Toxic effect on organs and organ systems is another major theme in classical toxicology that also has a role in ecotoxicology. Organs can be targets of toxicant effects as in the case of the liver cancer mentioned above or can be routes of toxicant entry into the body as in the case of the integument, breathing organs, and digestive tract. Contaminant effects on organs and organ systems are diverse. For example, pyrethroid pesticides modify essential ion exchange across amphibian skin. Alternatively, exposure to low pH or high metal concentrations impact fish gills in such a way that normal ion and gas exchange are altered. In other cases, some contaminants (i.e., teratogens) can cause abnormal organ development. In aquatic biota, a large number of studies have revealed a broad range of pesticides representing a variety of chemical classes to induce embryotoxicity and teratogenicity in nontarget fish, amphibia, and invertebrates, which result in organ malformations, delayed hatching, growth suppression, and embryonic mortality. For example, fish embryos develop cardiovascular abnormalities if exposed to high concentrations of PAH. Other contaminants compromise immunological competency, increasing susceptibility to infection. These examples represent only a few of the possible organ or organ system effects of contaminants on nonhuman species.

An issue attracting considerable attention at the moment is the ability of some environmental contaminants to modify endocrine functions such as those essential for sexual development and viability, or optimal metabolic activity. For example, the presence of the antifouling paint constituent, tributyltin, caused pervasive imposex (imposition of male features such as a penis or vas deferens on females) in whelk populations along the English and Northeast Pacific coasts. Contaminants that act as estrogen include DDT and its replacement, methoxychlor; nonylphenol from surfactant and detergent synthesis; and synthetic hormones from birth control pills that enter waterways from sewage treatment plants. Still other endocrine disruptors such as ammonium perchlorate from military munitions disrupt thyroid function. Exposure studies at this level of biological organization emphasize target organs.

Some organs or organ systems are more prone to toxic impacts due to their close contact with environmental media, location relative to blood circulation, or specific function. In the classic example, the gills of aquatic organisms are often target organs for dissolved contaminants because of their intimate contact with the surrounding water. The liver or analogous organs in invertebrates are often sites of harmful effects because of their prominent detoxification function, that is, the liver cancer noted above in English sole was caused by contaminant activation during phase I reactions in the liver.

Whole Organism

Effects to individuals are used to make inferences about contaminant impacts on individual fitness, and indirectly, on populations and communities. The most commonly measured qualities are mortality, development, growth, reproduction, behavior, physiology, and bioenergetics. Lethal effects are measured under different exposure scenarios. These effects might be measured during acute (4 days or shorter) or chronic (longer than 10% of an individual's lifespan) exposures. Especially, the critical effect concentrations

are the most common indicators to quantitatively assess risks for species exposed to contaminants. Three types of critical effect concentrations are classically used: lowest/no observed effect concentration (LOEC/NOEC), x-percent lethal concentration (LCx), and no effect concentration (NEC) lethal effects might also be measured for contaminant exposure via different media such as water, air, food, and sediment. Most are studied in the laboratory in such a manner that physical, chemical, and biological factors influencing response to exposure are controlled. Therefore, mortality predicted for a particular exposure concentration might not completely describe the mortality that would occur in the field where exposed individual must successfully forage, compete with individual of other species, avoid predators, and interact with individual of the same species in order to remain alive. Exposure studies that involve whole organism emphasizes bioaccumulation, the net accumulation of contaminant in an organism from water, air, or solid phases of its environment.

The thematic areas of its current employment in the evaluation of genetic toxicity are vast, either in vitro or in vivo, both in the laboratory and in the environment, terrestrial or aquatic. Genetic toxicity techniques have been applied to a wide range of experimental models: bacteria, fungi, cells culture, arthropods, fishes, amphibians, reptiles, mammals, and humans. Furthermore, there is a significant species difference in the spectrum of toxicity observed, for example, the LD_{50} for acute TCDD exposure varies from 1 $\mu g\ kg^{-1}$ in the guinea pig, 20–40 $\mu g\ kg^{-1}$ in the rat, 114 $\mu g\ kg^{-1}$ in the mouse and rabbit, and 5000 $\mu g\ kg^{-1}$ in the hamster. The diversity of AhR pathway genes and the species difference of the complicated regulation process of toxicology in different animals may throw light on the history of early molecular evolution. Fishes are clearly the most utilized group, reflecting their popularity as bioindicator models, as well as specific concerns over the aquatic environment health. Amphibians are among the most sensitive organisms to environmental changes, mainly due to an early aquatic-dependent development stage and a highly permeable skin. Moreover, in the terrestrial approach, earthworms, plants or mammalians are excellent organisms to be used as experimental models for genotoxic evaluation of pollutants.

Population

Most of the experimental testing in ecotoxicology takes place at the individual level, but the protection goals for environmental risk assessment are at the population level (or higher), population modeling can fill this gap. But only models on a mechanistic basis allow for extrapolation beyond the conditions in the experimental tests. The life-history traits of individual form the basis of population dynamics, and population modeling thus requires a detailed understanding of the individual's behavior. The dynamic energy budget (DEB) model offers a flexible platform for the development of model at the individual level. Applying DEB model to population model can provide a mechanistic basis for extrapolation. Some of these pesticide effects at the population level have at most been plausible linked to subindividual or individual effects by the application of Bradford-Hill's criteria of causation. For example, in birds, population effects of pesticides have been linked to neurotoxicity and endocrine disruption. It is well known that DDT and its metabolite DDE had a devastating effect on many bird species due to a reduction of eggshell thickness of up to 90% and consequently, cracking. Additionally, a growing number of ecotoxicologists study population-level effects directly. Such studies emphasize vital data such as birth, death, stage change, or migration rates. Demographic models based on vital rates improve our ability to project consequences such as a drop in the population growth rate or increase in local population extinction risk. Some population studies treat the population as one in which individual is uniformly distributed in the area of interest but others consider the population as a metapopulation composed of subpopulations inhabiting habitat patches of different qualities, including varying levels of contamination. The differences in vital rates, including exchange rates among patches, are used to project contaminant exposure consequences. With metapopulation models, effects at a distance from a contaminated patch can be explored. For example, a population member can be exposed in one patch yet the effects might manifest in an uncontaminated patch after migration.

Community

Community ecotoxicology explores the consequences of contaminant exposure of and movement of contaminants within ecological communities. The majority of such studies are field studies either addressing scientific questions or applying knowledge to assess risk or define remediation action for a contaminated system. Like the biomarkers applied at lower level of biological organization, bioindicators are applied by community ecotoxicologists. Bioindicators might be particularly sensitive species whose absence suggests an adverse impact. A community metric such as species richness, evenness, or diversity might also be used as an indicator of an adverse exposure consequence. Any study in which biological systems are applied to assess the structural and functional integrity of ecosystems is referred to as a biomonitoring study. Exposure within communities is often explored in the context of contaminant trophic transfer. Depending on its properties, a contaminant can increase (i.e., biomagnification), decrease (i.e., trophic dilution), or not change in concentration with progression through a food web. For example, the most detrimental effects of herbicides in aquatic systems stem from the reduction of the complexity and structure of the plankton and the submerged vegetation, including periphyton. These algae and plants all act as food sources and refuges for phytophagous species such as water birds and amphibian tadpoles. Furthermore, Species of higher trophic levels, such as salmon, are most likely to be affected in population growth and productivity by indirect pesticide effects.

Additionally, contaminants such as methylmercury or persistent organic pollutants (POPs) such as DDT biomagnify. Biomagnification can lead to adverse consequences to higher trophic level species such as the raptors and other piscivorous birds. Studies of

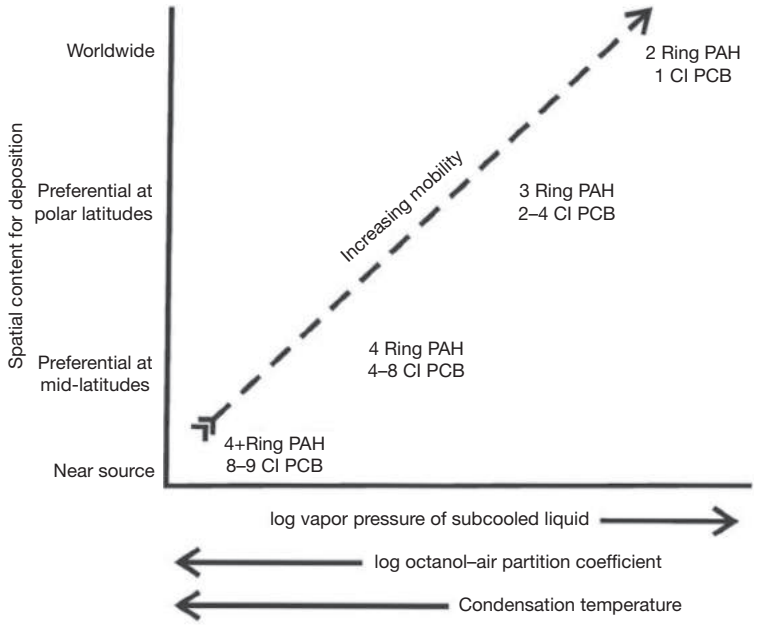

Fig. 4 Global movement of a POP is determined by several qualities including its (subcooled liquid) vapor pressure and condensation temperature which, together, determine its tendency to move into and remain in the atmosphere. A more volatile compound will be transported more by atmosphere movement than one that is less volatile. Its condensation temperature influences the latitudinal limits to which it might move. The octanol–air partition coefficient is also important because it reflects the POP's tendency to remain associated with the solid and liquid phases of the Earth versus the atmosphere. Here, polycyclic aromatic hydrocarbons (PAHs) with different numbers of aromatic rings and polychlorinated biphenyls (PCBs) with different numbers of chloride atoms are used to illustrate trends for global deposition of POP. This biospheric process is called global distillation.

food webs including omnivorous members require a measure of trophic status for species. A convenient measure of trophic status is provided by the nitrogen isotopic fractionation that occurs with each trophic exchange.

Ecosystems

Ecosystem-level studies vary widely in their spatial and temporal scales. Often ecosystem modeling techniques are applied to an easily definable ecosystem such as a contaminated lake or watershed. Fate and movement of contaminants are then modeled by computer or measured in extensive sampling programs. Larger-scale studies are required for contaminants prone to wide spatial dispersion via atmospheric transport. This category includes contaminants like mercury from coal power plants or contaminants used widely by society such as atrazine, an herbicide applied in the North American Corn Belt. For example, the results of mass-balance ecosystem model by Ecopath with Ecosim (EwE) approach suggested that salmon inputs specifically control PCB concentrations in stream-resident fish whereas Hg concentrations are more strongly influenced by diffuse background sources, and there exists species-specific differences in diet and growth, along with trophic pathways, can influence the magnitude of contaminant impacts by spawning salmon.

Often geographical information system (GIS) and remote sensing technologies are essential in these types of studies. In still other instances, a global perspective is required to adequately grasp the ecotoxicological consequences of contaminants. Current global issues are ozone depletion in the stratosphere due to chlorofluorocarbon (CFC) release, global warming due to greenhouse gas emissions, and global movement of persistent organic pollutants (Fig. 4). More and more frequently, large-scale issues are emerging as critical ones in ecotoxicology.

Current Trends in Ecotoxicology

A working knowledge of the movement and effects of environmental contaminants is recognized worldwide as essential to maintaining an acceptable quality to life. Ecotoxicology has emerged as the applied science that addresses the central issues of contaminants in the biosphere. Major challenges in this young science include the following: (1) the integration of causal explanations and knowledge arising at different levels of biological organization into a coherent whole; (2) integration of scientific, technical, and practical goals of ecotoxicologists; (3) consideration of ecotoxicological issues at increasingly wider spatial and longer temporal scales; (4) transformation from high-dose into low-dose effect; (5) the toxic effects of mixtures of contaminants; (6) the specify, effectivity and sensitivity, of biomarkers; (7) standardize experimental conditions in ecotoxicology; (8) "Omics" and bioinformatics in (eco)toxicology. Additionally, general improvements in technology are needed to develop the research of ecotoxicology.

Endangered Species

P Kareiva and J Floberg, The Nature Conservancy, Seattle, WA, USA

Introduction

Biologists are concerned that the world is facing an extinction crisis, in which a large fraction of the Earth's species will disappear by 2100. The passenger pigeon, which numbered in the billions and was once the most abundant bird in North America gradually went extinct under our watch, with the last individual dying in the Cincinnati zoo in 1919. The Northern Right whale, once one of the North Atlantic's most important marine species, now numbers only 200–300 individuals, and the death of just one female is newsworthy. Although scientists agree that an unprecedented number of species are at risk of imminent extinction, and that the rate of biodiversity loss rivals the great extinction events of geological history, the science of extinction faces several big unknowns. Most notably, although scientists have named and described about 1.75 million species, they have still barely scratched the surface of Earth's total biological diversity. In fact, about 15 000 new species are described each year, and these discoveries are not limited to obscure or small-bodied groups – for example, a new species of large mammal is discovered approximately every three years. Clearly, it is hard to know how many species are going extinct when we do not even know how many species there are. It is not surprising then that estimates of extinction rates vary by an order of magnitude, ranging from lower than 10 species lost per day to over 100 species lost each day.

Even though quantifying global extinction rates is highly uncertain, we have a good understanding of what factors are likely to make a species endangered. Moreover, as nations have become alerted to the extinction crisis, international institutions and governments around the world have started to identify endangered species (species at risk of going extinct in the near future) and many countries have laws that afford special protection to these at-risk species. Our scientific understanding of species at-risk or endangered species comes from four main arenas: (1) our theoretical understanding of the population biology of small populations, (2) statistical studies relating the number of resident species to habitat availability and geography, (3) monitoring and tracking of endangered species in the United States, which was the first country to pass a law protecting endangered species and has since accumulated over 30 years of data on its endangered species, and (4) global lists and analyses of endangered species compiled by the International Union for the Conservation of Nature and Natural Resources (IUCN). If we can develop a predictive science of endangered species, then there is hope of avoiding the demise of the thousands of at-risk species currently on the brink of extinction throughout the world.

Predicting Future Extinction and Factors That Make Species Endangered

Dramatic statements regarding the loss of biodiversity have become commonplace in both the scientific literature and the popular media. However, if you look closely at these claims, you will see that, although they are consistently pessimistic, they do not seem to agree about exactly how bad the current extinction crisis is. Estimating extinction rates is complicated and involves a series of assumptions and educated guesses. Rather than attempting to count actual extinctions, most researchers use indirect methods to estimate extinction rates. Habitat destruction is widely considered to be the major cause of extinction and endangerment of species. Unlike other major causes of endangerment, such as pollution, exploitation, introduced predators, and disease, habitat destruction (typically deforestation for the terrestrial environment) is relatively easy to quantify over vast land areas using satellite imagery. Given an estimate for the rate of habitat loss, researchers might then ask `how many species are expected to become extinct with each million hectares of habitat destroyed?' To answer this question, one must know something about the relationship between habitat area and species diversity. Species–area curves show the relationship between the diversity of species and the physical size of an island, habitat patch, or sampling space. The general pattern is that species initially accumulate rapidly as area increases, but the rate at which new species are added gradually declines, until eventually all of the species present in a region are accounted for. This saturating relationship between diversity and area is one of the most robust patterns in all of ecology. Species–area curves have been successfully applied to many different taxa in a wide variety of settings and terrestrial habitats. The implication of the general shape of this relationship is that there will initially be few consequences of habitat destruction (i.e., a small percent of species will become extinct), but as the process continues and more and more habitat is destroyed, the impact on biodiversity becomes more extreme (**Fig. 1**). The relationship between species diversity, S, and area, A, is described by the equation

$$S = cA^z$$

where c is a constant reflecting the number of species in a habitat of area A, and z is the rate of species accumulation as A increases. Estimates of z are crucial if one wants to predict the impact of habitat destruction on diversity. Larger z values are typical of true oceanic islands and for species with relatively limited movement, while smaller values are common for virtual islands that really are areas embedded within a continuous landscape (such as parks surrounded by agriculture) and for highly mobile species.

 doi:10.1016/B978-0-444-63768-0.00487-X

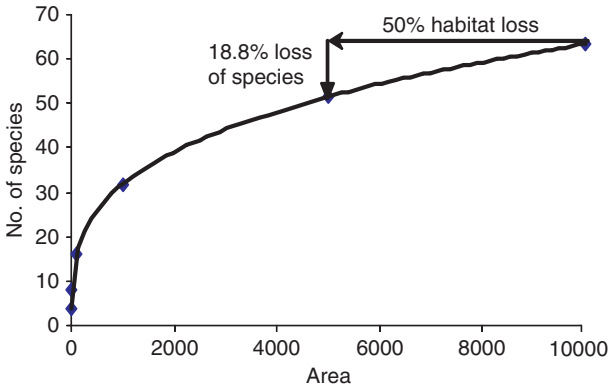

Fig. 1 A species–area curve ($S=cA^z$), where S is the number of species in habitat of area A, and c and z represent constants that depend on the type of species being considered and the type of habitat involved. In the curve shown $c=4$ and $z=0.3$. Using such a curve, one can estimate extinction of species associated with any fraction of habitat loss.

Although we may not be sure of the value of z in the species–area curve, the idea that habitat conversion or destruction causes loss of species is well-documented. This means that even without having data on particular species, ecologists can anticipate that species associated with particular habitats will be endangered if too much habitat is lost. For example, even though there are not counts of plants and animals declining where forests are logged, we can still be sure that some of the forest residents are endangered by habitat loss. The mechanism by which habitat loss endangers species is reduction in population size. If there is less habitat for a species, then that species must have fewer individuals. A small population size endangers a species for several reasons which we discuss below. But first it is worth recognizing that the tendency to use the phrases `habitat loss' and `habitat destruction' can be misleading. Habitat does not disappear – it is converted to a different type of landscape, such as farmland or logged forests with remnant patches of woodland left standing. Historical deforestation events have generally not produced the magnitude of extinction one would expect from a simple application of species–area curves. Between 90% and 99% of Puerto Rico was logged, yet only 10% of the resident terrestrial bird species in that forested habitat went extinct. Similarly at least 90% of the forests in eastern United States were logged, yet only three forest-dwelling birds went extinct. Although these percentages are qualified by the awareness that we have only recently been able to adequately track whole taxa such as birds for extinctions, it is still true that the risk of extinction can be tempered by the quality of converted habitat, which may not always be as uninhabitable as a species–area curve implies.

Population size is the best indicator of a species' endangerment. First, small populations are at greater risk of extinction because they are more susceptible to chance misfortune such as failing to mate successfully or to survive a winter in spite of there being an average likelihood that individuals in the population should succeed. For instance, if we flip a coin 100 times we will probably get roughly 50 `heads' and 50 `tails'. But if we flip a coin only ten times, there is a greater chance of getting a more lop-sided result, such as 10 `tails' – and if tails meant a chance death, then clearly a small population size is a great disadvantage. These effects are referred to as demographic stochasticity and usually apply to populations of reproductive females substantially less than 100. Of course, environments fluctuate due to droughts, heat waves, or unusually harsh winters, and species we normally think of as being much more numerous than 100 can be driven to unusually low numbers by temporarily poor environmental conditions, and then become at risk of extinction due to demographic stochasticity. Mathematical models of population extinction in fluctuating environments suggest that populations smaller than 1000 are likely to be at substantial risk because of a combination of fluctuating environments and demographic stochasticity. A second unfortunate attribute of small populations is that they usually occupy small areas. Any time a population is restricted to a small area it is at risk of being exterminated by one catastrophic event such as a wildfire or a large flood.

For some species there is a positive feedback whereby a decline in population size also causes a predictable (as opposed to chance) decline in survival or reproductive success of the remaining individuals. When reductions in population catalyze further population decline, it is called an Allee effect. Allee effects can occur in certain species that experience difficulty in finding a mate when at low density. Imagine, for example, the difficulties that a whale might have in finding a mate if there are only a few hundred whales left throughout an enormous ocean. One reason the Northern Right whale is not recovering, even though all hunting on it has been halted, is that mates cannot locate one another in the vast ocean. Allee effects have been well documented in certain small populations of plants that rely on insect pollinators such as bees. Bees often specialize on visiting abundant plant species because they can more efficiently gather pollen and nectar if they keep visiting the same common flower; as a result a plant species that becomes too scarce may be neglected by pollinators and hence fail to reproduce. Allee effects can also arise when social interactions become impaired at low population size. For example, animal species that rely on cooperative group hunting may be incapable of bringing down large prey if the group becomes too small.

Lastly, small population size can imperil a species because of genetic effects. Individuals in small populations may have no choice but to mate with related individuals. Mating with kin is called inbreeding, and inbreeding can severely reduce the survival or reproductive fitness of any offspring that are produced (a phenomenon called inbreeding depression). Inbreeding tends to

increase homozygosity because two related individuals are more likely to share the same version of a gene than are two unrelated individuals. Offspring that are homozygous for many genes may be worse off than individuals that are highly heterozygous for a couple of reasons. First, heterozygosity (having two different alleles for a particular gene) can be beneficial if the two alleles result in the production of two different versions of a protein. For certain genes, producing multiple versions of proteins can be correlated with greater physiological flexibility or improved immune system function. Homozygotes lose this advantage. Second, many harmful versions of genes are recessive or masked by the presence of a healthy version of the gene inherited from the other parent. But an individual that is homozygous for a harmful allele will express the genetic disorder. Examples of human genetic disorders caused by recessive alleles include cystic fibrosis, tay-sachs, and phenylketonuria. Both of these mechanisms can cause reduced fitness of inbred offspring, and reduced fitness of individuals will translate into reduced population growth and increased risk of extinction for the population as a whole.

Even in the absence of inbreeding, small populations tend to lose genetic diversity over time. Unique alleles (versions of genes) are lost due to genetic drift. Moreover, mutations, which are the source of new alleles, are rare and therefore fewer new alleles are generated in small populations. This loss of genetic diversity can be devastating to a population. Unlike natural selection, which increases the frequency of adaptive or beneficial alleles, genetic drift is completely random with respect to adaptiveness. In other words, either good or bad versions of genes may be lost, just by chance, and the odds of these random losses are higher when a population is small.

The rate at which genetic diversity is lost from a population does not depend on the total population size, but rather on what is called the effective population size. Effective populations are always less than the actual population because they refer to a concept called an ideal population. An ideal population is one with a 50:50 sex ratio, every individual being equally successful at mating and reproducing, and the same population size year-after-year. A population that departs from these ideal conditions has an effective population that is lower by an amount that is roughly proportional to the degree to which the ideal conditions are violated. Population genetics theory provides models for estimating effective population size given information on how a population departs from the ideal conditions. The reason the effective population size of any species is inevitably less than the numerical abundance of species is because sex ratios commonly depart from 50:50, the number of matings and offspring per parent is usually variable in wild populations, and populations in nature fluctuate. The important point is that species with small effective population size lose genetic diversity far more rapidly than species with large effective populations. Although small populations are always more at risk than larger populations, species that are represented by chronically small populations often do not show severe genetic inbreeding. These `naturally' and chronically small populations may have evolved mating systems and genetic mechanisms that have reduced inbreeding depression in comparison to large populations that are suddenly driven to low numbers by human activities. This distinction between chronically small populations and newly small populations is one reason that criteria for identifying which species are at risk typically factor in trends in abundance and recent declines in addition to population size.

When talking about endangered species it is important to note that anything that makes populations small imperils a species. Even if the cause of a species decline is halted because fishing or hunting has been halted, or the last remaining habitat is protected, a small population may still be doomed to extinction. Once populations shrink below a certain threshold level they enter an extinction vortex in which inbreeding depression, chance misfortune, disrupted social systems, and reduced genetic variability all conspire against their persistence and make the situation worse with each new generation. In those circumstances captive breeding may be the only hope. In short, small population size equals an endangered species, and declining populations can also equal an endangered species because prolonged declines will inevitably produce small populations. One key question is how small does a population have to be to be endangered? The answer depends on the mating system (do a few males get all the females? how uneven is reproductive success?) and rate of reproduction. Certainly any population below 1000 is at risk of extinction, and populations as high as 10 000 can be highly endangered if most of the individuals are males or too young or too old to reproduce.

Endangered Species in the United States

The USA was the first country to give endangered species legal status and in so doing helped define the science of endangered species. As early as 1964 the Department of Interior produced a list of 62 species at risk of extinction in the US. When the Endangered Species Act (ESA) was implemented in 1973 there were 392 endangered or threatened species on the list. The ESA itself defines endangered as a species "in danger of extinction throughout all or a significant portion of its range." Although the ESA does not give any population sizes or explicit scientific criteria, it is clear from the record of listings (when species are officially called endangered or threatened and afforded legal protection) that small population size is the dominant criteria. The median population size of species when listed is 1075 for vertebrates and 120 for plants. When one realizes that all of these individuals will not be capable of reproducing (e.g., too young, too old, cannot find mate), those population sizes are disturbingly low if one is to have hope of recovering the species so that they are no longer endangered. As of 2006, there are 1272 endangered and threatened species in the USA with a very uneven taxonomic distribution. The percentage of species in the US listed as endangered or threatened are by major taxa: 19% for mammals, 15% for fish, 12% for bird, 11% for amphibians, 8% for invertebrates, and 5% for plants.

When species are listed as endangered or threatened, the US government requires a description of the major threats that are placing the species at risk of extinction. By reviewing the listed threats for all the US species it is possible to arrive at an estimate of the major sources of endangerment. As expected, habitat destruction is by far the most widely identified threat, affecting

approximately 85% of all the species listed as threatened or endangered in the USA. Alien or introduced species is the second most common threat (affecting 49% of listed species), followed by pollution (24%) and overexploitation (18%). Notably underrepresented as endangered species in the US are marine organisms. Only 39 marine species (and many of these are fish such as salmon and steelhead that spawn in fresh water) are listed as threatened or endangered in the US. Only one of these marine endangered species is an invertebrate – the white abalone in California. The paucity of marine species that are listed under the ESA is not a reflection that marine organisms are not endangered. Rather marine organisms are more poorly known taxonomically, and population data are generally lacking. They are under water and hence their plight is less conspicuous than is, for example, a large terrestrial bird. Most biologists think that with further study we will find many marine species that are endangered – often because of habitat degradation and pollution.

Patterns of Endangerment at the Global Level

The most objective and authoritative information on global species rarity can be found in the IUCN Red List of Threatened Species, which was first conceived in 1963. The IUCN, also known as the World Conservation Union, is an international conservation network including over 10 000 scientists and 1000 organizations from around the world whose mission is to influence societies to conserve their natural diversity. Every 4 years, the IUCN hosts a World Conservation Congress, where the current status of global species rarity is scientifically evaluated in a Global Species Assessment that is based on the IUCN Red List of Threatened Species. The Red List, which currently lists 7181 endangered or critically endangered species, includes a regularly updated online database and represents an ongoing effort to track the status of all species. The Red List evaluation of species in terms of their risk of extinction falls into three steps. First a species is taken up for evaluation – to date only 38 047 species have been considered for evaluation. Of those species considered, some have to be dropped because the data are too scarce (roughly 10% of the species IUCN has attempted to evaluate have run into problems because of data scarcity). Obviously, the initial selection of which species to evaluate is also biased towards species that might be at risk – in no way is the selection of species random. If the data are adequate, then the third step is taken where each species is assigned to one of seven categories: extinct, extinct in the wild, critically endangered, endangered, vulnerable, near threatened, and least concern. Species at risk of extinction (defined by IUCN as threatened) include the three categories of critically endangered, endangered, and vulnerable. The criteria used to assign species to different risk categories are intended to be quantitative and objective, and to focus on data that could be realistically obtained if sufficient effort were made. Although the criteria in **Table 1** describe specific numerical thresholds between categories and appear to provide a data-driven way to assign rarity among species, caution is advised. One weakness of the approach is that the criteria do not reflect life-history variation or idiosyncratic natural history, and instead represent a `one size fits all' approach. In other words, the intent is that these criteria are to be used to evaluate all species, excluding microbes. However a population of 100 fruit flies has a much greater potential for recovery than a population of 100 sea turtles that do not reproduce until they are 20 years old. Also species differ greatly in how flexible or adaptable they are in their habitat – a small population size represents a much greater risk

Table 1 IUCN criteria to evaluate species for threatened status

	Critically endangered	*Endangered*	*Vulnerable*
A. Trend of loss in total numbers of mature individuals in a taxon[a]	$\geq$80%	$\geq$50%	$\geq$30%
B. Limited geographic range, based on either			
extent of occurrence[b]	$<$100 km^2	$<$5000 km^2	$<$20 000 km^2
area of occupancy[b]	$<$10 km^2	$<$500 km^2	$<$2000 km^2
C. Limited remaining individuals, based on either	$<$250 and 25% decline	$<$2500 and 20% decline	$<$10 000 and 10% decline
(i) numbers of mature individuals with decline	Expected in 3 years or one generation[c]	Expected in 5 years or two generations[c]	Expected in 10 years or three generations[c]
(ii) numbers of mature individuals	$\leq$50	$\leq$250	$\leq$1000[d]
D. Expected extinction rate in the wild based on quantitative study[e]	$\geq$50%	$\geq$20%	$\geq$10%

[a]Trend over a period of 10 years or three generations, whichever is longer (up to a maximum of 100 years). A greater percentage loss is required to be critically endangered, endangered, or vulnerable ($\geq$90%, $\geq$70%, and $\geq$50%, respectively) where threats to loss are clearly reversible and understood and have ceased.

[b]Also require at least two of the following: severe fragmentation/few locations, continuing decline, or extreme fluctuations in numbers.

[c]Criteria are still satisfied for C (i) with any continuing decline if each subpopulation has few individuals, if there is a high percentage of the total number of individuals in any one subpopulation, or if there is an extreme fluctuation in numbers of mature individuals.

[d]Vulnerable status also requires the area of occupancy to be less than 20 km^2 or number of locations $\leq$5.

[e]Trend over a period of 10 years or three generations for critically endangered status, 20 years or 5 generations for endangered status, and for all categories within 100 years maximum.

A species is critically endangered, endangered or vulnerable by meeting at least one of A–D in the appropriate column.

for an inflexible species than a generalist species with ample physiological and behavioral plasticity. The implications of life-history differences can become a focal point of debate about whether species should be listed or not. For instance, some marine experts have argued that certain decline criteria in **Table 1** do not apply to so-called resilient fish stocks which can be sustained at a tiny fraction of their precatch levels. Secondly, the numerical data likely embody huge uncertainties. Endangered species by their very nature are few in number and are often difficult to count and assess because they frequently occupy fragmented and/or impacted habitats and can be scattered over large areas. Moreover, analyses that are used to determine the expected population declines or probabilities of extinction for species are potentially misleading for species because data quality is often poor or population distributions are not well understood. There is a constant tension in developing the Red List between ensuring sufficient data are available to assign appropriate status and erring on the side of caution to list poorly understood globally endangered species so that they receive appropriate conservation attention (**Table 2**).

One of the biggest challenges in addressing endangerment is our limited ability to prioritize conservation actions because we have incomplete and skewed geographic and taxonomic knowledge. Assuming a conservative 10 million total species in the world, only a fraction have been described, a much smaller fraction described and evaluated for risk, and an even tinier fraction upon evaluation is judged to have enough data to make a risk determination (**Fig. 2**). In addition to not knowing much, what we do know is highly biased so that some taxa are much better studied than others; for instance, whereas nearly 40% of the known vertebrate species have been evaluated for rarity, less than 5% of the plants species have, and less than 1% of the invertebrate species have, and essentially no fungi have. Marine and freshwater species are also much less understood than terrestrial species. For example, though marine and freshwater areas cover more than 70% of the Earth's surface, only 6% of described fish species have been evaluated for rarity. Among the well-studied taxa where species are known and have been evaluated for risk of extinction, endangerment varies five to tenfold (**Fig. 3**). There is also a wide range of endangerment within taxa, with some classes being much more threatened than others. For example, amphibians stand out for having a rate of endangerment that is roughly twice that of mammals and four times that of birds. One reason for the vulnerability of amphibians might be their permeable skin which exposes them to pollutants and other environmental stressors, plus the fact that they typically require multiple habitats (aquatic and terrestrial) as opposed to just one habitat. If either their aquatic or terrestrial habitat has been lost or degraded they

Table 2 Definitions of threats used in IUCN Red List in order of importance[a]

Habitat loss/degradation	Human-induced land and/or water impacts associated with aqua/agriculture, logging, mining, land management, and infrastructure development
Intrinsic factors	Species specific factors that increase vulnerability such as limited dispersal, poor recruitment/reproduction/regeneration, high juvenile mortality, inbreeding, low densities, skewed sex ratios, population fluctuations, and restricted ranges
Harvest (hunting and gathering)	Reduction of species numbers for human use such as food, medicine, fuel, cultural, or scientific applications and materials for direct use or trade
Alien species	Invasive species directly affecting an endangered species through competition, predation, hybridization, and pathogens/parasites
Pollution	Land pollution, water pollution, and atmospheric pollution (including climate change). Pollution can be heat/cold, noise, light or chemical
Human disturbance	Impacts related to recreation/tourism, research, war/civil unrest, transport, and fire
Changes in native species	Changes in competitors, predators, prey/food base, hybridizers, pathogens/parasites, and mutualisms
Natural disasters	Includes storms/flooding, temperature extremes, wildfire, volcanoes, and avalanches/landslides
Other (accident, persecution)	Includes fisheries or terrestrial bycatch, collision with vehicles/buildings/pylons, and pest control

[a]Definitions are illustrative and may not include all conceivable examples for each category.

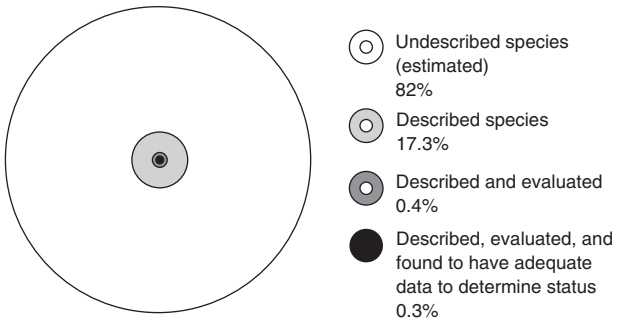

Fig. 2 The relationship between (hypothetical) total species and species that have been evaluated for globally threatened status. Only the bullseye area has been evaluated (0.3%) of a conservative total of 10 million species. In some rare cases (143), undescribed species were evaluated for threatened status where museum or herbarium collections were made and immediate listing would make some tangible benefit to those species' conservation.

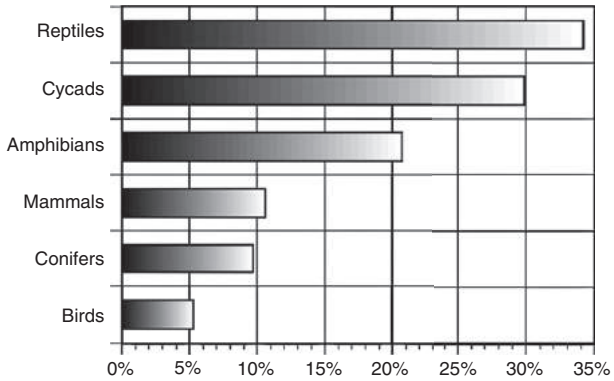

Fig. 3 The percentage of species that are classified as endangered or critically endangered by IUCN within taxa that have been comprehensively evaluated. Reptiles in this figure only include order Testudines, order Crocodylia, and family Iguanidae (~4% of all reptile species) and therefore may not represent the percentage of reptile endangerment as a whole.

will not be able to complete their life cycle. A handful of evolutionary lineages at the family and order level can be identified as especially endangered among mammals, amphibians, and birds. These higher-order evolutionary lineages with uniquely severe levels of endangerment include albatrosses, kiwis, carnivores, manatees, salamanders, and true toads.

Globally, the greatest source of endangerment is primarily habitat loss and degradation (Fig. 4); in fact, the next nearest risk factor after habitat loss is only one-fifth as frequent. The predominance of habitat loss as a source of endangerment provides the rationale for the widespread use of species–area curves in conjunction with deforestation rates to estimate global extinction in the terrestrial environment. Most terrestrial endangered species are in tropical rainforests, which parallels the fact most terrestrial species are in tropical rainforests. For well-studied taxa, one can ask how many endangered species are truly on the brink of disaster, which can be defined as those globally endangered species that are found at only one site. It turns out there are 795 such species spread among 595 sites in the world. If we were committed to zero extinction, these are the endangered species under imminent risk that would command our greatest attention. Whereas most extinction in the historical record has occurred on islands with their isolation and small population sizes, these contemporary imminent extinctions are increasingly in mainland areas where human activities have created isolated islands of habitat.

Ecology of Endangerment

Just as all individuals must die, all species eventually become extinct. However, the life spans of species are not random: some groups of species tend to have high rates of extinction and short life spans, whereas other groups have low rates of extinction. The risk of extinction is higher for some taxonomic groups than others. For example, within North America a high proportion of aquatic species are endangered. The factor most clearly related to endangerment is body size, where species with larger body size are more likely to become extinct. For example, the megafauna of North America, which included such species as the woolly mammoth, sabertooth cat, and the giant ground sloth, were lost approximately 8000 years ago. Analyses of extinction risk among families of birds showed that larger body size and lower fecundity were related to higher chance of extinction, and this remains the case today.

Another clear pattern is that species with small geographic ranges tend to be more prone to extinction. This is why many conservation efforts focus on endemic species – these are species whose distribution is limited to only one defined area (e.g., a country, ecoregion, or island). Depending on how small the geographic distribution is, an endemic species can be quite vulnerable to human perturbations because disruption over a limited area can lead to their extinction globally. Lastly, species with very specialized requirements are most likely to be endangered – largely because if something goes wrong with their diet, or habitat, they are unable to thrive in altered conditions. In sum, species with large body size, narrow geographic range, and specialized habitat or food requirements are more prone to extinction. The upshot of this is that as we accelerate the extinction rate, we will increasingly find ourselves in a world filled with small bodied, widely distributed, generalist species – science fiction projections of a world populated by rats, cockroaches, and gulls may not be far off the mark.

Discussion of extinction and endangered species often create an impression of hopelessness and despair. Fortunately, by paying attention to the science of endangered species, it is possible to take measures to recover species. Approximately 10% of the populations of threatened and endangered species in the USA are actually now increasing, and 30% are stable. Also globally, among species with a known trend, approximately 15% of the threatened bird species and 40% of threatened amphibian species have stable or increasing populations. In addition, several prominent species that were at one time endangered have in fact been recovered. The gray whale off the coast of California has now been restored to historical population levels thanks to a cessation of harvest. The American alligator may be an even more dramatic success story. This species was near extinction in the mid-twentieth century and now has a population of nearly a million in the US. Its source of endangerment was hunting for the skins and loss of

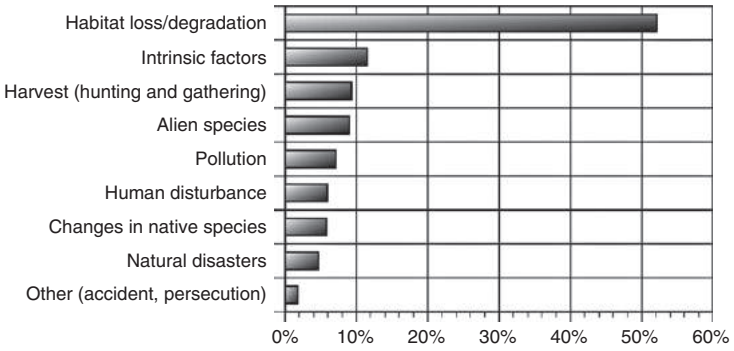

Fig. 4 The percentage of species that are classified as endangered or critically endangered for each IUCN threat category. Endangered species often suffer from multiple threats. Results are heavily biased toward amphibians, birds, and mammals, since threat data have only been comprehensively compiled for these groups. Definitions for threats are in **Table 2**.

habitat due to the draining of wetlands. With the abatement of these threats, the alligator population quickly recovered. In some cases Herculean captive breeding programs have rescued species from the brink of extinction. The Peregrine falcon had totally disappeared from eastern North America by 1964. A massive breeding program that drew on falcons from Europe, Australia, and South America yielded the release of 1300+ birds between 1974 and 2000. The reintroduction was so successful that these falcons are no longer considered endangered. If threats are abated and a species can be bred in captivity, then endangered species need not remain at risk forever.

There are also other reasons for optimism. Because habitat loss is understood to be the primary threat to species, many conservation-minded organizations and government agencies have shifted from a species to a habitat conservation focus. In the process they have secured larger areas where key ecological processes are more likely to remain intact, and larger populations of endangered species can potentially persist or develop. Recently, the rediscovery of the ivory-billed woodpecker in the Big Woods of Arkansas, USA was thought to be partially the result of previous efforts to conserve bottomland hardwood forests in the region. By preserving large habitat landscapes, we can overcome our lack of species knowledge, and thereby protect species we think we lost or do not even know exist. Beyond a habitat-based approach, our greatest scientific need when studying endangered species is likely to be more attention to evolutionary adaptability. Human impacts are so great and so rapid, that the best insurance against extinction will often be adaptability. It is unclear to what extent we can actually manage adaptability in endangered species, as opposed to simply having to work with the situation as it stands without any proactive efforts. Endangered species with ample genetic variability and behavioral plasticity may well be able to get through bottlenecks of low population size and recover from their at-risk status.

Invasive Plant Species☆

Beth A Middleton, Wetland and Aquatic Research Center, Lafayette, LA, United States

Glossary

Adaptation Change in the genetic structure of a population due to natural selection, which leads to an improvement in function in relationship to the environment.

Biological control The control of invasive species via enemies such as predators, parasites, herbivores or competition.

Diversity-resistance hypothesis Communities with high levels of diversity are less invaded by exotic species.

Ecosystem function/service Major processes and their interplay within ecosystems including primary and secondary production, decomposition, mineral cycling, and energy transfer. In the social sciences, ecosystem service is a nearly equivalent term for ecosystem function, particularly as used to describe functions of ecosystems as they affect humans, for example, production as food support for wildlife or humans, biomass as a buffer from storm damage.

Enemy release hypothesis Invaders escape their traditional predators in a new geographical area, and are therefore at an advantage to native species.

Exotic species A species growing outside of its native range.

Introgressive hybridization The introduction of genes novel to the species (or type) by either by inter- or intra-specific hybridization. Introgressive hybridization of an invasive species with native or non-native species could create new genotypes of the invasive species.

