while others are allowed to vary with changing conditions. When a given parameter of the internal environment is maintained at a constant level, or within a relatively small range, it is said to be regulated; an example of this is the internal body temperature of most mammals. However, other aspects of the internal environment may be allowed to vary with changes in the external environment, and are said to be conforming, such as the water content in certain intertidal algae. It is likely that organisms reach an evolutionary `compromise' between the potential physiological stress incurred by allowing a given parameter to vary with changes in the environment and the metabolic expense incurred by regulation.

Ecophysiology, or ecological physiology, is an area of research where physiological parameters are used to quantify the interaction between the external environment (i.e., ecology) and internal environment of the organism (Fig. 1). As such, this field is not really different from physiological ecology although some may choose one term over the other to reflect a relatively greater emphasis on ecological or physiological processes as part of their research program. One of the earliest areas of research within the ecophysiological realm was the field of `energetics', which was pioneered by H. T. Odum (1924–2002) and examines the energy flux between organisms and the environment. Energetics remains an important area of research, and the field of modern energetics includes studies of the energy required to perform a certain task (e.g., cost of transport) as well as of energy budgets – how energy is acquired and used by the organism (over various timescales) in performing all the tasks important to its survival, such as foraging, reproducing, growing, etc. Other current areas of research in ecophysiology include (but are not limited to): (1) energy acquisition in systems without light for primary production – how carbon is fixed to form the basis of food webs (e.g., hydrothermal vents); (2) modifications to the oxygen transport system – how animals respond to life in oxygen limited (e.g., elevation) or anaerobic environments (e.g., tidal marshes); (3) physiological responses to short-term, unpredictable, environmental stressors – how organisms respond to temporary, but life-threatening, changes in their environments, such a sudden, dramatic increase in ambient temperature (e.g., heat shock proteins). It is important to note that these research areas span a large range of biological organization: from whole-organism, or behavioral, responses to molecular responses. In addition, ecophysiologists often focus on environments that pose myriad and extreme physiological challenges to organisms that inhabit them. Two examples of environments of this type that have been well studied by ecophysiologists are the desert and the marine intertidal.

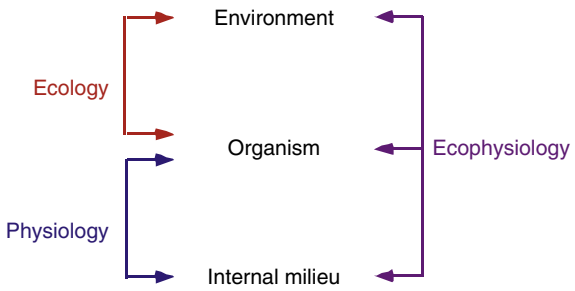

Fig. 1 Schematic diagram indicating the relative roles of ecology and physiology in creating the field of ecophysiology.

 doi:10.1016/B978-0-444-63768-0.00531-X

Example 1: The Desert

Organisms that live in the desert must maintain the internal environment in the face of high temperatures, large daily temperature fluctuations, and a perpetual scarcity of water. Whole-organism, or behavioral, responses are often used to mitigate these temperature extremes. Because muscles operate more effectively when they are warmer, behavioral thermoregulation is often employed to warm muscles after a cool desert night. By sunning on a warm rock, desert reptiles (ectotherms that produce little metabolic heat) warm themselves in the early morning and quickly reach a temperature that facilitates locomotion and feeding behaviors. However, mid-day temperatures frequently reach levels that present a thermal challenge. At high temperatures, animals encounter problems of evaporative water loss, which affects osmotic balance (maintenance of blood and intracellular volume), ionic balance (maintenance of chemical gradients), and acid–base balance (maintenance of internal pH) of the organism. At still higher temperatures, protein damage, including the deterioration of metabolic enzymes, occurs. Therefore, desert reptiles typically retreat to underground burrows or other shaded locations to avoid the heat of the day and are only active near dawn or dusk (crepuscular). Some mammals have taken this behavior to an extreme, and are active only during the cooler temperatures of the night (nocturnal). Here, mammals have an advantage because they are endothermic (i.e., produce substantial metabolic heat) and are able to maintain an internal temperature above that of the environment. Because muscles can be warmed by metabolic heat, nocturnal activity can be used to reduce water loss. Thus, evolutionary history may constrain the behavioral response of a given organism to a particular environmental stressor.

The stressors associated with the desert climate have also resulted in modifications, or adaptations, of the morphology and physiology of desert inhabitants. These adaptations often facilitate the retention of water. In plants, for example, leaves are greatly reduced or lost entirely thereby reducing evaporative water loss. Succulent for water retention stems are acquire. Interestingly, these modifications have occurred independently in several unrelated lineages, such as cacti in the Americas and euphorbs in Africa. In addition, some lineages of desert plants, notably CAM plants, have modified photosynthetic reactions with reduced CO_2 requirements. These plants keep their stomata (pores used for gas transfer) closed during the day, thereby reducing evaporative water loss. Animals also demonstrate physiological modifications to retain water in the desert. Kangaroo rats have highly modified kidneys that allow them to recover most of the water in their urine, and thus reduce excretory water loss. In fact, kangaroo rats are able to survive almost entirely on `metabolic water', that is, water produced as a by-product of the conversion of glucose into ATP. Consequently, they can survive without drinking water for extremely long periods of time.

The desert environment can also be used to illustrate research questions or ecological `problems' that are of interest to ecophysiologists. For example, how long does it take a basking lizard (an ectotherm) to achieve its preferred body temperature to warm its muscles for effective foraging and escape behaviors? To answer this question, a researcher might construct a simple mathematical model that includes the potential sources of heat gain and loss: total heat (H_T) = metabolic heat (H_M) ± conductive heat (H_C) ± convective heat (H_V) ± radiant heat (H_R) ± evaporative heat (H_E) (**Fig. 2**). The researcher might use this to make specific predictions, and then test this prediction by collecting empirical measurements from a model lizard (containing a thermocouple) placed on a basking rock. Alternately, measurements could be taken from a number of lizards of a given species in a certain size class sunning themselves in a desert environment to construct an equation that quantifies the rate of heat gain in lizards basking on rocks under a given set of environmental conditions.

Example 2: The Intertidal

The marine intertidal is the region of the shore that emerges with outgoing tides and submerges with incoming tides. Organisms in this habitat must tolerate breaking waves, which impose large and seasonally variable physical forces on the organisms. Exposed intertidal organisms, descendants of entirely aquatic ancestors, must cope with extreme desiccation stress. Tidepool organisms, or those that remain in small remnant pools of water, encounter fluctuations in water temperatures, water quality, and dissolved oxygen in the water. In addition, the longer tidepools remain separated from the ocean, the more conditions deteriorate.

As the tide recedes, organisms in the highest portion of the intertidal or attached to vertical surfaces are literally left `high and dry' – essentially thrust into a terrestrial environment. Exposure to heat and wind causes water loss, which in turn causes desiccation. Shelled invertebrates close their shells to protect their soft tissues from direct exposure. Small, mobile invertebrates and fishes hide within the intertidal algae, where they are sheltered from direct exposure, in a microenvironment with increased humidity. Many species of algae have evolved thick cuticles to reduce water loss by evaporation; other algal species have evolved the ability to tolerate large losses in water content for short periods of time. This latter group of algae serves as an example of species that do not attempt to maintain a constant internal milleu. Instead, they conform to surrounding conditions and are physiologically tolerant of the concomitant changes in tonicity and osmolarity. There are boundaries to every species' tolerance and zero percent water content would be fatal for these algae, but large changes in water content are tolerated. By either regulating or conforming, intertidal organisms can persist until they are submerged again by the incoming tide.

Cracks and crevices in the landscape often contain pools that persist between high tides, and many intertidal organisms can be found there. However, organisms living in these microhabitats face a different, but no less demanding, set of challenges between tides. These pools are typically small and shallow. During emersion, they are heated by the sun and experience large thermal fluctuations. These pools also have large surface areas, and water evaporates from the pools over time, which causes the salinity in the pools increase. Tidepool organisms also `pollute' their environment by releasing nitrogenous wastes into the water. Because these environmental challenges will vary depending on the elevation, size, and depth of a tidepool, intertidal fish species tend to

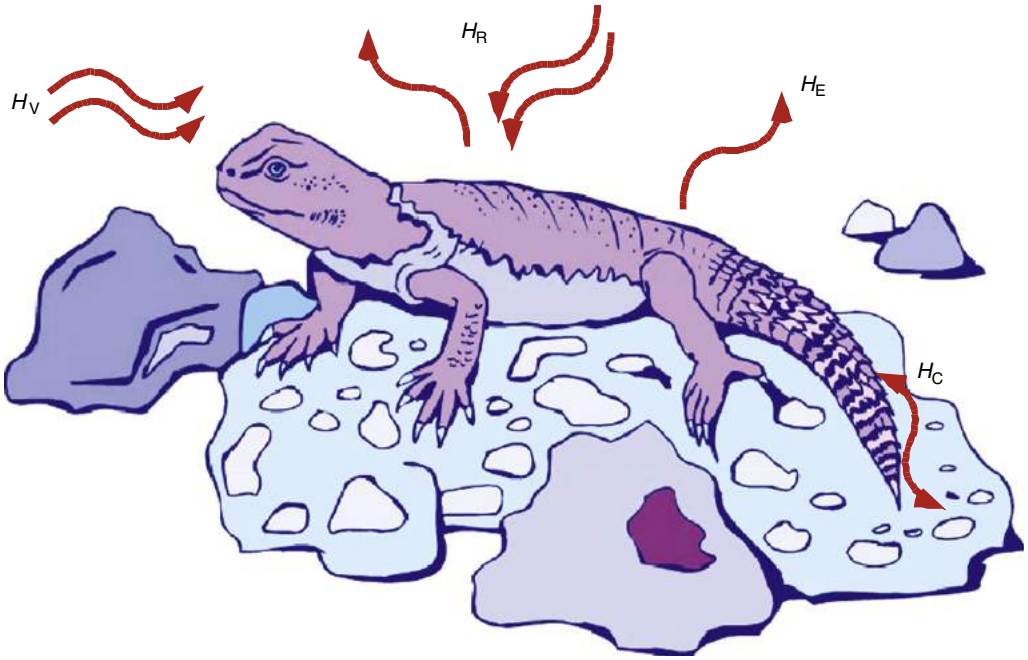

Fig. 2 Heat is transferred between an organism and its environment by radiation (H_R), convection (H_V), conduction (H_C), and evaporation (H_E). Information about ambient temperature, wind speed, color of the organism, etc., can be used to generate a model to predict the rate of heat transfer between an organism and the environment to answer specific ecophysiological questions: e.g., how fast can a lizard achieve its preferred body temperature?

distribute themselves according to their ability to either compensate internally or be tolerant of fluctuations in temperature, salinity, and nitrogen. Species that can accommodate wider fluctuations in these environmental variables tend to be found higher in the intertidal, where pools are exposed longer and conditions become more extreme.

Animals that remain in emergent tidepools also consume most of the dissolved oxygen in the water, which creates another physiological stressor. Tidepool algae or plants may exacerbate this problem by consuming oxygen at night, although they release oxygen into the pool during the day (sometimes to dangerously high levels). Because dissolved oxygen levels are typically low in tidepools, some tidepool fishes have evolved the ability to breathe air. An air-breathing fish that remains in a pool will take an `air breath' from the surface, and hold the air in its mouth, where oxygen is extracted. Some tidepool fishes also have rigid gills and gill filaments that remain erect when unsupported by water, which allows oxygen extraction to continue while air contacts the respiratory surfaces of the gill filaments. If tidepool conditions become too unfavorable, fishes with these gill modifications can exit the tidepool and potentially move to a new tidepool until the tides return and conditions improve. Emergent tidepool fishes may also extract oxygen through the skin, via a process termed cutaneous respiration. However, aerial respiration does pose a challenge for eliminating acidic and nitrogenous wastes, which normally diffuse readily through the gills into the surrounding water. In addition, because evaporative water loss occurs rapidly in a terrestrial environment, ionic and osmotic regulation are also problematic for these fishes. In fact, evaporative water loss may limit the distance and nature of the terrestrial excursions undertaken by marine intertidal fishes.

Ecophysiology, Ecomorphology, and the Ecomorphological Paradigm

The term ecophysiology, as interpreted broadly, also includes two related fields: functional morphology (or ecomorphology) and biomechanics. Studies in the field of functional morphology typically pertain to an animal's ability to move about in its environment (locomotion), to acquire energy (feeding), and to transmit its genes to the next generation (courtship and reproduction). Consequently, this field is particularly concerned with quantifying `performance' variables. Performance variables aim to quantify an animal's ability to survive and succeed in its habitat, such as maximum speed of locomotion, metabolic cost of transport, feeding rate, and maximum bite force. Biomechanics, in contrast, considers how the physical properties of the tissues that comprise an organism affect its ability to survive and succeed in its environment. This field includes studies that assess the strength and elasticity of animal and plant tissues (bone, tendon, cuticle, stems) to determine if environmental or behavioral stressors may contribute to failure of the organism to survive in its habitat, and modeling studies that atomize the organism into simple systems and consider the energy used and work being performed by that particular system.

A cornerstone of these and other related fields is the `ecomorphological paradigm', which states that structural or physical or even physiological differences among organisms are often reflections of differences in their ecology. For example, piscivorous

fishes might have long, sharp teeth for capturing prey, while planktivorous fishes may have lost teeth altogether and use modified gill arches to filter prey out of the water column. Therefore, diet can be predicted to some degree by tooth and gill morphology, and vice versa.

The Comparative Method

Modern ecophysiologists and related fields often rely upon the comparative method for studying patterns and processes. This method allows researchers to infer evolutionary processes from consistent correlations between specific modifications to organisms and a particular habitat. For example, several different plant lineages that live in desert habitats have lost their leaves (as described above). This morphological modification is hypothesized to minimize the absorption of solar radiation and loss of water. This change has occurred independently in several plant groups (i.e., the desert habitat was invaded multiple times by different plant groups), and the closest nondesert relatives of these plants do not show these morphological adaptations, which reveals that the plants did not have these traits prior to invading. Therefore, we infer that leaf loss is a trait that arose in direct response to living in the desert. By making these across and within-group comparisons, ecophysiologists can infer that leaf loss is an adaptive response to desert living that provides a fitness advantage to the plant species that possess it.

Conclusions

Ecophysiology attempts to understand the potential limits placed on organisms by their physiology, how organisms respond to particular environmental challenges, and how organisms have adapted to their ecological niches. In this context, it is important to note that while many environments are stressful and have the potential to disrupt homeostasis, the organisms that live in these environments are able to grow, mature, and reproduce under these challenging conditions. We can determine how a given species copes with an extreme environment through studies of specific physiological mechanisms. Behavior is the highest or broadest level of potential mechanism, followed by the system, organ, cellular, and molecular levels. Studies of animal behavior and functional morphology typically describe the highest levels of potential mechanisms. At lower levels, biomechanical and classical physiological mechanisms are examined. Ecophysiologists often hypothesize that these mechanisms represent adaptations to the ecological niche of the organism, and hypothesized adaptations are tested using the comparative method.

Ecosystems

AK Salomon, University of California, Santa Barbara, CA, USA

What Is an Ecosystem?

Coined by A. G. Tansley in 1935, the term 'ecosystem' refers to an integrated system composed of a biotic community, its abiotic environment, and their dynamic interactions. A diversity of ecosystems exist through the world, from tropical mangroves to temperate alpine lakes, each with a unique set of components and dynamics (Fig. 1). Ecosystems can be classified according to their components and physical context yet their classification is highly dependent on the spatial scale of scrutiny. Typically, boundaries between ecosystems are diffuse. An 'ecotone' is a transition zone between two distinct ecosystems (i.e., the tundra–boreal forest ecotone).

History

Over 70 years ago, Sir Arthur Tansley (Fig. 2) presented the notion that ecologists needed to consider 'the whole system', including both organisms and physical factors, and that these components could not be separated or viewed in isolation. By suggesting that ecosystems are dynamic, interacting systems, Tansley's ecosystem concept transformed modern ecology. It led directly to considerations of energy flux through ecosystems and the pathbreaking, now classic work of R. L. Lindeman in 1942, one of the first formal investigations into the functioning of an ecosystem, in this case a senescent lake, Cedar Creek Bog, in Minnesota. Inspired by the work of C. Elton, Lindeman focused on the trophic (i.e., feeding) relationships within the lake, grouping together organisms of the lake according to their position in the food web. To study the cycling of nutrients and the efficiency of energy transfer among trophic levels over time, Lindeman considered the lake as an integrated system of biotic and abiotic components. He considered how the lake food web and processes driving nutrient flux affected the rate of succession of the whole lake ecosystem, a significant departure from traditional interpretations of succession.

By the late 1950s and early 1960s, system-wide energy fluxes were quantified in various ecosystems by E. P. Odum and J. M. Teal. In the late 1960s, Likens, Bormann, and others took an ecosystem approach to studying biogeochemical cycles by manipulating whole watersheds in the Hubbard Brook Experimental Forest to determine whether logging, burning, or pesticide and herbicide use had an appreciable effect on nutrient loss from the ecosystem. This research set an important precedent in demonstrating the value of conducting experiments at the scale of an entire ecosystem (see the section entitled 'Whole ecosystem experiments'), a significant advancement which continues to inform ecosystem studies today.

Ecosystem Components and Properties

Ecosystems can be thought of as energy transformers and nutrient processors composed of organisms within a food web that require continual input of energy to balance that lost during metabolism, growth, and reproduction. These organisms are either 'primary producers' (autotrophs), which derive their energy by using sunlight to convert inorganic carbon into organic carbon, or 'secondary producers' (heterotophs), which use organic carbon as their energy source. Organisms that perform similar types of ecosystem functions can be broadly categorized by their 'functional group'. For example, 'herbivores' are heterotophs that eat autotrophs, 'carnivores' are heterotrophs that eat other heterotrophs, while 'detritivores' are heterotrophs that eat nonliving organic material (detritus) derived from either autotrophs or heterotrophs (Fig. 3). Herbivores, carnivores, and dertitivores are collectively known as 'consumers'.

Classifying organisms according to their feeding relationships is the basis of defining an organism's 'trophic level'; the first trophic level includes autotrophs; the second trophic level includes herbivores and so on. Ecosystem components that make up a trophic level are quantified in terms of biomass (the weight or standing crop of organisms), while ecosystem dynamics, the flow of energy and materials among system components, are quantified in terms of rates.

Typically, ecologists quantifying ecosystem dynamics use carbon as their currency to describe material flow and energy to quantify energy flux. Material flow and energy flow differ in one important property, namely their ability to be recycled. Chemical materials within an ecosystem are recycled through an ecosystem's component. In contrast, energy moves through an ecosystem only once and is not recycled (Fig. 3). Most energy is transformed to heat and ultimately lost from the system. Consequently, the continual input of new solar energy is what keeps an ecosystem operational.

Solar energy is transformed into chemical energy by primary producers via photosynthesis, the process of converting inorganic carbon (CO_2) from the air into organic carbon ($C_6H_{12}O_2$) in the form of carbohydrates. Gross primary production is the energy or carbon fixed via photosynthesis over a specific period of time, while net primary production is the energy or carbon fixed in photosynthesis, minus energy or carbon which is lost via respiration, per unit time. Production by secondary producers is simply the amount of energy or material formed per unit term.

Fig. 2 Sir Arthur G. Tansley coined the term ecosystem in 1935. From *New Phytologist* 55: 145, 1956.

A careful distinction needs to be made between production rates and static estimates of standing crop biomass, particularly because the two need not be related. For example, two populations at equilibrium, in which input equals output, might have the same standing stock biomass but drastically different production rates because turnover rates can vary (**Fig. 4**). For example, on surf swept shores from Alaska to California, two species of macroalgal primary producers grow in the low rocky intertidal zone of temperate coastal ecosystems (**Fig. 5**). The ribbon kelp, *Alaria marginata*, is an annual alga with high growth rates, whereas sea cabbage, *Hedophyllum sessile*, is a perennial alga with comparatively lower growth rates. Although they differ greatly in their production rates, in mid-July, during the peak of the growing season, these two species can have almost equivalent stand crop biomasses.