Invasive species Alien species native to another continent.

Pangea Single "supercontinent" present during the Triassic Period before present day continents began to drift apart. In the context of invasive species, the "New Pangea" refers to the state produced by higher levels of species migration supported as modern day humans travel more freely between continents.

Resource-enrichment hypothesis/fluctuating resources hypothesis Communities are more invaded by exotics if amounts of unused resources within the community are higher.

☆*Change History*: March 2018. Beth A Middleton updated text, updated table 2 and some of the references.

Transgenic weeds Genetic modified (GM) types with genes from both wild and agricultural sources, which escape into either fields or natural habitats. Potentially modified traits include genes for drought tolerance, resistance to herbicides, resistances to herbivores.

The Invasive Species Problem

Global Perspective

Invasive species aggressively invade new continents so the world's flora is becoming more homogeneous. Benign components of their original habitats, invasive species can become dominant and aggressive in new geographical regions. These species are thought to be both drivers and symptoms of environmental change. Certain types of habitats have a propensity to be invaded by opportunistic exotics, for example, riverine wetlands, which have a relatively large amount of disturbance because of regular changes in water depth, flow, sediment, and nutrients.

Once established, invasive species cause many problems for humans in that they degrade natural communities. Invasive pests and diseases damage agricultural species. Exotic aquatic species can cut off local commerce by stopping boat traffic along rivers. These species also cause local electricity emergencies by clogging the operation of hydroelectric dams, particularly in countries that rely on hydroelectric power such as New Zealand.

Invasive species are those species that arrived on continents after the 16th century after human global travel, commerce and migration increased. While species have moved between continents for millennia, global travel by humans has greatly accelerated the rate of intercontinental movement of species. New invasions of species have paralleled the movements of humans worldwide, and the associated spread of invasive species has caused the decline of native species on their continents of origin. This relatively free movement of biota between continents has created a "New Pangea." Continents will have more species as new invasive species arrive, but the displacement and extinction of native species caused by invasive species ultimately will cause the worldwide number of species to decrease. Exotic species introductions are generally unintentional, although there are many documented cases of species being transported to other continents for horticultural or agricultural purposes.

From a philosophical perspective, invasive species are not just another for the species richness list because invasives cause environmental degradation. While some authors criticize the furor over invasive species as being akin to xenophobia, the perspective that invasive species are problematic in natural areas is fundamentally dissimilar to the idea that foreigners can cause harm to a society. The concern of ecologists over invasive species is due to the damage invasive species cause to natural plant communities.

In North America, there are 50,000 nonindigenous species, 3000 of which are invasive. Hawaii has more than its share of invasives with 860 invasive species. Each year, $137 billion per year are spent to eradicate invasive species in the United States (Figs. 1 and 2), and $26 billion are spent to combat crop weeds.

Types of Invasive Species

Alien species from other continents

Most commonly, invasive species are defined as aggressive alien species from other continents. Invasive plant species often share certain characteristics such as fast and high seed production, vegetative reproduction, rapid growth, and a tolerance for a wide range of environments.

Surprisingly, scientists do not always know on which continent an invasive species originated, but the source continent and population of the invader can be determined by genetic analysis. In the case of the North American populations of *Hydrilla verticillata*, the dioecious form of this aquatic invasive is similar to types found in Bangalore, India, while the monoecious form resembles plants from Seoul, Korea. *H. verticillata* in New Zealand may have been introduced from Australia, where the species invaded centuries ago. The determination of the geographic origin of an invasive species can be a useful first step toward determining factors that can control the invasive species. The place of geographical origin can be checked for parasites that control the spread of the invasive species there, and subsequently this knowledge could be used in the design of biological control methods.

Introduced disease species can also be devastating to native plant species. One example is the butternut (*Juglans cinerea*) canker, a disease which likely came to North America from Asia. The butternut canker has infected populations of butternut trees since the 1960s, a similar situation to that of Dutch elm disease and Chestnut blight, affecting American elm and chestnut, respectively. These three diseases have nearly eliminated important tree species and undoubtedly altered the function of the Eastern deciduous forests of North America.

Hybrid species with introgressed genes

Sometimes exotic species form hybrids with native species, so that subsequently the newly emerged hybrid becomes dominant in either the novel or native geographic location. For example, *Typha* x *glauca* is a hybrid of *Typha latifolia* and *Typha angustifolia*, which has displaced native *T. latifolia* in many locations in North America. Hybridization can create new genotypes either via inter- or intra-specific combinations of invasive species with either native or non-native types. Introgressive hybridization may make species more

Fig. 2 *Eichhornia crassipes* (water hyacinth) is a floating aquatic species native to South America, but invasive in tropical and subtropical wetlands around the world. Photo by Beth Middleton.

invasive than they would be otherwise, and may be a contributing factor in the aggressiveness of *Lythrum salicaria* (Fig. 3) *Myriophyllum spicatum*, *Phalaris arundinacea*, *Phragmites australis* and *Typha* x *glauca*, especially in North America.

In restoration areas, genetic integrity may be compromised in situations where invasive species have either been intentionally planted or when invasive species have taken over sites. Hybrid cordgrass (*Spartina alterniflora x Spartina foliosa*) has taken over restoration sites in San Francisco estuaries. These cordgrasses differ in size from native cordgrasses, and are not used by the endangered clapper rail (*Rallus longirostris*), the species for which the coastal marsh restoration projects are designed. Invasive hybrid species threaten the success of restoration sites, both by comprising the genetic integrity of the vegetation, and altering the functional qualities of the site.

Transgenic Weeds

The potential exists for new types of invasive species to emerge with introgressed genetic material from transgenic crop species transferred to related native or invasive species. Transgenic sunflowers (hybrids of native and transgenic *Helianthus annuus*) are often found adjacent to GM (genetically modified) sunflower fields because of genetic introgression. Only a few studies have determined if transgenic weeds pose a threat similar to that of invasive species. In one study, transgenic oilseed rape, potato, maize and sugar beet were no more invasive or persistent in fields and natural areas than the traditional crop species. However, 42% of native sunflower populations adjacent to GM sunflower fields are transgenic hybrids, and these genes persist in these transgenic weed populations for at least five generations. Transgenic traits for disease, insects or herbicides could give a competitive advantage to wild species, thereby conferring a higher level of invasibility to these transgenic weeds. Transgenic traits could also be transferred to endangered species, in a situation paralleling the genetic erosion of cutthroat trout populations in the White Mountains of Arizona (see "Hybrid Species with Introgressed Genes"). The consequences of the presence of transgenic weeds in crop or natural plant communities will depend on their fitness, ability to spread, level of the genetic erosion of the populations of native species, and their overall ability to displace other species as invasives in natural communities.

Fig. 3 *Lythrum salicaria* (purple loosestrife) of short stature at the northern extreme of its invasive range near Amos, Quebec, Canada. Photo by Beth Middleton.

Invasion Hypotheses

Many hypotheses have been developed to describe the dynamics of invasion, and these explanations variously describe how a barrier to invasion is removed so that an invasive species is successfully transferred to a new location. The explanations are not mutually exclusive.

Hypotheses

Preemption hypothesis

Undoubtedly an important reason why invasive species do not always invade habitats, the preemption hypothesis suggests that invasives can be prevented from invading because of the presence of other species. In other words, the plant colonization window for an invasive species is closed, because other species are physically occupying the space. Though often overlooked, preemption is logically one of the most important forms of invasive species exclusion. If a species is already occupying a space, it is difficult for an invasive species to eject that species from the space.

Enemy release hypothesis

The Enemy release hypothesis is the idea that invasive species are less impacted by enemies (e.g., herbivores) than native species, because in the new geographical location, the invasives species are freed from the parasites that kept their growth in check in their native environment. Therefore, invasive species are thought to compete more successfully with native species in their invasive environment, because the native species have not been released from their traditional enemies. The enemy release hypothesis is the basis for biocontrol programs.

The introduction of the pests of invasive species can have a dramatic impact on the growth and spread of invasive species in biocontrol programs, which is evidence that the enemy release hypothesis is operating. Also, plant species are sometimes taller in their introduced ranges, and this is often attributed to the absence of their traditional parasites. Most invasive plant species have an average of 16 parasites in their native range, but only three in their introduced range.

Related to the idea that invasives may be larger in their introduced ranges is the idea that these species may be larger because these have introgressed genes from hybridization with native species. Following this idea, these invasive species may not be the same as their progenitors in their region of origin (Introgression Hypothesis; see section "Types of Invasive Species"). With novel genes introduced, the invasive species with introgressed genes may be larger and at an advantage to the original invasive type.

Resource hypothesis, resource-enrichment hypothesis, fluctuating resources hypothesis

Resource-related hypotheses assume that invasive species are limited by resource availability. According to the various resource hypotheses, invasion is related to the availability of resources including nutrients, light, and water. The resource-enrichment and fluctuating resources hypotheses assume that communities are more invasible if amounts of unused resources are higher.

Diversity-resistance hypothesis

The diversity-resistance hypothesis suggests that communities with high levels of diversity are less invasible by exotic species, as based on ideas of competitive exclusion and niche theory. If niches are narrower and already filled, competitive exclusion bars new species from entering very diverse communities. The opposite idea is also claimed that is, that communities with high levels of diversity are more invasible by exotic species. Actually, field studies support both claims. However, studies of the pattern of species invasion at large regional scales suggest that species rich landscapes are more invaded by invasive species than species poor landscapes.

Geographical range hypothesis

After an invasive species has initially established on a new continent, the best predictor of the invasive range is the climatic range of the species on its home continent. Thus, after the invasive species' successful establishment on a new continent, the species is likely to spread throughout the entire climatic range. This spread may take decades or centuries. The geographic range hypothesis is related to niche theory but carried to a landscape scale, because of the idea that species grow best in certain climates and environments. Modelers who attempt to project the eventual spread of an invasive species on a new continent use the ecological niche characteristics of the native range. An interesting wrinkle on this idea is that as world climates warm, the poleward migration of invasive species may occur, with their overall distributions enlarging or shrinking depending on their abilities to migrate, and occupy habitats within the new climate. In particularly, certain tropical or subtropical species are likely to move northward (e.g., *Eichhornia crassipes*).

Removing Isolation Mechanisms—Intercontinenal Migration

Invasive species transmission

Species are limited in their ability to move to new continents by geographical isolation, and this limits the majority of the world's species from becoming invasive species on another continent. Dispersal overcomes the isolating mechanisms that prevent the movement of species from one continent to another, and species have varying levels of abilities to disperse across the barrier and successfully open invasion windows. Species can move by natural dispersal vectors including wind, animal, and water transport. (See Middleton, 1999 for an extensive species list of seed dispersal mechanisms for world plant species.)

After plant species successfully disperse and establish on a new continent, many of these can spread locally by vegetative reproduction. One successful propagule can start a new population, and many plant species spread solely or mostly via asexual means (e.g., bulbils of *Dioscoria oppositifolia*, plant fragments of *E. crassipes* (Fig. 4), *Salvinia molesta*, *Elodea canadensis*, and *H. verticillata*). Wind-dispersed invasive species with prolific seed production can also spread rapidly after their initial introduction (e.g., *Phragmites* spp. and *Typha* spp.). Also, recently established northern invasive species may adapt quickly through selection for earlier flowering time, so that seed production may increase at the northern invasion front.

Transmission by travelers and commercial shipments

Historically, invasive species have moved between continents as human travel and migration increased. As climates and hardiness zones shift in North America, horticultural demands are likely to favor African and Middle Eastern species that are more successful in hotter and drier environments. Thus, a new wave of horticultural introductions are likely to accommodate those demands. Hitchhiking species cling to travelors' luggage, mud on shoes, and probably even the tires of airplanes. Recirculating air in airplanes transfers germs from one passenger to another on transcontinental flights, after which the travelers themselves deliver the novel diseases to new continents. Invasive species passively cling to transport vessels. The Antarctic now has at least 207 alien species, and these invasives mostly originate from ballast discharge.

With the current level of international travel, new introductions of invasive species are inevitable. However, international agreements attempt to address the problems associated with the international transport of organisms. The Global Ballast Water Convention is an international agreement passed in 2004, which will eventually require ships to comply with discharge limits, and establishes inspection and enforcement procedures.

Fig. 4 *Lythrum salicaria* (purple loosestrife) is an emergent perennial species native to Eurasia, and an invasive species of wetlands in northern North America. Photo by Beth Middleton.

Invasive Species in Natural Communities

Composition and Functional Change

Ecologists consider invasive species to be a serious threat to the biodiversity of natural areas. Invasive species may change the microenvironment for native species for example, by changing light, air and water environments in plant habitats. Most studies show that the numbers of native species decrease in habitats after exotic species invade, and the tall invading species are often the most serious problems. In some cases, invasive species may outcompete native species, for example, *Oenothera deltoides* declined in native communities with invasive grass species because of the thatch and associated shade created by the grasses. Subsequently, the germination of *O. deltoides* is reduced, and eventually the population numbers of the species decline. However, invasive species may not always eliminate native species. Recent studies of *L. salicaria* in North American wetlands suggest that the presence of this invasive species does not eliminate native species, but instead, reduces their size.

Emerging research suggests that the function of ecosystems dominated by invasive species differs from those dominated by equivalent native species (Table 1). One study of riparian floodplain function in the southwestern United States showed that after invasion by *Tamarix chinensis*, half of the functional traits of importance in riparian floodplain function differed from native *Populus fremontii* floodplain forests (Stromberg, 1998). The impacts of invasive species on ecosystem *L. salicaria* function may be subtle, and yet have far reaching effects for the function of the system. If dominant species that are important as food sources in the system are replaced by less useful invasive species, the secondary production of animals higher on the food chain may be affected. For example, *L. salicaria* did not support fish populations because the species decomposed at a different rate than a native sedge species (*Carex lyngbyei*) that it replaced in the Fraser River Estuary of the northwestern United States. Here, a shift of dominant species caused a loss of the productivity of the fisheries, because the invasive *L. salicaria* does not provide a seasonally equivalent food base for the invertebrate species that support the fish populations. Shifts in function due to invasive species may be profound, but we understand little about the overall threat of invasive species from this perspective.

Invasion and Disturbance

The majority of invasive species invade native communities after disturbance, so that these species are common in old field and restoration sites. However, some invasive species can invade natural areas without the help of human disturbance. In wilderness canyons of southern Illinois, *D. oppositifolia* (Chinese yam) can invade floodplains of streams via bulbils (asexually produced disseminules). *Lygodium microphyllum* (Old World climbing fern) invades tree islands in the Everglades of Florida. Also, *Impatiens glandulifera* is dispersed along rivers in Central Europe. These three examples are situations where flood pulsing along stream channels spreads the disseminules of invasive species. Invasives that are maintained by natural disturbances are particularly problematic from a management perspective, because the same natural disturbances, which are critical in maintaining plant community types, also maintain these invasive species.

Table 1 Potential shifts in ecosystem function in areas with invasive species

Function	*Specific shift in function*
Productivity	– Biomass of native plant species reduced – Size of animals feeding not supported as well by invasives, for example, bog turtles (*Clemmys muhlenbergii*) smaller in wetlands with *Lythrum salicaria*
Soil/water/salinity/geomorphological relationships	– Surface/ground water levels changed – Erosion/sedimentation levels changed – Soil content (silt/clay/sand proportion) changed – Organic matter dynamics in long-term succession changed – Organism function in stream channel, bank stabilization, or island building capacity changed – Water infiltration of ground is changed (repelled or absorbed more easily than native species)
Community attributes	– Species richness of native species lowered – Early succession dominated by invasives, so that maturation or establishment of later successional species is impeded – Displaces native species
Disturbance attributes	– Fire frequency changed – Differs from native species in its ability to tolerate disturbance/perturbations such as wind, flooding, herbivory/insectivory/parasitism, animal foraging or digging
Nutrient dynamics	– Nutrient availability lowered, for example, pH lowered by adding salinity or acidity so that nutrients become less available – Adds nutrients, for example, leguminous invader and associated bacteria fixes nitrogen
Decomposition dynamics	– Rate of decomposition shifts, so that litter or nutrient dynamics are altered
Secondary production	– Species at the top of food chain changed, for example, invasive species does not provide the same level of food support to specific higher order organisms
Habitat structure	– Habitat structure differs from that of native species in plant height, density, openness, or light characteristics so that animal foraging, nesting or burrowing is impacted

Invasive Species Control

Restoration of Natural Conditions Following Anthropogenic Disturbance

Often the best time to attempt to control an invasive species is immediately after the first individual establishes, and before it sets seed. Attentive natural areas managers and restorationists often have stories of killing that first invading purple loosestrife plant in its first year of growth in a newly restored wetland. Some countries (e.g., New Zealand) request that citizens report the first sightings of various invasive species, so that the invasive can be removed before it infests the area. However, after the first individuals have established, invasive species are difficult if not impossible to eliminate. To control invasive species, natural disturbances have been used such as fire, flooding, manual removal, shading, substrate removal, herbicide and biocontrol. However, the success of implementing natural disturbance to remove invasives is situation dependent. Fire may be a good means of controlling invasive shrubs in prairies in the midwestern United States; however, fire is not appropriate in Hawaii because indigenous species there did not evolve with fire. Also, invasive species may alter fuel loads so that fires may be more or less frequent in an ecosystem after these species invade.

Habitat Protection via Banning of Invasive Introductions

Many countries have laws to prevent the intentional introduction of invasive species. In the United States, the introduction of alien species is regulated by the USDA Animal and Plant Health Inspection Service, and the movement of species across international boundaries into the U.S. is highly regulated. Laws vary from country to country. A good source of information on the restrictions for the movement of organisms between countries is given on the website of The International Portal on Food Safety, Animal and Plant Health: http://www.ipfsaph.org/En/default.jsp.

Biological Control

Biocontrol of invasive species sometimes can be achieved through the introduction of a parasite from the region of the invasive species' origin (Table 2), but the danger exists of introducing yet another invasive species, which could create harm to native species. The negative effects of the introduction of organisms to control invasive species may not be immediately apparent, but may arise suddenly many years after introduction of the biocontrol agent. One biocontrol success story is in the control of *Opuntia vulgaris* in India, a species which was introduced from Brazil. A scale insect (*Dactylopius ceylonicus*) was released in 1795, and the insect completely controlled the cactus in India. However, in a similar attempt to control *Opuntia* on the island of Nevia in the Lesser Antilles, disaster occurred with wide reaching and unintended consequences. In 1957, the cactus moth (*Cactoblastis cactorum*) released to control *Opuntia* on Nevis, but the moth escaped to destroy populations of the rare *Opuntia spinosissima* in the Torch Wood Hammock Preserve in the Florida Keys. Having now reached the Gulf Coast and spread by hurricanes, the cactus moth has spread across the region to Louisiana, and could eventually threaten populations of cactus in the southwestern United States.

Insects pests of *L. salicaria* have been introduced from Eurasia to control this invasive in North America. However, these insect species may attack related species of *Lythrum* native in North America. Furthermore, some studies suggest that the insects do not eliminate *L. salicaria* but only reduce the biomass of the species as compared experimentally inside and outside of insect exclosures. Other studies suggest that *L. salicaria* does not necessarily pose as severe a risk to wetland communities, as the release of the insect species. *L. salicaria* does not reduce the species richness of other species, although the effect on the function of the wetland may be impacted.

Table 2 Mechanisms for the control of invasive plant species

Method	*Advantages*	*Disadvantages*
Hand or machine cutting	Labor intensive although less so than some other methods	Most species grow back from underground parts
Cover cut stems with object (e.g., dark plastic bag)	Plants usually don't grow back after cutting/covering	Labor intensive
Root pulling	Removes underground parts of plant that may regrow	Disrupts the soil and may encourage reinvasion of the exotic species from seeds or plant fragments
Herbicide application	Easy to accomplish relative to more labor intensive methods	May kill native species
Handcutting with herbicide application to cut shoots (Bradley Method)	Very effective removal mechanism, especially for woody species	Uses herbicides, although in very small amounts
Herbicide	Can be effective in the removal of certain species; less labor intensive than other mechanisms, so that it can be used to treat large tracts of land	Improper usage may harm the health of users and/or the environment
Biocontrol (release of insects or pathogens transferred from their continent of origin)	Can target the invading species only	Pests may be unpredictable; native species may be damaged

The introduction of parasites to control invasive species is not always very successful from the perspective of the survival of the introduced parasite. Sometimes the habitat requirements of the parasite are not met, so that these parasites become extinct shortly after introduction. Biocontrol can fail because the parasite can not be maintained in the invasive environment.

Many argue that biocontrol is worth the risk that the parasite might damage the environment because the cost of doing nothing may be higher than any potential cost incurred or harm caused by the biocontrol agent. While the benefits of releasing biocontrol agents to the ecosystem may be profound, the potential effects of harmful biocontrol agents are impossible to project. For example, who could have thought that a cactus moth released in the Lesser Antilles would be capable of making its own way across the Gulf Coast of North America? Others use the same reasoning regarding the lack of ability to project the effects of biocontrol agents, to argue that the usage of biocontrol agents is never warranted.

Global Warming

Species may increase in size with warming as many do from tidal marsh systems in experimental mesocosms. In some cases, the seeds are larger in exotic versus native populations, for example, seeds of the exotic shrub, *Cytisus scoparius* are larger in North America vs. Europe.

Physical Control

The physical control of invasive species by digging, removal, and harvesting (Table 2) may or may not be feasible depending on the size of the invasive population, and number of available people to help with the removal (Box 1). Sometimes, the invasive species has built a large reserve of seeds in the soil, so that seedlings from germinated seeds grow to replace the removed adults in the soil disturbed by the removal activities. Often, the invasion potential increases with the amount of disturbance created by the removal of invasive species, so care should be taken in physical removal programs not to disturb the sites. Especially in restoration projects, it is important to remove invasive species by hand, or the resulting vegetation will be unsatisfactory to meet the regulatory requirements

Box 1 Think globally, act locally: volunteer programs for invasive species control, and research data collection

Volunteers can help with the invasive species problem by volunteering their time to help in management and research projects. The control of invasive species can often be achieved by the removal of invasive species from natural communities, an effort greatly helped by teams of volunteers. The "weed pulling organizations" are regionally coordinated, and these organizations often have websites with information for volunteers. A short search on the Internet can help volunteers locate an organization in their region engaged in weed removal activities. A few agencies for volunteers to check include The Nature Conservancy, California Invasive Plants Council, Hawaiian Ecosystems at Risk, Invasive Plant Association of Wisconsin, Midwest Invasive Plant Council, Southeast EPCC, and Texas Invasives.

Volunteers also can donate their time to help researchers collect data, e.g., the U.S.G.S. purple loosestrife volunteer program. Volunteers in this program collect data on *Lythrum salicaria* around the world. See: http://www.nwrc.usgs.gov/special/purplel/.

of the restoration process. In such cases, the best approach is to remove invasive species immediately, before the invasives become widespread in the restoration area.

Invasive species can be snipped at the base by hand with a long handled clipper, while carefully avoiding native species. It is also possible to cut woody species, and then cover the stump with a heavy dark plastic bag, which will keep the stump from regrowing. After cutting invasives, the remaining native species are at an advantage since they are already established. After cutting invasives, the native species may regrow to shade and reduce the invasive species after the treatment. This selective clipping method is very time consuming, but can have very good results for reestablishing native plant communities that have become invaded with invasive species. Also, the removal of exotic species without attention to the restoration of native species can pave the way for further exotic species spread.

Mechanical mowing with a tractor or by hand with a scythe can be an ideal way to reduce the amount of an invasive species and encourage native species, particularly if the mowing is done in certain seasons. For example, mowing in the late spring and early summer reduced the amount of *Arrhenatherum elatius* and increased the native *Danthonia californicum* in a grassland. Harvesting by hand also can remove invasive species. Kudzu (*Pueraria lobata*) is sometimes harvested for cattle forage, and the invasive *Prosopus juliflora* can be used for fuel wood (the famed mesquite barbecue charcoal) (Fig. 5). The downside of putting invasive species to a "good" use after their harvest is that the transfer of biomass elsewhere can spread seeds or disseminules.

Herbicide

Herbicides are widely used to remove invasive species, but the success of their application depends on the situation and the species involved. Herbicide eliminated *E. crassipes* (Fig. 4) in Lake Hartbeespoort, South Africa, but only after four large scale aerial spraying episodes followed by spot spraying from boats. Sometimes herbicides work best in combination with other removal methods. For example, woody invasive species in grassland or forest situations can be controlled by a combination of hand cutting and application of an appropriate herbicide to the cut stump. Without herbicide or stump covering (see above), most woody species simply grow back from the stump after cutting. Direct application of herbicide to the stump is often an effective method of woody species removal, but at the same time, little herbicide is released to the surrounding environment.

k-Dominance Curves

RM Warwick, KR Clarke, and PJ Somerfield, Plymouth Marine Laboratory, Plymouth, UK

Introduction

Curvilinear plots or distributional representations extract information on patterns of relative species abundances in an assemblage without reducing that information to a single summary statistic, such as a diversity index. In fact, such plots provide the raw material that is extracted by the full range of possible measures that combine richness and evenness components of diversity. Unlike multivariate methods, these distributions extract universal features of community structure which are not a function of the specific taxa present, and which may be related to levels of biological stress. *k*-Dominance curves belong to this class of techniques, and have been quite widely used in the context of environmental assessment.

The Method

From a traditional ecological viewpoint diversity may be thought of as the number of groups (usually species) present in an assemblage, or how evenly those groups occur in the assemblage. These aspects of diversity are generally termed richness (species richness for example) and evenness. High richness equates to high diversity, and a highly dominated assemblage (i.e., one with low evenness) is considered to be less diverse than a more even one.

Diversity measures tend to be measures of richness (e.g., Margalef's richness index), evenness (e.g. Simpson's index), or are constructed in such a way as to combine the two components in one measure (e.g. Shannon–Wiener index). The Berger–Parker index) is the proportional abundance of the most abundant species in an assemblage and is a measure of dominance. Where no single species is overwhelmingly dominant, it is useful also to consider the dominance of the two most abundant species, the three most abundant, and so on. In an assemblage a family of indices may be defined: 1-dominance, 2-dominance, 3-dominance, and in general *k*-dominance, which is the combined dominance of the *k* most abundant species. Plotting values of *k*-dominance against species rank gives the *k*-dominance curve. Ranked species abundance (dominance) curves are based on the ranking of species (or higher taxa) in decreasing order of their importance in terms of abundance (or biomass). The ranked abundances, expressed as a percentage of the total abundance of all species, are plotted against the relevant species rank. The *k*-dominance curve, therefore, is simply a `cumulative' ranked species abundance curve in which cumulative proportional abundances are plotted against species rank, or often log species rank. The log scale compresses the information about low-ranked species so that the curves reflect a greater contribution from evenness than richness components of diversity. Obviously, the length of a curve along the *x*-axis is determined by the number of species in the assemblage under consideration, while dominance may be assessed by the height and shape of the curve. The higher the curve, the less diverse (and more dominated) is the assemblage it represents. To compare dominance separately from the number of species, the *x*-axis (species rank) may be rescaled from 0 to 100 (relative species rank), to produce Lorenz curves.

Fig. 1 shows *k*-dominance curves calculated from species abundances of infaunal invertebrates from a marine intertidal sand-flat. Animals were collected using different sieve meshes, and sample sizes were scaled with mesh size. Each curve is calculated from the averaged abundances from four replicates. Note that there is little or no overlap in species composition between samples collected on the largest mesh and on the two smaller meshes, but the method allows a simultaneous comparison of the dominance/diversity structure in each. The curve for invertebrates extracted using a 1 mm mesh is higher than the curves for invertebrates extracted using 250 or 63 μm meshes for all values of *k*. Thus, the assemblage in the 1 mm-mesh samples is unambiguously less diverse than the others.

The curves for invertebrates sieved on 250 and 63 μm meshes in Fig. 1 cross. It has been argued that diversity can only be unambiguously assessed when the curves to be compared do not overlap or cross, as different diversity indices biased toward species richness or evenness will rank these assemblages in opposite ways. However, intersecting plots are informative in that they illustrate differences in dominance relative to species richness in a way that a single univariate index does not.

Whether *k*-dominance curves are plotted from the species abundance distribution or from species biomass values, the *y*-axis is always scaled in the same range (0–100). This facilitates the abundance/biomass comparison (ABC) method of determining levels of disturbance.

Transformations of *k*-Dominance Curves

Very often *k*-dominance curves approach a cumulative frequency of 100% for a large part of their length, and in highly dominated communities this may be after the first two or three top-ranked species. Thus, it may be difficult to distinguish between the forms

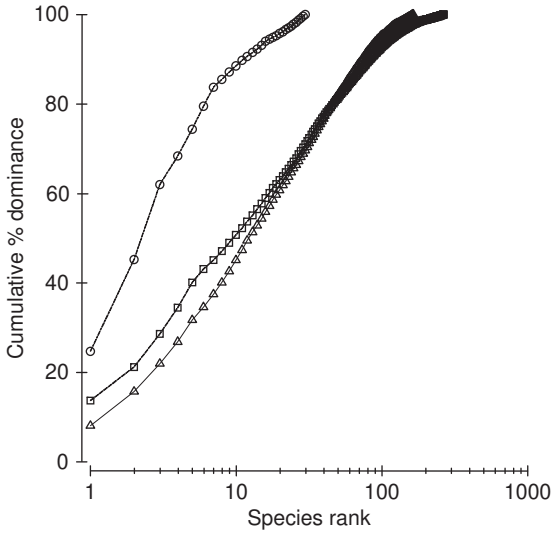

Fig. 1 *k*-Dominance curves for samples of invertebrates from a marine intertidal sand-flat. Each curve is based on average abundances in four replicate samples collected using a particular combination of sieve mesh and sample area: 0.1 m^2 sieved on a 1 mm mesh (circles); 0.006 25 m^2 sieved on a 250 μm mesh (squares); 0.000 39 m^2 sieved on a 63 μm mesh (triangles).

of these curves. The solution to this problem is to transform the y-axis so that the cumulative values are closer to linearity. The modified logistic transformation has been suggested for this:

$$y_i' = \log[(1 + y_i)/(101 - y_i)]$$

Partial Dominance Curves

A second problem with the cumulative nature of *k*-dominance curves is that the visual information presented may be over-dependent on the single most dominant species. The unpredictable presence of large numbers of a species, perhaps an influx of the juveniles of one species, may give a false impression of disturbance. With genuine disturbance, one might expect patterns of *k*-dominance curves to be unaffected by successive removal of the one or two most dominant species in terms of abundance, and the use of partial dominance curves has been recommended. These compute the dominance of the second-ranked species over the remainder (ignoring the first ranked species), the same with the third most dominant, etc. Thus, if a_i is the absolute (or percentage) abundance of the ith species, when ranked in decreasing abundance order, the partial dominance curve is a plot of p_i against log i ($i = 1, 2, \ldots, S - 1$), where $p_1 = 100a_1/\sum_{j=1}^{S} a_j$, $p_2 = 100a_2/\sum_{j=2}^{S} a_j, \ldots, p_{S-1} = 100a_{S-1}/(a_{S-1} + a_S)$.

Earlier values can therefore never affect later points on the curve. **Fig. 2** shows partial dominance plots from the sand-flat study. In this case it does not lead to a novel interpretation of the data, instead showing a similar pattern to that revealed by simple *k*-dominance plots but in a different form.

Hypothesis Testing

Plotting all of the curves from a fully replicated study can produce complex graphs in which the pattern may be difficult to discern. **Fig. 3** shows the replicate curves from the sand-flat study. It is clear that all replicates in the 0.5 mm samples are less diverse than all samples collected on smaller meshes, but is there evidence for differences in dominance/diversity between the 250 μm samples and the 63 μm samples? If *k*-dominance curves are calculated for replicates at a number of sites, times, or conditions, a measure of dissimilarity can be constructed between any pair of curves, for example, based on their absolute distance apart, summed across the species ranks. When computed for all pairs of samples in a study, this provides a (ranked) triangular dissimilarity matrix, essentially similar in structure to that from a multivariate analysis; thus, 1-way and 2-way ANOSIM tests that are used in multivariate analysis can be used in exactly the same way to test hypotheses about differences between *a priori* specified groups of samples. In this case the test shows unequivocally that there is a significant difference between the 250 μm samples and the 63 μm samples: curves within groups are more similar to each other than they are to curves in different groups. What the test does not reveal is the form of those significant differences. For this we need averaged plots (e.g., **Fig. 1**) or plots based on subsets of replicates.

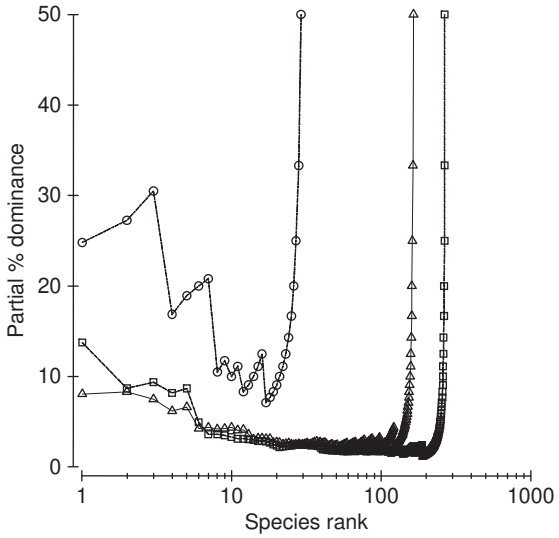

Fig. 2 Partial-dominance curves for samples of invertebrates from a marine intertidal sand-flat. Each curve is based on average abundances in four replicate samples as in **Fig. 1**.

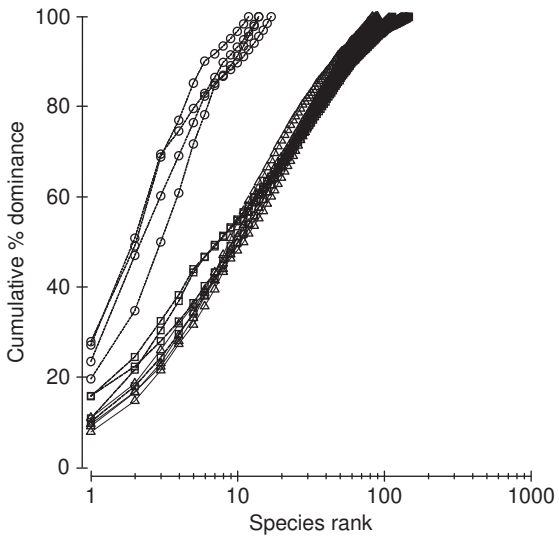

Fig. 3 *k*-Dominance curves for samples of invertebrates from a marine intertidal sand-flat. Each curve is based on abundances in a single sample. Four replicate samples were collected using three combinations of sieve mesh and sample areas as in **Fig. 1**.

Polychaetes/Amphipode Index☆

C Chintiroglou and C Antoniadou, Aristotle University of Thessaloniki, Thessaloniki, Greece

Extended Synopsis

The urgent need to assess the state of marine coastal ecosystems and to preserve their biodiversity led to the invention of a variety of ecological indices. Polychaetes and amphipods are major taxa in coastal communities and several studies support their abilities to reflect the integrated conditions over a time period. The polychaetes/amphipode index, simply referring to the ratio of their abundances, is based on the different sensitivity of these two taxonomic groups to disturbances, with the former being more tolerant than the latter. The performance of this index has been tested, with varying degrees of success. Polychaetes/amphipode index is an easy, rapid, and cost-effective approach, and it appears sensitive to the assessment of various contaminants integrating the seasonal oscillations of the fauna in sorted soft sediments. However, its applicability is dubious in assorted sediments and on hard bottoms. The index, also, performs badly when the samples are impoverished, or when polychaetes are not the dominant taxon. Therefore, its applicability is limited and approaches ranking either the entire benthic fauna with respect to its sensibility, or a specific taxonomic group, gain importance in ecological quality assessment. Rather recently, to overcome the drawbacks in the applicability of the polychaetes/amphipode index, a modified version has been proposed by considering the ratio of opportunistic polychaetes to amphipods at first, and then, by considering the ratio of their frequencies after excluding the opportunistic *Jassa* amphipods. This latter index named as Benthic Opportunistic Polychaetes Amphipods index (BOPA), has been calibrated to meet the requirements of the Water Framework Directive. BOPA is a promising tool as it performs well in both coastal and transitional waters, and even in very poor communities.

Benthic Ecosystems: A Synopsis on Research Trends

The comprehensive study of marine benthic ecosystems started in the middle of the previous century (1950–60), focused at an early stage on the Mediterranean Sea. The pioneers of the research center of Marseille set the methodological groundwork of this scientific field, to be followed thereafter by a great worldwide endeavor for the exploration of benthic communities. The early, fundamental knowledge laid the ground for new enquiries about the development of a scientifically documented method to analyze and assess the state of marine coastal ecosystems. The creation and mathematical processing of adequate databases to simulate the dynamics of marine ecosystems is another objective imposed by international directives (WFD 2000/60/EC; MSFD 2008/56/EC) and the original convention for the biodiversity conservation of Rio (1992).

Ecological Quality and Ecological Indicators

The assessment of ecological quality is a current issue in marine research. The approaches to assess the ecological quality of a given water body, are based either on the physical, chemical (priority substances including), or biological elements of the system. The biological elements proposed for this topic have been manifold, ranging from molecular to ecosystem level. However, the most fundamental implement seems to be the benthic fauna as (1) it shows small natural variability compared to pelagic one, (2) it is well responding to organic pollution, and (3) it is rather localized, which means that most species are either sessile or discretely motile, thus not performing large-scale migrations. So they do reflect the integrated conditions over a time period. The concept of ecological indicators has been developed for this assessment; meaning any organism whose presence and/or dominance in a particular area can reveal the prevailed environmental conditions, characterizing the degree of community change or pollution effect. It is widely accepted that when more than a few species are taken into consideration, the indices' validity increases. Therefore, instead of working with a specific taxon, it is better to consider the ratio of taxonomic or functional units (i.e. species, genus, families, trophic guilds, reproductive mode, life strategies, ecological requirements); this approach has led to the invention of a wide number of ecological indicators which have been tested in several cases of pollution with varying degrees of success.

Polychaetes/Amphipode Index

Distribution of Polychaeta and Amphipoda in Coastal Communities

The taxonomic groups of Polychaeta and Amphipoda are among the prominent biota in coastal ecosystems, both in terms of species richness and abundance. Given their ecological significance, literature references confirm their status as sensitive

☆*Change History:* March 2013. C Chintiroglou and C Antoniadou updated Abstract, Extended synopsis, the Polychaete/Amphipods index the reference section, Figures 1, 3 and added Figures 2, 4 and 5, and added Table 1.

 doi:10.1016/B978-0-12-409548-9.00599-6

environmental indicators and support their utility as key taxa for biomonitoring. However, before these taxa can be used to specify disturbances, as demanded by international directives and conventions, it is necessary to provide a database on their distribution on natural benthic communities with comprehensive base line information on their presence at various geographic areas. The distribution of these two taxa shows significant differences with respect to the type of substratum, and therefore their ratio will be examined separately. In general, Polychaeta is the most dominant group in soft-substratum communities comprising over half of both the species richness and the numerical abundance; on hard substratum Polychaeta and Amphipoda co-occur, usually comprising over one third of both species richness and numerical abundance.

Definition of the Polychaeta/Amphipoda Index

The Polychaeta/Amphipoda (P/A) index simply refers to the ratio between the abundance of polychaete species to the one of amphipods. The basic thought behind this approach is the different sensitivity of these two taxonomic groups. Polychaetes, as a taxon, are in general resistant to pollutants, since many species are positively correlated with organic enrichment. As a result, after disturbances, several opportunistic polychaete species are favored and increase their abundance. Amphipods, as a taxon, are more sensitive and experience high mortality after severe pollution events. Still there are some species, such as *Elasmopus rapax*, *Jassa falcata*, *Podocerus variegatus*, and *Corophium* sp., which can proliferate by increased organic load. Several forms of this index have been tested (e.g., the opportunistic species instead of the total polychaete fauna, or some genera of polychaetes), since this taxon is the most important in disturbed areas because it contains a large number of both tolerant and sensitive species, whose gradient can reflect the degree of organic pollution. The use of log10 has been suggested for the calibration of the P/A index, with the addition of one monad to the denominator (i.e., log10 (P/A + 1)). So, the index has low values, below 1 (≤ 1), when the benthic communities are not disturbed and exceeds 1 (> 1) when they are affected from pollution events. Important attributes of such an index should be its reliability in ecological quality assessment, as well as the easy use and broad applicability to various ecosystems.

Modified Version of the Polychaeta/Amphipoda Index: The Opportunistic Polychaete/Amphipode Ratio (P_O/A Index) and the Benthic Opportunistic Polychaetes Amphipods Index (BOPA Index)

The Polychaeta/Amphipoda (P/A) index has been recently modified (Dauvin and Ruellet, 2007), again in accordance with the taxonomic sufficiency principle, that is, reduction of the taxonomic classification effort (Dauvin *et al.*, 2003; Ellis, 1985). Thus, only opportunistic polychaetes and amphipods were considered; the former animals have been exclusively included in the new formula of the index and the latter ones have been excluded from calculations. Latter on, relative frequencies were used instead of abundance data mostly to define the limits of BOPA in conformity with the requirements of the Water Framework Directive (WFD 2000/56 EU). According to the above BOPA can be written as follows: BOPA index = log $(f_P/(f_A + 1) + 1)$, where f_P is the opportunistic polychaete frequency (ratio of the abundance of the opportunistic polychaetes to the total abundance in the sample) and f_A is the amphipod frequency after excluding the opportunistic *Jassa* genus (ratio of the abundance of the amphipods except of *Jassa* to the total abundance in the sample). The addition of the two monad terms in the formula was done to allow the division when f_A is null $(f_A + 1)$ and to allow a logarithmic calculation when f_P is zero $(+1)$. The index ranges from 0, when there are no opportunistic polychaetes indicating an area with excellent environmental conditions, to log2, when there are no amphipods (except of *Jassa*) indicating an area with degraded environmental conditions. The index has been calibrated to define the five classes of environmental quality (**Table 1**) set by the WFD.