Ecosystem Efficiency

The efficiency of energy transfer within an ecosystem can be estimated as its 'trophic transfer efficiency', the fraction of production passing from one trophic level to the next. The energy not transferred is lost in respiration or to detritus. Knowing the trophic transfer efficiency of an ecosystem can allow researchers to estimate the primary production required to sustain a particular trophic level.

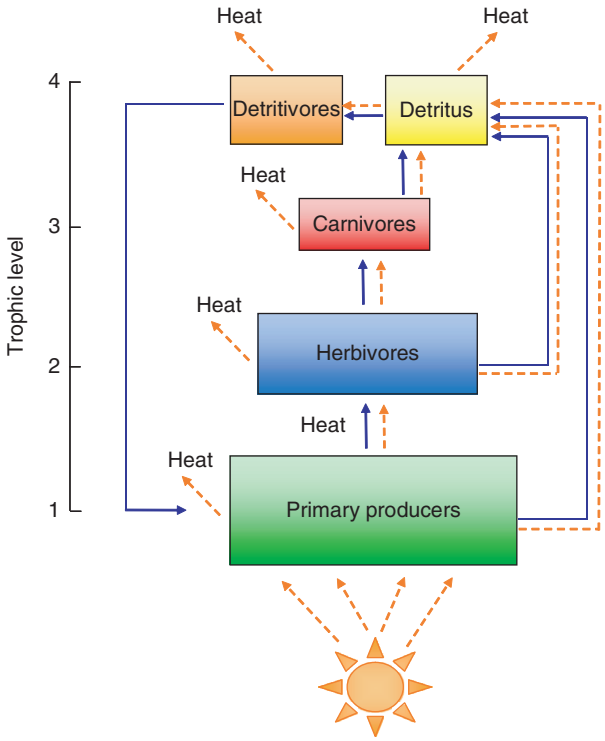

Fig. 3 Energy flows and material cycles in an ecosystem. Materials move through the trophic levels and eventually cycle back to the primary producers via the decomposition of detritus by microorganisms. Energy, originating as solar energy, is transferred through the trophic levels via chemical energy and is lost via the radiation of heat at each step. Adapted from DeAngelis DL (1992) *Dynamics of Nutrient Cycling and Food Webs*. New York, NY: Chapman and Hall.

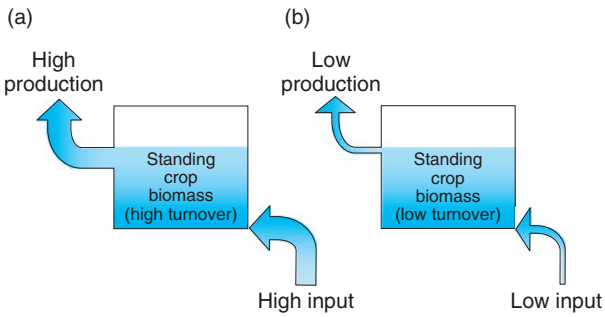

Fig. 4 Standing crop biomass is not always correlated to production rates. Here, two hypothetical species with populations at equilibrium, where input equals output, have an equivalent standing crop biomass but differ in their turnover rates. Population (a) has high input, high production, and high turnover rates, whereas population (b) has low input, low production, and low turnover rates. In reality, populations are rarely at equilibrium so standing crop biomass fluctuates depending on input rates and the amount of production consumed by higher trophic levels. Adapted from Krebs C (2001) *Ecology: The Experimental Analysis of Distribution and Abundance*, 5th edn. San Francisco: Addison-Wesley Educational Publishers, Inc.

For example, in aquatic ecosystems, trophic transfer efficiency can vary anywhere between 2% and 24%, and average 10%. Assuming a trophic efficiency of 10%, researchers can estimate how much phytoplankton production is required to support a particular fishery. Consider the open ocean fishery for tuna, bonitos, and billfish. These are all top predators, operating at the fourth trophic level. According to world catch statistics recorded by the Food and Agriculture Organization, in 1990, 2 975 000 t of these predators were caught, equivalent to 0.1 g of carbon per m^2 of open ocean per year. To support this yield of tuna, bonitos, and billfish, researchers can calculate the production rates of the trophic levels below, assuming a trophic efficiency of 10% and equilibrium conditions. Essentially, to produce of 0.1 gC m^{-2} yr^{-1} of harvested predators (tuna, bonitos, and billfish) requires 1 gC m^{-2} yr^{-1} of pelagic fish to have been consumed by the top predators, 10 gC m^{-2} yr^{-1} of zooplankton to be consumed by the pelagic fishes, and 100 gC m^{-2} yr^{-1} of phytoplankton. Note that these values represent the production that is transferred up

Fig. 5 (a) In the low intertidal zone of temperate coastal ecosystems, (b) the ribbon kelp, *Alaria marginata*, is an annual alga with high growth rates, whereas (c) the sea cabbage kelp, *Hedophyllum sessile*, is a perennial alga with lower growth rates. During the peak of the growing season, these two species can have a similar stand crop biomass but differ greatly in their production rates because one is an annual and the other is a perennial. Photo by Anne Salomon and Mandy Lindeberg.

trophic levels. They do not represent the standing stock of biomass at each trophic level. Knowing the net primary production of the photoplankton allows researchers to estimate the proportion of this production that is taken by the fishery.

It has been estimated that 8% of the world's aquatic primary production is required to sustain global fisheries. Considering continental shelf and upwelling areas specifically, these ecosystems provide one-fourth to one-third of the primary production required for fisheries. This high fraction leaves little margin for error in maintaining resilient ecosystems and sustainable fisheries.

Large-Scale Shifts in Ecosystems

A growing body of empirical evidence suggests that ecosystems may shift abruptly among alternative states. In fact, large-scale shifts in ecosystems have been observed in lakes, coral reefs, woodlands, desserts, and oceans. For example, a distinct shift occurred in the Pacific Ocean ecosystem around 1977 and 1989. Abrupt changes in the time series of fish catches, zooplankton abundance, oyster condition, and other marine ecosystem properties signified conspicuous shifts from one relatively stable condition to another (Fig. 6). Also termed 'regime shifts', the implications of these abrupt transitions for fisheries and oceanic CO_2 uptake are profound, yet the mechanisms driving these shifts remain poorly understood. It appears that changes in oceanic circulation driven by weather patterns can be evoked as the dominant causes of this state shift. However, competition and predation are becoming increasingly recognized as important drivers of change altering oceanic community dynamics. In fact, fisheries are well known to affect entire food webs and the trophic organization of ecosystems. Therefore, one could imagine that the sensitivity of a single keystone species to subtle environmental change could cause major shifts in community composition. Given this interplay between and within the biotic and abiotic components of an ecosystem, resolving the causes of regime shifts in oceanic ecosystems will likely require an understanding of the interactions between the effects of fisheries and the effects of physical climate change.

Studying Ecosystem Dynamics

Stable Isotopes

Important insights into ecosystem dynamics can be revealed through the use of naturally occurring 'stable isotopes'. These alternate forms of elements can reveal both the source of material flowing through an ecosystem and its consumer's trophic position. This is because different sources of organic matter can have unique isotopic signatures which are altered in a consistent manner as materials are transferred throughout an ecosystem, from trophic level to trophic level. Consequently, stable isotopes provide powerful tools for estimating material flux and trophic positions.

The elements C, N, S, H, and O all have more than one isotope. For example, carbon has several isotopes, two of which are ^{13}C and ^{12}C. In nature, only 1% of carbon is ^{13}C. Isotopic composition is typically expressed in δ values, which are parts per thousand differences from a standard. For carbon,

$$\delta^{13}C = \left[\left(\frac{^{13}C/^{12}\,C_{sample}}{^{13}C/^{12}\,C_{standard}}\right) - 1\right] \times 10^3$$

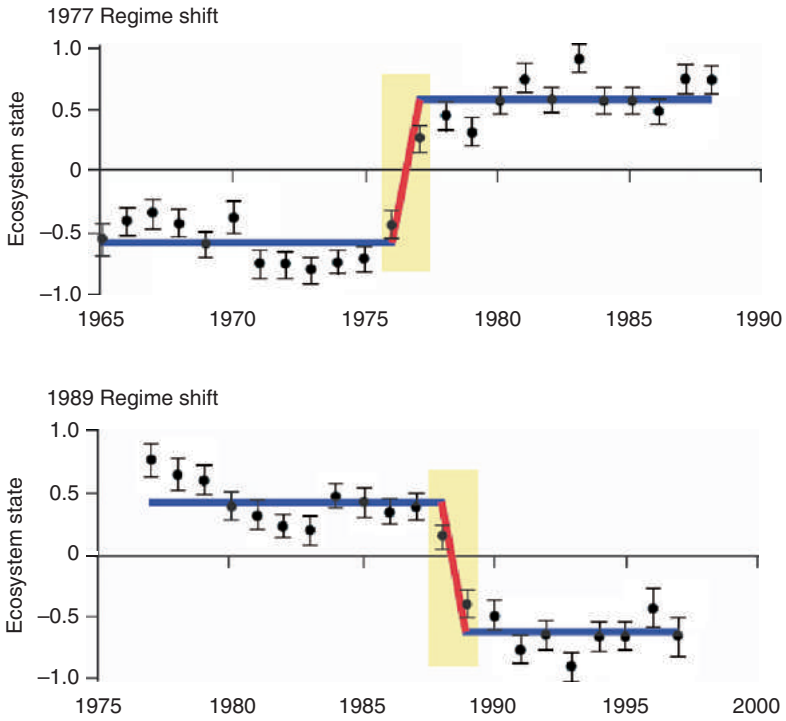

Fig. 6 Distinct shifts in ecosystem states, also referred to as 'regime shifts', occurred in the Pacific Ocean ecosystem around 1977 and 1989. The ecosystem state index shown here was calculated based on the average of climatic and biological time series. From Scheffer M, Carpenter S, Foley JA, Folke C, and Walker B (2001) Catastrophic shifts in ecosystems. *Nature* 413: 591–596.