Function and Evaluation of the P/A Index and the BOPA Index

Soft-substratum communities

In soft bottoms, which constitute the largest ecosystem in terms of spatial coverage, granulometry is thought to be the major structuring factor. As the sediments become coarser, polychaetes diversity tends to increase, until larger clusters prevail (i.e., boulders, pebbles, and gravels) that will unavoidably cause a decline to the interstitial fauna. In soft sediments, few species of amphipods occur, mainly of the genus *Ampelisca*. The performance of P/A index has been comprehensively tested in soft-substratum communities of the English Channel and the NW Spain coasts after some severe oil spill events. At the most affected

Table 1 Lower limits of the BOPA index and correspondence to the five classes of ecological quality (EcoQ) set by the WFD Reproduced from Dauvin, J.C., Ruellet, T., 2007. Polychaete/amphipod ratio revisited. Marine Pollution Bulletin 55, 215–224.

BOPA index	*EcoQ*
≤ 0.04576	High
≤ 0.13966	Good
≤ 0.19382	Moderate
≤ 0.26761	Poor
≥ 0.26761	Bad

communities P/A index rapidly increased in values for about 3 years after the episode; afterwards, P/A gradually decreased. These results were attributed to the very low abundance of amphipods due to their high mortality after the oil spill, and to their subsequent recovery, as they started to re-colonize the sediment when the environmental conditions improved. An exception to the above pattern was observed at two more sites, where the ratio showed constantly high values during the study period, due to a very strong dominance of opportunistic polychaetes, such as *Chaetozone setosa*, *Spiochaetopteros costarum*, *Melinna palmata*, and *Diplocirrus glaucus*. So, the spill seemed to have little effect on these two sites, as the community structure is probably driven by some other ecological factors. The BOPA index has been also tested using the previous data sets reporting moderate to poor ecological quality, reflecting a decrease in amphipod abundance and a dominance of opportunistic polychaetes. After a decade BOPA values decreased again indicating the recovery of amphiopods that originally dominated the studied benthic community.

The performance of the same methodology in several communities of the eastern Mediterranean (Thermaikos Gulf), gave confounded results (**Fig. 1**).

Thermaikos Gulf has been characterized as moderately polluted by several methods (i.e., diversity indices, biotic indices, abundance/biomass comparison, multivariate analyses), with a northward gradient toward organic enrichment. Yet, P/A values were higher to the less-disturbed sites (four stations), as opposed to the organically polluted ones (two stations). This was rather unexpected, since all polychaetes collected from the last sites were typical opportunistic species. However, these two sites were characterized by significantly reduced species richness and abundance, linked to their proximity to a small outfall acting as a point source of various pollutants. Considering amphipods, a total of 14 species have been collected, among which *Elasmopus rapax* and *Ampelisca diadema* – two well-documented tolerant species (Antoniadou *et al.*, 2011; Simboura and Zenetos, 2002) – dominated. In that case we have two facts that violate the theoretical assumptions of P/A index: (1) some samples were very impoverished, creating large problems to the function of most ecological indicators and (2) although none *Jassa* amphipod has been recorded, most species are considered as tolerant according to updated information. Thus, the basic thought behind P/A (i.e. polychaeta=resistant to pollution; amphipoda=sensitive to pollution) seems inappropriate to these results. A probable explanation would consider the differences in the sediment type between these two examples; the sorted fine sands or muddy fine sands in Atlantic, as opposed to the unsorted sediments of Thermaikos with shell fragments of various sizes creating a type of hard substratum which attracts several amphipode species. Therefore, the wide-scale applicability of P/A seems to be restricted, as it is affected by the geography and the habitat heterogeneity that influence the biodiversity of an area. The application of the BOPA index at the same data set gave slightly different results (**Fig. 2**), although again overestimating the ecological quality at the most disturbed stations (5 and 6). Ecological quality ranged from excellent to poor, mostly classified as good or moderate, following a decreasing temporal trend. In all cases polychaetes dominated benthic communities. A clear problem in the applicability of the index derives from the fact that only *Jassa* amphipods are considered as opportunistic, whereas according to recent publications almost all amphipods collected from the study area (i.e. 10 of the 14 identified species) are assigned as tolerant.

Hard-substratum communities

Until recently, very few indices have been proposed for biomonitoring hard-substratum communities, despite the attractiveness of the subject, mostly due to the difficulties involved in the research of rocky bottoms. Recent efforts (biomonitoring of the photophilic, the sciaphilic, and port communities) conducted in the Mediterranean gave the opportunity for the establishment of such indices.

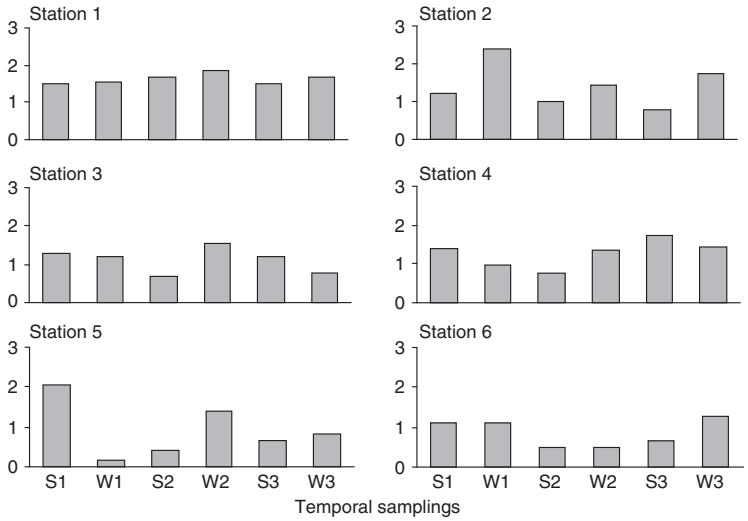

Fig. 1 The performance of P/A index in assorted soft sediments (Thermaikos Gulf), where S=summer, W=winter, and 1–3 the successive years of the study. Note that station 5 and 6 were the most affected sites.

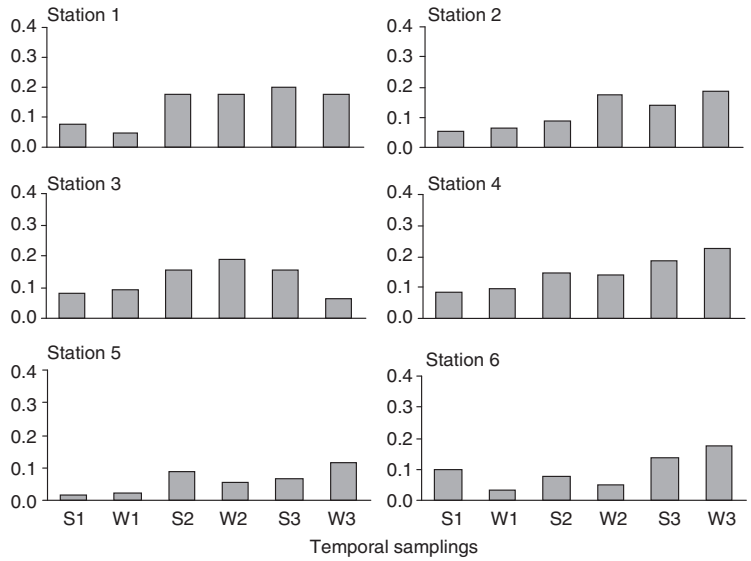

Fig. 2 The performance of BOPA index in assorted soft sediments (Thermaikos Gulf), where S = summer, W = winter, and 1–3 the successive years of the study. Note that station 5 and 6 were the most affected sites.

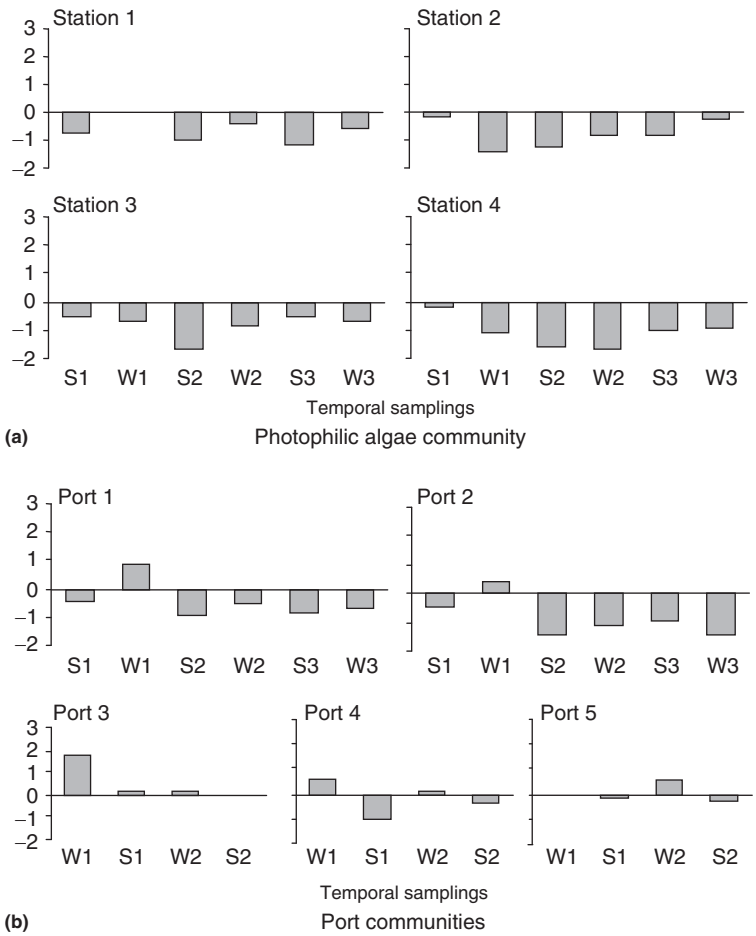

Fig. 3 The performance of P/A index on organically polluted hard-substratum communities (Thermaikos Gulf, North Aegean Sea), where S = summer, W = winter, and 1–3 the successive years of the study.

On rocky bottoms, zoobenthos is commonly related to algal structure and zonation. This does not necessarily mean dependence to the presence of particular macroalgal species, but rather to the morphological complexity and architecture of the algal cover and epiphytes. P/A index was applied on both a disturbed and undisturbed coastal area of the Aegean (Thermaikos Gulf and Chalkidiki peninsula, respectively). The results clearly show that the application of both indices is inappropriate in hard bottom (**Fig. 3–5**). P/A gains negative values in all the disturbed sites, whereas BOPA is below 0.1 in all cases classifying the ecological status as excellent or good considering both disturbed and undisturbed sites.

Thus, both indices clearly failed to detect any pollution effect. A possible reason of these results is the different response of the fauna in hard substratum with respect to pollution that contradicts P/A index assumptions. In hard bottoms, as opposed to soft sediments, amphipods constitute a major group with many species capable of proliferating by the increased organic load, building very dense populations. So, in the case of the photophilic algae community in Thermaikos, the species *Elasmopus rapax*, *Corophium sextonae*, *Caprella acanthifera*, and *Stenothoe monoculoides* increased their density, as did the species *Elasmopus rapax*, *Corophium acutum*, *C. sextonae*, and *Erichthonius brasiliensis* in ports. In contrast, in the undisturbed sciaphilic algae community, no amphipod

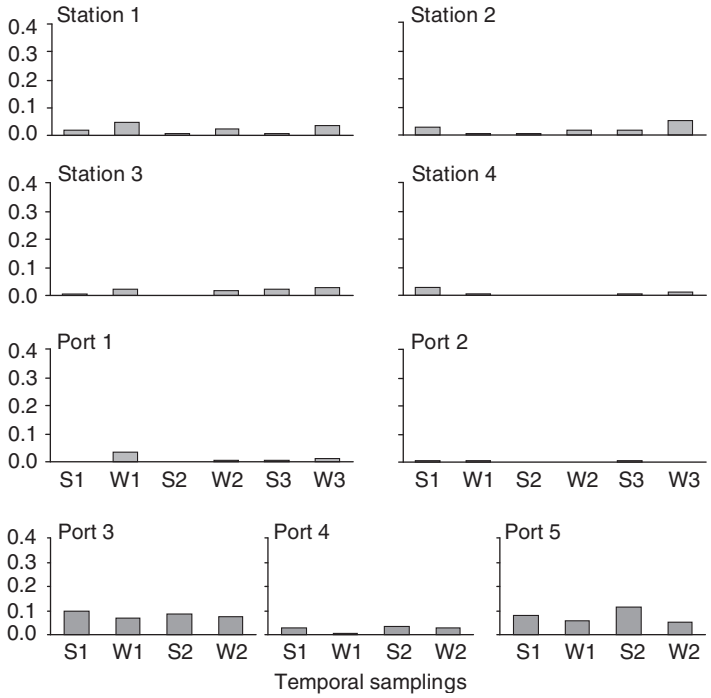

Fig. 4 The performance of BOPA index on organically polluted hard-substratum communities (Thermaikos Gulf, North Aegean Sea), where S = summer, W = winter, and 1–3 the successive years of the study.

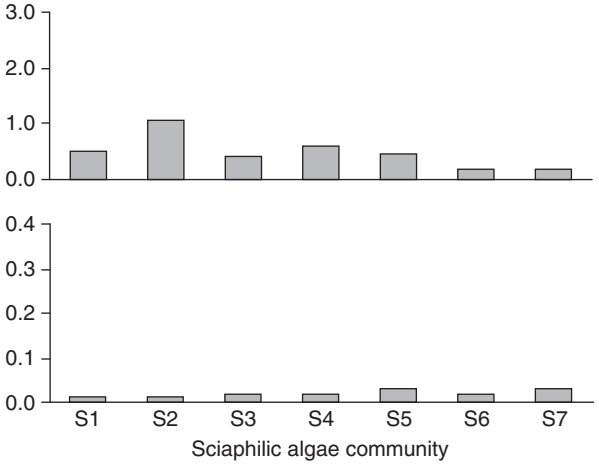

Fig. 5 The performance of P/A index (upper graph) and BOPA index (lower graph) on undisturbed hard-substratum communities (Chalkidiki peninsula, North Aegean Sea), where S1–S7 are the sampling sites.

species showed increased dominance. Consequently, the index performs unlikely to its predictions (P/A≤1=unpolluted; P/A1=polluted), since it is the denominator that increases with the pollution effect, as if the polychaetes were the sensitive group and amphipods the resistant. Moreover, as also stated previously, many amphipod species apart from the genus *Jassa* are tolerant to organic input violating the theoretical background of both indices and of BOPA in particular.

Perspectives and pitfalls

Any ecological index should hold some general attributes: it should (1) be robust and easy to handle, without the need of either laborious field or laboratory work, or complicated calculations to be used by non-experts; (2) be sensitive to any pollution event, as well as to detect gradients of disturbance; (3) assess different types of contamination; (4) incorporate seasonal variations; and (5) be applicable to various ecosystems and geographical areas.

P/A and BOPA indices follow some of the above desirable features. They are based on very simple calculation formulae and appear sensitive to the assessment of various contaminants, as they have been successfully implemented to detect alterations such as oil spill and waste material disposal. Both indices integrate seasonal oscillations of the fauna, whereas BOPA index can be applied in very poor communities, in which most indices fail to give valid results. BOPA seems to be more promising than P/A index for ecological quality assessment, mostly because it can be applied also in very poor communities, and because it is well fitted to the objectives of the WFD. However, BOPA index must be tested over geographic sectors and habitat types, and it should be, probably, modified by excluding all opportunistic amphipod species from its denominator to improve its reliability. A question arises on the discriminative power, robustness, and wide-scale applicability of both indices. Obviously the applicability of P/A and BOPA index is completely improper on hard bottoms, while it is dubious considering assorted sediments, in which the structure of polychaete and amphipode fauna is highly variable and driven mainly by a complex of ecological factors. Also, the performance of P/A index is bad when samples are impoverished or when polychaetes are not the dominant taxonomic group, while in the case of BOPA index the inclusion of only *Jassa* genus in the opportunistic amphipods can be strongly argued. Due to the above drawbacks P/A index has a rather limited applicability and approaches of ecological quality assessment should rank the entire benthic fauna with respect to either its sensibility/tolerance to pollution (e.g. biotic indices such as AMBI or BENTIX), or a specific taxonomic group (e.g. the polychaete index of Bellan, the amphipod index of Bellan-Santini, or the peracarid index of Chintiroglou). It is true, however, that the entirety of biotic indicators suffer from some of the above weaknesses (Blanchet *et al.*, 2008; Borja and Dauer, 2008; Borja *et al.*, 2008, 2009; Dauvin *et al.*, 2007; Diaz *et al.*, 2003), and it seems that no approach is a panacea offering a solution in all cases of environmental deterioration, demonstrating the necessity for intense scientific research on this topic under a multi-criteria approach.

General Remarks

Scientific research for the ecological quality assessment of coastal ecosystems has been intensified during the last decade. However, the general application of ecological indices is till date problematic and a complete proposal is still missing, mainly due to the high complexity of these systems and the general lack of adequate time-series data. Four basic concepts have been deployed (the diversity–stability hypothesis, the rivet hypothesis, the redundant species, and the idiosyncratic response hypothesis), among which the idiosyncratic response seems to better fit the marine environment. Each geographic sector contains inter-correlated populations. Several species thought as sensitive in one area, are more resistant to another. Most important is the national cooperation in broad geographic sectors to detect the environmental limits for each community, keeping in mind that each hypothesis should assess the divergence from a reference condition, in which the benthic community holds its normal state. To successfully meet this goal, the science of complexity, studying chaos and order, could be a relevant tool playing a leading role.

Protected Area

Yan Xie, Institute of Zoology, Chinese Academy of Sciences, Beijing, China

Introduction

Biodiversity is the key foundation of human survival and development. However, global biodiversity is declining rapidly and has become the most severe factor threating safety of humanity. From 1970 to 2012, the global wildlife populations fell by 58%, and we may witness a 2/3 decline during the period from 1970 to 2020. Protected areas (PA) have long been the cornerstone of biodiversity conservation tactics. PAs are critical for maintaining a healthy environment for people and nature. They are essential for biodiversity conservation and vital to the cultures and livelihoods of indigenous peoples and local communities. They also deliver clean air and water, bring benefits to millions of people through tourism, and provide protection from climate change and natural disasters.

IUCN defines protected areas as "A clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values." In view of the global current and future population, development trend and crisis pressure, the limited funds, scientific research, manpower, technology, time, etc. must be focused on the most important hot spots and key areas—PAs.

History and Current Status

PAs have a long history. For example, India set aside specific areas for the protection of natural resources over 2000 years, Europe protected some areas as hunting grounds nearly 1000 years ago. Punkaharju Esker Nature Reserve established in 1843 in Finland is one of the oldest PAs in the world. The first true national park came in 1872 with the dedication of Yellowstone by United States law "as a public park or pleasuring ground for the benefit and enjoyment of the people." 1866, the British Colony of New South Wales in Australia reserved 2000 ha of land for protection and tourism. Later additions created a park complex now known as the Blue Mountains National Park. In 1885, Canada gave protection to hot springs in the Bow Valley of the Rocky Mountains, an area later named Banff National Park. China's first PA could be the Nanhaizi—a royal hunting ground back to 1000 BC. Nanhaizi was the biggest wetland in South Beijing with 216.5 km^2 which was bigger than Beijing city in Qing Dynasty (1636–1912). It preserved the last population of David's deer which is endemic species of China. Before Nanhaizi was destroyed in 1900, some deer were sent to Europe and population expanded. After more than 80 years, 20 deer were reintroduced back to China and now the population increased to 3000. This demonstrated that Nanhaizi could be considered as a PA.

The modern PA movement has 19th century origins in the then "new" nations of Australia, Canada, New Zealand, South Africa, and the United States, but during the 20th century the idea spread around the world. The result was a remarkable expansion in the number of PAs. Nearly every country passed PA legislation and designated sites for protection. PAs continue to be established, and received a boost in 2004 when the Convention on Biological Diversity (CBD) agreed an ambitious Program of Work on PAs (Fig. 1).

The expansion history largely depending on political status of each country. The modern PAs in China were started to establish in 1956, with the first 20 years increased very slow due to cultural revolution, started to increase quickly from 1980s when the country opened to the world, and got its fastest development in numbers, areas and management quality since early 21st century. Now PAs have reached to over 10,000 occupying over 18% of the terrestrial land of China.

Realizing the importance of PAs to biodiversity conservation and therefore for survival of human being, the world's governments have committed to establish and manage PAs through Sustainable Development Goal Targets 14.5 (marine), 15.1 (terrestrial and freshwater), and 15.4 (mountains), Aichi Target of CBD 11 of the Strategic Plan for Biodiversity 2011–20, and numerous other international agreements such as the World Heritage Convention and the Ramsar Convention on Wetlands. By April 2016, under 15% of the world's terrestrial and inland waters, just over 10% of the coastal and marine areas within national jurisdiction, and approximately 4% of the global ocean are covered by PAs (Fig. 2). The Parties of CBD have agreed 20 "Aichi Targets" in which Aichi Target 11 addresses PAs, calling for at least 17% of terrestrial and inland water, and 10% of coastal and marine areas to be

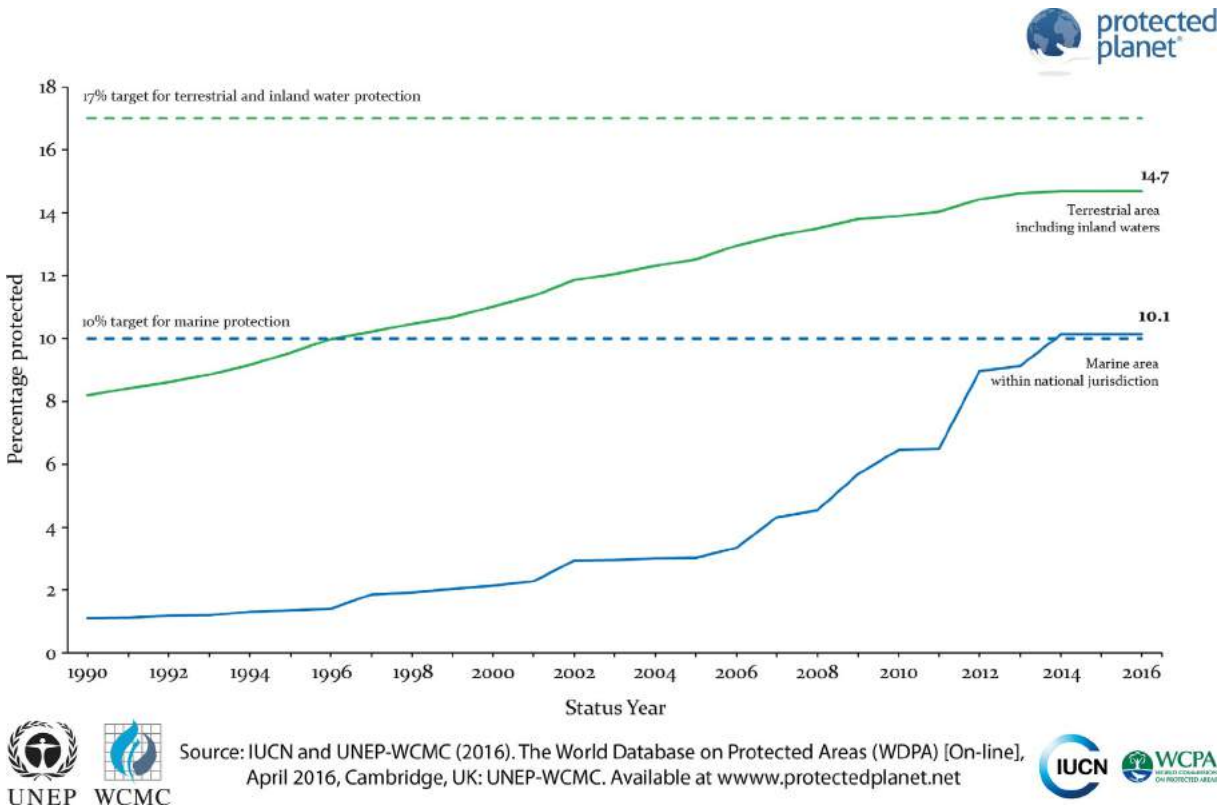

Fig. 1 Development of protected areas in the World.

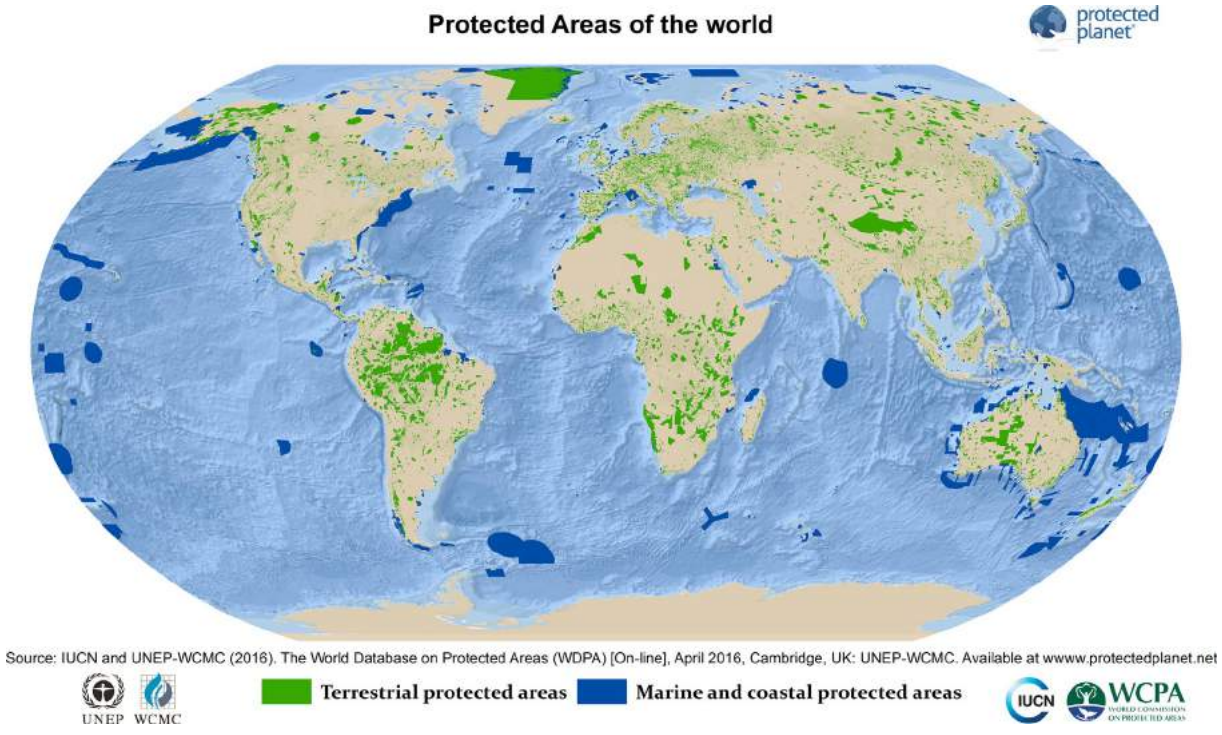

Fig. 2 Map of protected areas in the World in 2016.

established by 2020, including especially areas of particular importance for biodiversity and ecosystem services that are conserved through effectively and equitably managed, ecologically representative and well-connected systems of PAs and other effective area-based conservation measures, and are integrated into the wider landscapes and seascapes.

Role of PAs

Ensuring a more sustainable future for people and the planet will require greater recognition of the important role that PAs play in underpinning sustainable development. PAs are a key part of national and local responses to address harmful incentives to biodiversity, biological invasions, anthropogenic impacts and climate change challenges will help to halt biodiversity loss, improve food and water security, increase the resilience of vulnerable human communities to cope with natural disasters, and promote human health and well-being. PAs also play a key role in enhancing fish stocks and strengthening sustainable management of fisheries, and PAs in landscapes can promote sustainable production of natural resources in areas under agriculture, aquaculture and forestry.

However, the role of PAs largely depends on the management effectiveness. Conservation effectiveness of PAs varies in PAs and countries, with some showing positive on habitat or species conservation and some negative. However, selected studies that had counterfactual assessments of PAs, either of species populations or habitats, where outcomes could be attributed to PAs. Evaluation on change in the Red List Index for species for which PAs cover more than half of their important sites (key biodiversity areas) relative to those species for which less than half of their key biodiversity areas are protected, the result showed that the rate at which species are sliding toward extinction was halved for species with more than half of their range inside PAs. Globally, the Living Planet Index reports an average decline in vertebrate populations of 52% from 1970 to 2015. The same index of vertebrate populations for PAs shows a decline of only 18%. The synthesis in 2015 concluded that partial PAs significantly enhanced density and biomass of fish relative to open fishing areas, while fully no-take reserves in turn yielded a significantly higher biomass of fish relative to partially PAs.

A global analysis of the effectiveness of the full range of marine PAs found that, on average, coral cover within marine PAs remained constant, while coral cover on unprotected reefs declined, although the differences were not statistically significant. While the short-term differences between unprotected and protected reefs were not statistically significant, the trend in the differences could be significant over the long-term if the trends remained constant. Their results also suggested that older marine PAs were generally more effective in preventing coral loss.

Problems Existing in PA Management

These PAs are cornerstones of biodiversity conservation policy in the world and important in maintaining ecosystem functions and services. It is also the case, however, that obsolete, unreasonable, or unbalanced planning and legal protections for PAs make the overall management of these different PAs very poor. The many roles PAs could play in biodiversity conservation, therefore, far from being fulfilled.

Many PAs are not yet fully implemented or managed. Marine PAs are lagging far behind land and inland water PAs although there are now great efforts to rectify this situation. This is necessary because although the rate of growth has been impressive, many PAs have been set up in remote, unpopulated or only sparsely populated areas such as mountains, ice-fields and tundra and there are still notable gaps in PA systems in some forest and grassland ecosystems, in deserts and semideserts, in fresh waters and, particularly, in coastal and marine areas. Many of the world's wild plant and animal species do not have viable populations in PAs and a substantial proportion remain completely outside PAs.

The tension between community development and biodiversity conservation can be difficult to resolve. A large number of key ecological-function areas are located in impoverished and underdeveloped regions. Restrictions on resource use in these areas need to be accompanied by better compensation mechanisms and support policies.

Following are the key areas for improving effectiveness of PA management.

PA Management Categories

PAs are by no means uniform entities however; they have a wide range of management aims and are governed by many different stakeholders. At one extreme a few sites are so important and so fragile that no-one is allowed inside, whereas other PAs encompass traditional, inhabited landscapes and seascapes where human actions have shaped cultural landscapes with high biodiversity. Some sites are owned and managed by governments, others by private individuals, companies, communities and faith groups. PAs in China could be described using established national categories, such as nature reserves, scenic and historic areas, and forest parks, as well as international categories, such as natural and mixed heritage sites, wetlands of international importance, global geo-parks, and biosphere reserves, as well as new categories as national parks since 2013, and they are current now managed by a dozen governmental departments. There are also quick investment to establishing private PAs for commonweal with donation funding from private companies.

In order to speak a common language, The IUCN developed PA management categories as an important global standard for the planning, establishment and management of PAs, recognized by the CBD and adopted by many countries. Due to PAs exist in an astonishing variety—in size, location, management approaches and objectives, the IUCN PA management categories are not a straitjacket but a global framework to guide improved application of the categories.

IUCN first effort to develop the PA management categories was in 1934 and after many revisions, the IUCN General Assembly meeting approved the new system in 1994 and the first guidelines were published by IUCN and the World Conservation Monitoring Centre (WCMC) later that year. IUCN secured the endorsement of the system by the CBD, at the seventh Conference of the Parties in February 2004. The latest revision was done in 2008 with publication of Guidelines for Applying PA Management Categories. The current version of the IUCN PA management categories are summarized below.

Ia *Strict nature reserve*: Strictly protected for biodiversity and also possibly geological/geomorphological features, where human visitation, use and impacts are controlled and limited to ensure protection of the conservation values.

Ib *Wilderness area*: Usually large unmodified or slightly modified areas, retaining their natural character and influence, without permanent or significant human habitation, protected and managed to preserve their natural condition.

II *National park*: Large natural or near-natural areas protecting large-scale ecological processes with characteristic species and ecosystems, which also have environmentally and culturally compatible spiritual, scientific, educational, recreational, and visitor opportunities.

III *Natural monument or feature*: Areas set aside to protect a specific natural monument, which can be a landform, sea mount, marine cavern, geological feature such as a cave, or a living feature such as an ancient grove.

IV *Habitat/species management area*: Areas to protect particular species or habitats, where management reflects this priority. Many will need regular, active interventions to meet the needs of particular species or habitats, but this is not a requirement of the category.

V *Protected landscape or seascape*: Where the interaction of people and nature over time has produced a distinct character with significant ecological, biological, cultural and scenic value: and where safeguarding the integrity of this interaction is vital to protecting and sustaining the area and its associated nature conservation and other values.

VI *PAs with sustainable use of natural resources*: Areas which conserve ecosystems, together with associated cultural values and traditional natural resource management systems. Generally large, mainly in a natural condition, with a proportion under sustainable natural resource management and where low-level nonindustrial natural resource use compatible with nature conservation is seen as one of the main aims.

The category should be based around the primary management objective(s), which should apply to at least three-quarters of the PA—the 75% rule.

More and more countries have adopted the IUCN PA management category system, including Australia, South Korean, New Zealand, Canada, South Africa, Laos, and India.

PA Zonation

Many PA however promote multiple-uses (and are thus not only focused on nature conservation) or suffer from human disturbance inside their borders. One option to answer the challenges of combining the needs of economic and social development and the ecological requirements of the species and habitats that PA seek to protect is to design zoning schemes inside PA. Such zoning schemes can spatially and temporally refine the list of activities allowed and banned through the mapping of "functional zones." Different zoning models are used in different countries and within single countries. The UNESCO's Man and the Biosphere Programme (MAB)'s system of core, buffer and transition zones holds considerable influence and many countries adopted a similar system with three zones, given different names by different countries. Starting to become widespread in the 1980s, buffer zones are some of the most common zoning tool and are usually defined as zones where only a limited list of nondestructive activities are allowed, and located between strict conservation zones and zones outside the PA. However, the zonation system is too crude and failed guide PA management practices. More detailed zonation system, with clear zoning names referring to management strictness, clear allowed activities, level of impact to nature and permit management systems should be established and promoted around the world, is believed to be more effective to improve management level of PAs (Table 1).

System Planning

System planning is an organized way to carry out conservation planning for PAs at the macro level. It is recognized as a key management principle for increase the effectiveness of in situ biodiversity conservation. As explained by IUCN-WCPA, system planning in relation to PAs is about: (a) defining the priority of PAs as a worthwhile national concern; (b) defining the relationships between different units and categories of PAs, and between PAs and other relevant categories of land or sea; (c) taking a more strategic view of PAs; (d) defining roles of key players in relation to PAs and the relationships between these players; this may include building support and a constituency for PAs; (e) identifying gaps in PA coverage (including opportunities and needs for connectivity) and deficiencies in management; and (f) identifying current and potential impacts—both those affecting PAs from surrounding land or sea, and those emanating from PAs which affect surrounding land or sea.

Table 1 Proposed PA zonation system

Zone name	*Description*	*Activities allowed*	*Impact on biodiversity*	*Restrictions on activities*
1. Closed zone	Sanctuaries for species very sensitive to disturbances. Human disturbances strictly controlled	Nondestructive scientific monitoring Enforcement patrols and footpaths Fireproofing Very limited religious practice in sacred sites	Very low	Permit needed for scientific research. Religious practice limited to a very low number of individuals requiring permits
2. Active management zone	Areas where limited human intervention is necessary to manage and restore habitats in order to achieve the conservation goals	Habitat and species management (including through grazing) Ecological restoration Local species reintroduction	Positive to low	Permit needed for scientific research and expeditions
		Small-scale expeditions guided by PA staff Scientific research with little disturbance (e.g., specimen collection, interventionist conservation experiment) Trail for motorized vehicles (staff only)	Low	
3. Limited use zone				
3A. Limited visitor use zone	Areas for light visit, tourism and recreation	Nature tourism Access roads, weather shelters, rest pavilions, camp sites Traditional wilderness-based lifestyle and customs, (low densities and in ways compatible with the conservation objectives)	Medium	Tourism submitted to entry fees. No high impact accommodation or recreational activities unrelated to the nature area (golf, etc.). Control on access roads
3B. Limited resource use zone	Areas for sustainable natural resource utilisation	Hunting (if allowed by national laws) Fishing Collection of wild nontimber forest products (NTFP)	Medium	Resource use permit system ensuring the viability of populations
		Grazing	Medium[a]	
4. Reasonable use zone	Areas for PA management, heavier tourism and local residents	Tourist centre (accommodations, etc.) High intensity tourist areas Staff housing PA administration office areas Parking Residential areas Small-scale agriculture for auto-consumption in the PA	High	Ban on fertilizer and pesticide use wherever it can impact water quality or feeding habitats
5. External support zone (outside the PA)	Areas outside the PA but submitted to increased environmental scrutiny and collaborating closely with PA managers. The aim of such areas is to mitigate the impacts of surrounding human activities and PAs on each other	Large-scale agriculture Plantations Fish ponds	Very high[a]	Ban on fertilizer and pesticide use wherever it can impact water quality or feeding habitats. Extractive industries, etc. submitted to environmental impact assessment and a no net loss of biodiversity standard
		Extractive industries, pipelines, power lines, cell phone towers, etc.	Very high	

Unless stated otherwise, the impact described in column "impact on biodiversity" is negative.
[a]These activities can have a positive impact if they are part of species or habitat management actions (implemented in a two active management zone).

Over the years, IUCN-WCPA has developed guidelines on the main characteristics and considers that the main characteristics of a PAs system should include:

- *Representativeness, comprehensiveness and balance*: ability to represent or sample the full variety of biodiversity and other features such as landform types, and landscapes or seascapes of cultural value, so as to protect the highest quality examples, especially threatened and underprotected ecosystems, and species globally threatened with extinction.

- *Adequacy*: supporting the viability of ecosystem processes as well as species, populations and communities that make up the country's biodiversity.
- *Coherence and complementarity*: the extent to which each site makes a positive contribution to the system as a whole.
- *Consistency*: the application of management objectives, policies and classifications to individual sites under comparable conditions in standard ways.
- *Cost-effectiveness, efficiency and equity*: an appropriate balance between the costs of and benefits flowing from PAs, equity in their distribution, and efficiency in terms of the minimum number and size of PAs needed to achieve system objectives.
- *Persistence*: the ability to promote the long-term survival of biodiversity contained within a PA by maintaining natural processes and viable populations and by excluding or overcoming threats.
- *Resilience*: the ability to adapt and sustain primary conservation objectives of the site and the system overall in the face of climate change and other global change factors.

Legislation and Enforcement

The global conventions noted below as the main instruments concerning a nation's PAs are the CBD, UNESCO's World Heritage Convention, the Ramsar Convention and the Conservation of Migratory Species of Wild Animals (CMS). Some regional law instruments spell out important commitments and guidance for PA legal frameworks, such as African Convention on the Conservation of Nature and Natural Resources, Convention on the Conservation of European Wildlife and Natural Habitats, Convention on Nature Protection and Wild Life Preservation in the Western Hemisphere, UNESCO Man and the Biosphere Programme. Many of these commitments, as with global treaties, generate national obligations that require legislative action for implementation.

At the national level, over last 100 years, almost all countries have issued relevant legislation to secure PA supervision and management. However, legislation status varies largely among different countries and different regions. Some countries have issued laws or regulations for each PA types, such as Republic of Korean and Japan. Although diverse legislation make implementation more flexible, but duplication, gaps or contradiction among different legislation could bring problems when implementing laws. To address the issue, some countries have issued one unified law to manage all PAs. For example, Federal Nature Conservation Act 2002 of German, National System of Conservation Units 2000 of Brazil, PA Act 2003 of South Africa, PA Act (1949 revised 2015) of Kenya, National Integrated PAs System Act 1992 of Philippines, and PA System Act 1997 of Peru. Australian government issued Environment Protection and Biodiversity Conservation Law to replace several legislations issued before and unify management standards of all types of PAs. There are also many countries have include PAs managed by indigenous or local communities and private PAs into national PA management system. By 2011, Australia have 42 indigenous PAs, about 1/4 of national PA system, and India has several thousand community PAs around the whole country.

However, many countries PAs are governed not by legislation but by a patchwork quilt of administrative rules, regulations, and guidelines issued by various departments and agencies. This means, of course, that the existing legislative framework is insufficient to deal with some of the major threats to PAs, and this is a major reason why critics of PAs in these countries have referred to them as "paper parks," saying that they are characterized by the "threewithouts." They are without a management agency, without staff, and without recurrent funding.

Good legislation would largely improve PA management effectiveness. IUCN Guidelines to Legislation of PAs lists following important elements to be included into PA legislations based on good practices in the world: Policy and objectives, Institutional arrangements, Planning for PAs, Establishment of PAs, PAs management, Conservation agreements, Regulated activities, Compliance and enforcement, Environmental and social impact assessment, and Special financial tools.

Community Participation

Local people in and around PAs has long history of coexisting with nature, and their traditional culture and knowledge are part of the nature. Governments and PA managers should incorporate customary and traditional resource use, and control systems, as a means of enhancing biodiversity conservation. WWF and IUCN/WCPA have adopted principles and guidelines concerning indigenous rights and knowledge systems, consultation processes, agreements between conservation institutions, decentralization, local participation, transparency, accountability, sharing benefits and international responsibility. The five principles are as follows:

Principle 1: Indigenous and other traditional peoples have long associations with nature and a deep understanding of it. Often they have made significant contributions to the maintenance of many of the earth's most fragile ecosystems, through their traditional sustainable resource use practices and culture-based respect for nature. Therefore, there should be no inherent conflict between the objectives of PAs and the existence, within and around their borders, of indigenous and other traditional peoples. Moreover, they should be recognized as rightful, equal partners in the development and implementation of conservation strategies that affect their lands, territories, waters, coastal seas, and other resources, and in particular in the establishment and management of PAs.

Principle 2: Agreements drawn up between conservation institutions, including PA management agencies, and indigenous and other traditional peoples for the establishment and management of PAs affecting their lands, territories, waters, coastal seas, and

other resources should be based on full respect for the rights of indigenous and other traditional peoples to traditional, sustainable use of their lands, territories, waters, coastal seas, and other resources. At the same time, such agreements should be based on the recognition by indigenous and other traditional peoples of their responsibility to conserve biodiversity, ecological integrity and natural resources harbored in those PAs.

Principle 3: The principles of decentralization, participation, transparency and accountability should be taken into account in all matters pertaining to the mutual interests of PAs and indigenous and other traditional peoples.

Principle 4: Indigenous and other traditional peoples should be able to share fully and equitably in the benefits associated with PAs, with due recognition to the rights of other legitimate stakeholders.

Principle 5: The rights of indigenous and other traditional peoples in connection with PAs are often an international responsibility, since many of the lands, territories, waters, coastal seas and other resources which they own or otherwise occupy or use cross national boundaries, as indeed do many of the ecosystems in need of protection.

Glossary

Assisted colonization The intentional movement and release of an organism outside its indigenous range to avoid extinction of populations of the focal species. Also called "assisted migration," especially when applied to plants.
Conservation introduction The intentional movement and release of an organism outside its indigenous range.
Conservation translocation The intentional movement and release of a living organism where the primary objective is a conservation benefit: this will usually comprise improving the conservation status of the focal species locally or globally, and/or restoring natural ecosystem functions or processes.
Ecological replacement The intentional movement and release of an organism outside its indigenous range to perform a specific ecological function.
Indigenous range All areas where a species is thought to have lived based on historic records and paleoecological evidence.
Population restoration Any conservation translocation conducted within the indigenous range.
Translocation The human-mediated movement of living organisms from one area, with release in another.
Reinforcement The intentional movement and release of an organism into an existing population of conspecifics.
Reintroduction The intentional movement and release of an organism inside its indigenous range from which it has disappeared.
Reintroduction biology Research designed to improve the outcomes of reintroductions and other translocations conducted for conservation purposes.

What Is Reintroduction?

Reintroductions are becoming increasingly frequent, and are one of many tools used worldwide to combat losses of biodiversity (Fig. 1). A reintroduction is an attempt to re-establish a wild population of a species in a location where it used to occur. It involves removing individuals from a source population, either captive or wild, and deliberately releasing them where they used to occur to restore a population. This deliberate movement with free-release is referred to as "translocation." Several types of translocations are conducted for conservation reasons. Like reintroduction, "reinforcement" is a form of "population restoration," but it differs from reintroduction in that it aims to bolster a population that still exists. In some cases it might be deemed necessary to establish a population of the species outside its indigenous range, in which case the translocation constitutes an "introduction" rather than a "reintroduction." Conservation introductions can constitute "assisted colonization" (or "assisted migration"), meaning species are introduced to new sites where they can escape from current or future threats. Alternatively, they can constitute "ecological replacement" where the species is introduced to perform the ecological function of an extinct species. The collective term "conservation translocation" is used to cover all of these types of translocation as long as they are conducted primarily for conservation benefit.

Conservation translocations are often part of species recovery programs, where the objective is to increase distribution and/or abundance of the species to ensure its long-term survival. The other main motivation is to restore ecosystems by reintroducing or trying to replace species that were components of those systems, a process often called "re-wilding" if large keystone species are involved (Donlan *et al.* 2005). Consequently, conservation translocation and ecological restoration are closely linked. Conservation translocation is also closely linked to the ecological concept of "habitat," meaning the suite of biotic and abiotic factors that determine whether a species can persist at a site. The most fundamental prerequisite for reintroduction is that there must be good reason to believe that the factors causing the local extirpation of the species have been addressed.

History of Conservation Translocations

People have moved other species from one place to another for thousands of years. Most of these movements have been accidental, for example the transmission of our parasites such as bacteria, viruses, and lice, and hitchhikers such as seeds and rodents. However, we have also deliberately tried to establish a wide range of species in new places. These species were predominantly food resources, that is, crops, livestock, and fish and game species, including many of the food resources used today. However, people also moved species for other reasons, such as erosion control, religious ceremonies, or simply because they

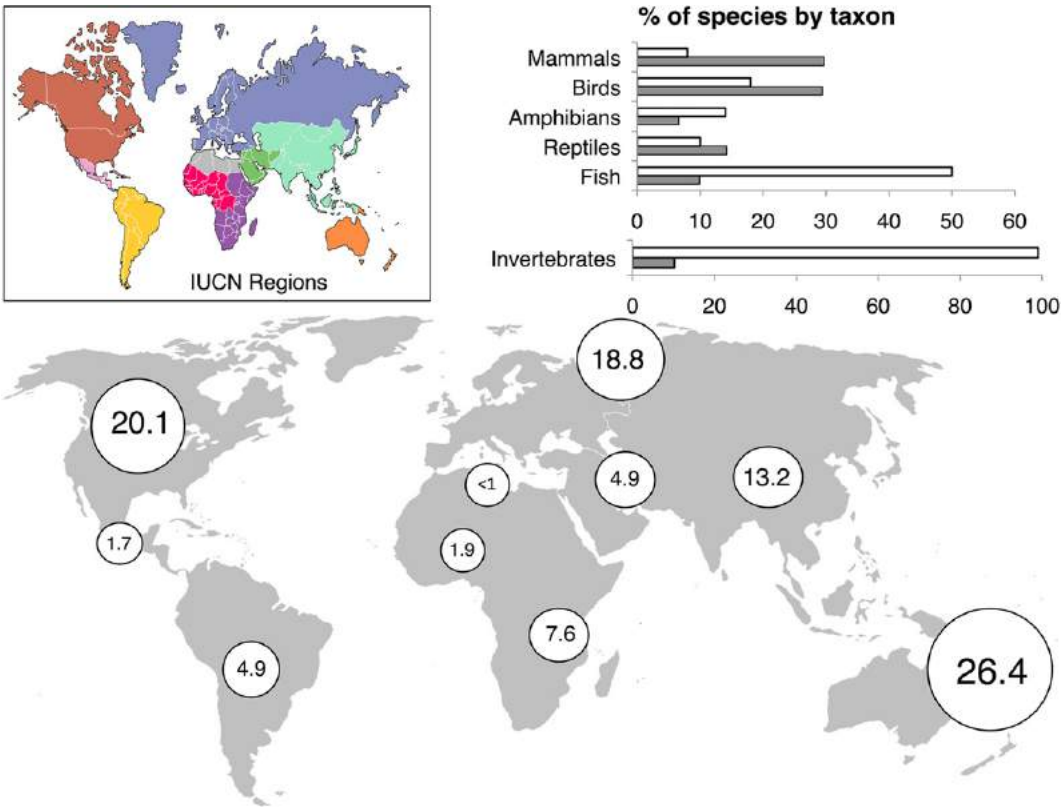

Fig. 1 Regional and taxonomic make-up of the 303 animal species featured in conservation translocations recorded in the IUCN database. The figures on the main map show the percentages of these species found in each IUCN region. The color inset map shows the 10 regions, which from west to east: North America and Caribbean (*brown*), Meso-America (*pink*), South America (*gold*), North Africa (*gray*), Central and West Africa (*crimson*), East and Southern Africa (*purple*), West Asia and the Middle East (*green*), Europe and the Mediterranean (*blue*), Asia (*pale green*), and Oceania (*orange*). The histograms compare the taxonomic makeup of the featured species (*gray bars*) to that found in nature (*white bars*). Modified from Seddon, P. J., Griffiths, C. J., Soorae, P. S., and Armstrong, D. P. (2014). Reversing defaunation: Restoring species in a changing world. *Science* **345**, 406–412.

enjoyed those species. The acclimatization societies of the 19th century tried to introduce a huge range of species to French and English colonies for a range of reasons, including nostalgia for European species and a desire to enhance the flora and fauna in the colonies. By the late 19th century it had become clear that many introduced species had become invasive, and were in fact degrading the flora and fauna through their impacts on native species.

Conservation translocations were motivated by a desire to reverse the impacts that humans have had on native species, not only through invasive species but also through our own hunting and other impacts to species' habitats. Two famous translocation programs occurred in the late 19th century on opposite sides of the world (**Table 1**). In New Zealand, it was recognized that invasive stoats (*Mustela erminea*) were driving native flightless birds to extinction. Consequently, Richard Henry was appointed caretaker of stoat-free Resolution Island which was designated a reserve. With the help of his dog, Henry caught hundreds of kākāpō (*Strigops habroptilus*; **Fig. 2**), a nocturnal parrot, and tokoeka (*Apteryx australis*), a type of kiwi, and rowed them out to an offshore island free of stoats. Unfortunately stoats swam to the island soon after and exterminated the introduced birds, but similar actions almost 100 years later saved the species from extinction (**Table 1**). In the late 19th century in the USA, it was recognized that snowy egrets (*Egretta thula*) were possibly being driven to extinction by people killing the birds for their showy plumes. The Tabasco sauce magnate Ned McIlhenny responded by reintroducing the species to a private sanctuary on Avery Island, Louisiana, using eggs sourced from remnant populations. This in turn served as a source population for other reintroductions, possibly saving the species from extinction. Ironically he later contributed to the deliberate introduction of the nutria (*Myocastor coypus*), an invasive rodent that has major negative impacts on Louisiana's wetland ecosystems to this day.

Translocations for conservation reasons have continued over the subsequent 120 years, with an apparent increase since about 1960 due to increased concerns about habitat loss, pollution, invasive species, overharvesting, and other forms of human persecution. Many of the translocations are considered great successes in terms of species recovery, ecosystem restoration, or both (**Table 1**). These successes have inspired further use of translocations, so that the scope of translocation has increased, both in terms of the conservation problems being addressed, but also the diversity of taxa and ecosystems involved (e.g, Germano and Bishop, 2009). However, it was realized by the 1980s that many conservation translocations were failing to establish populations. Although there being some failures is inevitable due to the uncertainties inherent in translocations, many translocations appear to

Table 1 Some notable conservation translocations

Date	*Translocation*
1894	First translocations of the kākāpō (*Strigops habroptilus*; **Fig. 2**) to Resolution Island in an attempt to save this flightless parrott that was rapidly declining on the New Zealand mainland due to exotic mammalian predators. This attempt failed due to stoats (*Mustela erminea*) colonizing the island. However, the kākāpō was saved from extinction by introducing it to Little Barrier and Codfish Islands in the 1980s, giving an example of a species being saved by assisted colonization
1895	Reintroduction of captive-bred snowy egrets (*Egretta thula*) to Ned McIlhenny's private wildfowl refuge, which provided a source population used to recover the species in the wild in the south-eastern USA
1907	Reintroduction of captive-bred American bison (*Bison bison*) to the Wichita Mountains Wildlife Preserve in Oklahoma, leading to the recovery of this once-abundant species that was decimated by hunting in the 19th century
1911	First reintroduction of captive-born Alpine ibexes (*Capra ibex ibex*) to the Swiss Alps, leading to the recovery of the population. Reintroductions were also conducted in Austria, Germany, France, Slovenia, and Italy
1961	Start of reintroduction program for the southern white rhinoceros (*Ceratotherium simum simium*) using stock from the remnant population in Hluhluwe–Imfolozi Park which had recovered following protection from poachers. The southern subspecies is now abundant in parks throughout South Africa and Swaziland despite increased poaching over the last decade, whereas the northern subspecies (*C. s. cottoni*) is extinct in the wild
1964	Translocation of 36 South Island saddlebacks (*Philesturnus carunculatus*) from the single surviving population on Big South Cape Island, off Stewart Island, New Zealand, after it was invaded by black rats (*Rattus rattus*). The birds were introduced to Big and Kaimohu Islands, resulting in the species being saved
1974	Start of peregrine falcon (*Falco peregrinus*) reintroductions and reinforcements to restore North American populations reduced by pesticides such as DDT. The species was removed from US list of endangered species in 1999 following the release of >6000 captive-bred falcons
1977	The black robin (*Petroica traversi*) endemic to New Zealand's Chatham Islands is saved from extinction by reintroduction. The last seven birds from Little Mangere Island, where the habitat had been degraded by seabirds, were translocated to Mangere Island following cat eradication and reafforestation
1982	Reintroduction of the Arabian oryx (*Oryx leucoryx*) to Oman using captive-bred animals from the San Diego Wild Animal Park. Although the population increased until about 1996, it subsequently declined to near extinction due to illegal hunting. However, reintroductions have also taken place in Saudi Arabia, Jordan, and the United Arab Emirates
1983	Initiation of the reintroduction program for the large blue (*Maculinea arion*; **Fig. 3**), a Lycaenid butterfly, in the UK. Reintroducing the species required understanding its complex habitat requirements, particularly its dependency on the ant *Myrmica sabuleti*
1984	Reintroduction of the greater Indian rhinoceros (*Rhinoceros unicornis*) to Dudhwa National Park, India, following decline of the species due to habitat loss and hunting
1984	Reintroduction of lake sturgeon (*Acipenser fulvescens*) to the Mississippi and Missouri Rivers begins
1987	Reintroduction of the red wolf (*Canis rufus*) to the Alligator River National Wildlife Refuge in North Carolina, the first reintroduction of a carnivore species that had been declared extinct in the wild
1989	First reintroduction in the Mallorcan midwife toad (*Alytes muletensis*) recovery program, which resulted in the species being downgraded from "Critically Endangered" to "Vulnerable"
1990	Start of translocation program for the Hawaiian monk seal (*Monachus schauinslandi*). This may be the first translocation program for a marine mammal, and has involved translocating pups to islands where they have higher survival due to reduced aggression from males and shark predation
1992	Start of reintroduction program for the takhi (Przewalski's horse, *Equus ferus przewalskii*) in the Gobi Desert in Mongolia
1994	Reintroduction of Atlantic salmon (*Salmo salar*) to tributaries of the Rhine River begins. Salmon were formerly abundant in the Rhine and an important food source to people, but were extirpated by the 1950s due to overfishing and pollution
1994	First reintroductions of native Australian mammals to a fenced sanctuary, Karakamia, where exotic mammalian predators had been eradicated, leading to a network of fenced sanctuaries where >60 reintroductions of at least 23 species have occurred. Native burrowing mammals such as the eastern bettong (*Bettongia gaimardi*; **Fig. 4**) act as "ecosystem engineers," hence their reintroduction has helped restore ecosystem processes. However, some species have probably become over-abundant due to lack of of regulation formerly performed by extinct native predators
1995	Reintroduction of the gray wolf (*Canis lupus*) to Yellowstone National Park, Montana, Wyoming and Idaho, resulting in substantial ecosystem changes through the reintroduction of this top predator
1996	Extensive reintroduction of the Mauna Kea silversword (ahinahina, *Argyroxiphium sandwicense* subsp. *sandwicense*) (>3000 individuals planted) following the control of the feral sheep and mouflon which had decimated this once common plant
2000	First reintroduction of a New Zealand bird, the Little spotted kiwi (*Apterx owenii*), to a fenced sanctuary, Zealandia, where exotic mammalian predators had been eradicated. This has led to a network of fenced sanctuaries where many native species have been reintroduced, including species that that were previously extinct on the mainland
2001	Translocation of two UK butterfly species (marbled white *Melanargia galathea* and small skipper *Thymelicus sylvestris*) into sites north of their range margins as a test case of assisted colonization in response to climate change
2004	First introductions of exotic Aldrabra giant tortoises (*Aldrabrachelys gigantea*; **Fig. 5**) to Mauritian offshore islands to restore the grazing and seed dispersal performed by the extinct Mauritian *Cylindraspis* species
2006	The Bolson tortoise (*Gopherus flavomarginatus*) reintroduced to the wild in New Mexico using captive-bred animals descended from the remnant wild population in Mexico. This is apparently the first wild population north of the Rio Grande for $>10{,}000$ years

(*Continued*)

Table 1 Continued

Date	*Translocation*
2008	Seedlings of the Florida torreya (*Torreya taxifolia*) planted >500 km north of its current range (**Fig. 6**). Although the translocation was originally conceived as a reintroduction to part of the species' prehistoric range, it was widely interpreted as an assisted colonization in response to climate change, leading to intensive debate on that topic
2011	Reintroduction of Atlantic salmon to tributaries of Lake Ontario begins more than 100 years since the species was extirpated from the lake
2012	Introduction of Tasmanian devils (*Sarcophilus harrisii*) to Maria Island, probably the first assisted colonization motivated by a disease threat (devil facial tumor disease)
2016	First translocation of juvenile western swamp tortoises (*Psuedemydura umbrina*) to sites south of the species' indigenous range, probably the first assisted colonization of a vertebrate motivated by climate change

Fig. 2 The flightless kākāpō (*Strigops habroptilus*) was saved from extinction by translocating the remaining birds to offshore islands where the species had probably never occurred, an example of assisted colonization being used in response to impacts of invasive predators. Photo credit: Neil Fitzgerald.

have been poorly conceived. In addition, most translocations at that time were poorly monitored, so little was learned from them. Consequently, in recent decades guidelines and regulations have been developed to improve the conception, planning, and monitoring of translocations. In addition, the science of reintroduction biology has been developed to improve translocation outcomes (Seddon *et al.*, 2007). These developments are covered in the sections below.

Scope of Conservation Translocations

Conservation translocations have traditionally been associated with reintroductions of birds and mammals. The books of case studies published by the IUCN Reintroduction Specialist Group since 2008 (available via the website below) give an idea of the taxonomic breakdown of recent translocations. Of the 303 animal species featured in the first four books, mammals, birds, and reptiles were overrepresented compared to their abundance in nature, while amphibians, fish, and especially invertebrates were vastly underrepresented (Seddon *et al.* 2014; **Fig. 1**). Nevertheless, there have been notable invertebrate translocations, such as the reintroduction of the large blue (*Maculinea arion*) to the United Kingdom (**Table 1**, **Fig. 3**). Recent conservation translocations have become more varied, the number of taxa have become more numerous, and their intended purpose has diversified.

Translocations of 279 animal species in North America from 1974–2013 mostly consisted of reintroductions and reinforcements, with these occurring at similar frequencies (Brichieri-Colombi and Moehrenschlager, 2016). However, assisted colonizations were also documented for species such as the fringed darter (*Etheostoma crossopterum*), white sands pupfish (*Cyprinodon tularosa*), wood frog (*Rana sylvatica*), ornate box turtle (*Terrapene ornate ornata*), gopher tortoise (*Gopherus polyphemus*) and wild turkey (*Meleagris gaallopavo*). Ecological replacements also occurred, as the yellow crowned night heron (*Nyctanassa violacea*) was released to replace the extinct Bermuda night heron (*Nyctanassa carcinocatactes*), and releases of greater prairie-chicken (*Tympanuchus cupido*) were being contemplated to replace the extinct heath hen (*Tympanuchus cupido cupido*).

Fig. 3 The large blue (*Maculinea arion*) was reintroduced to the United Kingdom after detailed research on its habitat requirements, which includes a parasitic relationship with the ant *Myrmica sabuleti* whose persistence is affected by grazing practices. Photo credit: David Simcox Habitat Designs Ltd.

While assisted colonization, such as the introduction of kākāpō to offshore islands (**Table 1**), has been used for over a century to protect species from inescapable threats such as invasive predators, it will be increasingly motivated by climate change. In the United States, the Torreya Guardians translocated seedlings of the Florida torreya (*Torreya taxifolia*) to areas beyond its current range to save the species from climate-induced threats. This translocation was originally conceived as a reintroduction to part of the species' prehistoric range. However, it was subsequently interpreted as an assisted colonization in response to climate change, starting intensive debate on that topic (McLachlan *et al.* 2007). Although strongly opposed by some people, assisted colonization appears to be an essential strategy for managing some long-lived tree species in the face of climate change, and is generally well accepted by foresters (Williams and Dumroese 2013). It may be equally essential for long-lived slowly-dispersing animals. The 2016 translocations of the western swamp tortoise (*Pseudemydura umbrina*) south of its indigenous range in Western Australia constituted the first vertebrate assisted colonizations that were clearly motivated by climate change.

Increases in the frequency of conservation translocations are particularly evident for plants. In China alone 154 species, of which 78% were nationally listed as threatened and included 87 endemics, have been translocated for conservation purposes. Surprisingly 26% of the 154 species, have been moved beyond their indigenous range, primarily as assisted colonizations to escape human-imposed threats such as large-scale habitat destruction.

While reintroductions specifically, and conservation translocations generally, are primarily associated with terrestrial ecosystems, recent evidence also shows that an increasing diversity of species are being translocated in marine environments for conservation purposes (Swan *et al.* 2016). Some iconic species translocated include the Hawaiian monk seal (*Monachus schauinslandi*) (**Table 1**) and the Antillean manatee (*Trichechus manatus manatus*) in Brazil, while the Atlantic walrus (*Odobenus rosmarus rosmarus*) was recently proposed for reintroductions in eastern Canada. Over the last 39 years, at least 242 marine species were translocated for reintroductions, reinforcements, assisted colonizations, or ecological replacements (Swan *et al.* 2016). Reinforcements were almost three times as frequent as reintroductions. Species consisted primarily of coastal invertebrates (44%) such as corals and sea fans as well as plants (30%) such as mangroves and sea grasses. Unlike most reintroductions of terrestrial fauna, 60% of conservation translocations in marine environments were aimed at restoring ecological functions within target ecosystems.

IUCN Reintroduction Specialist Group

Reintroductions are conceptually appealing for a wide variety of reasons, which can span potential benefits for individual species or for broader ecosystem function. Intertwined with such benefits are related motivations or outcomes that can span aesthetic, sociological, cultural, political, or economic aspects. These in turn may differ according to species, scale, and economic context. For example, considerations would differ for releases of corals on a small boulder in the ocean compared to those associated with reintroducing tigers into all Asian countries that might have habitat for them. Bringing species back to places from where they have disappeared is inherently appealing to many people, but good intentions alone do not mean that reintroductions will be effective. Perceived benefits for certain considerations, such as reducing the likelihood of global species extinction, could also entail risks on other levels if, for example, the release of an organism might harm other species in the receiving ecosystem, threaten the

Fig. 4 Jason Cummings releasing an eastern bettong (*Bettongia gaimardi*) at Mulligans Flat Woodland Sanctuary in Canberra, Australia. Bettongs are considered to be "ecosystem engineers," hence their reintroduction is critical to restoring the ecosystem processes. Photo credit: Woodlands and Wetlands Trust and Stephen Corey.

Fig. 5 Mauritian Wildlife Foundation staff filling water troughs for Albabra giant tortoises (*Aldrabrachelys gigantean*) on Round Island, Mauritius. The species was introduced to the island as an ecological replacement for the extinct tortoise that formerly inhabited it. Photo credit: Katie Macfarlane.

livelihoods of local people, or compromise industrial interests. Overeagerness may result in poorly planned reintroductions, but extreme risk aversion may result in useful translocations not being conducted. Scientifically based, evidence-driven guidance can help to curtail rash decisions on either end of the spectrum, while improving the efficacy of actions that are taken.

By the 1980s the frequency, taxonomic diversity, and geographic variation of reintroductions was beginning to grow due to surging interest spurned by actions for several high profile species (**Table 1**). At the same time, challenges and failures were starting to become more apparent, especially through assessments of bird and mammal translocations. In particular, captive-bred individuals and sensitive or threatened species had relatively low rates of success at establishing populations. A primary shortcoming of most programs was that extensive effort and resources were expended for release stages, but follow-up monitoring was generally limited. This lack of information compromised the ability of managers to respond to issues within reintroduction programs over time, and also hampered improvements to reintroduction practice in general.

To prevent potentially irresponsible activities including releases of invasive species, while harnessing potentially positive actions including reintroductions, the IUCN released "The IUCN Position Statement on Translocation of Living Organisms" in 1987. In the following year the IUCN Reintroduction Specialist Group (RSG) was founded to inform and encourage good practice in reintroductions, and to track such initiatives as well as possible. The practitioners that came to constitute the RSG were distributed globally, had diverse expertise, and spanned many sectors including academia, government agencies, and nongovernment organizations. The

Fig. 6 Connie Barlow planting a seedling of the Florida torreya (*Torreya taxifolia*) in North Carolina. This translocation was conceived as a reintroduction to part of the species' prehistoric range, but has been widely interpreted as assisted colonization in response to climate change. Photo credit: Torreya Guardians.

IUCN Guidelines for Reintroductions were drafted by 1995, and officially printed by the RSG in 1998. These were the first official guidelines that IUCN released on any topic, and have been among the most utilized conservation guidance documents worldwide. In addition to publications in the primary literature, the RSG has published five books of case studies.

Guidelines for Conservation Translocations

Over the decade after the original guidelines were released, increases in reintroductions worldwide, improvements in scientific knowledge and management tools, escalation of climate change as a biodiversity threat, and increasing occurrences of conservation introductions triggered a desire for them to be revised. Following 4 years of refinements, new guidelines were released in 2013 (IUCN/SSC 2013). These are now available in eight languages (English, French, Spanish, Portuguese, Korean, Russian, Arabic, Chinese), and further translations are currently under development. The 2013 Guidelines clearly distinguish conservation translocations from other translocations based on the primary motivations underlying such activities. The motivations for conservation introductions are also covered in greater depth, including the distinction between assisted colonization and ecological replacement.

Potential benefits for the translocated species and the receiving ecosystem are positioned against seven primary risks: risk to source population, ecological risk, disease risk, associated invasion risk, risk of gene escape, socio-economic risk, and financial risk. Compared to previous guidelines, there is particular emphasis on animal welfare and the reduction of adverse impacts on the cultural, sociological, or livelihood impacts of affected human communities. Community buy-in is also positioned as increasingly important since even iconic initiatives such as the release of Arabian oryx (*Oryx leucoryx*) in Oman became compromised by disenfranchised community groups. More than before, the 2013 guidelines present conservation translocations as a process of iterative decision making where alternatives to translocations are considered, feasibility and risk of action or inaction is continuously evaluated, and monitoring data inform subsequent management alternatives. Among such alternatives are decisions of what individuals and release areas could be selected and how their suitability can be improved through various management tools.

Sound planning within the guidelines is underpinned by tiered goals, objectives, and actions that are directly linked to the design of monitoring programs, and potential exit strategies when desirable results have been achieved or undesirable outcomes become overwhelming. Biological and social feasibility are assessed while considering the regulatory environment and availability of resources that would be required to conduct conservation translocations responsibly. The guidelines outline a process that is likely to improve translocation programs worldwide, and is potentially applicable to any species. The RSG has also worked with other IUCN specialist groups over time to further develop taxon-specific guidelines for species such as primates, bears, elephants, and galliforms.

The 2013 guidelines have been increasingly integrated into jurisdictional policy. Canadian federal and provincial governments are required to consider the IUCN guidelines for any conservation translocations in the country, Scotland developed a national code for conservation translocations, and the European Commission adopted the IUCN guidelines as their standard for managing conservation translocations of species within the context of changing climatic conditions. Governments worldwide develop regulations of relevance to conservation translocations on national or regional levels, and increasing opportunities should be pursued to formally integrate the guidelines into these regulatory policies. Such approval processes should also be based upon extensive consultation with affected stakeholders to improve the acceptance and efficacy of conservation translocations.

Recent developments in genomics and genetic engineering have raised the possibility of resurrecting species that have previously gone extinct. Indeed the birth in 2008 of a Pyrannean Ibex (*Capra pyrenaica pyrenaica*), a subspecies that had gone extinct at the beginning of the millennium, made these theoretical possibilities a reality. A rapid evolution of technological developments, and surging public or scientific interest, prompted the desire for IUCN to develop guidelines that would deal specifically with the potential "De-Extinction" of species. From a conservation perspective, many of the fundamental considerations for conservation translocations are also applicable to such scenarios, as proxies of previously extinct species may be created for release within or beyond the indigenous ranges they once occupied. A special task force was formed and in 2016 the IUCN published guidelines on creating proxies of extinct species for conservation benefit (IUCN/SSC 2016).

Reintroduction Biology

The term "reintroduction biology" refers to research designed to improve practice related to conservation translocations. This term appears to have been first used at the conference "Reintroduction biology of Australasian fauna" in April 1993, and first appeared in the scientific literature later that year in a paper from a presentation at the conference. Very few articles had been published on conservation translocations up to that time, but subsequent exponential growth in the publication rate has resulted in there now being >150 articles published each year. There have also been several recent books published on reintroduction biology (Hayward and Somers 2009; Ewen *et al.* 2012; Maschinski and Haskins 2012; Armstrong *et al.* 2015; Jachowski *et al.* 2016).

Like any applied science, reintroduction biology aims to provide information that will allow practitioners to make good decisions. Part of this simply involves monitoring translocations and making the information available so people can learn from previous experience. The early reintroduction literature was dominated by such descriptive accounts, and they continue to play an important role (see volumes of case studies available via the RSG website). However, learning from descriptive studies is a slow process, and often leads to unreliable inference. Consequently, over the last 15 years there have been efforts to advance the science of reintroduction biology by encouraging the development of a clear theoretical basis, and strengthening inference using experiments, quantitative modeling, and meta-analysis. To facilitate decision making, researchers need to be able to address questions such as:

- What is the probability that a species will persist at a proposed site?
- How is this probability affected by a proposed postrelease management regime?
- What is the expected postrelease survival under a particular release strategy?
- What is the expected population growth rate, and carrying capacity?
- How will this population trajectory affect retention of genetic diversity?
- What effects is the species expected to have on ecosystem processes at the site?
- What is the risk of a particular pathogen being introduced, and what impacts might occur?

Armstrong and Seddon (2008) suggested that such issues could be categorized into 10 key questions at three different levels of biological organization—the population, metapopulation, and ecosystem (**Fig. 7**).

The reintroduction biology literature has indeed become more question-focused over the last decade, and is using more sophisticated methods. However, the links to real management decisions is often unclear. Consequently, the RSG is now promoting increased use of structured decision making and adaptive management to ensure that improved information results in improved decisions. "Structured decision making" means choosing the optimal management option based on clearly defined objectives and predictions, and "adaptive management" means updating such decisions based on learning.

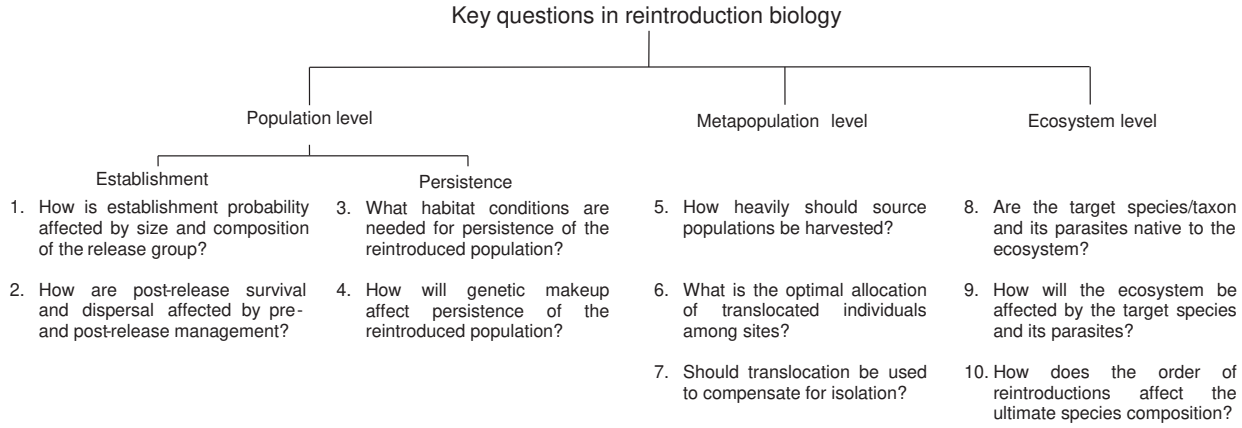

Fig. 7 Ten key questions in reintroduction biology, divided into questions at the population, metapopulation, and ecosystem level. From Armstrong, D. P. and Seddon, P. J. (2008). Directions in reintroduction biology. *Trends in Ecology and Evolution* **23**, 20–25.

A common misunderstanding is that reintroduction biology aims to improve the "success rate" of translocations, and therefore that this success rate should increase over time. This idea is misleading for three reasons. First, the concept of "success rate" is problematic because definition of success depends on the specific objectives of a given translocation—for example, is the main objective simply to establish a population at the site, or might it be to maintain a population with high genetic diversity, or to restore a particular ecosystem function? Second, maximizing success rate is an illogical goal because it means avoidance of risky translocations regardless of the potential benefits. Third, we do not necessarily expect success rates to rise, as the challenges involved in translocations do not remain constant over time. As discussed above, the scope of translocation as a conservation tool has broadened over time and will continue to change in the future. Reintroduction biology should aim to develop the best possible tools for making practical management decisions in the face of these challenges. Ultimately the iterative process of sound planning, evidence-based decision making, and integrated management will continue to increase the positive impact conservation translocations make in the restoration of species, reduction of extinctions, and maintenance of ecological processes.

Source–Sink Landscape

Wenwu Zhao, Lizhi Jia, and Stefani Daryanto, Beijing Normal University, Beijing, China
Liding Chen, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, China
Yue Liu, Beijing Normal University, Beijing, China

Introduction

"Source" often refers to the origin of an object or matter, while "sink" often refers to the deposition of the same object or matter. These definitions originated from the research of atmospheric pollution in the context of global climate change in which "source" is the unit system where materials or bionts emigrate, while "sink" is the unit system where materials or emigrant bionts are deposited during the process of earth surface layer material (**Fig. 1**). In the study, "source" and "sink" were also used to analyze the cause and effect of atmospheric pollutants and the concept was then adopted by the United Nations Framework Convention on Climate Change which defines "source" as the process or activity which can emit greenhouse gases and aerosols, while "sink" as the process or activity in which the greenhouse gases and aerosols are absorbed (e.g., into the soil or organic materials during the carbon or nitrogen fixation) (United Nations, 1992). According to the above definitions, emissions from factories or residential areas and traffic are all considered as "source", while "sink" are the ecosystems such as forests that can absorb atmospheric pollutants.

With the application of the "source" and "sink" concept in different field of studies, the terminology of "source" and "sink" has also evolved accordingly and it often includes different meanings. In ecology, the concept of "source" and "sink" was originally applied to study the dynamic of heterogeneous population and to reflect the process of migration, diffusion and destruction of species (Boswell *et al.*, 1998; Finkenstadt and Grenfell, 1998; Fox and Fox, 2000; Foley *et al.*, 2005). In habitats with rich resources, higher birth rate than death rate is usually found, increasing the number of population. This population may then colonize other habitats and it is called the "source" population. In habitats with poor resources, on the other hand, population loss often outnumbers the new offspring and consequently, this "sink" population requires immigration of individuals from other habitats to maintain the number of population (**Fig. 2**). This definition is similar when plaques occur in which the "source" population is correspondingly referred to the plaque "source" while the population in which the plaque spreads is referred to the "sink" population (Dunning *et al.*, 1992; Green, 1994; Kindvall, 1995; Hill *et al.*, 1996; Holyoak and Lawler, 1996; Leibold *et al.*, 2004; Guo, 2014). For example, a small songbird blue tit (*Parus caeruleus*) population reproduces under two kinds of forest habitats: one

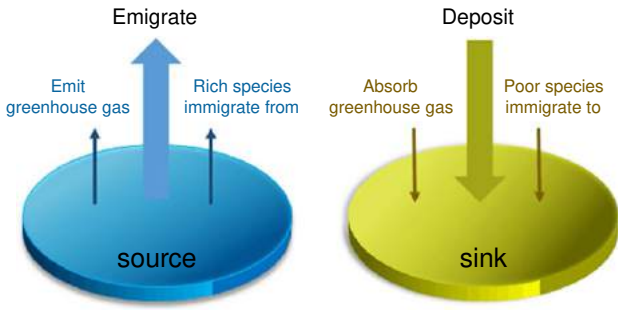

Fig. 1 Different applications of "source" and "sink" process.

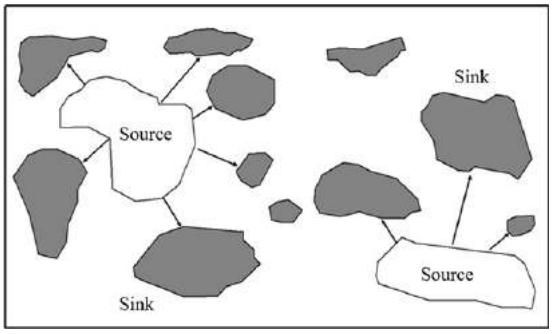

Fig. 2 Sources and sinks (Dunning *et al.*, 1992).

habitat is dominated by deciduous oak (*Quercus pubescens*) and the other is dominated by evergreen oak (*Quercus ilex*). Under normal condition and in the absence of migration, the annual blue tit population in deciduous oak dominated forest somehow increases while the population in the evergreen oak decreases. When the blue tit population perched in the deciduous oak dominated forest migrates to the evergreen oak forest, this population is considered as the "source" population, while that in the evergreen oak dominated forest is considered as the "sink" population.

The classification of a sink or a source, however, is not constant, but may change over time due to changes of climate and land management. The occurrence of climate change, for example, may reverse the above example on the blue tit population. If the blue tit population perched in deciduous oak dominated forest decreases with climate or vegetation change, the "source" population may be transformed into "sink" population following the migration of the blue tit population in the evergreen to deciduous forest. Similarly, the arctic tundra is likely to shift from carbon (C) sink to source as the temperature rises (Oechel *et al.*, 1993), which increases the oxidation of soil organic matter. In contrast, reforestation of degraded areas and the application of soil conservational practices will gradually change the cultivated soil in China and elsewhere from C source to C sink (Lal, 2004a, 2004b; Yu *et al.*, 2009).

Definition of the Source and Sink Landscape

Until the end of the last century, studies of landscape pattern and ecological process are stagnant due to complex ecosystem processes (Li and Reynolds, 1995). Chen *et al.* (2006) then introduced the concept of "source" and "sink" into the landscape pattern analysis and proposed the source–sink landscape theory which can be helpful to understand the coupling relationship between landscape pattern and ecological process. In the source–sink landscape theory, landscape types are classified as either "source" or "sink" landscape based on their function in an ecological process. "Source" landscape is a landscape type which contributes positively to the development of an ecological process, while a "sink" landscape is the one which is reversely contributes to the development of the same ecological process. From this point forward, "source" and "sink" always refer to the landscape-scale ecological processes (i.e., "source landscape" and "sink landscape"; **Fig. 3**).

The source–sink landscape theory which was originated from the source–sink theory of atmospheric pollution is now mainly used to study the effect of landscape patterns on ecological process. The theory has been used to the study of a wide range of fields, from biodiversity protection to urban heat island effect. For example, sloping croplands in a mountainous area, farmlands with high fertilizer application, or urban settlements play the role of "source" for nonpoint source pollution. In contrast, other landscape types such as grasslands, forests and wetlands located in the downstream direction of the "source" play the role of "sink". For soil and nutrient loss, "source" is the place where soil and nutrient are originated. Unless there are forests, grasslands or wetlands in the downstream position of the "source", this soil and nutrient will flow directly into the earth's surface or underground water, causing nonpoint source pollution. Similarly, some landscapes releasing CO_2 are considered as "sources" of greenhouse gas emission, while other landscapes absorbing CO_2 are considered as "sinks". A "source" in terms of biodiversity protection is an area which can provide habitat or resources for certain species, while "sink" is the area which has negative impact to the survival of the species.

The Characteristics of "Source" and "Sink" Landscapes

The Relative Categorization of "Source" and "Sink" Landscape

The categorization of a landscape as a "source" or "sink" is not absolute, but mainly depends on the role of that landscape type in an ecological process. Due to changes in numerous environmental variables over time, however, some sinks may act as sources and vice versa during the course of the same ecological processes. Although a landscape type can function both as a source and a sink, the landscape can be seen as a "source" when the source function is greater than the sink function. However, when the source function is less significant than the sink function, the landscape type can be viewed as a "sink" (**Fig. 3**). Due to the fact that source–sink landscape theory is based on specific ecological processes, it is important to define the ecological process studied when determining a landscape as a "source" or a "sink". During the process of soil loss, a grassland can intercept the sediment from the

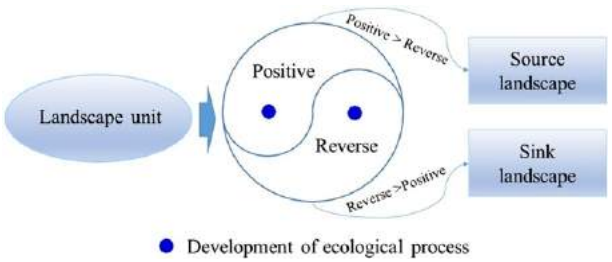

Fig. 3 The concept of source–sink landscape.

upslope position, and therefore functions as a sink. However, the same grassland can also produce sediments and therefore functions as a source. The balance between sediment yield and sediment interception thus determines the role of the grassland, whether it acts as a "source" or a "sink". A grassland is considered as a "source" when the amount of sediment yield is larger than the interception. In contrast, if the amount of sediment interception is larger than the yield, the grassland will then be considered as a "sink".

Linking the Categorization of a "Source" and "Sink" Landscape with the Process Studied

The fundamental difference between a "source" and a "sink" is that a "source" plays a positive role in promoting the ecological process studied, while a "sink" has a reversely influence on the process (Chen *et al.*, 2006). The classification of a landscape as a "source" or a "sink", however, may be different for different ecological processes. A landscape may be a "source" for a certain ecological process and is likely to be a "sink" for another ecological process. A farmland ecosystem is a "source" landscape for nonpoint source pollution due to the use of fertilizer and pesticide; however, it may become a "sink" for global C cycle because of its ability to fix CO_2. Therefore, one must always refer to an ecological process to determine the role of a landscape as a "source" or a "sink" in the process studied.

Different Magnitude of a "Source" or "Sink" Landscape in an Ecological Process

In an ecological process, different landscapes may have a different magnitude as a "source" or a "sink" by having different contributions to the corresponding ecological process. Despite farmlands, vegetable fields and orchards are all "sources" for nonpoint source pollution, one may contribute to a greater extent as a nonpoint source emitter compared to the others. Similarly, when forestland and grassland are both "sinks" for nonpoint source pollution, their contributions on nutrient absorption are different.

"Source" and "Sink" Landscape Evaluation Model

The source–sink landscape theory is supposed to regulate the ecological process from the point view of landscape pattern. The basic premises of source–sink landscape theory are to: (i) analyze the function of a landscape type (as a "source" or a "sink") in an ecological process, (ii) identify different "sources" or "sinks" in the landscape, and (iii) estimate the contribution of different landscape types in the ecological process. Because "source" and "sink" are defined within certain ecological process, the nature of the "source" and "sink" in a landscape will change when the ecological process changes. Chen *et al.* (2003b) proposed the location-weighted landscape contrast index. According to the theory and methods of Lorenz curve, this index includes three landscape properties: slope, distance and relative altitude to target points (e.g., monitoring stations and watershed outlet) (**Fig. 4**). The location-weighted landscape contrast index can be expressed as:

$$LCI = SODBC/SOFBC$$

where *LCI* is the location-weighted landscape contrast index relative to the watershed outlet monitoring point location (slope, distance and relative altitude to target points); *SODBC*, *SOFBC* are the irregular trilateral area composed of the cumulative curves of source and sink landscape area, respectively. Compared with *OFB* curve, the type of landscape displayed by *ODB* curve is located closer to the watershed outlet monitoring point.