Consequently, δ values express the ratio of heavy to light isotope in a sample. Increases in these values denote increases in the amount of the heavy isotope component. The standard reference material for carbon is PeeDee limestone, while the standard for nitrogen is nitrogen gas in the atmosphere. Natural variation in stable isotopic composition can be detected with great precision with a mass spectrometer.

Stable isotopes record two kinds of information. Process information is revealed by physical and chemical reactions which alter stable isotope ratios, while source information is revealed by the isotopic signatures of source materials. When organisms take up carbon and nitrogen, chemical reactions occur which discriminate among isotopes, thereby altering the ratio of heavy to light isotope. This is known as 'fractionation'. Although carbon fractionates very little (0.4‰, 1 SD = 1‰), the mean trophic fractionation of δ^{15}N is 3.4‰ (1 SD = 1‰), meaning that δ^{15}N increases on average by 3.4‰ with every trophic transfer. Because the δ^{15}N of a consumer is typically enriched by 3.4‰ relative to its diet, nitrogen isotopes can be used to estimate trophic position. Stable isotopes can provide a continuous measure of trophic position that integrates the assimilation of energy or material flow through all the different trophic pathways leading to an organism. In contrast, δ^{13}C can be used to evaluate the ultimate sources of carbon for an organism when the isotopic signatures of the sources are different.

Stable isotopes can track the fate of different sources of carbon through an ecosystem, because a consumer's isotopic signature reflects those of the key primary producers it consumes. For example, in both lake and coastal marine ecosystems, δ^{13}C is useful for differentiating between two major sources of available energy, benthic (nearshore) production from attached macroalgae, and pelagic (open water) production from phytoplankton. This is because macroalgae and macroalgal detritus (specifically kelp of the order Laminariales) is typically more enriched in δ^{13}C (less negative δ^{13}C) relative to phytoplankton due to boundary layer effects. Researchers have exploited this difference to answer many important ecosystem-level questions. Below are two examples.

During the late 1970s and early 1980s, in the western Aleutian Islands of Alaska, where sea otters had recovered from overexploitation and suppressed their herbivorous urchin prey, productive kelp beds dominated. There, transplanted filter feeders, barnacles and mussels, grew up to 5 times faster compared to islands devoid of kelp where sea otters were scarce and urchin densities high. Stable isotope analysis revealed that the fast-growing filter feeders were enriched in carbon suggesting that macroalgae was the carbon source responsible for this magnification of secondary production.

In four Wisconsin lakes, experimental manipulations of fish communities and nutrient loading rates were conducted to test the interactive effects of food web structure and nutrient availability on lake productivity and carbon exchange with the atmosphere. The presence of top predators determined whether the experimentally enriched lakes operated as net sinks or net sources of atmospheric carbon. Specifically, the removal of piscivorous fishes caused an increase in planktivorous fishes, a decrease in large-bodied zooplankton grazers, and enhanced primary production, thereby increasing influx rates of atmospheric carbon into the

lake. Atmospheric carbon was traced to upper trophic levels with $\delta^{13}C$. Here, naturally occurring stable isotopes and experimental manipulations conducted at the scale of whole ecosystems illustrated that top predators fundamentally alter biogeochemical processes that control a lake's ecosystem dynamics and interactions with the atmosphere.

Whole Ecosystem Experiments

Large-scale, whole ecosystem experiments have contributed considerably to our understanding of ecosystem dynamics. With its beginnings in wholesale watershed experiments in the 1960s, ecosystems are now being studied experimentally and analyzed as system of interacting species processing nutrients and energy within the context of changing abiotic conditions. This is particularly relevant these days given the effects of anthropogenic climate forcing and pollution in both terrestrial and oceanic ecosystems.

A classic series of whole-lake nutrient addition experiments conducted in northwestern Ontario by David Schindler and his research group illustrated the role of phosphorus in temperate lake eutrophication. To separate the effects of phosphorus and nitrate, the researchers split a lake with a curtain and fertilized one side with carbon and nitrogen and the other with phosphorus, carbon, and nitrogen. Within 2 months, a highly visible algal bloom had developed in the basin in which phosphorus had been added providing experimental evidence that phosphorus is the limiting nutrient for phytoplankton production in freshwater lakes. Certainly, algae may show signs of nitrogen or carbon limitation when phosphorus is added to a lake; however, other processes often compensate for these deficiencies. For instance, CO_2 is rarely limiting because physical factors such as water turbulence and gas exchange regulate its availiblity. Further, nitrogen can be fixed by blue-green algae. These species, which are favored when nitrogen is in short supply, increases the availability of nitrogen to algae, and the lake eventually returns to a state of phosphorus limitation. The practical significance of these results is that lake europhication can be prevented with management policies that control phosphorus input into lake and rivers.

Using Management Policies as Ecosystem Experiments

It has become increasingly common to use management policies as experiments and test their effects on ecosystem dynamics. An excellent example of this approach is the use of marine reserves to investigate the ecosystem-level consequences of fishing. Essentially, well-enforced marine reserves constitute large-scale human-exclusion experiments and provide controls by which to test the ecosystem effects of reducing consumer biomass via fishing at an ecologically relevant scale. Dramatic shifts in nearshore community structure have been documented in well-established and well-protected marine reserves in both Chile and New Zealand. In northeastern New Zealand's two oldest marine reserves, the Leigh Marine Reserve and Tawharanui Marine Park, previously fished predators, snapper (*Pagrus auratus*) and rock lobster (*Jasus edwardsii*), have increased in abundance by 14- and 3.8-fold, respectively, compared to adjacent fished waters. Increased predation leading to reduced survivorship and cryptic behavior of their herbivorous prey, the sea urchin (*Evechinus chloroticus*), has allowed the macroalga (*Ecklonia radiata*) to increase significantly within the reserves, a trend that has been developing in the Leigh reserve for the past 25 years (**Fig. 7**). Although this provides evidence that fishing can indirectly reduce ecosystem productivity, the trophic dynamics described above are context dependent and vary as a function of depth, wave exposure, and oceanographic circulation (**Fig. 8**). For example, both in the presence and absence of fishing, urchin densities decline to nearly 0 individuals per m^2 below depths greater than 10 m due to unfavorable conditions for recruitment, despite the presence or absence of snapper and lobster, while at depths above 3 m, wave surge can preclude urchin grazing both inside and outside the reserves. Furthermore, where oceanic conditions hinder urchin recruitment, the effects of fishing on macroalgae become less clear-cut. These physical constraints highlight the importance of abiotic context on biotic interactions. Ultimately, one can gain a lot of information by using management policies as experiments.

Although policy experiments have played an important role in elucidating ecosystem dynamics, in many cases, it is politically intractable or logistically impossible to experiment with whole ecosystems. Under such circumstances, researchers have used alternative techniques to explore ecosystem dynamics. Models in ecology have a venerable tradition for both teaching and understanding complex processes. Ecosystem models are now being used to gain insight into the ecosystem-level consequences of management policies, from fisheries to carbon emissions. For more information on ecosystem models and using management policies as experiments, see the section entitled 'Social–ecological systems, Humans as key ecosystem components'.

Ecosystem Function and Biodiversity

Accelerating rates of species extinction have prompted researchers to formally investigate the role of biodiversity in providing, maintaining, and even promoting 'ecosystem function'. Typically, studies experimentally modify species diversity and examine how this influences the fluxes of energy and matter that are fundamental to all ecological processes. In many cases, studies are designed to document the effects of species richness on the efficiency by which communities produce biomass, although the effects of species diversity on other ecosystem functions such as decomposition rates, nutrient retention, and CO_2 uptake rates have also been examined. Several seminal studies report a positive relationship between biodiversity and ecosystem function. Yet, the generality of the results, and the mechanisms driving them, have provoked considerable debate and several counterexamples exist.

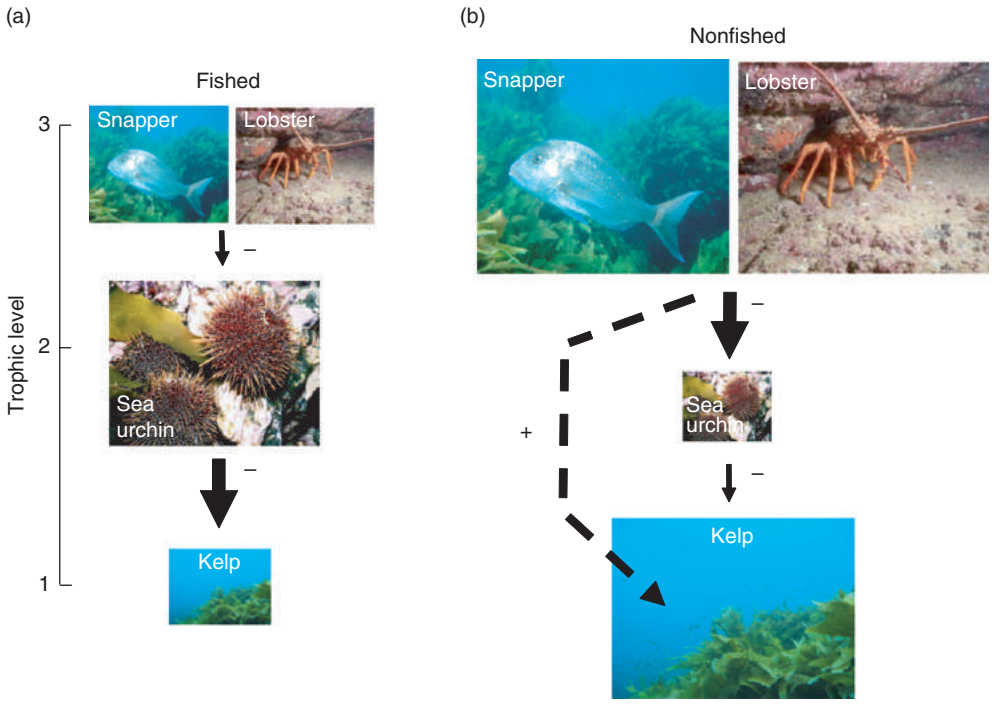

Fig. 7 (a) In nearshore fished ecosystems in northeastern New Zealand, snapper and lobster densities have been reduced due to fishing pressure resulting in high sea urchin densities, urchin barrens, and reduced kelp production. (b) In marine reserves, where previously fished snapper and lobster have recovered, sea urchins that have not been consumed by these predators behave cryptically, hiding in crevices. Consequently, kelp forests of *Ecklonia radiata* dominate. Photos by Nick Shears, Hernando Acosta, and Timothy Langlois.