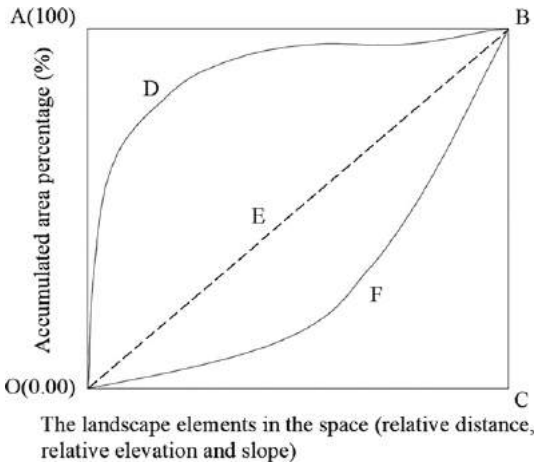

Fig. 4 Scheme figure of the location-weighted landscape contrast index.

The value of the index can well reflect the influence of landscape spatial pattern on ecological process (Cook, 2002). This model connects landscape pattern and ecological process and gives full consideration of the relationship between them. Furthermore, the model allows quantitative research and forecasts the relationship between landscape pattern and ecological process. For an ecological process in a landscape, the "source" and "sink" landscape evaluation model can be expressed as following:

$$LCI = \log\left\{\sum_{i=1}^{M} Si_{ODBC} \times Wi \times Pci / \sum_{j=1}^{N} Sj_{OFBC} \times Wj \times Pcj\right\}$$

where Si_{ODBC} and Sj_{OFBC} are the irregular triangular area composed of cumulative curve of the ith "source" landscape and the jth "sink" landscape in the Lorentz curve, respectively; M and N are the number of "source" and "sink" landscape, respectively; Pci and Pcj are the percentage of ith "source" landscape and the jth "sink" landscape in the catchment, respectively. Logarithm of the calculation results is mainly to control the range of LCI changes which will change around 0. When the value of LCI is 0, it means that the "source" landscape and "sink" landscapes are evenly distributed on the basin scale, and the contribution of this pattern to nonpoint source pollution is balanced on a watershed scale. When the LCI value is greater than 0, it indicates that the "source" landscape in the river basin contributes more to the monitoring point than the "sink" landscape, and the river basin may have more output of nonpoint source pollutants. When the value of LCI is less than 0, it indicates that "sink" landscape contributes more to the export monitoring point of the drainage basin than "source" landscape, and the pollutant output from this basin should be relatively small. In theory, the larger the value of LCI, the more nonpoint source pollutants should be output from the watershed, and vice versa.

O (0.00) is the watershed outlet, horizontal axis (OA) is the cumulative percentage of landscape type (range: 0 ~ 100); vertical axis (OC) is the relative distance between landscape type and watershed outlet (range: 0 ~ the maximum distance from the monitoring station) or slope gradient (range: 0 ~ the maximum slope gradient within the watershed); ODB and OFB is area cumulative curve of different landscape. OEB represents the absolute mean distribution curve, and if the "source" landscape and "sink" landscape is evenly distributed in the catchment, the OEB distribution curve will appear.

Application of Source–Sink Landscape Theory

The proposal of source–sink landscape theory is mainly based on the ecological balance theory in ecology. It explores the ways to regulate an ecological process by analyzing the spatial balance or distribution of "sources" and "sinks" in a landscape. The source–sink landscape theory, for example, can be applied in the following fields.

Landscape Pattern Design and Nonpoint Pollution Control

According to the source–sink landscape theory, some landscape types play the role of "source" and the other landscape types play the role of "sink" during the transport process of materials. The nonpoint source pollution, especially the eutrophication of aquatic ecosystems, is virtually induced by the imbalanced spatiotemporal distribution of nutrients. Identifying and managing the source of the contaminants (or nutrients), as well as minimizing the emission are therefore the most reliable methods to reduce the nonpoint source pollution. Generally speaking, there are two approaches to prevent excess nutrients from entering the aquatic system. One is to generate zero emission from each landscape unit so that there will be no contamination induced. The other one is to design the landscape pattern so that the contaminants are intercepted before entering the surface or subsurface water. Chen *et al.* (2003a,b) showed that there is a close relationship between the spatial distribution of "source" and "sink" in a landscape and the nonpoint source pollution. Thus, in order to reduce the risk of nonpoint source pollution, it is feasible to control nutrient loss from spatiotemporal scale by exploring the spatial combination of different landscapes in a watershed ecoplanning to control nutrient loss in a heterogeneous landscape (Turner and Gardner, 1991; Haines-Young and Chopping, 1996).

The source–sink landscape theory has been used in the research of nonpoint source pollution for many years. Chen *et al.* (2002) analyzed the relationship between the location-weighted landscape contrast index and nonpoint source pollution in the watershed scale by examining four typical small watersheds in the Yuqiao reservoir basin as the research object, and nonpoint source pollution as the target process. The result showed that the effect of different landscape patterns on the surface water quality can be evaluated by a source–sink landscape model at the watershed scale. Similarly, Chen *et al.* (2009) monitored the water quality of two adjacent watersheds for 3 years in the northeast black earth area, China. The results showed that the source–sink landscape index can well reflect the effect of landscape pattern on water quality and can be used to determine the risk of the occurrence of nonpoint source pollution. The source–sink landscape theory can be used to make the source–sink landscape risk identification and provide basis for decision-making in the treatment of nonpoint source pollution in Three Gorges Reservoir Area (Wang *et al.*, 2016a, b). According to the "source–sink" landscape theory, Fang *et al.* (2016) analyzed the concentration and amplitude difference of soil heavy metals (Pb, Cu, and Cd) in forest and construction land of Shanghai Pudong New District by using the sliding window analysis. The results showed that the source–sink landscape theory can be applied to the study of nonpoint source pollution.

The "source–sink" landscape index can reflect the spatial variation of total nitrogen (TN) and provides a reference for the evaluation of nonpoint source pollution in the Heihe river basin (Sun *et al.*, 2012; Zhang *et al.*, 2017). Similarly, the "source–sink"

landscape index can help researchers to clarify the role of infrastructure in reducing nonpoint source N pollution in a Mediterranean climate (Mcconaghie and Cadenasso, 2016).

In the study of the ecological process of soil erosion—a significant form of nonpoint source pollution—sloping croplands which increase soil erosion are considered as "source", while the forest and grassland which reduce soil erosion are considered as "sink". The contribution of different landscape to soil erosion can be characterized by the C factors (crop management factors) of the universal soil loss equation (USLE). By using USLE, researchers establish a multiscale soil erosion evaluation index in order to explore the relationship between landscape pattern and soil erosion. This index can effectively reflect the relationship between land use pattern and soil erosion process, and provide technical supports to optimize the design of regional land use pattern and comprehensive management of regional soil erosion (Fu *et al.*, 2006; Zhao *et al.*, 2012). The effect of watershed landscape pattern on soil erosion can be well-revealed by using the "source–sink" landscape theory (Xu and Zhou, 2008; Yang *et al.*, 2012). According to the "source–sink" theory of soil erosion, slope-HRUs landscape index (SHLI) can reflect the relationship between landscape pattern and soil erosion processes to a certain extent in the Yanhe watershed, China (Zhou and Li, 2015; Li and Zhou, 2015). By using the "source–sink" landscape theory, Chen *et al.* (2016a, b) also showed that there is strong relationship between soil erosion processes and land cover changes in the Loess Plateau in China observed in 1987, 1995, and 2007.

"Source" and "Sink" Landscape Pattern Design and Biodiversity Protection

The key to protecting biodiversity is to protect the habitats of endangered species (Tilman *et al.*, 1994; Lomolino and Perault, 2001; Marsh and Trenham, 2001). Using the source sink landscape theory, one can evaluate the spatial relationships between the dwelled patches and the surrounding patches to determine habitat suitability for species survival. Rich habitat patches and the surrounding resource patches act as the "source" for those species. Yet they may become unsuitable for the survival of the species if they are disturbed. When leaving them uncontrolled, disturbance can turn resource-rich habitat patches into "sinks". If more resource than disturbed patches are available for the target species, this landscape pattern is to be beneficial for the survival of the species. On the contrary, a landscape pattern would generate adverse effects for species survival and protection if it has more sinks than sources. Therefore, the suitability of the landscape pattern for a species can be evaluated by using "source" and "sink" landscape evaluation model, in which the role of different landscape types is identified.

For biodiversity protection evaluation, one should aim at actual "sources" and consider these source patches as points. Then, the landscape evaluation model is used to analyze the role of the surrounding landscape pattern on these "sources" (points), and to clarify how landscape pattern may assist the conservation of the target species. Li *et al.* (2014) classified the function of nature reserve and determined the development direction and the management framework based on the source–sink landscape theory. Liu *et al.* (2016) pointed that the "arthropod island"–shrub relationship, referred to as a source or sink in terms of the source–sink landscape theory during the ecological processes (Chen *et al.*, 2008; Wei *et al.*, 2012), could have important ecological implications on the succession processes of desertified ecosystems (Liu *et al.*, 2013; Zhao and Liu, 2013).

"Source" and "Sink" Landscape Pattern Design and Urban Heat Island Effects

An urban ecosystem is highly influenced by human activities. As the urban area develops, common issues related to urbanization (e.g., urban heat island effect and traffic jam) become increasingly serious, mostly due to inappropriate design of the urban landscape patterns. Using the source sink landscape approach, the occurrence of urban heat island effect and heavy traffic could be considered as the imbalance between "source" and "sink" in an urban area. Urban landscape consists of "gray landscape" (i.e., buildings and roads), "blue landscape" (i.e., rivers, lakes), and "green landscape" (i.e., gardens, turfs, vegetation belts). Different landscape types play distinct roles in the urban heat island effect. Since the over-centralized-distribution of gray landscape results in temperature increase, gray landscape can be considered as the source of the heat island effect. In contrast, the blue and green landscape may reduce temperature and alleviate the urban heat island effect. Since blue landscapes always have lower temperature than the gray landscape and provide a comfortable environment for the residents, adding the number of blue and green landscapes on heat island effect mitigation is always preferable to any city. However, in most cases, the proportion of the blue and green landscapes is limited. Consequently, it is necessary to spatially regulate the gray, blue and green landscapes based on their features as the "source" and "sink" landscape.

According to the source–sink landscape theory, the Lorenz curve and the Gini index were used to describe the distribution of "hot" towards "cool" land cover around a landscape center, and the first law of geography was echoed, which presents an interesting cross-disciplinary topic (Chen *et al.* 2016a, b). Ayanlade (2016) examined the seasonal and diurnal variations in land surface temperature (LST) between different landscapes in Nigeria. He found that differences in LST patterns between the urban areas and its surrounding rural areas might be caused by urban expansion resulting from the removal of vegetation and high heat capacity of construction materials in the central of urban area. Li *et al.* (2017) found that it is essential to design and transform the landscape in specific ways based on the heterogeneous effects of landscape pattern on the thermal environment to mitigate urban heat island.

Conclusions

The relationships between landscape pattern and ecological process are the core issues of landscape ecology. They are also the hot spots of landscape ecology research because it is not always easy to link landscape pattern and ecological process. Yet the source–sink landscape model, that originated from the source–sink theory of atmospheric pollution (Chen *et al.*, 2006), can be applied to the study of nonpoint source pollution control, biodiversity protection and urban heat island effect. Due to the variability of landscape pattern and ecological process, however, the same landscape type can be categorized either as a "source" or a "sink", depending on the ecological process studied. Similarly, different landscape types may have different contribution in the corresponding the ecological process. Determining the ecological process and identifying the "sources" and the "sinks" in the landscape including their extent of contribution are the key strategies to fully apply the source–sink landscape theory into practice.

Spatial Subsidy

DM Talley, University of California, Davis, Davis, CA, USA

Introduction and Definition

There is an increasing appreciation in ecology for the fact that even seemingly insular and discrete habitats are often deeply interconnected. This connectivity can arise from a number of mechanisms, including the provision of trophic resources from outside the focal habitat. This subsidization from across the habitat boundary is known as `spatial subsidy'. Synonyms and related terms include allochthonous inputs, trophic subsidy, and cross-boundary subsidy. Spatial subsidy arises when nutrients, food resources (detritus, primary producers, or prey items), or consumers move across boundaries, thus `subsidizing' local food resources in the `recipient' habitat with those from other `donor' habitats or ecosystems.

The conceptual origin for the integration of spatial subsidy into our understanding of ecosystems goes back at least to the late 1800s, when the strong trophic interactions between terrestrial and limnetic ecosystems were recognized. Spatial subsidy gradually became better integrated into ecology, in particular with respect to oceanic, riverine, and limnological ecosystems. More recently, we have seen an expansion of recognition of spatial subsidy due to the work of Gary Polis and colleagues, who integrated landscape, population, and food web ecology by focusing on the contributions of spatial subsidy to ecosystem dynamics.

Subsidies can occur between any two habitats, from those that are relatively similar (e.g., different water masses within the ocean) to those that are strikingly dissimilar (e.g., benthic and pelagic or terrestrial and aquatic habitats). Further, these subsidies can occur across a vast range of temporal and spatial scales, and can be driven by a range of biotic or abiotic processes, with ramifying effects throughout the ecosystem.

An understanding of spatial subsidies is critical to basic, theoretical, and conservation ecology. So despite the fact that ecologists often tend to focus tightly on a specific habitat or subdiscipline, external forcing due to spatial subsidies can often be the dominant factor driving the dynamics within a given habitat. Subsidies can have effects at the population level for individual species; at the community level, through changing species interactions; and at the ecosystem level, altering biodiversity and stability patterns.

This article presents examples of spatial subsidies that result from the movement of nutrients, food resources, and consumers. Along the way, key aspects of the mechanisms (e.g., unidirectional vs. bidirectional; biotic vs. abiotic) and scale (temporal and spatial) of subsidies are addressed, as well as the types of effects these subsidies have on the recipient ecosystem. Finally, the implications of understanding spatial subsidies for basic, theoretical, and conservation ecology are presented.

Movement of Nutrients

The movement of nutrients between habitats can greatly alter primary productivity in the recipient habitat, leading to trophic cascades and alterations of the community of consumers. Two specific cases are presented here: the Aeolian movement of nutrients from the African continent to the Amazon rainforest, and the input of marine-derived ornithogenic guano to island ecosystems in Baja California, Mexico.

The Amazon rainforest is a relatively nutrient-poor habitat, and the nutrient budget there is heavily subsidized through wind-blown deposition of sediments originating in Africa (**Fig. 1**). This nutrient subsidy from over 5000 km away and across a vast ocean deposits as much as 13 million tons of phosphorus per year in the Amazon Basin, and is responsible for much of the primary production in the recipient habitat. This increase in production, driven by abiotic mechanisms (wind) and occurring over vast spatial and temporal scales, has cascading effects throughout the rainforest ecosystem.

Another well-studied example of spatial subsidy of nutrients comes from arid islands in the archipelago of Bahia de los Angeles, in Baja California, Mexico (**Fig. 2**). As in many other systems, seabirds here have been shown to be effective transporters of marine-derived nitrogen and phosphorus from the aquatic to the terrestrial ecosystems, thus providing a surplus of nutrients for terrestrial plants. In most years, this nutrient subsidy has only minimal effects, since water is often the limiting factor for primary production in these desert environments. Yet during the occasional wet periods, this abundance of marine-derived nutrients allows those islands frequented by seabirds to have tremendous increases in plant growth relative to those islands less frequented by birds. This biotically mediated nutrient subsidy not only alters the composition and stability of the plant community, but the periodic pulse of production in turn alters the abundance, diversity, and composition of the island arthropod and in turn songbird communities, with effects that last well beyond the occasional wet year.

There are numerous other examples of nutrients being transported between ecosystems with dramatic effects for the recipient habitats. In the Galapagos, sea lions transport marine nutrients onshore, affecting primary productivity on beaches; in riverine systems, upstream habitats represent a source of nutrients, and downstream ones a sink; upwelling transports deep

oceanic nutrients upward into the surface zone, where they can fuel plankton blooms; salmon transport marine nutrients to the rivers, where they die and are taken up by the local plants and algae, fuelling both the aquatic and terrestrial food webs. It is worth noting that humans mediate a number of these spatial subsidies – for example, anthropogenic nutrient inputs have dramatic effects on near-shore habitats in many areas, leading to shifts in plant and animal communities and occasionally eutrophication.

Movement of Food Resources

In many cases, food resources themselves (in the form of prey or detritus, the latter including carrion and dead plant material) are passively or actively moved between habitats. A thorough discussion of detrital inputs is available elsewhere in this volume, so here we will touch on that topic only briefly, and focus instead on the movement of prey.

Detritus represents a significant food resource for many systems, both terrestrial and aquatic, and spatial subsidies through detritus are common across many natural boundaries. Terrestrial coastal areas receive as much as 2000 kg m^{-1} of shoreline per year in the form of dead algae, seagrass, and carrion; leaf and litter fall represent massive inputs of detritus into stream ecosystems; benthic communities in aphotic zones are entirely dependent on detritus and food resources coming from the photic zone of the ocean, and new volcanic islands often have food webs based entirely on detrital input aerially deposited from other terrestrial ecosystems. Spatial subsidy through movement of detritus is a common phenomenon occurring across a range of spatial and temporal scales, and is generally driven by abiotic forcing (e.g., wind, waves, gravity, or currents).

The movement of prey items similarly impacts a vast number of habitats. A clear example is illustrated by the movement of emerging aquatic insects, where one study found as much as 97% of the biomass of emerging insects from a stream was transported to riparian terrestrial consumers including birds, herpetofauna, and arthropods. Other groundbreaking research on stream systems clearly showed a strong seasonal and reciprocal dynamic to spatial subsidy – during the summer, terrestrial invertebrates falling into the stream subsidized aquatic consumers, representing 44% of the total energy budget for fishes. Conversely, during the spring emergence of aquatic insects, allochthonous inputs from the aquatic environment provided the terrestrial ecosystem (specifically birds) with more than 25% of their total energy, and as much as 98% for a species of wren. This biotically mediated reciprocal flux between the forest and stream can alter community structure by causing top-down effects from subsidized predators. The dynamic and reciprocal nature of this spatial subsidy,

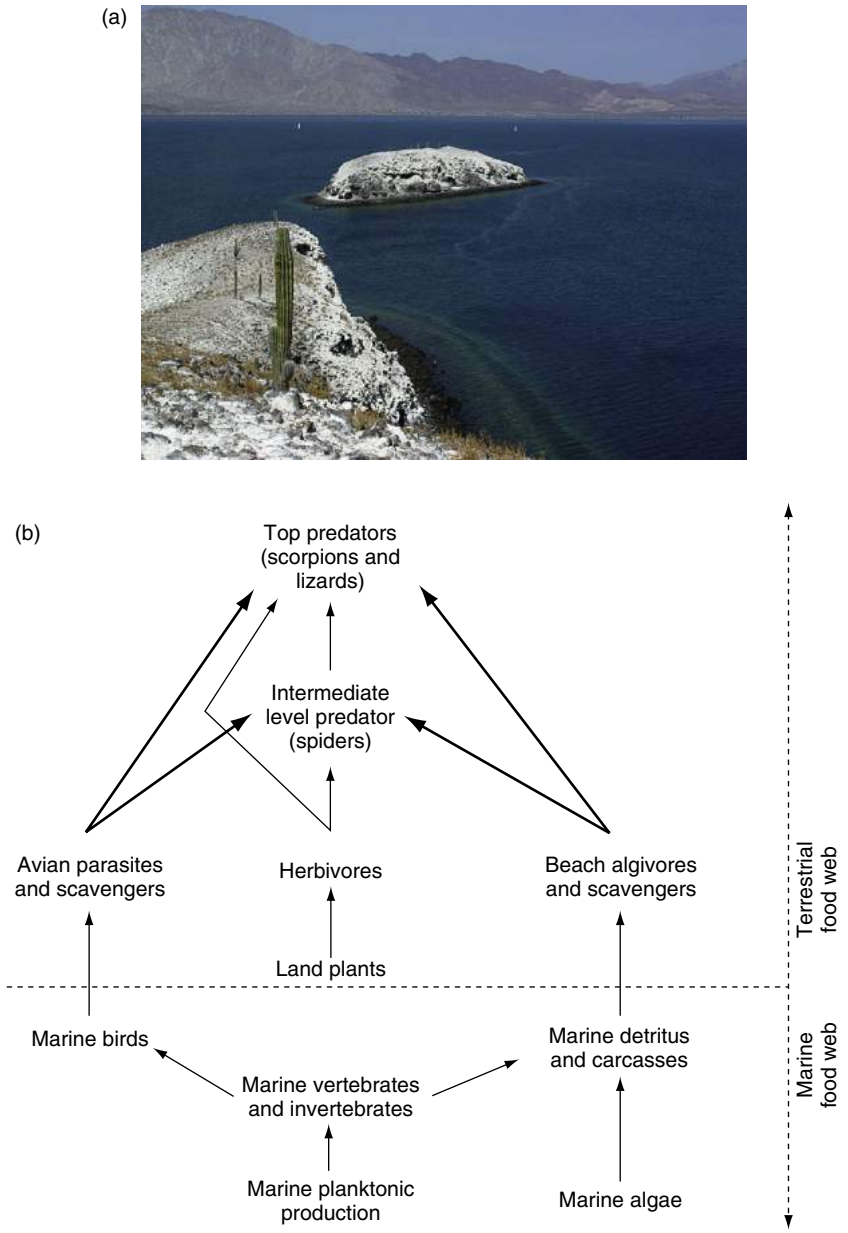

Fig. 2 (a) The Gemelitos islands in the archipelago of Bahía de los Ángeles, Baja California, Mexico. The high levels of marine-derived nutrients deposited on the islands by seabirds represent a subsidy to the terrestrial and intertidal systems, with dramatic effects on recipient communities. (b) A schematic food web for these small islands, showing the importance of marine subsidy. Redrawn from Polis, G.A., Hurd, S.D., 1995. Extraordinarily high spider densities on islands: Flow of energy from the marine to terrestrial food webs and the absence of predation. Proceedings of the National Academy of Sciences of the United States of America 92, 4382–4386.

while rarely experimentally tested, is likely common in nature, particularly wherever adjacent habitats undergo asynchronous pulses of productivity.

Spatial subsidies through the movement of prey items are, however, not confined to those that cross the aquatic–terrestrial boundary as in the examples above, but are commonplace in many environments and at many spatial scales. In particular, organisms which undergo `ontogenetic shifts' in foraging or habitat-use patterns often mediate these subsidies. Cicadas, termites, and other emerging insects provide a subsidy from belowground to aboveground ecosystems; ontogenetic shifts in foraging and movement patterns of California killifish (*Fundulus parvipinnis*, a small wetland resident fish) subsidize predators in subtidal ecosystems with energy these fish derived from foraging as juveniles in high intertidal pools; migrations of potential prey items, from Monarch butterflies to caribou, provide consumers in distant habitats with substantial trophic subsidies. Taken as a whole, subsidies resulting from the movement of prey (or detritus) can range in distance from a few centimeters to many thousands of kilometers, and over timescales from a matter of hours to decades.

Fig. 3 A coyote (*Canis latrans*) foraging on marine organisms in an intertidal salt marsh. Coyote densities in coastal regions can be more than an order of magnitude higher relative to areas where they receive no marine spatial subsidies. Photo Credit L. Goodwin, Aquatic Adventures Science Education Foundation.

Movement of Consumers

In a fashion similar to the movement of prey items, the movement of consumers can be a mechanism creating spatial subsidy. As in the other examples presented here, this can occur between two terrestrial habitats, two aquatic habitats, or between terrestrial and aquatic environments.

There are numerous examples of terrestrial mammals that make forays into aquatic habitats in order to forage. In fact, there are over 45 species of terrestrial mammals documented to feed at least in part on marine resources, consuming over 200 marine taxa. For some terrestrial mammals, such as coyotes (*Canis latrans*), this consumption allows predator population densities to persist several orders of magnitude over what it would be in areas without the ability to forage on marine foods (**Fig. 3**). This increase in population density of these omnivores in turn allows them to depress other prey resources such as small rodents, thus leading to `apparent trophic cascades', where subsidized consumers are able to exert a greater force on the local food web than would be possible based on *in situ* resources alone.

Similarly, migrating consumers can have profound effects in one habitat due to the trophic subsidy they receive from another. In the case of geese, the populations that breed in the Canadian arctic have been subsidized for several decades by agricultural production. This allochthonous agricultural resource provides a higher nutritional quality than do the historic feeding grounds, with profound results for both the goose populations and the habitats they inhabit. One is that the higher nutritional quality and abundant resources of the agricultural fields have caused a boom in population density for many species of geese. This, in turn, leads to an `apparent trophic cascade', with the abundant birds completely altering marshes in which they either did not feed historically or generally had lesser effects. The geese thus caused massive loss of vegetation and irreversible changes to soil conditions in many coastal marshes, with consequent loss of soil invertebrate species and impacts on those predators that use them (such as passerine birds and shorebirds).

As in the case of movement of prey items, consumer movements creating spatial subsidy occur across a range of habitat types and temporal and spatial scales. Krill move seasonally between feeding on algae beneath the Antarctic ice shelf to feeding on pelagic phytoplankton; a number of aquatic predators make foraging migrations over a broad range of spatial scales, in horizontal or vertical directions; a species of side-blotched lizards on the terrestrial-arthropod poor Islas Encantadas archipelago in the Gulf of California rely so heavily on intertidal food resources that they have evolved enlarged nasal salt glands to assist with removal of excess electrolytes; and humans forage across vast ranges of terrestrial and aquatic habitats, bringing back trophic subsidies from the interior of continents to the depths of the oceans.

The movement of consumers across boundaries is a key factor in the cross-system exchanges represented by spatial subsidies. Such exchanges are often driven by ontogenetic shifts in an organism's foraging or habitat-use pattern, but can also be realized whenever mobile consumers have the ability to cross a habitat boundary.

The Importance of Spatial Subsidy

Given the ubiquity of spatial subsidy and its potential to dramatically alter communities, populations, and environments, it is critical that these linkages be incorporated into ecological thinking. Understanding spatial subsidy illuminates both empirical and theoretical ecology, and informs conservation biology in theory and practice.

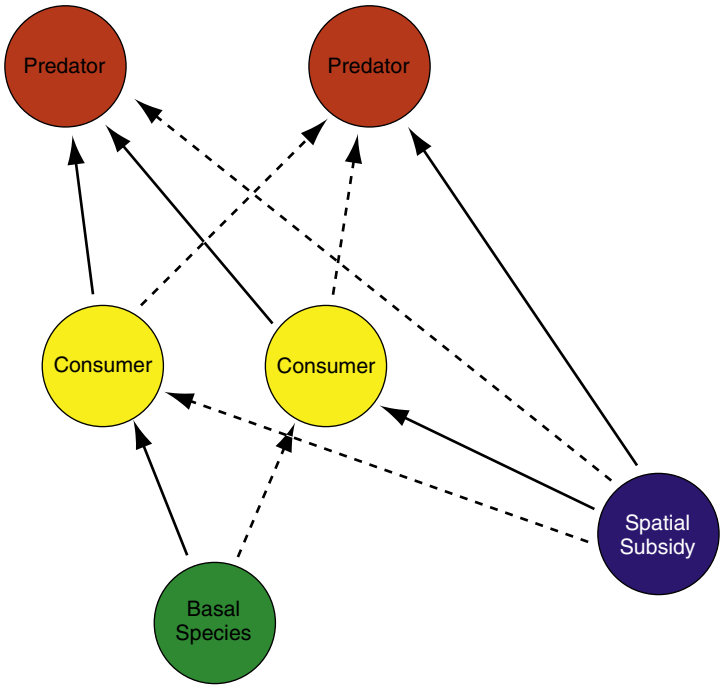

Fig. 4 Theoretical modeling suggests that the effect of spatial subsidy on food webs is dependent on a number of factors, including the abundance of subsidy and if the recipient species are specialists or generalists. In the tritrophic model illustrated here, a food web made up of generalist consumers (all arrows) would be stabilized by low to moderate levels of spatial subsidy. If the web were made up of specialists (dashed arrows removed), subsidies would be expected to destabilize the system. Adapted from Huxel *et al.* (2002).

As illustrated in many of the examples presented above, spatial subsidies are often the driving force structuring ecosystems, and as such are pivotal to developing a full understanding of the population of ecosystem dynamics. Subsidized consumers can push ecosystems to alternative stable states; allochthonous nutrient enrichment can completely alter the abundance and composition of primary producers, with profound effects throughout the ecosystem; and cross-system exchanges of resources can affect community stability and species diversity. In many cases, attempting to fully understand the dynamics of a focal habitat will be doomed to failure if external forcing through spatial subsidy is not considered. This has been appreciated for some time with regard to the effect of terrestrial systems on rivers, but only recently has the extent of spatial subsidy in so many ecosystems been acknowledged.

The importance to theoretical ecology of spatial subsidies has in recent years also seen a surge of interest, with exciting and illuminating results. Gary Polis made great strides in integrating the idea of spatial subsidy into food web dynamics and landscape ecology, and that work heralded the beginning of a number of studies examining the theoretical underpinnings of spatial subsidies (although it should be noted here that theoretical work on nutrients as a subsidy goes back somewhat farther). Modeling studies looking at the influence of allochthonous inputs across habitat boundaries, for example, predict strong effects on food web stability. Low to moderate amounts of allochthonous inputs relative to autochthonous productivity (that originating in the focal habitat) were shown to stabilize various kinds of food web dynamics. Other findings showed that food web structure influences the degree of impact of allochthonous inputs on the stability of food webs (**Fig. 4**). Specialization at the top trophic level (such as with scavengers) limited the indirect effects of allochthonous inputs. In contrast, generalists feeding on both local and allochthonous prey can exhibit increased densities due to the allochthonous resources, resulting in increased predation pressure on autochthonous prey and possible ecosystem-wide effects. These results match well with mensurative findings from nature, such as the coyote work referenced above.

Other models have suggested that differences among trophic levels in linkage among habitats significantly influence food web stability. If allochthonous resources are utilized by the second trophic level in a three trophic level system, then generalists (herbivores for example) will impact the first trophic level and provide increased resources for the third trophic level. Specialists at the second trophic level (perhaps detritivores) will not directly impact the first trophic level, but will provide increased resources for the third trophic level. These and other findings suggest that there is a wealth of information to be gained by incorporating spatial subsidies into theoretical models of communities and ecosystems.

Integrating an understanding of spatial subsidies is also critical to understanding ecological systems and theories, and this will provide various benefits to conservation, in both theory and practice. Several aspects of spatial subsidy relating to conservation

deserve particular attention: situations where subsidies have been altered by humans, and ways in which information about linkages can be used to improve the practice of conservation.

Anthropogenic Alterations

Human activity can alter the flow of spatial subsidy in a number of ways. Habitat fragmentation, for example, can increase subsidy (through small patches having greater `edge effects'), or can decrease trophic subsidy, by leaving some patches too distant from sources to allow natural flow. Further, human activity can directly block or increase subsidy relative to natural levels. For example, the movement of spatial subsidies between coastal consumers (utilizing aquatic resources) and inland habitats has been dissected in many regions by roads and highways, potentially restricting access to these trophic resources for wide-ranging species such as coyotes or small mammals. This lack of connectivity could have wide-ranging effects on terrestrial communities both by lowering population densities of consumers that are subsidized by aquatic resources and by restricting the flow of aquatic nutrients to inland.

There are numerous other examples: the creation of levees around rivers diminishes the aquatic subsidy to the surrounding terrestrial floodplain; urban development in coastal zones reduces the ability for terrestrial organisms to obtain spatial subsidy from the ocean; and destruction of foraging habitat along migratory bird flyways can greatly lessen the subsidy obtained from intermediate habitats. Over 90% of Pacific saltwater and Great Lake freshwater marshes have been lost, largely due to direct human habitat alteration, leading to limitation of aquatic resources available to terrestrial consumers. On southern California beaches in the United States, macrophyte wrack washing up in the intertidal provides a regular subsidy for macrofauna, which in turn provide food for shorebirds. The practice of `beach grooming' (using heavy equipment to remove macrophytes and debris from sandy beaches) in populated areas directly removes this subsidy and thus mitigates the associated bottom-up effects.

Anthropogenic processes and mechanisms of spatial subsidy can be even more direct, however. In any given year, millions of tons of crops are moved between continents, and some 75 million metric tons of marine biomass onto land worldwide, including 27 million tons of discarded nontarget animals (bycatch), as well as 126 500 t (dry weight) of algae, with ramifications for the entire oceanic ecosystem, as well as subsidizing human populations often quite distant from the ocean. Each of these movements of resources not only represents a spatial subsidy of its own, but also suggests that removing these quantities of organisms from the ecosystem may well be altering natural levels of subsidy occurring there.

Conservation Implications

Recognizing and understanding spatial subsidies is necessary for effective conservation. As most examples in this article illustrate, there are frequent, strong interactions between often seemingly disconnected systems, with one habitat's influence often dominating the dynamics of the other over vast temporal and spatial scales. Besides the conservation benefits inherent in an increased understanding of nature, there are some very specific areas in which recognizing spatial subsidies at the aquatic–terrestrial interface will benefit conservation science.

Siting decisions for areas of protection for threatened species or habitats will be greatly improved by integrating consideration of potential spatial subsidies into the decision-making process. For example, streams have traditionally been considered to be recipients, rather than sources, of trophic resources in terrestrial systems. Yet temperate forest herpetofauna have been shown to increase growth rates by as much as 700% through spatial subsidies arising from stream ecosystems.

A better understanding of these functional linkages also illuminates questions about buffer zones and spatial scale of protected areas. Studies of the effects of marine inputs on terrestrial ecosystems clearly demonstrate that it can be important to account for marine input to understand the dynamics of terrestrial systems. However, there is only inferential information regarding the distance offshore from which these resources originate. Fundamental questions are still unanswered about how far offshore one must protect a habitat to ensure adequate flow of allochthonous input. Nor is it clear how far inshore the effects of subsidies penetrate to impact terrestrial communities. An understanding of the spatial properties of these linkages will provide conservation biologists with better tools to protect threatened habitats and organisms. Efforts to establish effective marine protected areas will require a deep understanding of just how spatial subsidies between various marine habitats affect nearby (and distant) ecosystems.

Summary

Cross-system exchanges in the form of spatial subsidies are ubiquitous, even between seemingly distant and disconnected habitats. Subsidies can occur across a vast range of temporal and spatial scales, and can be driven by biotic or abiotic forcing (or some combination thereof). Spatial subsidies can have profound effects on entire ecosystems, with implications for species diversity, ecosystem stability, population dynamics, and persistence, often being the dominant factor driving ecosystem properties. Acknowledging and understanding spatial subsidies is critical to basic, theoretical, and conservation ecology.

System Omnivory Index☆

S Libralato, OGS (Istituto Nazionale di Oceanografia e di Geofisica Sperimentale), Sgonico (Trieste), Italy

Introduction

The system omnivory index (SOI) measures the distribution of feeding interactions among trophic levels of food webs, thus SOI allows for evaluating the complexity and connectivity of food webs.

Ecological networks are widely used in ecology to address theoretical concepts and to study properties of natural systems. In particular, networks of trophic interactions (food webs) are tools for describing ecosystems and for searching invariant properties in nature. Food webs represent elements (elsewhere also called nodes) connected through links (also termed edges): elements are group of species, a single species, or even the life-history stage of a population, while trophic links represent consumption (or predation) and are directed (predator eats prey). Complexity of food webs, i.e. the number and structure of trophic interactions, has been studied by ecologists since decades (Christensen, 1995; May, 1973; Neutel *et al.*, 2007; Pimm, 1980).

Complexity is an important feature of ecological food webs because it has been related to maturity and stability properties of ecosystems. Web-like and complex structured trophic networks imply the presence of omnivores, i.e., consumers feeding on more than one element of the food web. Thanks to prey-switching abilities, omnivores can possibly be only moderately affected by eventual fluctuations or decrease of one of the prey populations. Therefore, omnivory contributes in dampening perturbations affecting species of the ecosystem, allowing a short return time (resilience), and avoiding magnified propagation of disturbances (resistant). Moreover, omnivores' interactions increase stability through weak interactions that dampen the effects of alternative potential strong interactions (in an exemplified one consumer–two resources interactions). Web-like structured food webs are thus associated to ecosystems that are able to adsorb external shocks and to recover from perturbation. Understanding these capabilities of real food webs will enable to better manage ecosystems, promoting their persistence and avoiding anthropogenic disturbances that can lead to deep changes in ecosystem structure (Christensen, 1995; Fagan, 1997; Polis and Strong, 1996).

Measuring Complexity

The complexity of food webs is generally increasing with the number of elements (N), assuming a progressive increase of the number of links (L). However, for a given number of elements, different structures of the web (number of links) imply great differences in complexity. There are many measures applicable for quantifying the complexity of food webs (Banasek-Richter *et al.*, 2009; Neutel *et al.*, 2007), such as the direct connectance (C) represents the ratio between number of expressed links and number of theoretically possible links ($C=L\cdot N^{-2}$); the connectance index (CI) is excluding cannibalism and top predators effects and it is equal to $\mathrm{CI}=L\cdot(N-1)^{-2}$; the linkage density (LD) is the average number of links per element, that is, $\mathrm{LD}=L\cdot N^{-1}$. These measures of complexity have been developed for binary networks, in which for each couple of elements the interaction is set as absent (0) or existing (1), but there is no indication of its strength. Conversely, in weighted food webs, at each existing link is associated a strength of the interaction (weight), quantified by the consumption flow. Accounting for the interaction weights in the complexity measurement is relevant, given the importance of of weak interactions in determining stability properties of ecosystems. Moreover, topological indicators do not exploit the information on the direction of flows. However, direction of flows is a fundamental characteristic of predator–prey interaction, that is, the effects of the interaction are different for the prey and for the predator. Therefore, accounting of directionality of flows in trophic networks is important for capture real properties of ecological systems.

The SOI is intended to exploit the quantitative information carried by weighted and directed trophic networks for evaluating their complexity and thus for understanding the capabilities of ecosystems to respond to natural and anthropic perturbations. In particular, the SOI is a measure of the degree of omnivory in the trophic network, that is, a measure of the distribution of feeding interactions among trophic levels (Christensen and Pauly, 1993).

Definition

Given a trophic network of n elements, the SOI is calculated as the weighted average of the elements' omnivory, this latter calculated as the omnivory index (OI). The OI of the consumer element i with trophic level TL_i is quantified as the variance of the trophic levels of its preys (TL_j) (Williams and Martinez, 2004); thus

☆*Change History:* March 2013. S Libralato introduced small edits in the text of the article including citations, added the sections "Applications" and "References", and added **Fig. 6**.

$$\mathrm{OI}_i = \sum_{j=1}^{n} \left[\mathrm{TL}_j - (\mathrm{TL}_i - 1)\right]^2 \cdot \mathrm{DC}_{ij} \qquad [1]$$

where the contribution of each prey j to the variance of the consumer is proportional to the fraction of prey j in the diet of consumer i (DC_{ij}). The SOI of a given trophic network is quantified as the weighted average of the OI of all consumers of the network (Christensen and Pauly, 1993); thus

$$\mathrm{SOI} = \frac{\sum_{i=1}^{n} [\mathrm{OI}_i \cdot \log (Q_i)]}{\sum_{i=1}^{n} \log (Q_i)} \qquad [2]$$

where the weighting factors are taken as the logarithm of each consumer food intake (Q_i). This allows for accounting of the different strengths of consumer interactions and thus accounts for intra-element interaction strengths. The logarithm is used on the observation that consumptions are approximately log–normally distributed within the system (Christensen and Pauly, 1993).

Properties

The SOI is influenced not only by the number of links in the web but, other factors being equal, also by topological configuration of links and by their weights, these latter intended as the total flow to consumer. In the following, the effects of different topological configurations on SOI will be explored by comparing networks with equal number of elements but different structure.

Number of Links

From a chain-like web, the augmentation of the number of links imply an increase of the network's SOI. This is observed even if the total number of elements and total flows to each consumer are kept constant. The increase in SOI, therefore, is due to the inevitable increase of the number of omnivorous species in webs with increasing number of links, as shown in **Fig. 1**.

This is coherent with definition and main reasons for the develoment of the SOI as a measure of complexity of food webs (Christensen and Pauly, 1993). Increasing values of SOI measure the increase of omnivory elements that are found in nature in developed and mature ecosystems.

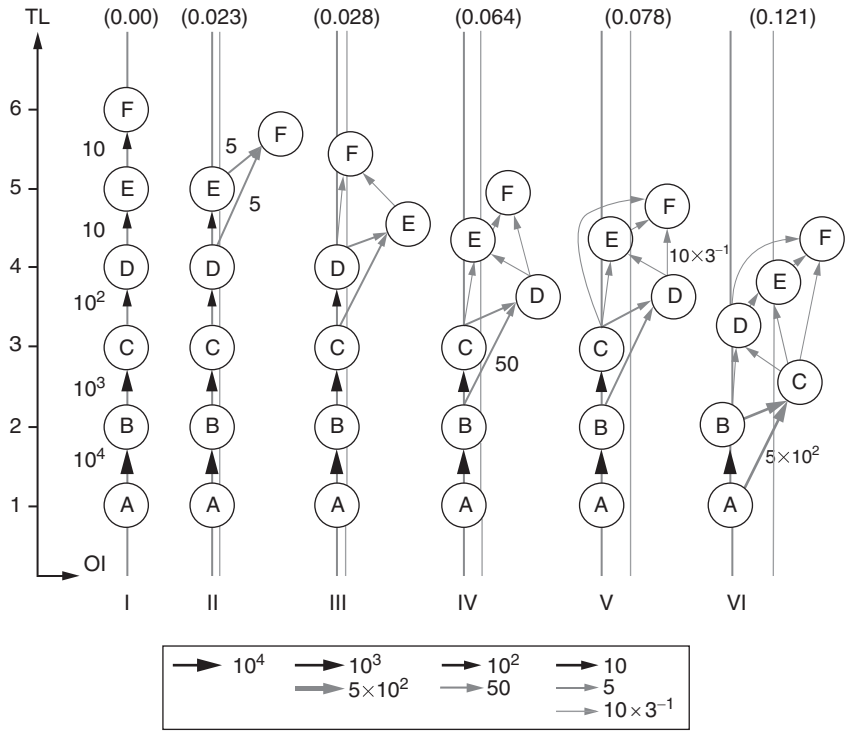

Fig. 1 Effect of network complexity on the value of the SOI. Elements of the networks are displaced on *y*-axis according to effective trophic level, and on *x*-axis according to OI values, with zero at the vertical continuous line for each network. Vertical dotted line represents the SOI of each web (values are reported above between parentheses). Keeping constant the number of compartments and total consumption for each consumer, the number of links in the trophic web (thus complexity) increases from case I to VI and so does SOI. Flows are expressed in hypothetical units (key legend at the bottom) but natural webs are mimed by assuming gross efficiency (ratio between consumption and production) for each element is equal to 50%.

However, keeping constant the number of links and thus of omnivorous elements, the SOI augments also when omnivores feed on nonadjacent trophic levels. As shown in Fig. 2, the increase in the number of levels between two trophic levels exploited by the same omnivore will produce a disproportionate increase in SOI, disregarding the number of links in the web (kept constant in the schematic example of Fig. 2).

Predators consuming preys at two very different trophic levels can produce high imbalances in natural systems. Productivity and ecological cost (total energy needed to produce biomass) are increasing for decreasing trophic levels and therefore equal exploitation by a predator has quite a different impact on the two populations: in particular, the switch between consumption on lower trophic level to the higher one can deplete this latter. In case of predation on nonadjacent trophic levels, therefore, high values of SOI are related to instability of the system (Neutel *et al.*, 2007).

This effect of high SOI due to extreme differences on trophic level of omnivores' preys is dampened down when omnivory is distributed over a range of trophic levels, even including extremely different ones (Fig. 3). Comparison with Fig. 1 implies that generalist species contribute to omnivory more than species characterized by low omnivory level (i.e., species that prey on lower number of trophic levels).

Weight of Links

SOI is also affected by the absolute amount of consumption flow rate. Keeping fixed the proportions of preys in the diet of predators but changing the absolute amount of flows, although not affecting OI of each element of the network, deeply influence the SOI of the network. Increasing flows to elements characterized by low omnivory definitely reduces the SOI of the system, while increasing consumption flows for omnivorous species will produce an increase of SOI of the web. An exemplification of such effects is reported in Fig. 4.

Therefore, generally, the SOI is not independent from the absolute values of consumption flows. This implies that particular attention should be paid when comparing food webs described with a different unit since their SOI estimates might not be comparable.

Biological Resolution

Building the food web of an ecosystem does not produce a univocal result in terms of structure. According to needs and focus of the analysis, the food web can have different biological resolution: that is to say, the same ecosystem can be described through a food web with a different number of elements. To be consistent with the same real ecosystem, however, there needs to be a correspondence between elements of the food webs and flows and biomasses should be coherent (thus total consumption of an element resulting from the lumping is equal to the sum of consumptions of aggregated elements). Equivalent food webs built by aggregating some elements illustrates the effect on SOI of the biological resolution used for building the food web (Fig. 5).

Topological indicators, such as connectance and linkage, are more influenced than SOI by aggregation as shown in Fig. 5. In particular, aggregation of primary producers has no effect on SOI, for it considers only consumers in food webs with directed interaction. Moreover, the accounting of consumption flows allows for balancing the aggregation of links in the SOI evaluation.

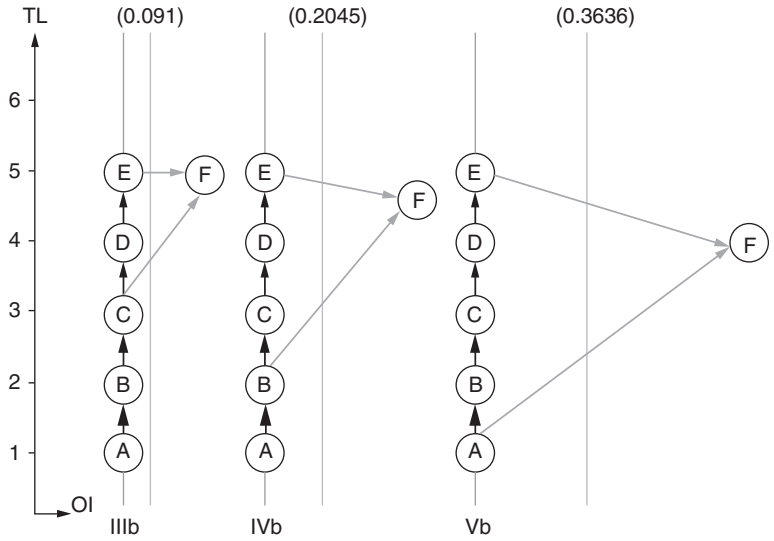

Fig. 2 Effect of feeding on nonadjacent trophic levels on the value of the SOI, other factors being constant. Number of compartments, total consumption for each consumer, and the number of links in the trophic web are kept constant. SOI is increasing as the omnivory of element F with regard to two groups of increasing distance in terms of trophic levels (network IIIb follows networks I and II of Fig. 1). Network representation is done according to Fig. 1.

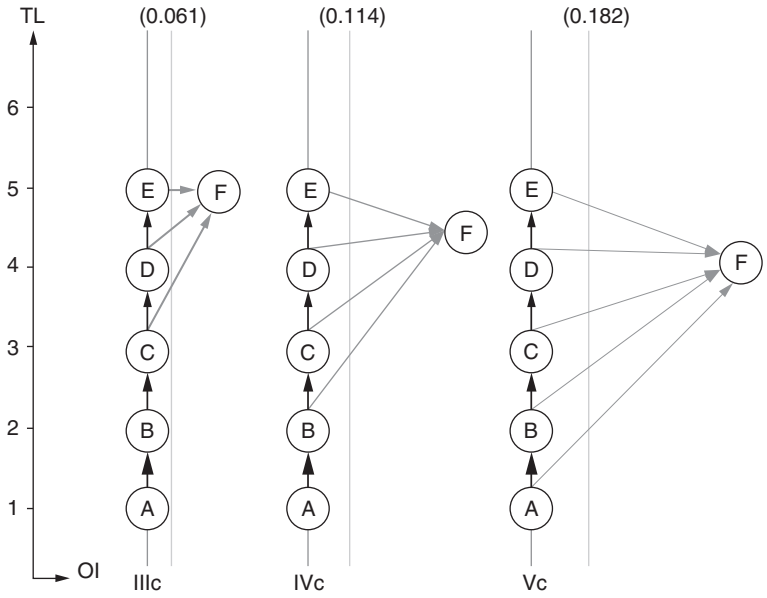

Fig. 3 Effect of feeding an increasing number of adjacent trophic levels on the value of the SOI. Number of compartments and total consumption for each consumer are kept constant. SOI increases as the number of links increases. Note that network IIIc follows networks I and II of **Fig. 1** and that the numbers of links of IIIc, IVc, and Vc are equal to the numbers of links of networks III, IV, and V of **Fig. 1**, respectively.

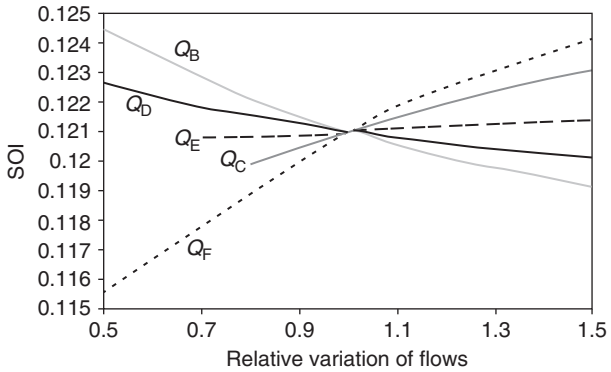

Fig. 4 Effects on SOI due to changes on consumption flows (Q) at different elements of network VI of **Fig. 1**. Elements with high omnivory with respect to average omnivory in the system (F, C, E) have positive relationship between SOI and induced changes on consumption flow. Increasing flows to elements with low omnivory (B, D) produces decreasing values of SOI.

Applications

SOI has been applied as an ecosystem indicator to evaluate complexity of real food webs and ecosystem health. Comparison of stability and complexity indexes (including SOI) for coastal marine food webs, highlighted positive correlation between SOI and magnitude of change and recovery time, thus suggesting that SOI is inversely related to stability at least in the marine ecosystems analysed (Perez-Espana and Arreguin-Sanchez, 1999).

Moreover, application of SOI and other ecological indicators on the basis of outputs of protected and fished marine food webs standardized by number of elements, showed that SOI is sensitive to fishing (Libralato *et al.*, 2010). This result suggests that SOI can be efficiently used as an ecological indicator for evaluate the effects of fishing on ecosystem food webs.

Recently, in a broad meta-analysis including 75 well documented marine food webs distributed globally (Heymans *et al.*, 2012), SOI and other ecological indices were calculated. Results showed that SOI differences were not significant when food webs are grouped by size, depth, latitude and longitude classes. Conversely, significant differences in SOI were found when the food webs were grouped by ecosystem types (Chi square; $P=0.04$; with SOI of reef > shelf > bay > lagoon > coastal > estuary) and by exploitation (Chi square; $P=0.03$; SOI exploited > SOI low or no fisheries) (Heymans *et al.*, 2012). Although SOI differences by ecosystem types do not have a clear explanation, results by exploitation further support SOI as a potential indicator for ecosystem stress induced by fishing, although further studies are needed.

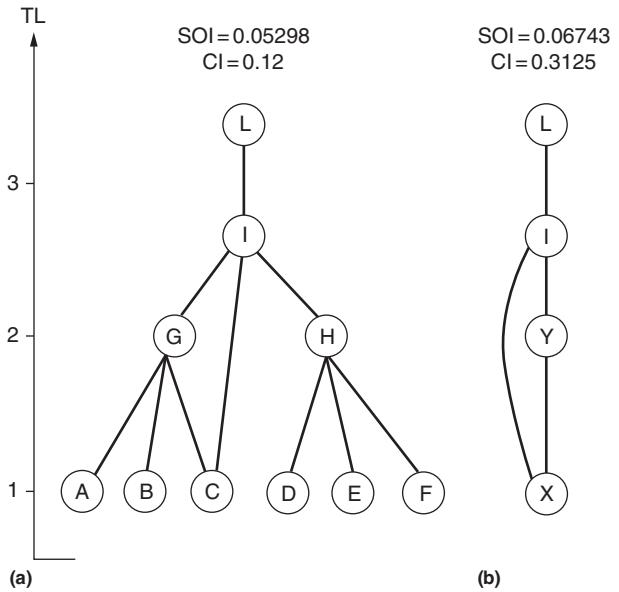

Fig. 5 Aggregation effect on SOI. Elements of network 'a' are aggregated in network 'b' according to trophic position and feeding elements. Element Y results from the aggregation of elements G and H; element X results from the aggregation of basal elements A, B, C, D, E, and F. Flows are aggregated accordingly. SOI and CI are reported above the respective food web. CI appears to be more sensitive to the number of links and elements than SOI; thus, this latter is less affected by lumping network elements.

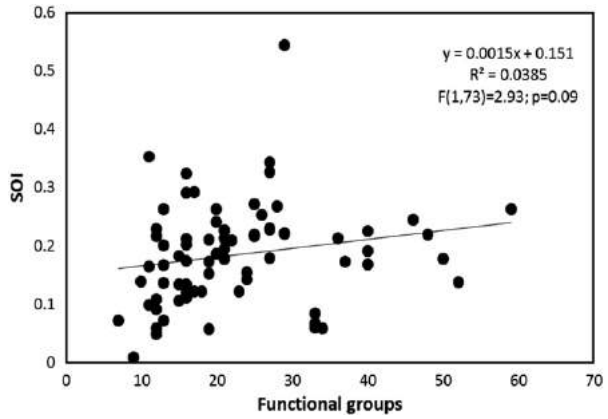

Fig. 6 Effect on SOI of the number of functional groups used in food webs to describe real marine ecosystems. Data regards the 75 models used in Heymans *et al.* (2012). Results show a linear trend non significant supporting theoretical invariance of SOI by the number of functional groups used to describe ecosystems.

Furthermore, using estimates from the 75 food web models collected in Heymans *et al.* (2012), **Fig. 6** shows no significant trend of SOI with number of functional groups thus confirming that SOI is an invariant measure independent from the number of components (nodes) of the model.

Capabilities

The SOI is therefore a good measure of the complexity of ecological networks of trophic interactions, and increasing values of SOI are, to a certain extent, representative of networks of increasing complexity that should be related to increase of maturity of ecosystems. However, extremely high values of SOI can be due to omnivores feeding on nonadjacent trophic levels that do not contribute to the complexity of ecosystems but can introduce instabilities. Therefore caution is needed when evaluating ecosystems characterized by the presence of those omnivores. In general, however, SOI appears to be a reliable measure of complexity and stability even in the presence of aggregation of elements of trophic networks and it is less affected by structural and topological changes introduced by lumping elements of networks. Application to real marine food webs,

moreover, highlighted the possibilities to use SOI as an ecosystem indicator also for stresses induced on ecosystems, such as effects of fishing on marine ecosystems.

Trophic Classification for Lakes☆

Fu-Liu Xu and Yang Jiao, Peking University, Beijing, China

A Review of Ecological Indicators for Trophic Classification for Lakes

The classical system of distinguishing lake trophic states can be traced to August Thienemann. He classified lakes according to their trophic conditions into oligotrophic (low trophy), eutrophic (high trophy), and dystrophic (lakes of boggy character, with highly colored water due to the presence of organic matter from decaying vegetation), on the base of the composition of lake bottom sediments and the associated benthic fauna. Since the 1960s and the 1970s, a number of attempts have been made to quantitatively evaluate the trophic state of lakes. Ecological indicators so far used for trophic classifications of lakes may be divided into physical, chemical, biological, and system-level aspects. They have been used solely as single-variable trophic indices or synchronously as multiparametric approaches. The single-variable trophic indices can be divided into abiotic and biotic aspects. Among the abiotic parameters including physical and chemical indicators, plant nutrients (phosphate, nitrate), oxygen demanded (biochemical (BOD), chemical (COD)), and transparency were usually used to assess lake trophic levels. Also, biotic parameters were often employed to assess lake trophic conditions, given the sensitivity of aquatic organisms, especially algae and macroinvertebrates, to eutrophication processes. Phytoplankton, both in running waters and lakes, turned out to be a reliable environmental tool when estimating different levels of trophy. With the exception of chlorophyll *a* (Chl-a) concentrations, phytoplankton cell number, species number, and biomass, some form of index, such as Hurlbert's, Margalef's, Menhinick's, Shannon's, Simpson's, and McNaughton's, has always been used in assessing eutrophication conditions in aquatic environments. Like phytoplankton, zooplankton indices have also been adopted for lake trophic classifications. For instance, zooplankton community size, structure, abundance, and biomass of micro- and macrozooplankton, the shift of Rotifer communities, as well as zooplankton assemblages were applied to classify the lake trophic status.

However, these relatively simple single-variable trophic state criteria represent subjective judgments, and may be limited spatially. Further, the use of descriptive classifications for lake trophic states such as oligotrophic, mesotrophic, eutrophic, and so on, could create difficulties when attempting to describe continuous changes in a lake's trophic state or in studying quantitatively the eutrophication mechanism. The multidimensional nature of the eutrophication phenomenon means that no single variable is representative of the eutrophication status of a given water body. More robust trophic state criteria or indices using multivariate approaches have been proposed by a number of investigators. The contributions of Carlson, Walker, and Porcella offer a 0–100 scale providing continuous numerical classes of lake trophic states and a rigorous foundation for quantitative studies of the mechanisms behind eutrophication. This effectively eliminates the subjective labeling associated with the use of oligotrophic, mesotrophic, and eutrophic states as indicators. The trophic state index (TSI) based on several biological, chemical, and physical indicators, especially the Carlson-type TSI, offers the most suitable and acceptable method for trophic classifications of lakes. Mathematical methods play a very important role in lake trophic classifications in terms of parameters chosen, weighting factor calculation, and sample classification. Exploratory statistical regression analysis has been used to investigate relationships between the related parameters and eutrophication levels. Further, cluster analysis, fuzzy analysis, principal component analysis, and artificial neural networks have proven to be powerful tools in lake eutrophication assessment. Another important attempt at a multiparametric classification of trophic conditions was undertaken by Zurlini by combining the exact probabilities from Organization for Economic Cooperation and Development (OECD) of the log normal frequency distributions of chlorophyll, nitrogen, and phosphorus concentrations as well as Secchi depths. Additionally, several other researchers applied remote sensing technologies or geographic information system (GIS) technology to the trophic classification for lakes.

A Case Study: Trophic Classification for Lake Chaohu in China

Design and Calculation of Trophic Classification

A GIS-based method of lake eutrophication assessment was undertaken to study the spatial distribution of eutrophication conditions in lake environments. A trophic state index (TSI) consisting of six physical, chemical, and biological indicators including total phosphorus (TP), total nitrogen (TN), chemical oxygen demand (COD), Secchi disk depth (SD), chlorophyll-a concentration (Chl-a), and phytoplankton biomass (CA) was constructed to describe the eutrophication state of the lake environment. A 0–100 eutrophication scale was also developed to indicate seven different trophic levels within the lake environment: 0–30 representing oligotrophic, 30–40 lower-mesotrophic, 40–50 mesotrophic, 50–60 upper-mesotrophic, 60–70 eutrophic, 70–80 hypereutrophic, and 80–100 the extremely hypereutrophic. A representation of the spatial distribution of TSITP, TSITN, TSICOD, TSISD, TSIChl-a and TSICA was developed using the Inverse Distance Weighted (IDW) interpolation method. By

☆*Change History*: March 2018. Fu-Liu Xu updated Abstract, Keywords, Figure 1, Figure 3, and Figure 4.

This is an update of F.–L. Xu, Trophic Classification for Lakes, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3594–3601.

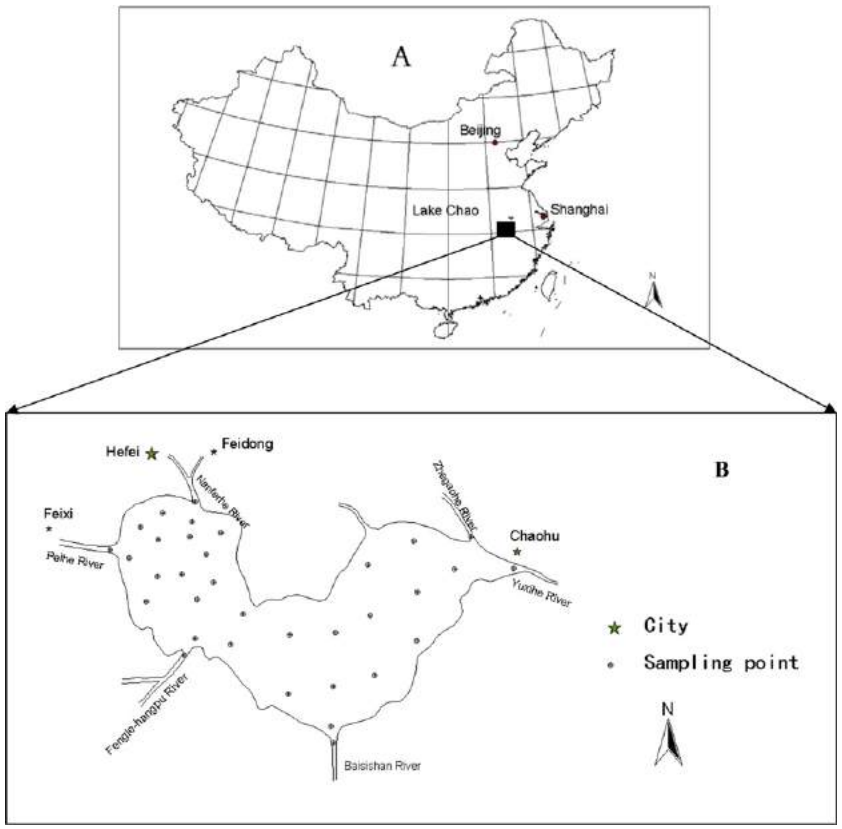

Fig. 1 Geographical location (A) and distribution of sampling points (B) of Lake Chao.

categorizing the interpolated values, a clear illustration of the different trophic levels was developed on six thematic maps. A Geographical Information System (GIS) overlay technique was applied to synthesize the information from the six thematic maps into a final map illustrating the spatial distribution of eutrophication conditions within the study area.

Study Area and Data Collection

Lake Chao is located in southeastern China (Fig. 1A). It has a mean surface area of 760 km^2, a mean depth of 3.06 m, and a mean retention time of 136 days. Lake Chao is one of the five largest fresh-water lakes in China, and the most eutrophic. Prior to the 1950s, the lake was well known for its scenic beauty and richness of aquatic life. Since that time, however, the lake has suffered from serious eutrophication. Increasing pressures from population growth and economic development in the drainage area are primarily responsible for the lake's current eutrophic state. The present conditions have had negative ecological, health, social, and economic effects on the lake and its utilization. Lake Chao was selected some time ago for inclusion in a nation-wide study of lake eutrophication conditions and processes. Accordingly, comprehensive research on Lake Chao has been carried out for more than 20 years (see Tu et al., 1990; Wang et al., 1995; Xu, 1994, 1996, 1997; Xu et al., 1999a,b,c).

Measurement and sampling of the lake's water for analytical purposes were performed monthly from April 1987 to March 1988. The water samples were collected using a van Dorhn sampler from 34 stations (Fig. 1B) at a depth of 0.5 m. The parameters chosen for measurement included both physic-chemical parameters (SD, pH, TN, TP, Si, COD, BOD, DO, etc.) and biological parameters (chlorophyll-a concentration (Chl-a), biomass concentration and the dry weight of both phytoplankton and zooplankton, and the number of phytoplankton cells). Thermal profiles were taken every 3 h at various points in the lake by means of a thermograph. A weather station located on the site provided 3-hourly measurements of atmospheric pressure, wind speed and direction, air temperature, humidity and solar radiation.

The flow chart of the GIS-based method for the lake eutrophication assessment is shown in Fig. 2.

TSI Calculation and Trophic Classification

Indicators selection

The TSIs was based on total phosphorus (TP, in mg/l of P), total nitrogen (TN, in mg/l of N), chemical oxygen demand (COD, in mg/l), Secchi disk depth (SD, in m), chlorophyll-a concentration (Chl-a, in mg/m^3), and phytoplankton biomass (CA, as C in mg/m^3) (see Table 1). The assessment standards for each indicator were based on those constructed for the Evaluation Standards

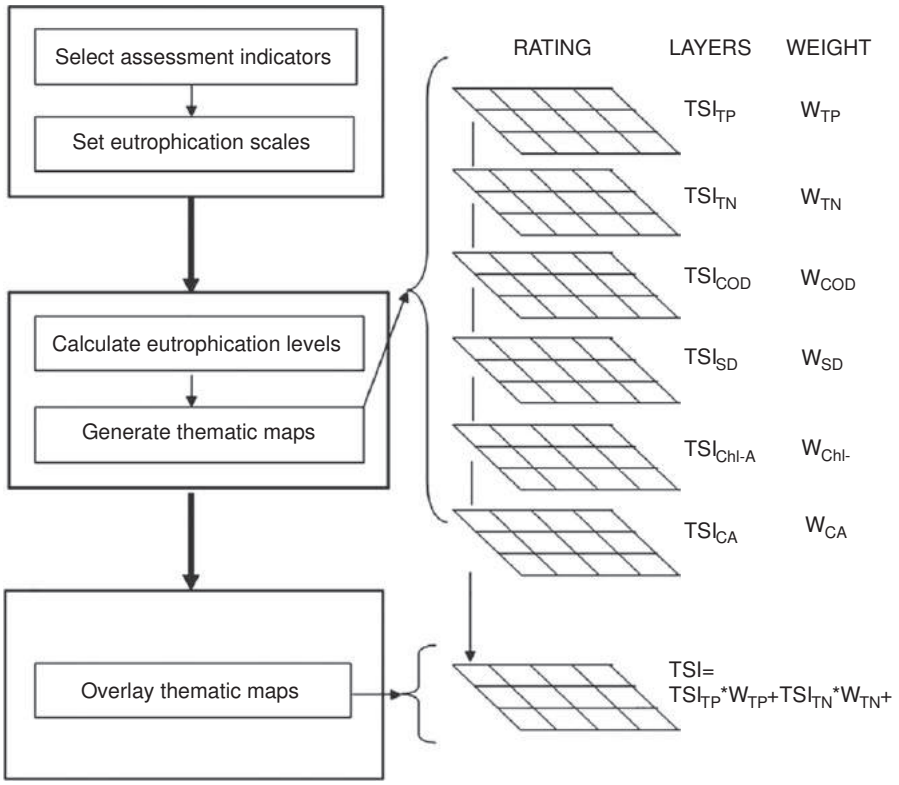

Fig. 2 The flow chart for the GIS-based method for lake eutrophication assessment.

Table 1 The scale of the trophic state index (TSI) and the evaluation standards for Lake Chao[a]

TSI	*Eutrophication level*	*TP (mg/L)*	*TN (mg/L)*	*COD (mg/L)*	*SD (m)*	*Chl-a (mg/m^3)*	*CA (mg/m^3)*
0	Oligotrophic	0.0004	0.010	0.06	48	0	/
10		0.0009	0.070	0.12	27	0.10	<50
20		0.0020	0.150	0.24	15	0.26	50
30		0.0046	0.300	0.48	8.0	0.66	100
40	Lower-mesotrophic	0.0100	0.600	0.96	4.4	1.60	150
50	Mesotrophic	0.0230	1.000	1.80	2.4	4.10	200
60	Upper-mesotrophic	0.0500	1.500	3.60	1.3	10.0	250
70	Eutrophic	0.1100	2.000	7.10	0.73	20.0	300
80	Hypereutrophic	0.2500	3.000	14.0	0.40	40.0	500
90	Extremely hypereutrophic	0.5500	4.600	27.0	0.22	100	800
100		1.2000	10.00	54.0	0.12	200	>800

[a]Consulting the trophic state index and evaluation standards for lake eutrophication of OECD (1982) and Japan National Environmental Institute (Aizaki et al., 1981), and for Lake Tai eutrophication in China (Jin et al., 1990).

for Lake Eutrophication designed for the OECD (1982) and the Japanese National Environmental Institute (Aizaki et al., 1981), and those used in assessing the eutrophication of Lake Tai in China (Jin et al., 1990) (see **Table 1**).

Calculation of eutrophication levels and generation of thematic maps

The following expression was used to calculate the lake eutrophication levels for each of the indicators:

$$\mathrm{TSI}_i = \left(\mathrm{TSI}_{k-1} + \left(\left(C_i - S_{i,k-1}\right)/\left(S_{i,k} - S_{i,k-1}\right)\right) \times \left(\mathrm{TSI}_k - \mathrm{TSI}_{k-1}\right)\right) \quad (1)$$

where C_i is the measured concentration of the i-th indicator (i = TP, TN, COD, SD, Chl-a and CA), TSI_k and TSI_{k-1} are the k-th and $(k-1)$-th *scales* of the i-th indicator, $S_{i,\,k}$ and $S_{i,\,k-1}$ are the evaluation standards of k-th and $(k-1)$-th scales of the i-th indicator (see **Table 1**).

The inverse distance weighted (IDW) interpolation method (Lam, 1983) with a spatial resolution of 500 × 500 m and ArcView Version 3.1 (ArcView 3.1, ESRI, Inc.) were used to generate the six thematic maps indicating the spatial distribution of eutrophication levels based on each indicator. The IDW interpolation method is based on the principle of assigning higher weights

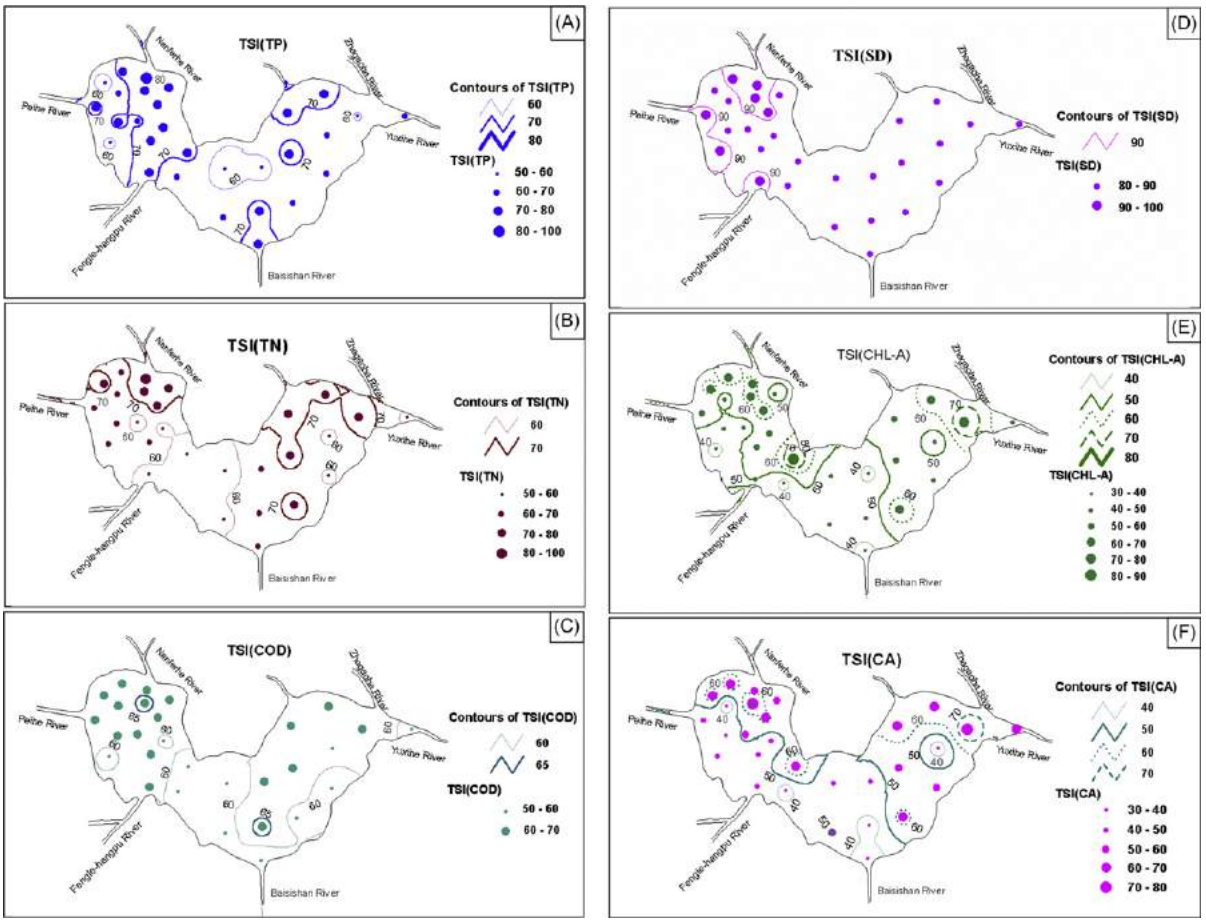

Fig. 3 Spatial distribution of the lake trophic state index based on each indicator: (A) TSI_{TP}; (B)TSI_{TN}; (C)TSI_{COD}; (D)TSI_{SD}; (E)$TSI_{Chl\text{-}a}$; (F) TSI_{CA}.

to data points closest to an unvisited point relative to those which are further away (Weber and Englund, 1992, 1994). In other words, the assigned weight is a function of inverse distance as represented in the following formula (Lam, 1983):

$$f(x,y) = \sum_{i=1}^{N} w(d_i) z_i \div \sum_{i=1}^{N} w(d_i) \tag{2}$$

where $f(x,y)$ is the interpolated value at point (x,y); $w(d_i)$ is the weighting function; z_i is the data value at point i; and d_i is the distance from point (x,y).

The interpolated values of any point within the dataset are bounded by $\min(z_i) < f(x,y) < \max(z_i)$, as long as $w(d_i) > 0$ (Lam, 1983). The IDW interpolation method has been widely used on many types of data because of its simplicity in principle, speed in calculation, easiness in programming, and credibility in interpolating surfaces (Lam, 1983).

The overlay of the thematic maps

The overlay technique, widely used in GIS applications (GIS by, 1994), was applied to synthesize the six thematic maps and develop the final eutrophication map. The following steps describe the synthesizing procedure used to analyze the six thematic maps:

(1) Development of an trophic state index (TSI) scale from 0 to 100 to label the different trophic levels (see **Table 1**).
(2) Application of this ordinal scale to all the pixels/cells on each thematic map; each pixel was assigned a value from 0 to 100 based on a comparison between its initial value and the eutrophication scales in **Table 1**.
(3) Analysis of the six thematic maps on a cell-by-cell basis. As a result, a final map illustrating the spatial distribution of eutrophication levels was produced. The following expression was used in the overlay operation to produce the TSI values:

$$TSI = (TSI_{TP}{}^{*}W_{TP} + TSI_{TN}{}^{*}W_{TN} + TSI_{COD}{}^{*}W_{COD} + TSI_{SD}{}^{*}W_{SD} + TSI_{Chl-A}{}^{*}W_{Chl-A} + TSI_{CA}{}^{*}W_{CA}) \tag{3}$$

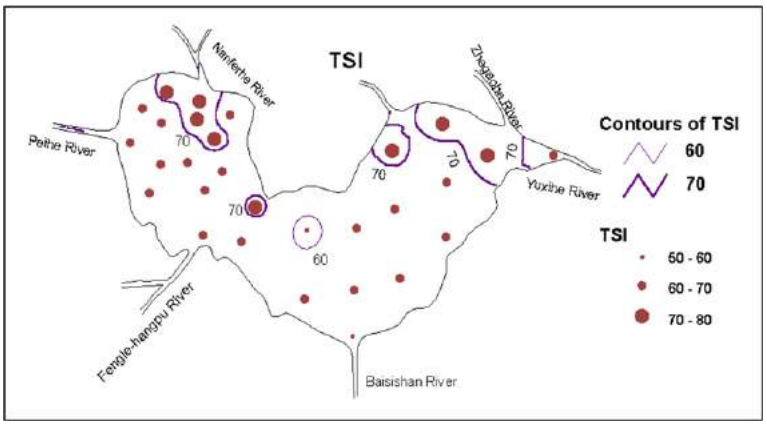

Fig. 4 Final map for the spatial distribution of the lake eutrophication based on overlay technique.

where TSI_{TP}, TSI_{TN}, TSI_{COD}, TSI_{SD}, $TSI_{Chl\text{-}a}$ and TSI_{CA} are the eutrophication levels for TP, TN, COD, SD, Chl-A and CA on the six thematic layers; W_{TP},W_{TN},W_{COD},W_{SD}, $W_{Chl\text{-}a}$ and W_{CA} are the weighting factors for each indicator (assumed as 1/6 for each indicator in the operation).

Trophic classification for Lake Chaohu

The thematic maps of TSI_{TP}, TSI_{TN}, TSI_{COD}, TSI_{SD}, $TSI_{CHL\text{-}A}$ and TSI_{CA} developed using the IDW interpolation method and the eutrophication scales are illustrated in Fig. 3A–F, respectively. The final TSI map developed as a result of the overlay technique is given in Fig. 4.

Fig. 3A shows the spatial distribution of TSI_{TP}. From it, one can see that the western part of Lake Chao is characterized mainly as severely eutrophic (TSI_{TP} 70–80), while the eutrophic field (TSI_{TP} 60–70) is distributed in the eastern part of the lake. The eutrophication levels near the river mouths are representative of eutrophic to extremely hypereutrophic (TSI_{TP} 60–90) conditions, while the upper-mesotrophic and eutrophic (TSI_{TP} 50–70) conditions can be observed in the open water areas.

Fig. 3B illustrates the spatial distribution of TSI_{TN}. The hypereutrophic field (TSI_{TN} 70–80) is mainly distributed in the northwestern and northeastern parts, near the river mouths. Most of the study area can be characterized as eutrophic (TSI_{TN} 60–70) centered in the southwestern and southeastern parts and upper-mesotrophic (TSI_{TN} 50–60) in the central part.

Fig. 3C shows the TSI_{COD} spatial distribution. Here, the upper-mesotrophic field (TSI_{COD} 50–60) is extended from the central to the southeastern part of the lake, with most of the remainder of the study area being characterized as eutrophic (TSI_{COD} 60–70).

Fig. 3D reveals the spatial distribution of TSI_{SD}. The extremely hypereutrophic field (TSI_{SD} 80–100) covers the entire lake. The eutrophication level near the river mouths in the western part of the lake is higher (TSI_{SD} 90–100) than that found elsewhere in the study area (TSI_{SD} 80–90).

Fig. 3E demonstrates the spatial distribution of $TSI_{CHL\text{-}A}$. The central and southwestern parts of the lake are characterized by mesotrophic and lower-mesotrophic fields ($TSI_{CHL\text{-}A}$ 30–50), with a strong mesotrophic field ($TSI_{CHL\text{-}A}$ 40–50) dominance. The northwestern and eastern parts of the study area are characterized as primarily upper-mesotrophic ($TSI_{CHL\text{-}A}$ 50–60), with the eutrophic field ($TSI_{CHL\text{-}A}$ 60–70) extending mainly near the river mouths in the same area. The severely eutrophic ($TSI_{CHL\text{-}A}$ 70–80) and the extremely hypereutrophic fields ($TSI_{CHL\text{-}A}$ 80–90) are limited to small areas in the central and eastern parts of the lake.

Fig. 3F indicates the spatial distribution of TSI_{CA}. The mesotrophic field (TSI_{CA} 40–50) extends from the southwestern to central parts of the lake, while the lower-mesotrophic field (TSI_{CA} 30–40) is limited to small areas in the same region. The upper-mesotrophic (TSI_{CA} 50–60) covers most of the northwestern and the eastern parts of the study area. The eutrophic range (TSI_{CA} 60–70) is found principally in the eastern part of the lake and in limited number of small areas in the northwestern part of the lake. The hypereutrophic field (TSI_{CA} 70–80) is only found near the mouth of the Zhegaohe River in the eastern part of the lake.

Finally, the overall TSI spatial distribution is illustrated in Fig. 4. Eutrophic conditions (TSI 60–70) cover most of the study area, while the hypereutrophic conditions (TSI 70–80) are distributed mainly near the river mouths in the northwestern and northeastern parts of the lake. A very limited area in the central part of the study area is characterized as upper-mesotrophic (TSI 50–60).

Discussions

The spatial distribution of Lake Chao's eutrophication levels derived from this study is closely correlated with the actual conditions of the lake. The northwestern and northeastern parts of the lake, especially the river mouths near the Nanfeihe and Zhegaohe Rivers, receive much more wastewater because of their nearness to Hefei City, the capital of Anhui Province, and Chaohu City, the second largest city in the lake's watershed (see Fig.1A). The nutrient contents which are primarily responsible for eutrophication (Rast and Holland, 1988; Ryding and Rast, 1989; Cooke et al., 1993) both in the lake's water and sediments, were far higher in

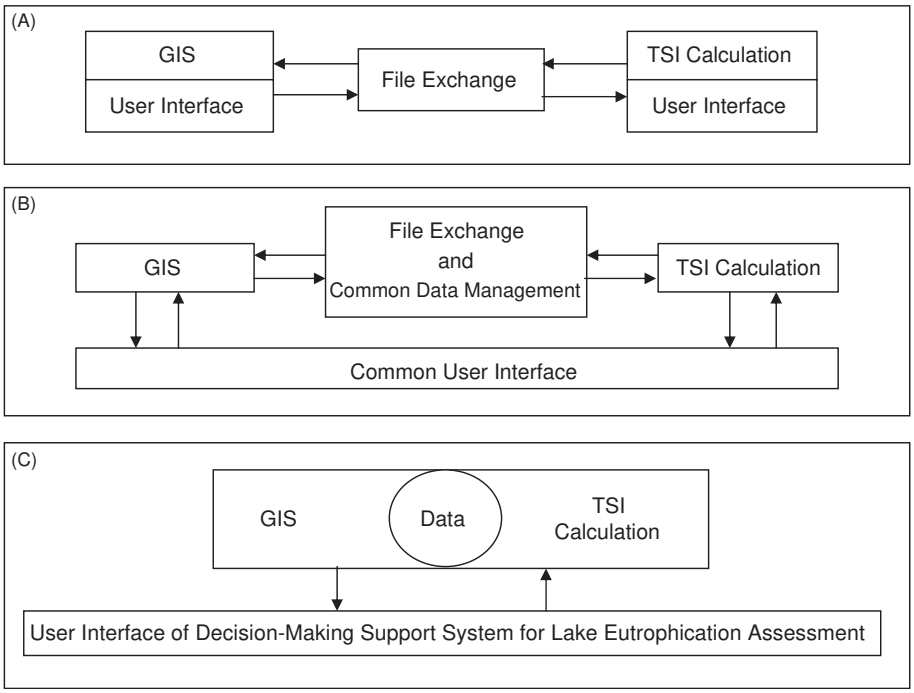

Fig. 5 The different periods or levels of GIS-based method for lake eutrophication assessment: (A) the first periods or levels; (B) the second periods or levels; (C) the third periods or levels.

these two regions than anywhere else in the lake (see **Fig. 3**A,B). The concentration of Chl-a and phytoplankton biomass, two of the more obvious symptoms of eutrophication (Rast and Holland, 1988; Ryding and Rast, 1989; Cooke et al., 1993), both followed similar trends in spatial distribution (see **Fig. 3**E–F).