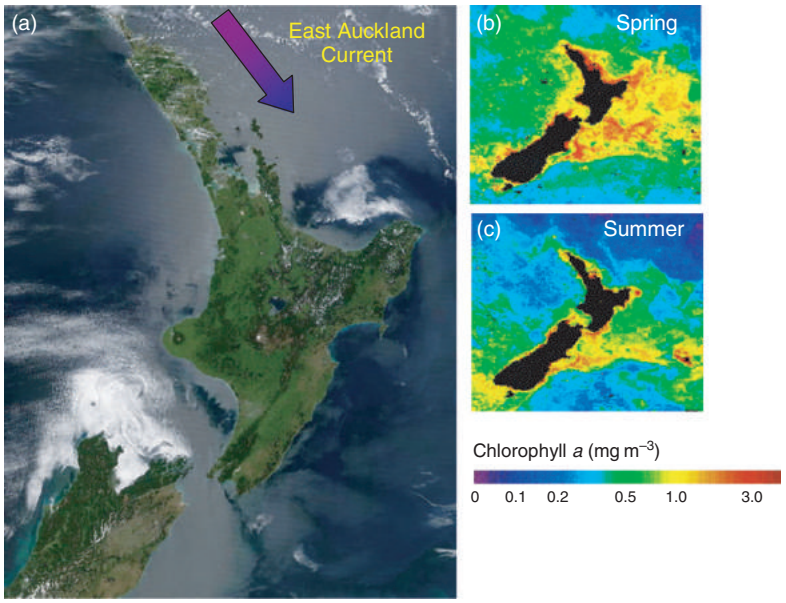

Fig. 8 The effects of fishing on nearshore ecosystems are influenced locally by wave exposure and regionally by oceanographic circulation. (a) In northeastern New Zealand, ocean circulation patterns influence nutrient delivery and thus (b) spring and (c) summer pelagic primary production. Satellite images: SeaWiFs Project, Ocean Color Web.

At the crux of the debate lies a question with deep historical roots: do some species exert stronger control over ecosystem processes than others? Imagine two distinct positive relationships between biodiversity and ecosystem function (**Fig. 9**). In type A communities, every single species contributes to the ecosystem function measured, even the rare species. By contrast, in type B communities, almost all of the ecosystem function measured can be provided by relatively few species, suggesting that many species are in fact redundant. Few empirical studies support type A relationships, rather, empirical evidence points to the

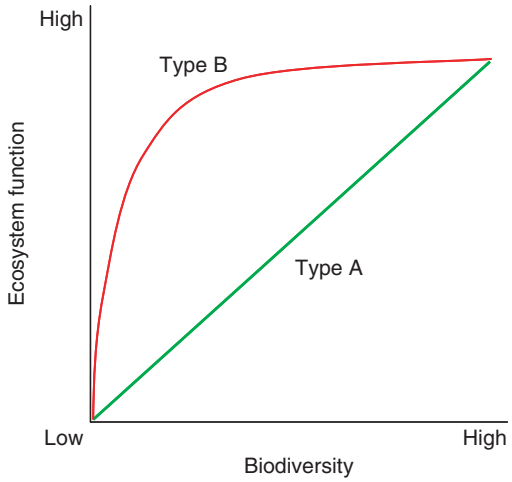

Fig. 9 Type A communities: every single species contributes equally to ecosystem functioning. Type B communities: ecosystem function is provided by only a few species.

prevalence of type B relationships. In fact, a recent meta-analysis of 111 such studies conducted in multiple ecosystems on numerous trophic groups found that the average effect of decreasing species richness is to decrease the biomass of the focal trophic group, leading to less complete depletion of resources used by that group. Further, the most species-rich polycultures performed no differently than the single most productive species used in the experiment. Consequently, these average effects of species diversity on ecosystem production are best explained by the loss of the most productive species from a diverse community. These results could be considered consistent with what has become known as the 'sampling effect'.

Critics argue that a positive relationship between species diversity and ecosystem function is a sampling artifact rather than a result of experimentally manipulated biodiversity *per se*. Such a 'sampling effect' can arise because communities comprising more species have a greater chance of being dominated by the most productive taxa. Yet, controversy surrounding the 'sampling effect' itself exists given the duality in its possible interpretation: is this a real biological mechanism that operates in nature or is it an experimental artifact of using random draws of species to assemble experimental communities? To add to the ecosystem function–biodiversity debate is the critical issue that many of these studies focus on a single trophic level and neglect or dismiss multiple trophic-level interactions, such as herbivory and other disturbances well known to alter ecosystem processes, calling into question the generality of these results.

Despite the controversy, these studies generally reinforce the notion that certain species exert much stronger control over ecological processes than others. However, identifying which species these are in advance of extinction remains a challenge. Nonetheless, identifying the mechanisms driving ecosystem functioning is an important conservation priority given that human well-being relies on a multitude of these functions.

Ecosystem Perspectives in Conservation Science

Ecosystem Services

Humans have always relied on nature for environmental assets like clean water and soil formation. Today, these assets are receiving global attention as 'ecosystem services', the conditions and processes by which natural ecosystems sustain and fulfill human life. Natural ecosystems perform a diversity of ecosystem services on which human civilization depends:

1. regulating services – purification of air and water, detoxification and decomposition of wastes, moderation of weather extremes, climate regulation, erosion control, flood control, mitigation of drought and floods, regulation of disease carrying organisms and agricultural pests;
2. provisioning services – provision of food, fuel, fiber, and freshwater;
3. supporting services – formation and preservation of soils, protection from ultraviolet rays, pollination of natural vegetation and agricultural crops, cycling of nutrients, seed dispersal, maintenance of biodiversity, primary production; and
4. cultural services – spiritual, esthetic, recreational.

Although critical to human existence, ecosystem services are often taken for granted or at best, greatly undervalued. This is ironic given that many ecosystem services are very difficult and expensive to duplicate, if they can be duplicated at all. Normally, ecosystem services are considered 'free' despite their obvious economic value. For example, over 100 000 species of animals

Fig. 10 Pollination services, provided by bees, bats, butterflies, and birds to name a few, have been valued at US$4–6 billion per year in the US alone. Consider the global value of this important ecosystem service. Photos by Steve Gaines, Heather Tallis.

provide free pollination services, including bats, bees, flies, moths, beetles, birds, and butterflies (Fig. 10). Based on the estimate that one-third of human food comes from plants pollinated by wild pollinators, pollination has been valued at US$4–6 billion per year in the US alone. Globally, the world's ecosystem services have been valued at US$33 trillion a year, nearly twice as much as the gross national product of all of the world's countries.

The idea of paying for ecosystem services has been gaining momentum. Yet, because ecosystem services are typically not sold in markets, they usually lack a market value. Given the value of natural capital, nonmarket valuation approaches are being developed by economists and ecologists to account for ecosystem services in decision-making processes. The notion being that economic valuation gives decision makers a common currency to assess the relative importance of ecosystem processes and other forms of capital.

Yet, assigning value to ecosystem services is tricky and some analysts object to nonmarket valuation, because it is a strictly anthropogenic measure and does not account for nonhuman values and needs. Yet, in democratic countries, environmental policy outcomes are determined by the desires of the majority of citizens, and voting on a preferred policy alternative is ultimately an anthropogenic activity. A second objection to nonmarket valuation is a disagreement with pricing the natural world and dissatisfaction with the capitalistic premise that everything is thought of in terms of commodities and money. The point of valuation, however, is to frame choices and clarify the tradeoffs between alternative outcomes (i.e., draining a wetland may increase the supply of developable land for housing but does so at the cost of decreased habitat and potential water quality degradation). Finally, a third objection to nonmarket valuation stems from the uncertainty in identifying and quantifying all ecosystem services. Advocates argue that economic valuation need not cover all values and that progress is made by capturing values that are presently overlooked.

Despite the uncertainties, valuing ecosystem services can sometimes pay off. When New York City compared the coast of an artificial water filtration plant valued at US$6–8 billion, plus an annual operating cost of US$300 million, the city chose to restore the natural capital of the Catskill Mountains for this watershed's inherent water filtration services and for a fraction of the cost (US $660 million). Ultimately, the valuation of ecosystem services, even if flawed, may get ecosystem processes on the decision-making table and lead to more sustainable policies in light of ever-expanding human populations.

Ecosystem services are threatened by growth in the scale of human enterprise (population size, per-capita consumption rates) and a mismatch between short-term needs and long-term societal well-being. With a global population soon to number 9 billion people, ecosystem services are becoming so degraded, some regions in the world risk ecological collapse. Many human activities alter, disrupt, impair, or reengineer ecosystem services such as overfishing, deforestation, introduction of invasive species, destruction of wetlands, erosion of soils, runoff of pesticides, fertilizers, and animal wastes, pollution of land, water, and air resources. The consequences of degrading ecosystem services on human well-being were examined in the Millennium Ecosystem Assessment (MA) 2005, which concluded that well over half of the world's ecosystems services are being degraded or used unsustainably. The MA developed global ecological scenarios as a process to inform future policy options. These scenarios were based on a suite of models that were designed to forecast future change. The MA based its scenario analyses on ecosystem services. Specifically, scenarios were developed to anticipate responses of ecosystem services to alternative futures driven by different sets of policy decisions. Following the completion of this ambitious ecological study, there is now a growing movement to make the value of ecosystem services an integral part of current policy initiatives.