Lake eutrophication, however, cannot be simply evaluated by a single physical, chemical, or biological parameter. It is a multidimensional feature (Shannon and Brezonik, 1972; Carlson, 1977; Cruzado, 1987). These single indicators cover different aspects of the lake eutrophication phenomenon. It is necessary, therefore, to apply several indicators simultaneously (including physical, chemical, and biological) to derive a more complete lake eutrophication assessment. Only through such a multi-dimensional approach can one capture all the features needed to yield a fully informative assessment of the eutrophic condition of a lake. Unfortunately, the sensitivity of a single-parameter and/or its weighting factor may be different in different lakes depending on the parameters used in the TSI (e.g., Therriault and Platt, 1978; Reckhow and Chapra, 1983; Powell et al., 1989; Boyle et al., 1990; Whitton and Kelly, 1995; Karydis and Tsirtsis, 1996; Danilov and Ekelund, 1999). The choice of suitable indicators and their weights is critically important in the eutrophication assessment of a specific lake. Hooper (1969) identified four important criteria useful in the development of eutrophication indices: (1) it should discriminate between changes associated with nutrient level and those associated with other categories of environmental change; (2) it should have considerable sensitivity to levels of enrichment; (3) it should have properties which are widespread geographically and short-lived geologically; and (4), it should be suitable for long-term surveillance and monitoring, that is, indices should both document past changes and serve as a predictive function.

Most of the current research has focused on the identification and selection of suitable indicators relative to assessing the eutrophic condition of a lake. The spatial distribution of eutrophication levels, however, is equally important in developing a complete picture of the trophic state of a lake. A GIS-based method to spatially assess lake eutrophication states was proposed in this paper. GIS technology is mainly adequate for distributed data which are within the resolution of the GIS grid, for example, land use, land cover (both can be deduced from sattelite inages), DEM, etc. The approach in this paper is not the same—the authors used rather limited number of observation points and a special technique (IDW) to calculate the GIS mesh values of variables. The methodology could have three different approaches depending on integration style and date exchange methodology between the GIS approach and the TSI calculations (see **Fig. 5**). The first is shown in **Fig. 5**A. Here, both the GIS and the TSI calculations belong to two separate systems, each having their own identifiable user interface. The GIS is used simply to display the results of the TSI calculations and their integration is limited to file exchange activity. The second approach is illustrated in **Fig. 5**B. Here, the GIS and the TSI calculations still belong to two separate systems. However, they possess a common user interface that is used to activate the GIS and TSI calculations as a single system, in addition to managing common data and file exchanges. This integrating style reduces errors associated with both data and file exchanges between separate systems. The third approach is presented in **Fig. 5**C. The GIS and the TSI calculations are now completely integrated as a Decision-Making Support System for Lake Eutrophication Assessment (DMSSLEA), having a uniform user interface and data sharing. In this approach, the TSI calculations are treated as an analysis function of the integrating system. The calculations are programmed using a specific GIS

programming language, for example, Avenue in ArcView, SML in Arc/Info PC version, MapBasic in MapInfo, or Genius in GanaMap. Here the GIS manages the spatial and attribute data, in addition to manipulating and displaying the results of TSI calculations.

The first approach was applied in the case study presented in this paper. The TSI calculations were developed using MS Excel 97, while the generation and synthesis of the six thematic maps was performed using the inverse distance weighted (IDW) interpolation method and overlay technique within the framework of a Geographic Information System (ArcView 3.1, ESRI, Inc.). The results of the TSI calculations were stored in Dbase format. The map indicating the boundary and sampling points in the lake served as the basis for visualizing the resulting spatial data (**Fig. 1**B).

Conclusions

A GIS-based method of lake eutrophication assessment was proposed with the purpose of studying the spatial distribution of eutrophication conditions in the lake environment. The method included the integration of GIS methodology into lake eutrophication assessment using a trophic state index. The inverse distance weighted (IDW) interpolation method was used for generating thematic maps indicating the spatial distribution of each of the Trophic State Indices. An overlay technique within the GIS framework was applied to analyze the information from the thematic maps in order to develop a final map illustrating the spatial distribution of eutrophication conditions in the lake. Results from the study indicate that the boundaries associated with different trophic levels (upper-mesotrophic, eutrophic and hypereutrophic) could be clearly defined in a final eutrophication map. This result comprises the principal advantage of the proposed methodology when compared with other attempts based on a multiparametric classification and assessment of lake trophic trends. The latter approach does not lead to a clear definition of the boundaries associated with differing trophic levels. As such, the proposed methodology could be of special interest to policy makers involved in lake management and planning, since policy makers need a more explicit view of trophic status and clear information on water quality.

Introduction

This article describes the common scientific meanings of the widely used "trophic index" in classifications in the field of monitoring and assessment. The term "trophic" does not have a distinct application in ecology and is generally used in the description of mean processes like feeding, nourishment, production potential, and food web.

The word "trophy" originates from the Greek word *trophē* which means nourishment or pertaining to nutrition or connected with a source of nutrition. Many other ecological terms are derivatives of the initial word "trophy": for example, trophic level, trophic niche, trophic guild, trophic net, trophic structure, trophic status, and trophic index. In order to classify a plant or animal community or to assess its quality status, for example, as a result of anthropogenic disturbance, trophic indices were developed. They are mostly applied in aquatic communities since aquatic ecosystems are relatively stable in space and time.

Two groups of trophic indices can be distinguished. The first one, the group of trophic status indices, focuses on the primary production potential. In the aquatic environment four types of trophic statuses of the waterbody can be distinguished: the oligotrophic, mesotrophic, eutrophic, and dystrophic status. The second group includes those indices that reflect the complexity of trophic relations between organisms. These indices have been commonly used in bioassessment of the aquatic ecosystem health in general—especially, those systems that have been severely altered as result of anthropogenic activities (e.g., water pollution, physical disturbances). Results of assessments are commonly ranged into quality classes. In the forthcoming sections main types of trophic indices are discussed, mostly used in assessment procedures to evaluate the ecological status of a defined biotope.

Trophic Status Indices

TRIX Index

This index represents the linear combination of the logarithm of four state variables:

$$\mathrm{TRIX} = (\mathrm{Log}_{10}[\mathrm{ChA} + \mathrm{aD\%O} + \mathrm{minN} + \mathrm{TP}] + \mathrm{k})/\mathrm{m}$$

where ChA is the chlorophyll-*a* concentration ($\mu g\,L^{-1}$), aD%O is the dissolved oxygen concentration as absolute percentage deviation from saturation ($=100\%$), minN is the mineral nitrogen, dissolved inorganic nitrogen (sum of $N_{nitrate} + N_{nitrite} + N_{ammonia}$ in $\mu g\,L^{-1}$), and TP is total phosphorus ($\mu g\,L^{-1}$).

The coefficients $k=1.5$ and $m=1.2$ are scale coefficients, introduced to obtain results on a 0–10 scale. TRIX results are arranged in four classes according to **Table 1**. The index characterizes succinctly the trophic levels in coastal marine areas and was adopted for this purpose by the Italian national legislation.

Values exceeding 6 TRIX units are typical for highly productive coastal waters, where eutrophication effects determine frequency of anoxia episodes in the water layer above the bottom. Values lower than 4 TRIX units are associated with scarcely productive coastal waters, while values lower than 3 are usually found in the open sea. Because of the log transformation of the four variables used, annual distributions of TRIX data over homogeneous coastal zones follow or are nearly equal to a Gauss curve.

Carlson's Trophic State Index

Transparency of surface waters is often related to the amount of plant nutrients in the water. The more the nutrients, the more the phytoplankton, and as a result the less transparent the water is. Measuring transparency is a common but indirect way to estimate roughly the trophic condition of a waterbody. This condition, called the extent of eutrophication, is a natural aging process of lakes, which is unnaturally accelerated by too many nutrients. Trophic state determination is an important aspect of lake surveys. Trophic state is not the same as water quality, but is one aspect of it.

The concept of trophic status is based on the fact that changes in nutrient levels (measured as total phosphorus) cause changes in algal biomass (measured as chlorophyll *a*) which in turn cause changes in lake clarity (measured as Secchi disk transparency). The trophic state index (TSI) is a convenient way to quantify this relationship. TSI is calculated independently from Secchi disk depth, chlorophyll *a*, and total phosphorus concentration. It should be taken into account that TSI was

Table 1 Categories of TRIX classes

TRIX value	*Trophic category*
<4	Low trophic level
4–5	Middle trophic level
5–6	High trophic level
6–10	Very high trophic level

Adapted from Moncheva, S., Doncheva, V., 2000. Eutrophication index ((E) TRIX)—an operational tool for the Black Sea coastal water ecological quality assessment and monitoring. International Symposium "The Black Sea Ecological Problems" Odessa: SCSEIO, pp. 178–185.

Table 2 Classes of TSI values and their ecological attributes.

TSI	*Chl* ($\mu g\ L^{-1}$)	*SD (m)*	*TP* ($\mu g\ L^{-1}$)	*Ecological attributes*
<30	<0.95	>8	<6	Oligotrophy: Clear water, oxygen throughout the year in the entire hypolimnion
30–40	0.95–2.6	8–4	6–12	Hypolimnia of shallower lakes may become anoxic
40–50	2.6–7.3	4–2	12–24	Mesotrophy: Water moderately clear; increasing probability of hypolimnetic anoxia during summer
50–60	7.3–20	2–1	24–48	Eutrophy: Anoxic hypolimnia, macrophyte problems possible
60–70	20–56	0.5–1	48–96	Blue-green algae dominate, algal scums and macrophyte problems
70–80	56–155	0.25–0.5	96–192	Hypereutrophy (light-limited productivity): Dense algae and macrophytes, algal blooms possible throughout summer
>80	>155	<0.25	192–384	Algal scums, few macrophytes

Adapted from Carlson, R.E., Simpson, J., 1996. A coordinator's guide to volunteer lake monitoring methods. USA: North American Lake Management Society Madison.

developed for use with lakes that have few rooted aquatic plants and little nonalgal turbidity. The formulas for calculating the TSI are presented below:

$$\mathrm{TSI\ (SD)} = 60 - 14.41\ \mathrm{Ln\ Secchi\ disk\ depth(meters)}$$
$$\mathrm{TSI\ (Chl)} = 9.81\ \mathrm{Ln\ chlorophyll}\ a(\mu \mathrm{g\,L^{-1}}) + 30.6$$
$$\mathrm{TSI\ (TP)} = 14.42\ \mathrm{Ln\ total\ phosphorus}\ (\mu \mathrm{g\,L^{-1}}) + 4.15$$

Each of these three variables can theoretically be used to classify a waterbody, because they are interrelated by linear regression. It is supposed that seasonal average values of variables are used for TSI calculation. If the three TSI values are not similar to each other, it is likely that algal growth may be light- or nitrogen-limited instead of P-limited, or that Secchi disk transparency is affected by erosional silt particles rather than by algae, or something else.

One considers that average TSI is a good indicator of water trophic status in general. Average $\mathrm{TSI} = (\mathrm{TSI(TP)} + \mathrm{TSI(Chl)} + \mathrm{TSI(SD)})/3$ and the values reflect ecological attributes that could be expected in temperate lakes (**Table 2**).

Trophic Diatom Indices

Diatoms are widely recognized and used as indicators of river and stream water quality, including trophic state conditions. The diatom trophic indices describe diatom distribution in relationship to either "dissolved" (~orthophosphate) or "total" phosphorus, that are mostly closely correlated with the nitrogen concentration in the water. Therefore, these indices are treated as broad indicators of the trophic status of water bodies.

Three trophic indices based on ecological properties of diatoms were developed in the 1990s:

1. The trophic diatom index (UK TDI), which is used in the United Kingdom. This index was developed by Kelly and Whitton (1995), later on revised by Kelly *et al.* in 2001.
2. The TDI developed by Coring *et al.* (1999), which is used in Germany (German TDI).
3. The TDI developed by Rott *et al.* (1999), which is used in Austria (Austrian TDI).

All these indices were designed for use in rivers, which means that they are not applicable in lakes and other stagnant water bodies. Calculation of the indices is based on the weighted average of the equation of Zelenka and Marvan for each diatom species. Two values are assigned to the species: a value reflecting the tolerance or affinity to a certain water quality (good or bad) and a value that indicates how strong (or weak) this relationship is. In addition, the index values are weighted by the relative abundance of the diatom in the sample (percentage of a particular diatom species in the sample):

$$\text{Index} = \frac{\sum_{j=1}^{n} a_j^* s_j^* v_j}{\sum_{j=1}^{n} a_j^* v_j}$$

where a_j is the abundance or proportion of species j in samples, s_j is the pollution sensitivity of species j (optimum), and v_j is the indicator value (tolerance).

Sensitivity value (s) is divided into five classes and varies from 1 (highly sensitive to phosphorous) to 5 (highly tolerant to phosphorous). Tolerance value (v) ranges from 1 (taxa with a broad distribution) to 3 (taxa that are restricted to a narrow range of nutrient conditions).

All TDIs mentioned are very similar in principal and differ in the number of species used and in the values of s and v which have been attributed to the species after compiling the data from literature and from ordinations. Also the number of the trophic classes distinguished may vary.

Benthic Trophic State Index

The ratio of gross production to respiration (P:R), measured quantitatively by oxygen flux rates, has long been used to characterize the trophic status of aquatic ecosystems. A ratio of 1.0 indicates a balance of photoautotrophic and heterotrophic processes, ratios <1.0 indicate heterotrophic dominance of processes, and ratios >1.0 indicate photoautotrophically dominated communities.

The benthic TSI is based on relative rates of sediment–water oxygen exchange in opaque (dark) and transparent (light) chambers incubated at or near ambient temperature.

The benthic TSI (BTSI) uses data from short-term metabolic measurements not as a quantitative measure of shoal community P:R, a continuous variable, but to assign a categorical value that broadly reflects the extent to which that environment supports the ecological processes associated with benthic autotrophy.

The BTSI, expressed in the values 0, 1, 2, or 3, is assigned to shallow sediments based on the relative magnitude of hourly rates of maximum net community production (NCP_{max}) and respiration (CR).

In calculating the BTSI, negative values are assigned to all oxygen fluxes into the sediment. When the BTSI increases, so does the degree of autotrophy, and thus the contribution to support grazing organisms, hypoxia reduction, nutrient sequestration, and biotic stability of the sediment. Ranges of gross production/respiration (P:R) associated with each BTSI value are shown in **Table 3** including examples of rates representative of each BTSI value (condition) and corresponding net community production at light saturation (NCP_{max}) and community respiration (CR).

Ranges of gross production/respiration (P:R) associated with each BTSI value are given including examples of rates representative of each BTSI value (condition) and corresponding net community production at light saturation (NCP_{max}) and community respiration (CR), both in mg O_2 m^{-2} h^{-1}. Negative values indicate fluxes from water to sediments. NA, not applicable.

The BTSI is a method to assess the functioning of shallow benthic ecosystems. It is methodologically relatively simple assessment method and reflects established ecological processes as the result of anthropogenic pressure. The BTSI relates potential benthic photoautotrophy to benthic respiration through discrete classification rather than the commonly used continuous variable of P:R ratio.

Oligochaete Trophic Index

The association of oligochaetes with organic enrichment of water was used to develop the "oligochaete trophic index." The index is based on the oligochaete community structure, where species were assigned to categories depending on their preference for, or tolerance of, oligotrophic, mesotrophic, or eutrophic conditions.

A number of modifications of the oligochaete trophic index have been developed since 1977. A modification index used in the Great Lakes (North America) is calculated as

$$c\frac{1/2 * \sum n0 + \sum n1 + 2\sum n2 + 3\sum n3}{\sum n0 + \sum n1 + \sum n2 + \sum n3}$$

where $n0$, $n1$, $n2$, and $n3$ are the total numbers of individuals belonging to each of the four ecological groups. Species characteristic

Table 3 Classification of shallow sediments by the BTSI.

BTSI	*P:R*	*Condition*	*NCP_{max}*	*CR*	*Sediment classification*
0	NA	$NCP_{max} \leq CR$	−25	−25	Totally heterotrophic
1	>0–0.5	$CR < NCP_{max} \leq 0$	−10	−25	Net heterotrophic
2	0.5–1.0	$0 < NCP_{max} \leq \lvert CR \rvert$	2	−25	Net autotrophic
3	>1.0	$\lvert CP \rvert < NCP_{max}$	50	−25	Highly autotrophic

Adapted from Rizzo, W.M., Berry, B.E., Wetzel, R.L., et al., 1996. A metabolism-based trophic index for comparing the ecological values of shallow-water sediment habitats. Estuaries 19, 247–256, with permission from estuarine Research Federation.

for oligotrophic waters are assigned to group 0, those for mesotrophic waters to group 1, those for eutrophic waters to group 2, and those for hypertrophic waters (*Limnodrillus hoffmeisteri* and *Tubifex tubifex*) comprise group 3.

The coefficient c depends upon the total oligochaete number per square meter as outlined as follows:

$c = 1,\ n > 3600;$
$c = 3/4,\ 1200 < n < 3600;$
$c = 1/2,\ 400 < n < 1200;$
$c = 1/4,\ 130 < n < 400;$
$c = 0,\ 0 < n < 130.$

Index values between 0.6 and 1.0 indicate mesotrophic conditions, while higher and lower values indicate eutrophic and oligotrophic conditions, respectively.

In general, when the index was applied to the Great Lakes, it appeared that the values give a reasonable evaluation of trophic conditions. Most sites in the upper lakes fall into the oligotrophic category, with areas of known higher productivity (near shore northern Lake Michigan; Saginaw Bay, Lake Huron) exhibit higher index values. Sites in Lake Erie generally fall into the mesotrophic range, while in Lake Ontario near shore sites were classified as mesotrophic, and offshore sites are oligotrophic.

Trophic Level Index

The trophic level index (TLI) is an indicator of lake water quality. Four parameters are combined to construct the TLI: concentrations of total nitrogen, total phosphorus, and chlorophyll *a*, and transparency. These parameters reflect the dynamics of the annual lake cycle. Nitrogen and phosphorus are essential plant nutrients. High levels of water-bound nitrogen and phosphorus most often come from agricultural runoff and urban wastewater, but can also come from geothermal inputs and deep springs that leach phosphorus from the rock geology.

Chlorophyll *a* is a good indicator of the total quantity of algae in a lake. Algae are a natural part of any lake system, but large amounts of algae decrease water clarity, make the water look green, can form surface scums, reduce dissolved oxygen levels, can alter pH levels, and can produce unpleasant tastes and smells. Transparency of the water is measured using a Secchi disk.

Calculation of the TLI:

- $TL_{nitrogen} = -3.61 + 3.01 \log (N_{total})$
- $TL_{phosphorus} = 0.218 + 2.92 \log (P_{total})$
- $TL_{transparency} = 5.10 + 2.27 \log (1/\text{Secchi disk depth} - 1/40)$
- $TL_{chlorophyl} = 2.22 + 2.54 \log (\text{Chl } a)$
- $TLI = (TL_{nitrogen} + TL_{phosphorus} + TL_{transparency} + TL_{chlorophyl})/4$

The higher the TLI, the worse the water quality. Trophic level ranges are grouped into trophic states for quantitative description as shown in **Table 4**.

Trophic states, as determined by the four key variables:

1. Microtrophic lakes are very clean, and often have snow or glacial sources.
2. Oligotrophic lakes are clear and blue, with low levels of nutrients and algae.
3. Mesotrophic lakes have moderate levels of nutrients and algae.
4. Eutrophic lakes are green and murky, with higher amounts of nutrients and algae.
5. Supertrophic lakes are fertile and saturated in phosphorus and nitrogen, and have very high algae growth and blooms during calm sunny periods.
6. Hypertrophic lakes are highly fertile and supersaturated in phosphorus and nitrogen. They are rarely suitable for recreation, and habitat for desirable aquatic species is limited.

Table 4 Trophic state and corresponding quantitative parameters of the trophic level index

Trophic state	*Nutrient enrichment category*	*TLI*	*Chl* a *(mg m^3)*	*Secchi disk depth (m)*	*$T_{phosphorus}$ (mg m^3)*	*$T_{nitrogen}$ (mg m^3)*
Ultramicrotrophic	Practically pure	0.0–1.0	<0.33	>25	<1.8	<34
Microtrophic	Very low	1.0–2.0	0.33–0.82	25–15	1.8–4.1	34–73
Oligotrophic	Low	2.0–3.0	0.82–2.0	15–7	4.1–9.0	73–157
Mesotrophic	Medium	3.0–4.0	2–5	7.0–2.8	9–20	157–337
Eutrophic	High	4.0–5.0	5–12	2.8–1.1	20–43	337–725
Surpertrophic	Very high	5.0–6.0	12–31	1.1–0.4	43–96	725–1558
Hypertrophic	Saturated	>6.0	>31	<0.4	>96	>1558

Trophic Index of Macrophytes

The trophic index of macrophytes (TIM) is a tool for indicating the trophic state of running waters. Concentrations of soluble reactive phosphorus in both the water body and sediment pore water were assigned to macrophyte species and related to their phosphorus demand. The TIM is calculated with Zelenka and Marvan's formula for the determination of the saprobic index:

$$TIM = \frac{\sum_{i=1}^{n} IV_a{}^{*} W_a{}^{*} Q_a}{\sum_{i=1}^{n} W_a{}^{*} Q_a}$$

where IV_a is the indicator value for species a, depending on the assigned trophic category, W_a is the weighting factor for the tolerance of species a, and Q_a is the quantity of species a in the river section.

TIM values were classified into trophic categories to indicate the trophic status of the river sections examined (Table 5).

Trophic Relation Indices

Infaunal Trophic Index

The infaunal trophic index (ITI) was developed to identify changed and degraded environmental conditions as a result of organic pollution in coastal waters. The approach is based on the allocation of macroinvertebrate species to one of four groups based on the type of food consumed by the species and where the food was obtained from.

The ITI and its response to organic pollution is based on the principle that with increasing organic enrichment the dominant feeding type changes from those species which feed at the interface of the sediment and water, such as suspension feeders (which occur in areas of low organic enrichment), through to species which are predominantly deposit feeders (in areas of high organic enrichment).

After determining the abundance of taxa belonging to each of next four feeding groups, (1) detrital feeders, (2) interface detrital feeders, (3) deposit feeders, and (4) specialized feeders, the ITI is calculated by combining these groups in the following formula:

$$ITI = 100 - 33.33\frac{(0n_1 + 1n_2 + 2n_3 + 3n_4)}{(n_1 + n_2 + n_3 + n_4)}$$

where n_{1-4} are the numbers of individuals in feeding groups 1–4 distinguished, and 0–3 are factors in the numerator (scaling factors).

Values of the index range from 0 to 100 with low values indicating degraded conditions. With the ITI seabed areas are classified into either "normal" (values 100–60), "changed" (60–30), or "degraded" (30–0).

The ITI has been tested widely in fully marine conditions and showed most statistically powerful results. However, due to the natural prevalence of deposit feeders in estuaries and the generally lower number of taxa, the ITI can act in an aberrant way in transient areas and is therefore not a useful indicator for estuaries. The index has a direct link to eutrophication indicators.

Marine Trophic Index

Differences in the trophic level of selected groups of species provide a reliable indicator of the integrity of an ecosystem. The marine trophic index indicates changes in the mean trophic level of fish communities regionally and globally. Trophic level is

Table 5 Classification of TIM values into trophic categories

TIM value	*Trophic state*
1.00–1.44	Oligotrophic
1.45–1.86	Oligomesotrophic
1.87–2.24	Mesotrophic
2.25–2.62	Mesoeutrophic
2.63–3.04	Eutrophic
3.05–3.49	Eupolytrophic
3.50–4.00	Polytrophic

Adapted from Schneider, S., Melzer, A., 2003. The trophic index of macrophytes (TIM)—a new tool for indicating the trophic state of running waters. International Review of Hydrobiology 88, 49–67, with permission from Wiley-VCH, STM.

defined as the position of an organism in the food chain and ranges from a value of 1 for primary producers to 5 for marine mammals and humans. The method to determine the trophic level of a consumer is to add one level to the mean trophic level of its prey.

The equation corresponding to a species trophic level calculation is

$$TL_i = \sum_j TL_j{}^* DC_{ij}$$

where TL_j is the fractional trophic level of the prey j, and DC_{ij} is the fraction of j in the diet of species i.

Thus defined, the trophic level of most fishes and other aquatic consumers can have any value between 2.0 and 5.0. Trophic level changes through the life history of fish, with juveniles having lower trophic levels than adults.

Existent annual fishery database supplies sufficient information for marine trophic index computing. Therefore, mean trophic level for year k may be found as

$$\overline{TL}_k = \frac{\sum_i (TL_i)^* (Y_{ik})}{\sum_i Y_{ik}}$$

where Y_i is the landing (catch) of species (group) i, and TL_i is the trophic level of species (group) i.

Trophic level estimates for fish, based on their diet composition, can be found in FishBase, the global online database for fish, and for invertebrates in the Sea-Around-Us database.

The marine trophic index is a powerful indicator of marine ecosystem integrity and sustainability of fisheries at the global and regional levels.

Whether a fishery is balanced from ecological point of view we may define with a "Fisheries in Balance" index (FIB) (Pauly *et al.*, 2000). Since biomass transfer efficiencies between trophic levels are only about 10%, it follows that the rate of biological production is much greater at lower than it is at higher trophic levels. Fisheries catches, at least to begin with, will tend to increase as the trophic level declines. At this point the fisheries will target species lower in the food web.

The FIB index is defined, for any year i, by

$$FIB = \log\left(Yi * \left(\frac{1}{TE}\right)^{TLi}\right) - \log\left(Yo * \left(\frac{1}{TE}\right)^{TLo}\right)$$

where Y_i is the catch at year i, TL_i is the mean trophic level of the catch at year i, Y_o is the catch, TL_o the mean trophic level of the catch at the start (o refers to any year used as a baseline) of the series being analyzed, and TE is the transfer efficiency of biomass or energy between trophic levels.

The FIB index is stable (zero) over periods of time when changes in trophic levels are matched by appropriate changes in the catch in the opposite direction. The index increases if both catches and mean trophic level increase for any reason, for example higher fish biomass, or geographic expansion, suggesting that the fishery was expanding to stocks previously not, or lightly exploited. Decreases may be observed when TL shows stepwise decline by a corresponding increase in catches.

Index of Trophic Completeness

The index of trophic completeness (ITC) is based on communities of freshwater macroinvertebrates. Species were divided into 12 trophic groups on the basis of their trophic characteristics(**Table 6**). Each trophic group fulfills a function in the benthic community. The

Table 6 Characteristics of the macroinvertebrate groups distinguished in the ITC, including the relative number of taxa per group present in the database

Trophic group, no.	*Diet*	*Feeding behavior*	*Food size (mm)*	*Relative number (%)*
1	Carnivory	Active shredder/chewer	>1	9.8
2	Carnivory	Passive shredder/chewer	>1	3.6
3	Omnivory	Shredder/chewer/collector	>1	5.9
4	Herbivory	Shredder/chewer	>1	7.8
5	Herbivory	Shredder/chewer	<1	2.6
6	Herbivory	Scraper	<1	26.3
7	Herbivory	Collector	<1	22.7
8	Herbivory	Filtrator	<1	8.7
9	Carnivory	Sucker (incomplete food ingestion)	>1	6.6
10	Carnivory	Sucker (total food ingestion)	>1	2.4
11	Herbivory	Sucker	>1	1.9
12	Omnivory	Shredder/chewer	<1	1.7

Table 8 Quality class score for the ITC with five classes.

Quality class	C_{tot}	*Quality description*
I	≥ 28	High
II	21–28	Good
III	14–21	Moderate
IV	7–14	Poor
V	0–7	Bad

Adapted from bij de Vaate, A., Pavluk, T.I. (2004). Practicability of the index of trophic completeness for running waters. *Hydrobiologia* 519, 49–60.

trophic characteristics of each group include the following criteria: plant/animal ratio in the diet, feeding mechanism, food size, food acquisition behavior, and energy and substance transfer ways. Any undisturbed benthic macroinvertebrate community should be represented by members of each of these 12 trophic groups, irrespective of the part of the river studied and its geographical region.

The ITC was developed to show the degree of benthic community functional completeness reflected via its trophic relations to other components of an aquatic ecosystem.

The modern modification of the ITC calculation presumes application of weight factor (**Table 7**), because the probability to meet species of different trophic groups in the aquatic community is unequal and quality of water and number of trophic groups present has no straight linear relationship.

The ITC is calculated using the formula

$$C_{\text{tot}} = \sum_{i=1}^{n} Ci$$

where C_{tot} is the total score for the index, n is the number of trophic groups present in the data set, and C_i is the Ln-transformed indicative value of trophic group i.

The relation between the ITC value and the quality classes is given in **Table 8** for an assessment system with five quality classes.

The index indicates the functionality of the community and is based on the assumption that in healthy environment all trophic groups will be present. Natural fluctuations (e.g., floods, drought, ice covering) may influence the community structure, but their long-term effects do not result in the extinction of trophic groups.

Recently a handy tool for the ITC calculation for macroinvertebrates was developed. It is called MaTroS (Macrozoobenthos Trophic Structure). The tool has a friendly interface with a simple algorithm for the index calculation (http://www.macro.nemi-ekb.ru/).

Summary

Applied research of aquatic ecosystems involves enormous amount of parameters to give a detailed description of ecological processes and to verify the degree of anthropogenic interference that takes place. To transform parameters studied into a clear and

integrated form indices are used of which the group of trophic indices is the most popular. Two groups of the indices are distinguished: trophic indices based on the primary production potential of ecosystems, and the indices based on the structure of energy and substance transferring between trophic levels of aquatic inhabitants. Trophic indices allow one to make comparative studies between very different aquatic ecosystems, even those that are located in different continents with completely different species compositions.

Turnover Time☆

EH Dettmann, US Environmental Protection Agency, Office of Research and Development, Narragansett, RI, USA

Introduction

Turnover time refers to the amount of time required for turnover or replacement by flow-through of the energy or a material contained in a system. Ecological units are generally open to flow-through of energy and materials. Carbon, nitrogen, phosphorus, and other materials, as well as energy, enter the system, may be incorporated into system components and later be released by respiration, excretion, decomposition, and other processes, and eventually leave the system. The material of interest may undergo a single cycle of incorporation and release within the system, or may be recycled many times before exiting. Some substances may be passively transported through the system. The concept of turnover is also applied to appearance and extinction of biological species in a local community, and can describe passage of individuals through a population through recruitment, emigration, and harvesting.

Turnover time provides a timescale for this replacement and is a tool for analyzing the significance of flow rates and the sizes of material and energy pools within a system or its components. The turnover time of a material is generally defined as the ratio of the quantity of that material in the system to its throughput or flow-through rate. This definition assumes that the rates of inflow and outflow are equal, that is, the system is in equilibrium (steady state). It is an average quantity, since the calculation provides no way to account for the transit time of an individual entity (e.g., an atom or molecule) through the system. Turnover time can be calculated at various spatial scales, for small ecosystems or large ones, such as the component subsystems of the global biogeochemical cycle of an element. Turnover times of subsystems will differ from that of the larger system of which they are a part.

Calculation of Turnover Time of Material and Energy

Turnover time (τ) for a flow of material is the ratio of the quantity of material in the system (M) to its flow rate (F) through the system, that is,

$$\tau = \frac{M}{F} \qquad [1]$$

Turnover time is the inverse of the fraction of material in the system that leaves per unit time. It may also be viewed as the amount of time required to put into the ecosystem an amount of the substance equal to that currently residing there, or for that amount to leave the system.

The units used to express the quantities in the numerator and denominator of eqn [1] must be consistent. For materials, the mass of the material in the system is M, and F is the flux (mass/time), with flux expressed using the same units for mass. If energy turnover is calculated, the ratio is of system energy content to energy flux, both expressed in consistent energy units.

Other timescales used in analyzing the dynamics of material flow through systems are age and transit time. The age of an entity is the amount of time that has elapsed since its entry into the system; its transit time is the total time between its entry into and exit from the system. Mean age is the mean age of all material in the system; mean transit time is the mean transit time of material leaving the system.

Generally, turnover time, mean age, and mean transit time may all change through time. Assuming constant flow rates, turnover time is constant only if the inflow rate equals the outflow rate. Otherwise, turnover time increases or decreases depending on whether inflow is larger or smaller than outflow. If the system is in equilibrium, the turnover time may be shown to be equal to the mean transit time, also called the residence time. The terms turnover time and residence time are often used interchangeably in the literature; this can result in confusion since these two quantities are generally not equal in systems that are not in equilibrium. Reentry of material that has exited the system can also complicate the analysis. If the system content and flow-through rate vary around central values, time-averaged values for M and F are often used to obtain an estimate of turnover time. If there is a rising or falling trend in the quantity of material in the ecosystem or its flow-through rate, the system is not in equilibrium, and one may need to calculate instantaneous turnover times at one point or a series of points in time.

Applications of Turnover Times in Ecosystem Analysis

Turnover time provides a useful tool for analysis of material fluxes, pool sizes, and the time required for pools to attain steady state after a change of inflow rate. The following examples illustrate a few of these applications for terrestrial and aquatic ecosystems.

☆*Change History:* August 2013. E Dettmann updated the section Species Turnover in Local Communities and added the article by Bolin and Rodhe (1973) to the Further Reading section.

These include applications to nutrient flows in the forest floor, changes in species composition in local communities, turnover of individuals in harvested populations, and pool sizes and dynamics for conservative materials and nutrients in aquatic systems. Similar techniques apply to calculation of pool sizes and transport properties of atmospheric ozone-depleting and greenhouse gases, but are beyond the scope of this section.

Turnover of Nutrients in Forests

Analysis of nutrient flows in forests must include consideration of turnover times of available nutrient pools. For instance, nutrients in litter and surface soils of temperate and wet tropical forests have very different turnover times. Storage of carbon and nutrients in litter and surface soils of wet tropical forests is relatively small, and any nutrients in dead plant or animal materials are rapidly released and made available to vegetation, resulting in short turnover times in this pool. In comparison, large quantities of carbon and nutrients are stored in the litter layer and surface soils of temperate forests, resulting in long turnover times for the nutrients stored in this compartment.

Species Turnover in Local Communities

The species composition of localized ecosystems may change, with new species immigrating and some species becoming locally extinct through mortality or emigration. Community ecology uses a number of definitions of turnover that estimate different aspects of change in community composition. The following describes some metrics of community change that are based on observations of species that are made at two successive times, t_1 and t_2 in a local ecological unit, such as an island or forest patch. N_{t1} and N_{t2} represent the total number of species in the community at times t_1 and t_2.

Change in species richness, one such metric, is defined as N_{t2}/N_{t1}, the ratio of the number of species present at the later time to that present earlier. This metric does not distinguish between numbers of species gained and lost during the time interval (t_1, t_2).

Two metrics of change in species composition of a community, turnover (colonization) rate and extinction rate, quantify local rates of appearance of new species (colonization) and extinction. These may be expressed as absolute numbers or as fractional gains or losses of species over the interval (t_1, t_2).

In the following, $C_{t1,t2}$ is the number of species common to observations at both t_1 and t_2. The number of new species that appear in the community during the time interval (t_1, t_2) is $N_{t2} - C_{t1,t2}$, and the number of species that become locally extinct in the same time interval is $N_{t1} - C_{t1,t2}$. The fractional turnover $(T_{t1,t2})$ of species in this time interval is defined as the ratio of the number of new species to the total number of species observed at time t_2:

$$T_{t1,t2} = \frac{N_{t2} - C_{t1,t2}}{N_{t2}} = 1 - \frac{C_{t1,t2}}{N_{t2}} \quad [2]$$

The fractional extinction $(E_{t1,t2})$ of species in this same time interval is defined as the ratio of the number of species that become locally extinct to the number of species at time t_1:

$$E_{t1,t2} = \frac{N_{t1} - C_{t1,t2}}{N_{t1}} = 1 - \frac{C_{t1,t2}}{N_{t1}} \quad [3]$$

Thus, $T_{t1,t2}$ and $E_{t1,t2}$ quantify the rates of local species appearance and disappearance within the time interval (t_1, t_2) as a fraction of the total number of species present; $N_{t2} - C_{t1,t2} = N_{t2}(T_{t1,t2})$ and $N_{t1} - C_{t1,t2} = N_{t1}(E_{t1,t2})$ express them as actual numbers of new species gained or old species lost. If these quantities are compared among studies over time intervals of differing length, they should be divided by the number of time units (e.g., years, decades) in the studies to which they refer so that they are all expressed in compatible time units. The ratios $(t_2 - t_1)/(T_{t1,t2})$ and $(t_2 - t_1)/(E_{t1,t2})$ are analogous to turnover times defined for mass or energy flow through a system.

Turnover and extinction rates for a community may or may not be equal. If the set of species in the community is the same at times t_1 and t_2, $N_{t1} = N_{t2} = C_{t1,t2}$, and both the turnover and extinction rates are zero. If the species composition changes in this time interval but the number of species stays the same, $N_{t1} = N_{t2} > C_{t1,t2}$, and the turnover and extinction rates are equal but nonzero. The total number of species in the community (species richness) may also change, in which case $T_{t1,t2} \neq E_{t1,t2}$.

Species turnover and extinction rates are used to investigate the influence of factors such as habitat fragmentation, patch size, and isolation from similar systems on species richness and the stability of species composition in local ecological units. Examples include the effects of island area and distance from other islands or the mainland on turnover and extinction rates of plant and animal species, and the dependence of local turnover and extinction rates of bird or other biotic communities in forest patches or other localized ecological units on system size.

Turnover concepts also apply to management of harvested populations such as marine fisheries, where increased adult mortality (from harvest) is theoretically compensated by increased recruitment of juveniles into the adult class due to reduced competition. Thus, entry and exit of individuals to and from the adult class create higher turnover within the population in response to harvest. The framework described here has also been applied to data for fossils to test hypotheses concerning appearance and extinction of taxa in the geological record and variation among phyla.

Lake Water Quality and Trophic State

Turnover time of water is a characteristic of a water body that is often used in analysis of its water quality and trophic state. Water acts as a carrier of substances such as nutrients and contaminants, and simple models employing the turnover time of water provide insight into the dynamics and pool sizes of these substances and ecological responses to their concentrations. The following examples for lakes illustrate this modeling approach.

The turnover time of water (τ_w) in a well-mixed lake is $\tau_w = V/Q$, where V is the lake volume and Q is the flow-through rate of water. Since water may enter lakes from numerous sources but often exits through a single localized outlet, flow through the outlet is often used to estimate flow-through rate. The terms water residence time and hydraulic detention time are often used in the limnological and engineering literature to denote water turnover time of a lake.

Turnover times vary widely among lakes; they are often on the order of months or years, but may be as long as a century or more for some very large lakes, for example, North America's Lake Superior and Lake Tahoe. Flows frequently vary on seasonal or shorter timescales that are less than lake turnover time, and long-term mean flow rates are often used to calculate mean turnover times.

The following examples illustrate use of turnover time of water in box models, sometimes called input–output models, to estimate concentrations in lake water of (1) conservative substances (those that are not removed from the water column, e.g., the chloride ion) and (2) nonconservative materials (ones that may be removed from the water column, for example, nutrients). The models are used to estimate steady-state concentrations in the water column for constant rates of input, and the dynamics of these concentrations after a change of input rate. Water flow rates are assumed throughout to be constant, so that the turnover time of water is constant. However, concentrations and turnover times of transported materials will vary if their loading rates change or their concentrations have not yet reached steady state. These models assume complete mixing, that is, they assume that concentrations of the materials of interest are uniform throughout the lake. Lack of complete mixing because of seasonal stratification or rapid flushing complicates the analysis, but does not change the underlying principles. The relationship between turnover times of water and transported materials will also be shown to depend on whether the latter are conservative.

Conservative substances

In the following, C denotes the concentration (mass/volume) in the water column of the material of interest, L its loading (input) rate (mass/time), Q the water flow-through rate (volume/time), C_{in} the mean concentration in inflows ($C_{in} = L/Q$), and t the time elapsed since the initial condition. The subscripts 'o' and 'ss' denote initial and steady-state conditions in the lake.

The rate of change of mass of a conservative substance in a lake is equal to the rate of input minus the loss rate:

$$V\frac{dC}{dt} = L - QC \qquad [4]$$

Therefore,

$$\frac{dC}{dt} = \frac{L}{V} - \frac{C}{\tau_w} \qquad [5]$$

For nonzero loading rates, this equation has the solution

$$C = \frac{\tau_W L}{V}\left[1 - \left(1 - \frac{V}{\tau_W L}C_o\right)e^{-t}/\tau_w\right] \qquad [6]$$

Since $\tau_w L/V = (V/Q)(L/V) = L/Q = C_{in}$, the mean concentration in the inflow, this may be written as

$$C = C_{in}\left[1 - \left(1 - \frac{C_o}{C_{in}}\right)e^{-t}/\tau_w\right] \qquad [7]$$

From its initial value of C_o at $t = 0$, the concentration asymptotically approaches C_{in}, the concentration in inflowing water. For $L = 0$ (no loading), the solution to eqn [5] is

$$C = C_o e^{-t}/\tau_w \qquad [8]$$

that is, the concentration decreases exponentially from the initial value, and asymptotically approaches zero. Thus, for both zero and nonzero loading rates, the steady-state concentration is

$$C_{ss} = \frac{\tau_w L}{V} = C_{in} \qquad [9]$$

The behavior of the concentration after onset of an increase in loading to the lake is shown in Fig. 1. The concentration increases (or decreases if $C_{in} < C_o$) from its initial value C_o and asymptotically approaches the steady-state value C_{ss}, with the rate of approach controlled by the water turnover time τ_w. At $t = 3\tau_w$, $C_{ss} - C$ will be 5% of the difference between C_{ss} and C_o. Since the asymptotic approach to steady state in eqns [6]–[8] is described by the factor e^{-t}/τ_w, τ_w is sometimes called the e-folding time for the concentration in this modeling framework. The turnover time of the conservative substance at steady state is the ratio of the mass in the water column at steady state to the throughput, or $(C_{ss}V/L) = \tau_w$, the same as that for water.

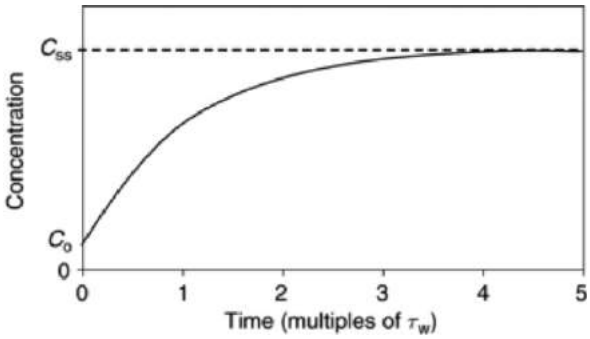

Fig. 1 Concentration versus time (in multiples of water turnover time τ_w) after an increase in loading rate. The initial and steady-state concentrations are C_o and C_{ss}, respectively.