Social–Ecological Systems, Humans as Key Ecosystem Components

Humans are a major force in global change and drive ecosystem dynamics, from local environments to the entire biosphere. At the same time, human societies and global economies rely on ecosystem services. As such, human and natural systems can no longer be treated independently because natural and social systems are strongly linked. Accumulating evidence suggests that effective environmental management and conservation strategies must take an integrated approach, one that considers the interactions and feedbacks between and within social, economic, and ecological systems. As a result, the concept of coupled 'social–ecological systems' has become an emerging focus in environmental and social science and ecosystem management. Social–ecological systems are considered as evolving, integrated systems that typically behave in nonlinear ways. The concept of resilience – the capacity to buffer change – has been increasingly used as an approach for understanding the dynamics of social–ecological systems. Two useful tools for building resilience in social–ecological systems are structured scenario modeling and active adaptive management.

Models of linked social–ecological systems have been developed to inform management conflicts over water quality, fisheries, and rangelands. These models represent ecosystems coupled to socioeconomic drivers and are explored with stakeholders to probe the management decision-making processes. Alternative scenarios force participants to be absolutely explicit about their assumptions and biases, thereby improving communication between stakeholders and exposing the ecological consequences of various management policies.

Adaptive management is an approach where management policies themselves are deliberately used as experimental treatments. As information is gained, policies are modified accordingly. This approach helps isolate anthropogenic effects from sources of natural variation and, most importantly, considers the consequences of a human perturbation on the whole ecosystem. In contrast, basic research on various parts of an ecosystem leads to the challenge of assembling all the data into a practical framework. Yet, biotic and abiotic ecosystem components are not additive, they interact. Due to these interactions, the dynamics of an ecosystem cannot be extrapolated from the simple addition of an ecosystem's components. Adaptive management examines the response of the system as a whole rather than a sum of its parts. Furthermore, this approach involves adaptive learning and adaptive institutions that acknowledge uncertainties and can respond to nonlinearities. In sum, structured scenario modeling and policy experimentation are tools that can be used to examine the resilience of social–ecological systems to alternative management policies and conservation strategies.

Ecosystem-Based Management

Recognizing the need to sustain the integrity and resilience of social–ecological systems has led to calls for 'ecosystem-based management', a management approach that considers all ecosystem components, including humans and the physical environment. With the overall goal of sustaining ecosystem structure and function, this management approach:

- focuses on key ecosystem processes and their responses to perturbations;
- integrates ecological, social, and economic goals and recognizes humans as key components of the ecosystem;
- defines management based on ecological boundaries rather than political ones;
- addresses the complexity of natural processes and social systems by identifying and confronting uncertainty;
- uses adaptive management where policies are used as experiments and are modified as information is gained;
- engages multiple stakeholders in a collaborative process to identify problems, understand the mechanisms driving them, and create and test solutions; and
- considers the interactions among ecosystems (terrestrial, freshwater, and marine).

Ecosystem-based management is driven by explicit goals, executed by policies and protocols, and made adaptable by using policies as experiments, monitoring their outcomes and altering them as knowledge is gained.

Traditionally, management practices have focused on maximizing short-term yield and economic gain over long-term sustainability. These practices were driven by inadequate information on ecosystem dynamics, ignorance of the space and timescales on which ecosystem processes operate, and a prevailing public perception that immediate economic and social value outweighed the risk of alternative management. Seeking to overcome these obstacles, ecosystem-based management relies on research at all levels of ecological organization, explicitly recognizes the dynamic character of ecosystems, acknowledge that ecological processes operate over a wide range of temporal and spatial scales and are context dependent, and presupposes that our current knowledge of ecosystem function is provisional and subject to change. Ultimately, ecosystem-based management recognizes the importance of human needs while addressing the reality that the capacity of our world to meet those needs in perpetuity has limits and depends on the functioning of resilient ecosystems.

Edaphic Factor☆

Nishanta Rajakaruna, College of the Atlantic, Bar Harbor, ME, United States
Robert S Boyd, Auburn University, Auburn, AL, United States

Introduction

This article describes the important roles geology and soil conditions play in the ecology and evolution of plant species and their associated biota. We seek to: (1) describe the edaphic factor as a life force responsible for generating and maintaining unique species assemblages and (2) emphasize the importance of conserving habitats with extreme edaphic conditions because of their biological diversity. First, we describe the edaphic factor: its definition and role in shaping the biotic world. Then we review our current knowledge of the ecology of unusual geologies, focusing on studies performed within and across biotic kingdoms. Further, we examine the process of plant evolution on extreme geologies, an area that has generated much interest among evolutionary biologists in the last few decades. Finally, we cover the applied ecology and conservation of plants and other biota restricted to unique geologies.

The Edaphic Factor: Its Role in Shaping the Biotic World

Ecologists have long noted the importance of geology in the global and regional distribution of organisms. Life, ranging from macro- to microscopic, exists on and within a mosaic of geologies that vary across both space and time. The contributions of geologic phenomena to maintaining and generating biotic diversity are twofold. First, large-scale geologic events (e.g., continental drift and rising of mountains) create discontinuous or patchy landscapes. Second, within this patchwork of landscapes, parental geologic materials such as igneous, metamorphic, or sedimentary rocks can become exposed, leading to the development of soils differing in chemical and physical characteristics. This creates opportunities for colonization and differentiation of species. The edaphic factor pertains to physical, chemical, and biological properties of soil resulting from these geologic phenomena. Discontinuities in the edaphic factor have contributed to the intriguing patterns of diversity we see in the biotic world. Edaphology is a branch of soil science that studies the influences of soils on organisms, especially plants. It includes agrology, the study of human uses of soils for agriculture, as well as how the features of soils affect human land use decisions.

According to soil ecologist Hans Jenny, soils owe their distinct characteristics to five interacting factors: climate, organisms, topography, parental rock, and time. If all but one factor (e.g., parental rock) remain unchanged, then variation in a soil body can be attributed to that one factor. Botanists have long recognized that the distribution, habit, and composition of vegetation are greatly influenced by the edaphic factor. The striking effects on vegetation of unusual and often extreme substrates (e.g., serpentine, limestone, dolomite, shale, gypsum) are apparent even to amateur naturalists. Whereas climate broadly defines major biomes (e.g., tropical rainforests, temperate deciduous forests, deserts, tundra), it is geology that enriches diversity within these zones. The role played by the edaphic factor in the distribution of plant species was keenly observed and recorded by many 18th- and 19th-century plant ecologists, who considered soils second only to climate as the major ecological determinant of plant distribution. It was in the twentieth century, however, that ecologists fully appreciated the role of the edaphic factor in generating habitats within which plants and their associated organisms live, interact, reproduce, and diverge over time.

Components of the Edaphic Factor

Plants generally obtain nutrient elements and water from soil. Thus, soil features that affect the availability and uptake of nutrients and water are of great importance to plants. Below is a brief overview of the soil features that most greatly affect plant growth.

Texture

Mineral particles in soils can be classified on the basis of their size (diameter). Clays are very small (<0.002 mm) particles, silts are larger (0.002–0.05 mm), and sands yet larger (0.05–2.0 mm). The percentage of each of these major particle classes soil determines the texture of a soil. Textures range from those predominantly containing one of the three major particle sizes and thus named for them (silt, sand, clay textures) or various intergradations (sandy clay, etc.). One major textural class (loam), which is ideal for plant growth, is not named for a predominant particle class because loam soils have similar amounts of all three particle

☆*Change History*: April 2018. Irene Martins has updated the text throughout the article.

This is an upadte of N. Rajakaruna and R.S. Boyd, Edaphic Factor, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1201–1207.

classes. Texture is important for plant growth because it influences water availability and soil fertility, that is, the ability of a soil to supply nutrients to plant roots. Open spaces among soil particles represent the pore space of a soil. This pore space may be filled by water, air, or plant roots. Thus, the amount of pore space greatly influences the amount of water that a soil can contain. The tightness with which water is held in pore spaces determines whether or not the water and dissolved mineral ions will drain through the soil profile or remain in place and be available for uptake by plant roots. Coarse textured soils (e.g., sandy soils) have large pore spaces that do not hold water tightly enough to prevent gravity from pulling that water into deeper soil layers. Very fine textured soils (e.g., clay soils) have very small pores. Small pores hold water strongly and thus retain much water despite the pull of gravity. However, they also hold water against the pulling power of plant roots and so provide only small amounts of plant-available water. Soil texture is also an important determinant of the cation exchange capacity (CEC) of a soil, that is, the ability of a soil to adsorb and exchange mineral ions essential for plant growth. Soils with higher percentages of clay or silt particles generally have a greater CEC.

Structure

The three-dimensional arrangement of soil particles gives rise to soil structure. In many soils, groups of particles are held together to create lumps of soil materials termed peds. The space between peds can be important in allowing penetration of water and roots to deeper soil layers.

Depth

Soil depth can greatly influence the types of plants that can grow in them. Deeper soils generally can provide more water and nutrients to plants than more shallow soils. Furthermore, most plants rely on soil for mechanical support and this is especially true for tall woody plants (e.g., shrubs, trees). A classic example of the influence of soil depth on plant communities is seen on granite rock outcrops in the southeastern United States. As the granite weathers, it can form pools of soil that vary in depth from a few millimeters at the margin to tens of centimeters in the middle. The shallow marginal soils support certain annual plants, whereas deeper soils support herbaceous perennials and still deeper soils are colonized by woody plants. Plant zonation in these soil pools can be striking (**Fig. 1**). Some soils can develop special soil horizons (horizontal soil layers characterized by distinct chemical and physical features) that limit the soil depth available to support plants. These special soil horizons include claypans, zones of soil which contain large amounts of clay, and hardpans, layers of soil particles that have been cemented together by the deposition of mineral materials. Hardpans include calcic horizons (commonly called caliche), in which calcium carbonate cements the soil particles. The net effect of these dense horizons is to impede or prevent root growth and thus limit the effective depth of the soil. They also may affect soil oxygenation by restricting drainage at times in which large amounts of water are present.

Organic Matter

Organic matter in soils ranges from recognizable plant parts (roots, leaves, stems) to humus, which is partly decomposed plant material that is amorphous and spongy in nature. Organic matter contributes to a soil's ability to retain nutrients and water (i.e., soil's CEC). It aids in holding nutrients because negatively charged compounds in humus attract and hold positively charged plant nutrient ions. It helps provide water because humus can absorb 80%–90% of its weight in water and therefore contributes to a soil's ability to hold water under drought conditions. Organic matter in soils is also an important food source for decomposer and detritivore organisms. Organic matter also contributes to soil color, a factor that affects a soil's thermal properties.

pH

Soil pH is an extremely important ecological parameter. Its most important effect on plant growth is its influence on ion availability in the soil solution. Ions in soils are important for two major reasons. One is that many soil ions contain elements required for plant growth. These elements, called essential nutrients, are primarily obtained from the soil. The second reason is that plants obtain most of their water from soil and the amount of dissolved ions in soil water can influence a plant's ability to take up water (see the following section). The influence of pH on ion availability stems primarily from the influence of pH on the solubility of the various compounds present in the soil. In general, soil compounds containing some elements are more soluble at some pH values than others. For example, iron is relatively insoluble at pH values of 8 or greater and plants with a high iron requirement may perform poorly in soils with high pH values. Similarly, many heavy metals become increasingly available for plant uptake at pH values of 4–5. Thus, plants growing in low pH soils are more susceptible to heavy metal toxicities.

Ion Availability

Although we mentioned ion availability under pH (above), we should also mention that some ions are abundant in some soils primarily because they have been deposited in those soils in great amounts. Certain salts (often Na, Mg, or Ca salts) may be abundant in some soils in quantities that greatly affect plant growth. These salts include those from seawater (as in salt marshes) or

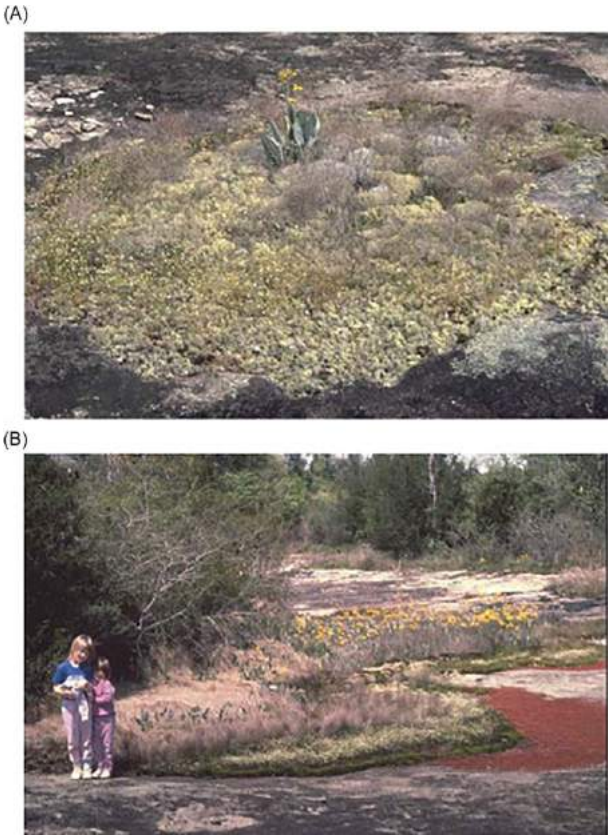

Fig. 1 (A) A small soil pool (about 2 m wide) on a granite outcrop in east-central Alabama. Shallow soil at the margins is dominated by lichens. The deepest soil in the center of the pool has been colonized by *Senecio tomentosus*, a yellow-flowered herbaceous perennial species. (B) A larger soil pool on the same granite outcrop shown in (A). Deep soil on the *left* (behind the children: Jenny and Kristina Boyd) is occupied by woody plants (shrubs and trees). The soil pool becomes more shallow to the *right*, where striking zonation of smaller plants can be observed. The most shallow soil on the extreme right is occupied by the small *red*-colored annual *Sedum smallii*. Slightly deeper soil to the left of the *Sedum* zone is dominated by moss (*Polytrichum commune*) and white-flowered annual *Arenaria* species. Still deeper soil between that zone and the woody plants is dominated by perennial grasses along with some *Senecio tomentosus*. Credit: R. S. Boyd.

those that build up in desert soils from evaporative concentration of relatively freshwater (e.g., the Great Salt Lake of Utah). Extensive irrigation of land in regions where there is high evapo-transpiration can also lead to accumulation of salts on the soil surface (i.e., secondary salinization). Salty soils (e.g., saline, sodic, saline-sodic soils) can impact plant growth by affecting water uptake, nutrient uptake or by causing toxicity due to specific ion effects. Water uptake can be slowed because the high ion concentration in the soil impedes water movement into plant roots. Nutrient uptake can be affected because ions can competitively inhibit the uptake of essential ions of similar size (e.g., Na^+ vs. K^+, Mg^{2+} vs. Ca^{2+}). Excess ions can also have specific toxic effects on plants by directly inhibiting essential physiological processes.

The Edaphic Factor in Ecology

Given the importance of soil features to plants, the edaphic factor's influence on plant ecology and evolution is unsurprising. In particular, soils with unusual features (extreme pH, nutrient imbalances, limited depth, etc.) may be a strong selective force shaping plant evolution. The floras of many unusual soils (serpentine soils, limestone soils, etc.) have at least some taxa that are found only on those soil types, whereas other species may evolve locally adapted populations (ecotypes, races, etc.). In many cases such taxa or populations have evolved in response to particular features of those soils. In other cases, unusual soils may be refugia for taxa that are unable to compete with species that dominate "normal" soils.

The ability of soils to affect ecology or evolution of organisms other than plants is less well known. It is also less likely for many animals, in part because their mobility and aboveground lifestyle render them less influenced by the various properties of soils. One soil feature that in specific cases has been shown to directly influence animal evolution is soil color. In habitats with little vegetation, such as deserts and beaches, the color of some animals has evolved to match the color of the soil. For example, white gypsum dunes, for which the White Sands National Monument in New Mexico is named, host a number of animals that are notably lighter-colored than those living on darker surrounding soils. These animals include

Fig. 2 The Ni tolerant insect *Melanotrichus boydi* (Heteroptera: Miridae) on a flower of its host plant, the California Ni hyperaccumulator *Streptanthus polygaloides* (Brassicaceae). The plant is found only on serpentine soils in California, and the insect is found only on *S. polygaloides*. The insect is tolerant of the high levels of Ni found in the plant tissues (usually >3000 μg Ni/g dry mass). The insects, about 5 mm long, contain about 800 μg Ni/g dry mass, enough to make them toxic to crab spiders that hunt for prey on flowers of *S. polygaloides*. Credit: R. S. Boyd.

insects, spiders, scorpions, lizards, amphibians, and mammals. The main selective advantage of this color matching is to provide camouflage that makes color-matched animals less likely to fall victim to predators. The evolution of burrowing and soil-dwelling animals is more likely to be influenced by soil properties due to the greater intimacy of their life histories with those soil features.

These direct effects of soils on biota are supplemented by a variety of indirect ways that soils may influence either animals or plants by affecting organism interactions. This is easily imagined when one considers the importance of plant communities in providing habitat for animals and other organisms. There are several intriguing cases of special plant–insect interactions under extreme edaphic conditions. Some plants endemic to heavy metal-rich serpentine soils harbor unique insect herbivores that are specialized to deal with the high metal concentrations found in the plant tissue (Fig. 2). It is rare to find cases in which the effects of soil on other organisms indirectly affect plants, but this does occur. For example, pocket gophers tunnel through soil and consume aboveground, and especially belowground, plant parts. In mountain meadows of Arizona, aspen trees suffer significant gopher-caused mortality on deep meadow soils but not on rocky outcrops where pocket gophers do not occur due to the lack of soil deep enough for them to make tunnels.

Soils and Biogeography

Landscape ecology is a subfield of ecology that examines the patterns and interactions between communities that make up relatively large areas. At this level of ecological scale, the pattern of soil types on a landscape may have important ecological consequences. One of these consequences is diversity (species richness, evenness). In a sense, patches of one soil type in a matrix of another are like islands in the sea (Fig. 3), and thus can be subjected to the ideas of Island biogeography. Island biogeography holds that the number of species present on an island is primarily determined by the size of the island and by its distance from sources of colonists. Thus, relatively small patches of unusual soils (i.e., edaphic islands) that are far from similar patches would be expected to have fewer species than large patches close to other areas of similar soils. This has been confirmed by recent studies of the flora on patches of serpentine soils in California.

Soils and Invasive Species

Invasive species are non-native species that become abundant enough to cause significant negative effects on some native species or the function of native ecosystems. Because soils are an important factor of the environment of organisms, it is no surprise that soil features can affect the ability of non-native species to become invasive. In many cases, disturbance of native communities (including changes in soils caused by disturbance) provides inroads for invasive species. Some studies have contrasted the susceptibility to invasion of unusual soils (such as serpentine soils) and more normal soils. The general conclusion is that the features of the unusual soils that make them challenging for plant growth often inhibit the invasiveness of non-native species. Anthropogenic activities can directly influence soil chemistry of some unusual edaphic habitats making such habitats conducive for colonization by invasive species. This appears to be the case for atmospheric nitrogen deposition on serpentine sites in California. Recent studies suggest that vehicle emissions along major highways in California may have increased the nitrogen content in serpentine soils. Non-native species, previously excluded from such soils due to nitrogen limitation, could potentially invade these unique habitats.

Fig. 3 Edaphic islands of serpentine outcrops in the Klamath Siskiyou Mountain range in northern California. The relatively barren serpentine outcrops (bare patches with reduced vegetation cover) are embedded in a mosaic of other geologies more favorable for plant growth. Credit: N. Rajakaruna.

It is common for invasive species (particularly plants) to impact soils and, through changes in soil characteristics, affect other organisms in those communities. For example, in northwestern US, diffuse knapweed (*Centaurea diffusa*; Asteraceae) has a direct soil-mediated impact on competing native plants. This invasive plant produces 8-hydroxyquinoline, a chemical that builds up in soils occupied by *C. diffusa* and poisons native plants growing in those soils. Invasive animal species have also been shown to alter soil features that then impact many other organisms in a habitat. For example, earthworms are not native to the forests of Minnesota but have been introduced in many locations. By consuming soil litter and accelerating its breakdown, these animals increase soil compaction, decrease water penetration, and change the nature of the litter layer habitat in ways that reduce its suitability for some native animals, herbaceous plants, and tree seedlings.

Plant Life on Selected Edaphic Conditions

Unusual edaphic conditions harbor unique plant associations often characterized by rarity and endemism. Such conditions also foster distinct morphological and physiological modifications leading to characteristic plant communities. One of the most remarkable edaphic habitats in which such unique plant communities are found is on serpentine soils derived from ultramafic and related rocks (i.e., rocks high in iron and magnesium silicates). Ultramafic rocks such as serpentinite and their associated serpentine soils are found throughout the world, concentrated, however, along continental margins and in regions of orogenesis (i.e., mountain building). Serpentine soils are unique in that they are often high in pH and heavy metals such as magnesium, nickel, and chromium, and generally low in essential nutrients, Ca/Mg ratio, and water-holding capacity. The rocks are often on open, steep slopes exposed to high light and heat conditions, and resulting soils are generally shallow and highly erodable (**Fig. 4**). The serpentine syndrome, the unique biological effects manifested by these extreme geoedaphic conditions, has led to research on plant physiology, ecology, and evolution in many parts of the world. Serpentine soils, although covering a mere few percent of the Earth's surface, host many endemic species. In the Californian Floristic Province, for example, 198 out of 2133 taxa endemic to that province are wholly or largely restricted to serpentine. Tropical islands of New Caledonia and Cuba provide even better examples of plant restriction to serpentine soils. In New Caledonia, 3178 taxa, roughly 50% of the native flora, are endemic to serpentine soils while in Cuba, 920 species, one-third of the taxa endemic to Cuba, have developed solely on serpentine soils. Similar restrictions and remarkable floristic associations are also found in serpentine areas of the Mediterranean, Africa, Australia–New Zealand, and Asia. Studies of metal hyperaccumulators (i.e., plants that accumulate at least 0.1% of their dry leaf weight in a heavy metal) of serpentine soils have not only led to the discovery of novel physiological pathways and their underlying genetic bases but have also laid the foundation for the development of innovative technologies such as phytoremediation (i.e., the use of hyperaccumulators to extract heavy metals from contaminated soils).

Gypsum ($CaSO_4 \cdots 2H_2O$), a substrate formed by the evaporation of saline waters, is also widely known for its distinctive indicator flora. The plant response to gypsum (gypsophily) manifests itself as unique communities consisting of gypsophilic endemics. While gypsum-associated plant communities are found in parts of Europe, deposits in xeric areas of the American southwest and adjacent Mexico are especially noted for their unique species composition.

Limestone forms by precipitation and lithification of $CaCO_3$, also leads to the formation of unique plant communities. In fact, some of the earliest observations on edaphic-plant relationships were made on landscapes overlying limestone and, by the late twentieth century, studies of limestone plant ecology had yielded a plethora of published work in both North America and Europe. Limestone and associated materials such as dolomite ($CaMgCO_3$) have exerted a profound influence on regional floras across the world resulting in unique vegetation compositions. Of interest are those temperate formations found on the White Mountains of

eastern California, Mount Olympus of Greece, the European Alps, and tropical formations of Jamaica, Cuba, Turkey, and parts of Asia.

In addition to habitats formed on geologies with extreme chemical composition, other edaphically influenced habitats, such as savannas, barrens, guano-rich bird nesting rocks, coastal bluffs, alkaline flats, and vernal pools are also important sites that harbor unique communities of plants and animals.

Evolution Under Extreme Edaphic Conditions

Plant species or distinct populations belonging to certain species can often be distinguished by their faithfulness to particular edaphic conditions (Fig. 5). Plants that grow on chemically or physically extreme substrates are often derived from populations found off such substrates, suggesting the role extreme soil conditions can play in generating plant diversity. Influential work conducted during the mid-twentieth century on the grasses of heavy metal-contaminated mine tailings provides a classic demonstration of the role natural selection plays in maintaining diversity. This work, and subsequent work on many plant species, demonstrate that populations can evolve tolerance to extreme edaphic conditions and that this may lead to reduced gene flow between the ancestral population and the divergent, edaphically specialized, population. Such reproductive isolation, followed by further divergence, sets the foundation for the origin of new plant species. Plants that have either evolved in situ (i.e., neoendemics) or those that have had broader distribution but are currently restricted to extreme substrates (i.e., paleoendemics) are called edaphic endemics. While most plant species can be found under a range of edaphic habitats, it is these edaphically specialized taxa and their ancestral species that have attracted the attention of plant physiologists and evolutionary ecologists alike.

Edaphic endemics provide a model system to examine the process of plant evolution from adaptation and reproductive isolation to genetic divergence. Closely related species pairs are often distinguished by their distinct edaphic preferences. Such pairs can be found on adjacent yet contrasting soils formed naturally due to variation in parental rocks or by anthropogenic acts such as quarrying, mining, and even depositing of chemical waste in landfills. The process of divergence might proceed as follows: some individuals of a species have genetically determined traits that allow them to successfully survive in adjacent, chemically harsh soils. These individuals could become founders of a distinct population characterized by their tolerance to the extreme edaphic condition. Such a transition to a new habitat, if accompanied by a reduction in gene flow, can bring about full-fledged speciation. Evolution of tolerance to extreme conditions can occur quite rapidly, even within a few generations. Current phylogenetic analyses provide strong support for rapid evolution of edaphic specialists as recently illustrated for the species pair *Layia glandulosa–L. discoidea* (Asteraceae).

Conservation of the Biota of Extreme Geologies

Habitats on extreme geologies, from natural outcroppings of serpentine rocks to barrens resulting from anthropogenic activity, harbor unique species assemblages. Unfortunately, ever-expanding agriculture and forestry, mining activity, and urbanization have drastically affected the biota of many areas with unusual geologies. Plants associated with heavy-metal-rich geologies (i.e., metallophytes) are not merely biological novelties: they are the optimal choice for the restoration of metal-contaminated sites across the world. Phytoremediation is a growing field that uses metal-hyperaccumulating plants in the remediation of metal contaminated sites. The raw material for such endeavors comes from species found on extreme geologies such as serpentine

outcrops, pointing to an immediate need for the conservation and detailed study of these habitats. Fortunately, recent years have seen the declaration of several preserves, set aside primarily due to their unique edaphic habitats and associated biota. Although they are spotty in their distribution and inadequate in number on a global scale, several preserves in the states of California, Oregon, and Washington, in the Province of Québec in eastern Canada, and in New Zealand and South Africa, have led the way in raising awareness of the immediate need for the conservation of these unique biotas. There has also been an urgent plea from those associated with research on metallophytes, advocating the prioritization of future research needs for the conservation of metallophyte diversity as well as the sustainable uses of metallophyte species in restoration and remediation of contaminated sites worldwide.

Endotherm☆

Marta K Labocha and Jack P Hayes, University of Nevada, Reno, NV, United States

What Is an Endotherm?

All organisms break complex molecules into simpler molecules, thereby obtaining energy to sustain life. This energy is used to transport ions, pump blood, move the body, and many other functions. Energy use ultimately leads to the production of internal heat. Endotherms are capable of producing sufficient internal heat to elevate their body temperature (or part of their body) above environmental temperature. In contrast, ectotherms can not produce sufficient internal heat to elevate their body temperature above environmental temperature. Endotherms have higher energy use than similar-sized ectotherms; consequently, endotherms consume more of the production by the ecosystem than do similar-sized ectotherms. The ability to be an endotherm depends on the rate of internal heat production, the size of the organism, the degree of insulation, and environmental circumstances.

Many endotherms, such as mammals and birds, elevate their entire body temperature above the environmental temperature. In other cases, endothermy is regional, such that only some parts of the organism (e.g., the brain or locomotor muscle of tuna or the flower of plant) are heated above environmental temperature. In some organisms, endothermy is not continuous but occurs only periodically or during particular activities. For example, brooding pythons heat their body only while incubating eggs, and insects elevate temperature of their active flight muscles only prior to and during flight.

In the older literature, the term endotherm was sometimes used interchangeably with the term homeotherm, but this usage is incorrect. Homeotherms are organisms that maintain relatively constant body temperature. In contrast, organisms whose body temperature varies substantially (generally tracking the environmental temperature) are called poikilotherms. Generally mammals freezing point of pure water). These fishes are homeotherms because their environmental temperature is relatively constant, not because they are thermoregulating. On the other hand, some, but not most, mammals and birds are heterothermic. That means their body temperature varies over a wider range than is typical for homeotherms (but it does not necessarily track environmental temperature as in poikilotherms). This variation in body temperature may occur over short timescales, such as nightly torpor in bats and hummingbirds or the rather variable body temperatures of some mammals, such as the egg-laying echidna. Variation in body temperature of birds and mammals may also occur over seasonal timescales, for example, as is seen in bears and ground squirrels. Animals that regulate their body temperature in the face of changing environmental temperature are called thermoregulators (**Fig. 1**). Thermoregulation and birds are homeothermic while most other animals are poikilothermic, but this is not always the case. For example, some Antarctic ice fish have body temperatures that show extremely little variation (and are below the can be accomplished physiologically by altering rates of heat production or heat loss. Animals may also thermoregulate behaviorally by selecting warmer or cooler microenvironments. Animals whose body temperature tracks the environmental temperature are called thermoconformers (**Fig. 1**).

Two other common terms in thermal physiology are cold blooded and warm blooded. These terms are no longer widely used by biologists because they convey little useful information beyond the temperature of an animal (or its blood). For example, animals may be cold blooded at one time and warm blooded at another depending on their thermal environment. Many reptiles have high body temperatures (i.e., are warm blooded during the day) when the thermal environment is hot, but they may be cold blooded when the thermal environment is cold (e.g., at night or during winter). Similarly heterothermic birds and mammals may be warm blooded during some parts of the diurnal or annual cycle and cold blooded at other times.