Nonconservative substances

Many substances are nonconservative in aquatic systems. The macronutrients phosphorus and nitrogen, for instance, may be removed from the water column by biological uptake and subsequent incorporation into sediments. Nitrogen may also be removed by denitrification. Such permanent losses may be included in models as loss terms.

Extensive use has been made of input–output models that employ water turnover time as a parameter to calculate mean concentrations of total phosphorus in lakes. Since concentrations of total phosphorus and chlorophyll *a* in lakes are correlated, these models provide a useful means of analyzing the effects of phosphorus loading on the trophic states of lakes. Equation [10] assumes that the loss rate of phosphorus from the lake water column to the sediments is proportional to the water's phosphorus content, with first-order rate parameter σ. The term $-\sigma VC$ represents only long-term loss of phosphorus to sediments; it does not include the fraction that is recycled from sediments to the water column.

$$V\frac{dC}{dt} = L - QC - \sigma VC \qquad [10]$$

This equation is the same as eqn [4] except for the addition of the loss term that represents sedimentation. Equation [10] has the time-dependent solution,

$$C = \frac{\gamma L}{V}\left[1 - \left(1 - \frac{V}{\gamma L}C_o\right)e^{-t/\gamma}\right] \qquad [11]$$

and the steady-state solution,

$$C_{ss} = \frac{L\tau_w}{V}\left(\frac{1}{1+\sigma\tau_w}\right) = \frac{L\gamma}{V} \qquad [12]$$

where γ is defined as

$$\gamma \equiv \frac{1}{1}\Big/\tau_w + \sigma = \frac{\tau_w}{1+\sigma\tau_w}$$

to simplify presentation of the equations. Note that eqns [6] and [11] have the same form, with τ_w in eqn [6] replaced by γ in eqn [11]. Thus, the time dependence of phosphorus concentrations (eqn [11]) is also described in Fig. 1, with the asymptotic (steady-state) concentration given by eqn [12] and the abscissa representing time in multiples of $\gamma = \tau_w/(1+\sigma\tau_w)$. The turnover time of phosphorus in the water column at steady state is therefore $\tau_p = \tau_w/(1+\sigma\tau_w)$. This equivalence may also be seen by calculating the ratio of the mass of phosphorus in the water column at steady state to the input rate $(C_{ss}V)/L$ in eqns [9] and [12]. The turnover time of phosphorus is less than that of water because phosphorus is lost to both outflow and sedimentation, resulting in a smaller steady-state concentration than if the rate constant for phosphorus loss (σ) were zero (see eqn [12]). The value of the rate parameter σ may vary among lakes, requiring lake-specific measurements. Variations of this model use alternate methods of characterizing the phosphorus loss term and address issues such as seasonal changes and nonconstant loading rates.

This approach provides a basis for estimating phytoplankton abundance in the water column. A frequently used relationship between phytoplankton chlorophyll *a* and phosphorus concentrations in lakes is $[\text{Chl } a] = 0.0731[\text{P}]^{1.449}$, where [Chl *a*] is the summer concentration of chlorophyll *a* (mg m^{-3}), and [P] (mg m^{-3}) may be estimated from eqn [12].

Nitrogen in Estuaries

This example demonstrates the use of the turnover time of freshwater (τ_{fw}) in estuaries to analyze nitrogen throughput and concentrations. This measure (τ_{fw}), often called the freshwater residence time or flushing time in the estuarine literature, is particularly useful in estuaries when the watershed is the primary source of a material of interest.

Estuaries are semienclosed coastal water bodies having a connection with the sea, and in which freshwater mixes with seawater. Unlike lakes, estuaries are not simple flow-through systems since the seaward boundary is both a source of seawater and nutrients

and an outflow. Estuaries typically exhibit salinity gradients, with salinity lower in the inner estuary, near freshwater sources, than at the seaward boundary. Spatial distributions of nutrients and other materials also exhibit gradients that reflect their sources.

Freshwater entering the inner estuary from the watershed usually remains in the estuary longer than seawater, much of which may enter on a flood tide and exit on the following ebb tide. Therefore, there may be a number of measures of water turnover time in an estuary: including the turnover time of freshwater (the focus here), seawater, or that of all water in the estuary.

The freshwater turnover time of an estuary depends on both its content and the input rate of freshwater. The freshwater content of an estuary depends in turn on its inflow rate and physical factors such as tidal forcing that determine its distribution and removal rate from the system. The turnover time of an estuary is variable, changing with the rate of freshwater inflow and tidal range. Depending on the application, one may wish to calculate a turnover time for a specific set of conditions, or a long-term mean value for mean forcing conditions. Turnover times for most estuaries range from days for small systems to months for large ones.

The turnover time of freshwater in the estuary may be determined by measuring its freshwater content and inflow rate, and calculating the amount of time required to replace this freshwater, $\tau_{fw}=V_{fw}/Q$, where V_{fw} is the volume of freshwater in the estuary, and Q is the inflow rate of freshwater from all sources. For an estuary with total volume V, V_{fw} is determined by calculating the volume of freshwater that must be mixed with a volume of seawater ($V-V_{fw}$) that enters across the seaward boundary to yield the mean volume-weighted salinity (S_e) of water in the estuary, as determined by measurements. From mass balance considerations,

$$V_{fw}=\left(1-\frac{S_e}{S_b}\right)V \qquad [13]$$

where S_b is the salinity of seawater outside the seaward boundary. Another experimental method for measurement of turnover time, practical only for small estuaries, is by continuous introduction of a conservative dye into the freshwater source until concentrations of dye at individual points in the estuary reach equilibrium. Turnover time is determined by then terminating dye input and measuring the e-folding time for the spatially averaged dye concentration – the time required to decline to e^{-1} times its equilibrium value, where e is the base of natural logarithms.

The following example illustrates use of freshwater turnover time to analyze steady-state throughput and concentration of total biologically active nitrogen in estuaries. Biologically active nitrogen (N) is defined here as dissolved inorganic nitrogen (ammonium, nitrite, and nitrate) plus dissolved and particulate organic forms. Nitrogen gas (N_2) is not included.

The rate of change of the mass of N in the estuary may be represented as the difference between all source and loss rates:

$$\frac{dN}{dt}=L_l+L_s-E-\alpha N \qquad [14]$$

where L_l is the loading rate of nitrogen from the watershed (including direct discharges to the estuary) and atmosphere, L_s is the inflow rate across the seaward boundary, E is the export rate of nitrogen across the seaward boundary, and αN is the loss rate of nitrogen within the estuary to processes such as denitrification, permanent burial in sediment, and incorporation in fish biomass. The parameter α is a first-order loss coefficient analogous to that for phosphorus loss in lakes (σ). The term αN does not include temporary loss from the water column of nitrogen that is taken up by phytoplankton, subsequently sinks to the bottom, and is eventually remineralized and returned to the water column. The steady-state solution of this equation may be found by setting $dN/dt=0$. The rate of export of that nitrogen which has entered from the watershed and atmospheric deposition (E_n) is the difference between the total export and inflow rates of nitrogen across the seaward boundary: $E_n=E-L_s$. The fraction of nitrogen originating from the watershed and atmosphere that is exported is $F_{E(l)}=E_n/L_l$. If watershed and atmospheric inputs of nitrogen are substantially greater than those across the seaward boundary, an analysis similar to that for phosphorus in lakes shows that $F_{E(l)}$ may be approximated as

$$F_{E(l)}=\frac{1}{1+\alpha\tau_{fw}} \qquad [15]$$

Application of this equation to data for a group of North American and European estuaries has shown that α has a value of approximately 0.3 per month. This function is shown in **Fig. 2**. Note that the longer the turnover time of freshwater, the larger the consumptive losses of nitrogen from watershed and atmospheric sources within the estuary, and the smaller the fraction that is exported across the seaward boundary. This relationship applies specifically to nitrogen. For other substances, the existence and details of an analogous relationship would depend on details of loss mechanisms. For instance, all of a conservative substance ($\alpha=0$) entering an estuary is exported for all residence times, since none is lost in the estuary.

Solving eqn **[14]**, the steady-state concentration of total nitrogen from all sources, spatially averaged over the estuary, may be shown to be

$$[N]_{ss}=\left(\frac{L_l\tau_{fw}}{V}+[N_s]\right)\frac{1}{1+\alpha\tau_{fw}} \qquad [16]$$

where V is the volume of the estuary, the first term in the parentheses represents the contribution to the nitrogen concentration in the estuary by loading from watershed and atmospheric sources, and the second term ($[N_s]$) is the contribution from nitrogen input across the seaward boundary. The multiplicative term to the right of the parentheses corrects these contributions for losses within the estuary. The concentration $[N_s]$ may be estimated as the seawater content of the estuary (V_{sw}) times the concentration of

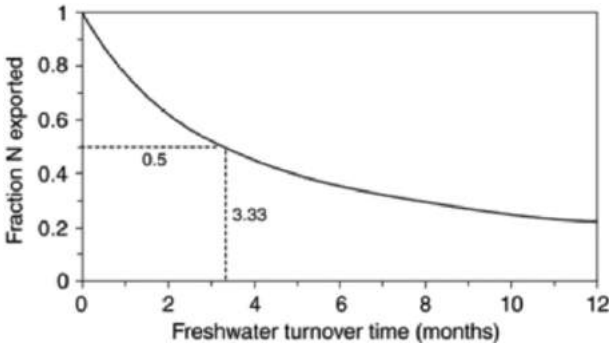

Fig. 2 The fraction of nitrogen (N) input from watershed and atmospheric sources that is exported across the seaward boundary of an estuary versus freshwater turnover time. The solid line shows the relationship $F_{E(l)}=1/(1+\alpha\tau_{fw})$ for $\alpha=0.3$ per month. For $\tau_{fw}=3.33$ months, half of the input from these sources is exported. For substances other than nitrogen, the existence and details of an analogous relationship would depend on loss mechanisms.

nitrogen at the seaward boundary ($[N_b]$), divided by V. Since $V_{sw}=V-V_{fw}$, where V_{fw} is given by eqn [13], $V_{sw}=(S_e/S_b)V$, and $[N_s]=[N_b](S_e/S_b)$. The spatially averaged concentration of nitrogen in the estuary from watershed and atmospheric sources alone,

$$\frac{L_1\tau_{fw}}{V(1+\alpha\tau_{fw})} \qquad [17]$$

increases as τ_{fw} increases and asymptotically approaches the limit $L_1/\alpha V$ for large values of τ_{fw}. Since estuaries generally exhibit spatial concentration gradients, the spatially averaged concentration $[N]$ is a measure of generalized estuary response to nitrogen loading, rather than a point measure.

Summary

Turnover time is defined as the ratio of the quantity of a material or energy in a system to its outflow rate. It may also be viewed as the inverse of the fraction of material or energy that leaves per unit time. For a system in equilibrium, the outflow rate is equivalent to the flow-through rate and the turnover time of a substance is equal to the residence time, that is, the mean transit time between entry into and exit from the system. Turnover time provides a timescale for the replacement of energy or materials in a system and is a useful tool for analysis of material and energy fluxes, pool sizes, and the time required for pools to attain steady state after a change in loading rate.

The concept of turnover is also applicable to analysis of species appearance and extinction rates in local systems, and to analysis of harvested populations such as in marine fisheries.

Wildlife Ecology☆

Melissa Songer, Smithsonian Conservation Biology Institute, Front Royal, VA, United States

Introduction

Wildlife ecology is the scientific discipline of applying ecological principles to the study of wildlife species and their habitats. Research goals typically include developing applied strategies for managing natural systems to achieve and maintain balance among wildlife, habitats, and humans, and often result in baseline data that can be used to inform wildlife management plans. The term wildlife is not strictly defined and through the years its use has ranged from including only terrestrial vertebrates to encompassing all wild animal and plant life. Historically, wildlife management mainly targeted game species, particularly birds and mammals that were traditionally hunted, and often with the goal of increasing their populations to bolster sport and subsistence hunting opportunities. During the 1960s the focus of wildlife management and research began to expand to include nongame species and other taxa, such as reptiles, amphibians, and even invertebrates. In modern wildlife management, rare and endangered species are a top consideration and usually prioritized over game species in management plans. During the past decade many new quantitative methods have been advanced and are becoming essential to management, conservation, and the science of wildlife ecology. This article will cover underlying principles and concepts, applications, and current directions of wildlife ecology research.

Underlying Concepts

Wildlife ecology studies can be approached from various scales and organization levels, ranging from the study of individual animals and their relationships with abiotic and biotic aspects of their environment, relationships among individual animals within populations of a species (e.g., social behavior, demography, population changes), interactions between different species (e.g., predator–prey relationships, parasitism, pathogens, competition), community structure, and ecosystems. Ecological concepts foundational to wildlife study are discussed below.

Ecosystems and Species Relationships

Ecosystems are often the analysis framework for wildlife ecology studies. An ecosystem is the basic system that supports and sustains life, including all living organisms which interact with each other and with nonliving components of their environment within a given area. All wildlife species have roles within their ecosystem, called niches, comprised of how a species obtains food and water, and how it interacts with other living and nonliving components of the ecosystem. A species' niche is not always unique and can overlap in some ways with other species.

All individuals and species exist within a community composed of many different species and interact through various relationships, such as competition (with individuals of the same species and between different species), predation, and facilitation. Use and consumption of resources is the underlying driver for most of these interactions/relationships, whether it is between two different species or within the same species. By definition a resource is something essential to an animal (e.g., food, water, shelter) which, when used by an individual animal, is no longer available to another individual.

When two different species need the same resources and there is not enough available to support all it leads to competition. Competition can negatively affect both species, though typically one species will be a superior competitor, leaving one species more negatively impacted than the other. Wildlife ecology studies on competition can help inform strategies for reducing impacts on a species of concern, for example, when competition between wildlife species threatens a rare or endangered species, or when domestic animals are outcompeting wildlife for essential resources. In most ecosystems, humans also compete with wildlife, often using and consuming at levels much higher than any wildlife species.

Competition can reach the point of affecting the survival and reproduction rates of the species facing competition, creating a situation referred to as natural selection—an underlying concept of evolution and ecology. The concept asserts that individuals that are most fit (able to survive in their environment) are the most likely to reproduce and pass along their genes to the next generation, thereby increasing the chances of perpetuating the characteristics that made the individual more fit to survive. This process is called natural selection because the individuals which are the most fit are "selected" by nature to survive and reproduce. Species gradually change as a result of this process and over hundreds or thousands of generations it can lead to the evolution of a distinct species.

Predation is a relationship between a predator and a prey species in which the predator consumes part or all of the prey. There are four basic types of predation: (1) herbivory, in which an animal species eats parts or all of a plant; (2) parasitism, in which one

☆This is an update of J.L. Rachlow, Wildlife Ecology, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3790–3794.

species (the parasite) feeds on another species (the host) in a way that may cause negative impacts but usually does not kill the host; (3) carnivory, in which the predator catches and consumes the prey; and (4) cannibalism, a rare occurrence when the predator species and the prey species are the same. Detritivory is the consumption of dead organic material by scavengers and does not affect the survival of the consumed species as in predation.

Though predator and prey often coexist in a stable way, various factors may cause the system to go out of balance. If predation levels are too high it could lead to a decrease in the prey population. Without sufficient prey, the predator species could also decrease. In human dominated systems, a more likely scenario impacting predator–prey relationships is the decline of predator populations, especially for larger mammals which require more habitat, are considered a threat to humans, and often are actively hunted. When predation levels are very low or even removed it can lead to a great increase a prey species and have an impact on other species as well. For example, if a prey species increases rapidly it could lead to insufficient food resources, creating a competitive situation that could also lead to the decline in populations of other species. Understanding predatory relationships are of critical importance to wildlife management.

Facilitation refers to a species relationship in which at least one of the species involved benefits from the relationship and neither species incurs a negative impact as a result. There are two basic forms; mutualism, in which the relationship is beneficial to both species, and commensalism, in which one species benefits and the other remains unharmed by the relationship. Mechanisms of facilitation include, a relationship that provides protection from environmental stress, reduces risk of predation, offsets competition from another species, improves access to resources, or aids in movement or migration. Facilitative relationships among species can influence species diversity and structure at the community level, not just the species that are involved in the relationship.

Altruism is a type of behavior that occurs within a species rather than between different species, when an individual acts in a way that increases the chance for survival of another individual while decreasing the chance of survival of the actor. This is usually seen between members of the same family, for example, parenting, in which altruism increases the survival rate for relatives that can pass on the same genes. It also occurs within species' social groups, for example, army ants forming body bridges to facilitate the movement of food to the group nests.

The Wolves of Yellowstone: A Case Study of Species Relationships

The history of wolves in Yellowstone National Park provides an example of the interdependencies among different species. Established in 1872, Yellowstone provided protection for wildlife, but excluded protection of predator species such as wolves, coyotes, and mountain lions. Wolves were generally considered a pest species and were hunted by park visitors and even rangers. They disappeared from the park by the 1920s and in 1967 became the first species listed as endangered in the United States. Over 30 wolves were released in Yellowstone during 1995–96 and have since established a relatively stable population (ranging from 9 to 16 packs). Wildlife ecologists have studied the impacts of the wolves on the ecosystem and found that their major prey species, the elk, decreased in number and were forced to forage more broadly into less preferred habitats, leading to lower consumption of willow trees—an essential resource for beavers. Reduced pressure on willows led to a substantial increase in the beaver population and more dams, and thus impacting the watershed by reducing erosion, replenishing the water table, and providing more habitat variety for fish, amphibians, and birds. The decrease in elk also led to higher availability of plants and berries eaten by grizzly bears, leading to an increase their population.

Competition and predation by wolves reduced coyote populations by half in only 2 years. In turn, the decrease in coyotes led to a rise in the number of foxes, and then followed an increase in coyote prey species (e.g., hares, deer, small rodents, and birds) and a change in the composition of local plants that are eaten by those prey species. Carcasses left by wolves provided food sources to scavengers such as vultures, ravens, eagles, bears, and martens. As a top predator, wolves fill a critical ecological role in the Yellowstone ecosystem and their return had far-reaching effects on a range of other wildlife species.

Population Growth and Regulation

Understanding factors that can influence the size of a wildlife population, such as species relationships and changing landscapes, is a primary focus of study in wildlife ecology. A population is a group of individuals living in the same area and sharing genetic information, while a species comprises all populations regardless of where they are located. A population can remain relatively stable or change drastically due to changes in their ecosystem caused by natural disaster, human activities, dynamics in species relationships, and other drivers. Population size changes are calculated based on the difference between the birth rate and the death rate of the group, along with the number of individuals leaving (emigration) or joining (immigration) the population. The difference between these numbers is the growth rate, which can be positive or negative. The maximum size that a population can grow and be supported within an environment without degrading the environment is called carrying capacity—a cornerstone concept of wildlife ecology.

Estimates of biological carrying capacity are based on availability of resources essential for a species and can be difficult to measure since resource availability is always changing. Survey methods usually do not account for other influences, such as competition with other species for the same resources (e.g., food, denning sites, etc.), wildlife diseases, or predation. In addition, some species have a cultural carrying capacity, which is the maximum number that will be tolerated by nearby human communities and can be much lower than the biological carrying capacity. A typical application in this area of wildlife ecology is

developing wildlife management strategies that can adjust for the factors that limit populations, and usually are designed to grow a particular population or increase its chance for survival. Another concern is the inflection point, which is the point at which individuals within a population can be removed and still maintain a maximum growth rate.

Population regulation refers to biological processes that counterbalance disruptive events (e.g., weather events, changing environmental conditions, disease outbreaks, etc.), causing wildlife populations to tend toward consistency in their numbers over time. Stability in a species' population is primarily maintained through changes in survival and reproduction rates. These rates can vary in response to changes in population density of a population and are, therefore, considered density dependent. Key feedback processes that help to maintain stability in populations are predator–prey relationships and competition for food or other resources. These provide negative feedbacks, that is, when a population size goes up, competition and predation also increase, causing a balancing decrease in that population.

Habitat and Habitat Selection

Habitat can be defined in relation to the land type (e.g., boreal, alpine, riparian, etc.), or related to its functional role for a species (e.g., nesting habitat, breeding habitat, shelter habitat, etc.). In the study of wildlife ecology, habitat is typically defined as the area that includes all the biotic and abiotic resources that an animal needs to survive and reproduce, including food and water, space, and shelter. Habitat assessment is a common focus in wildlife ecology studies and delineating a critical habitat for protection or improvement of habitat quality for a species, or community of multiple species, is a common application of these assessments. Assessing habitat quality can involve evaluating the availability of resources essential to the survival and reproduction of a species, a population, or a community of species, and understanding the influence of habitat quality.

The concept of species' habitat selection is based on the understanding that an individual animal will choose resources in a way that will increase their chances to survive and reproduce, and that those choices have evolved based on natural selection. Specific habitat selection behaviors may be learned from other individuals of the same species, or be may be instinctual or genetically inherent. Analyzing a species' selection of a habitat type within their ecosystem is typically done by observing the availability of all habitat types within that ecosystem and comparing it to the level of use of those available habitat types by a species. If a particular habitat type is used in higher proportion than its availability, then that habitat type is considered to be selected by the species. If a habitat type is being used at a level lower than its availability then it is considered to be not selected by the species. If the level of use of a habitat is similar to its availability then that is evidence that it is being used in a random way rather than being selected or not selected.

Studies comparing habitat use to availability help wildlife ecologists assess a species' habitat requirements, but are not as useful when trying to predict species distribution across landscapes. Resource selection functions provide methods for quantifying a species' habitat preferences and can include both categorical (e.g., vegetation, habitat type, etc.) and continuous variables (e.g., elevation, temperature, rainfall, etc.). Species presence can be detected via direct observations, such as capture, camera trapping, and radio or satellite telemetry, as well as indirect observations, such as through sign surveys (observing tracks, dung, and other evidence of species presence) and interviews with people who have observed the species. Species presence can then be assessed within a range of environmental variables to determine the key characteristics of areas where the species is present. Geographic Information Systems (GIS) has become an effective tool for extracting a range of abiotic and biotic variables relevant to resource selection and modeling habitat suitability.

Gurney's Pittas in Myanmar: A Case Study of Habitat Suitability Modeling

Gurney's Pitta was discovered in Myanmar and Thailand over 100 years ago, but little was known about this cryptic and rare species. Based on collection locations of 38 museum specimens, the Gurney's Pitta was known to be limited to semi-evergreen rainforest, located close to streams and gullies below 160 m in elevation, and using spiny palms at least 1 m tall for nesting. Conversion of lowland forest for crops, oil palm, and rubber deforested Gurney's Pitta habitat and caused major declines in their populations. By the early 2000s it was believed to be extirpated from Myanmar and on the verge of extinction, with only 11 pairs known to survive in a wildlife sanctuary in Thailand—making it one of the rarest birds in the world. Scientists from conservation nongovernmental organizations (NGOs) prepared to conduct ground surveys in Myanmar to determine whether there were any left in the country. Using land cover and deforestation data analyzed from satellite imagery along with vegetation maps, elevation, and slope data, wildlife ecologists were able to model potential suitable habitat based on known habitat requirements using GIS. Based on this map, field survey teams deployed to five sites identified as potential habitat areas where the birds had not been previously observed. The team found Gurney's Pitta at four of the five new sites and, combined with surveys at four historical sites, demonstrated that Gurney's Pitta survived in Myanmar, doubling the known global population. The findings provided justification for official protection of Lenya, an area proposed for national park status, and further spatial analysis assessed deforestation and mapped potential threats to aid in planning for conservation of the species.

Home Range

The concept of home range is foundational to understanding an individual's or species' use of space. An individual's home range is defined as the spatial area that encompasses its typical activities, including searching for food and shelter, predator avoidance, and

reproduction. All these activities are connected through an individual's movements. Though the concept is straightforward, there are complicating factors that need to be evaluated to obtain a home range that is biologically meaningful for a species, for example, assessing how to handle exploratory movements that are beyond the area of typical activities and determining how to exclude areas that are not being actively used but only crossed when an individual moves between areas of use. The home range can be assessed over 1-year or multiple years, or could target critical time periods such as a particular season or migration period.

Home ranges are typically based on location data obtained via radio telemetry or satellite/GPS tracking and there are various methods for delineating home range (e.g., simple convex polygons, adaptive or fixed kernel distributions, and local convex hulls are commonly used). However, more recent research shows that these methods are likely poor estimates that are biased by spatial autocorrelation, and estimates can be improved with an area-corrected kernel density estimation method. Recently, rapid advances in tracking (e.g., satellite/GPS collars, transmitters, tags, etc.) have made it possible for ecologists to obtain location data more frequently, over vast areas of land and sea, and for many years. In the past, tracking devices could only be used on medium or large mammals and birds, but miniaturization of devices, development of other remote detection devices (e.g., radar, fixed wing receivers), and improved battery life have allowed ecologists to study a broader range of species within a broader range of ecosystems. These technologies help increase the accuracy and reliability of home range and habitat selection analyses. Increases in availability and variety of satellite data along with improved tracking technology have elevated focus on the study of movement within wildlife ecology. Movement is fundamental to most ecological processes and relates to questions about impacts of habitat fragmentation, invasive species, wildlife disease, and climate change.

Traditionally, delineating home ranges is based on the assumption that they are clearly defined and established, though they may change seasonally. Many species are resident, and remain within a particular area throughout the year. Others species migrate in seasonally predictable patterns between two or more areas. However, there are some species which range widely over an annual period, not returning to any particular location and moving in a way that is seemingly not predictable through a movement system called nomadism. Understanding a species' movement system can be critical to developing effective wildlife management plans. especially for large ranging and rare species.

Monarch Butterflies: Challenges for Managing Migratory Species

A classic example of migratory behavior is the monarch butterfly, a species that, in the cold regions of North America, escapes the winter through massive movements south which create visual phenomena. Starting in October, thousands of monarchs in the north travel to Mexico and Southern California, sometimes over 5000 km, for the fall and winter months. Groups return to the same wintering grounds and sometimes the same tree for hibernation, even though they are not the same individual butterflies that came the year before. Wildlife ecologists continue to study how monarchs find their winter habitat; it appears to be a combination of the magnetic pull of the earth and the direction of the sun. Migration of species causes complexity in management planning for a rare species. Threats may be present in both summer and winter habitats as well as throughout migratory pathways, requiring research and conservation efforts in more than one country, sometimes separated by thousands of miles.

Territories are the subsets within a home range which are actively defended either by an individual, a pair, or a group of individuals. These areas support essential resources, space, mates, or offspring so that the efforts to maintain the territory are offset by the advantages of having control over the area. An individual, pair, or group dominates within its territory. Territories may be marked via scents or visual identifiers to warn potential invaders in an attempt to avoid conflict that uses energy and risks harm to individuals if a fight results. Not all species maintain territories. In some cases a species will form a social group that roams together and essentially functions as a moving territory, such as an ungulate species which form harems.

Dispersal and Distribution

Dispersal behavior refers to the movement of an individual animal from the location of its birth to its location of reproduction and differs from the cyclic patterns of migration behavior. Dispersal behavior, or the lack of dispersal, results in the distribution of a species or population. Distribution refers to the spatial arrangement or area occupied by a species or species' population. Dispersal and distribution help wildlife ecologists understand a fundamental question of ecology—why a species or populations of species are found where they are. Dispersal behavior can be instinctual or in reaction to something in the environment. There are three major causal drivers for dispersal—to improve opportunities to successfully compete for mates, to avoid breeding between closely related individuals, and to move away from areas where the population density and competition are high in favor of areas with more available resources. Whether an individual disperses or not can also be influenced by mating systems. For example, for species in which males are polygynous (having more than one mate), the males will often disperse to increase their chance to find new mates, while the females of the same species prioritize increased opportunities for obtaining resources. These females will usually not disperse because they have a better chance to find resources in areas which are familiar to them.

The distribution of a species is often limited by abiotic factors, such as temperature, precipitation, and climate. For example, reptiles and amphibians are especially affected by cold and are not found in arctic ecosystems. In general, species diversity decreases with increasing latitude (toward the poles) and increases with decreasing latitudes (toward the equator). Many species will move up and down in elevation in response to seasonal temperature changes. Some species are limited by temperatures that are too high, or areas that are too wet. Extremely dry environments, such as deserts, often do not have enough precipitation to support many species. Species only survive in these areas through behavioral or physical adaptations that make it possible to

survive, such as restricting foraging to nighttime, changing from eating grasses to succulents to increase moisture intake, and lighter colored coats to help reflect rather than absorb the sun's rays.

A species' distribution is limited by biotic and abiotic factors, and in general, species that have higher levels of abundance in a local population will have wider geographic distributions, while species that have lower levels of abundance and are more rare will have more narrow distributions. Studying a species' historic, current, and even predicted future range is a major focus of wildlife ecology. Understanding why a species distribution has changed or assessing how a species distribution might be expected to change can inform wildlife management decisions to help sustain a species in the face of increasing or changing threats.

Wildlife Genetics

Genetic diversity, the variability of genes within a species, represents the potential for of a species population to survive in the face of changing landscapes and increasing threats. When changes occur, a population with higher diversity will have a higher level of fitness, because there will be a better chance of having individuals with traits that can aid in their survival. If individuals are very similar (have low genetic diversity) the chances of the population having the traits needed to survive new conditions is lower, and can lead to reduction or extirpation (elimination) of the population from an area when conditions change.

When genetic diversity is reduced it will stay at the lower level or continue to be reduced, unless there is an addition of individuals from a population with different diversity, or over long time periods through chance mutations. When a population goes through a drastic reduction it is typically referred to as a population or genetic "bottleneck". Having fewer breeding individuals can lead to inbreeding (breeding between closely related individuals), which results in a higher likelihood of deleterious traits in the offspring and decreased fitness of the population overall. Small populations are also at higher risk of genetic drift, in which genetic diversity is reduced further due to random chance since few individuals are reproducing and passing on genes. The founder effect is an example of genetic drift that occurs when a small population separates from a larger population due to habitat fragmentation or other changes, and results in a population that is lower in genetic diversity and potentially very different from the original population. In some cases it can lead to speciation, the evolution of a distinct species.

Small populations, at higher risk due to their lower numbers and genetic diversity, must be carefully managed to maintain as much genetic diversity as possible. Population genetics research allows ecologists to compare genetics between populations that have become disjunct (genes no longer moving between them), assess the genetic structure and demographics of populations, and examine the progression of evolution and speciation. Habitat fragmentation has become one of the top threats to wildlife species, reducing available habitat and causing populations to become increasingly smaller and disjunct. In response, mapping land cover change and habitat fragmentation, assessing what causes barriers for a particular species or set of species (e.g., roads, unsuitable habitats, etc.), and developing strategies for maintaining connectivity among populations or restoring connectivity by developing corridors have become important areas of study in wildlife ecology.

Advances in genetic sampling techniques have greatly increased opportunities for applications in wildlife ecology. In the past, DNA was primarily extracted directly from captured wildlife through samples of blood or tissue. More recently, scientists have developed DNA extraction methods that can be accomplished noninvasively through hair, feces, skin, feathers, and other material that can be collected without direct contact with wildlife. DNA sampling allows wildlife ecologists to detect rare species, classify gender, and improve estimates of population size through mark-recapture studies.

Emerging Issues

We are currently facing the sixth mass extinction crisis in over 500 million years. Though some species go extinct due to natural processes, scientists estimate we are now losing species at 1000 to 10,000 times the typical rate, with an estimated 30,000 species going extinct each year. While the five previous extinction crises were brought about by major physical processes, the current crisis is attributed to human activities which have led to extensive loss and fragmentation of wildlife habitat, the spread of nonnative species within ecosystems, and climate change. Several wildlife ecology fields of study have emerged in response to the extinction crisis.

Effects of Climate Change on Wildlife

Increasing temperatures and changing precipitation patterns will have major impacts on ecosystems and the wildlife they support. As climate warms terrestrial habitat regimes are predicted to shift away from the equator toward the poles and to higher elevations, leading to changes in the distributions of wildlife species dependent on those habitats. We can already observe these impacts in some taxa, for example, in addition to shifting distribution patterns some bird species are changing migration routes, the timing of their migration, and locations of breeding grounds in response to the changing temperature patterns and availability of food resources. Disruption of natural ecological processes like migration can have cascading effects beyond the species initially impacted, because changes for one species can lead to changes in the dynamics of relationships among species. Terrestrial mammals cannot move as easily as birds, which can make it more challenging to adapt to the effects of climate change and changing landscapes. As natural areas are developed for transportation networks, expanding urban areas, and other human activities, this forms real barriers that could prevent animals from shifting into areas that have become suitable due to climate change.

Impacts of Climate Change on Lobsters

As oceans warm the latitudes and water depths also impacts marine and coastal wildlife species. Marine species are typically limited in the range of temperatures they can tolerate and many will need to move deeper and away from the equator to find suitably cold water. For example, changes in coastal water have pushed lobsters northward from southern New England, leading to a near collapse of the industry in Connecticut, Rhode Island, and New York, while Maine has seen more than double the number of registered lobster landings since 1994. As ocean temperatures continue to rise lobsters will continue their northward movement, eventually causing decline of the Maine industry as well. Less mobile marine species, such as coral, which cannot tolerate higher temps often do not survive, resulting in the bleaching of coral reefs. This phenomenon is already being observed around the world and even threatens the Great Barrier Reef.

In the face of imminent changes to climate, wildlife ecologists are working to monitor and predict these impacts in order to adapt management strategies to help mitigate negative effects on wildlife species and their ecosystems.

Invasive Species and Diseases

Globalization, along with increased and more rapid transportation, has led to increased travel and trade throughout the world. These interconnections have resulted in the introduction of nonnative, also called invasive, species to new ecosystems. In some cases these species survive and become superior competitors, leading to their rapid population growth which can degrade habitat, increase competition and predation to the detriment of native wildlife species, and set the system out of balance. It is estimated that invasive species have contributed to the extinction of 40% of species lost since the 17th century. In most countries invasive species have been detrimental not only to the environment, but costly in terms of impact to human health and the economy. Costs from pests introduced to the United States, United Kingdom, Australia, South Africa, India, and Brazil are estimated to be more than $100 billion annually.

Invasive House Sparrows and the Decline of Native Birds

Well-known examples of the impacts of invasive species include the intentional introductions of bird species from Europe to the United States. For example, beginning in the 1850s imported house sparrows were released in the northeast by various groups hoping to either reduce insect pests or bring birds that reminded immigrants of their homeland. Having evolved in different ecosystems, house sparrows did not have a natural predator and spread rapidly across the North American continent, except in far northern regions, growing to an estimated 150 million individuals. House sparrows do very well using human structures for nests, have a generalist diet, are productive breeders, and nest early in the year leaving fewer nesting sites available for native migrant species. They are aggressive birds that move other nesting birds out of nests by destroying eggs and nestlings. These characteristics make house sparrows superior competitors, leading to rapid increases in their numbers and the decline of native bird species such as American robin, chickadees, flycatchers, thrushes, tanagers, bluebirds, purple martins, and various sparrow species. Wildlife ecologists have developed strategies for supporting native species by building nest boxes designed to discourage nesting of house sparrows, for example, avoiding foods that attract house sparrows, placing boxes away from high traffic areas, keeping the box closed until native species returns from migration, and trapping out house sparrows if they become established. These strategies have helped reestablish native species, though they require continued maintenance. House sparrow populations have declined in recent years due to these types of interventions and other factors.

Globalization and invasive species have also increased threats to wildlife through facilitating the spread of diseases new to an area, for example, the invasion of the Asian tiger mosquito in the United States has been linked to the spread of the Zika virus. Wildlife trade and changes in land use bring humans and wildlife into contact, allowing diseases to spread among them. Out of all the diseases afflicting humans worldwide, an estimated 75% are zoonotic (originating from animals), for example, Ebola, SARS, influenza, and HIV/AIDS. With increasing interactions between humans and animals comes increased risk of disease and the need for research to understand and predict potential outbreak hotspots.

Wildlife species can also be devastated by disease outbreaks and it's estimated that they have had an even greater impact than invasive species. Humans are little prepared to intervene in these emergencies. For example, a disease called white-nose syndrome is a fungus that grows on the noses of bats in N. America while they are hibernating. It has spread rapidly and has killed over 5.7 million bats in just a decade. In some places it has wiped out over 90% of the bat fauna. The loss of bats could impact human food availability, it is estimated that in Wisconsin bats eating pests save $600 million to $1.5 billion by reducing the need for pesticides. Wildlife ecologists are working urgently to diagnose and surveil the diseases that impact wildlife and find management solutions for slowing the spread of the disease.

Human–Wildlife Conflict

Human populations continue to grow and encroach further into wildlife habitat, bringing increased opportunities for humans and wildlife to interface, which can result in human–wildlife conflict. As wildlife habitats are converted to agriculture and human residence the availability of food resources for wildlife is reduced, leading some wildlife species to seek forage from crops, gardens, and even garbage. This interface usually causes negative impacts on both sides, including injury or death of humans and wildlife, harm to human livelihood through livestock predation and damage to crops, destruction of homes, and potentially leading to the loss of populations of some species. Examples include baboons killing juvenile cattle in Namibia, Asian and African elephants

eating crops in countries across their ranges, orangutans eating palm oil plants in Indonesia, wolves and bear killing livestock in Europe, and deer foraging in gardens in the United States.

Historically, management techniques targeted removal or reduction of the wildlife populations involved in conflict through hunting, translocation, or other methods. More modern approaches seek to find coexistence among humans and wildlife, developing strategies for minimizing and mitigating conflict in ways that are not detrimental to wildlife species. Potential wildlife management solutions include fencing to keep wildlife away from crops and homes, careful land use planning, community management of natural resources, providing incentives for support of wildlife through ecotourism and wildlife friendly products, and human behavior modification such as avoiding dangerous times and places that are at high risk for wildlife encounters. Solutions must be designed for the community and situation as no one solution will work in all cases. For example, communities in Mozambique found that African elephants avoided chili pepper plants and began growing more as a means to deter them. Conversely, scientists in Sri Lanka report that Asian elephants there eat chili pepper and they are not deterred.

Restoring Species and Habitat

In the face of the Earth's sixth mass extinction crises, the field of wildlife ecology has expanded beyond efforts to maintain wildlife species and populations, broadening applications for restoring species and their habitats after they have been lost or greatly reduced. Restoration ecology research focuses on ecosystems that have been degraded or lost due to human activities, to understand impacts to ecological processes and species communities in order to inform strategies for restoring habitat for wildlife and ecosystem services (benefits to humans derived from healthy ecosystems). Examples of ecosystem restoration projects include planting of native trees and shrubs which have important roles in a damaged ecosystem; removal of invasive species through cutting, burning, or poisoning; and altering drainage patterns or soil content to encourage reestablishment of native species and ecological processes.

Beyond maintaining and restoring habitat for wildlife species at risk, wildlife ecologists also work to restore or return species to areas where the species' populations have become very small or extirpated from an area, or even have gone extinct in the wild. Strategies for bolstering or returning a species in an area include relocation, translocation, and reintroduction. When a population is small and faces an imminent threat due to invasive species, disease, habitat destruction, or other human activities that are underway or known to be coming, a population may be relocated (moved within its current home range) or translocated (moved to a new area outside its current home range) to another area where they have a better chance to survive. In extreme situations, such as in cases where there are very few individuals left in the world and they face a high likelihood of extinction or extirpation from an area, decision makers and managers may decide to remove a species from the wild. The objective is to capture the remaining individuals so they can be bred in captivity to build their numbers for eventual return to the wild.

Translocation can also be used as a strategy for bolstering very small populations, by moving individuals from a larger, stable population to a new area within its natural range. Reintroduction is a strategy that can be used to return a species to an area that was formerly part of the species' range, but where it has been extirpated from the area or gone extinct in the wild throughout the natural range. Individuals being released can be moved from another part of the range, but typically they are captive born, providing an opportunity for species from a successful breeding program to return to the wild. These individuals have no familiarity with the flora and fauna of their new environment and may struggle to find resources and survive. It can be especially challenging for a prey species that has not developed strong predator evasion skills. Often individuals are enclosed in the new area for an acclimation period and released, ideally with some form of tracking device so they can be monitoring and studied. When a species is reintroduced the threats which drove it to extinction are usually still present to some degree. Survival of these populations requires continued efforts to study and adapt management plans to help bolster the population, mitigate threats, and achieve coexistence with nearby human communities.

Black-Footed Ferrets: Back from the Brink of Extinction

Black-footed ferrets were thought to be extinct by 1979, due to humans targeting their prey (prairie dogs) and diseases such as canine distemper and sylvatic plague. When a population was discovered in Wyoming during 1981, the decision was made to capture any remaining ferrets to breed in captivity. Eighteen individuals became genetic founders of what has resulted in over 7000 kits born in six breeding centers. Based on captive breeding successes the United States Fish and Wildlife Service began reintroducing black-footed ferrets at eight sites in the western United States, one site in Mexico, and one in Canada between 1991 and 2009. Over time many sites were added by other organizations, with 24 reintroduction sites in total. There were many challenges, including lack of suitable habitat and prey, continued threat of disease, ferrets lack of experience catching prey, and opposition from land owners concerned about any efforts to increase prairie dog numbers or attempts to apply endangered species legislation to their land. The reintroduction effort has been slow and complicated, but through the work of governmental and nongovernmental land managers, scientists, and members of the public, black-footed ferrets are no longer extinct in the wild, with an estimated 500 individuals in release. Only four of the release sites are considered to have self-sustaining populations, and all wild populations will continue to be dependent for survival on conservation efforts to mitigate threats for the foreseeable future.

Cellular Automata

AK Dewdney, University of Western Ontario, London, ON, Canada

Introduction

Somewhere between ecology and computer science a nascent science struggles to be born. Cellular automata provide a simple, yet flexible platform for simulating a large variety of phenomena, some of which resemble ecological processes, at least in a wider sense. One thinks of chemical oscillators, seashell patterns, and epidemics, among other things.

Whether one is discussing lively chemical solutions, seashell patterns, or epidemics, the question inevitably arises as to what degree cellular automata model ecological processes in a useful (i.e., predictive) manner. This crucial point is discussed in the final section of this article.

Cellular Automata in General

The term `cellular automaton' hints at the marriage of two concepts, automata and cellular space, the latter being essentially an infinite square lattice. Automata *per se* have been the subject of a vast amount of research into their computing powers, particularly the languages they produce or recognize. The theory of automata has been a core subject in computer science from the beginning. It must be stressed that finite automata have powers of computation that are severely limited in comparison with a fully programmable computer.

Finite Automata

A finite automaton consists of a finite set of states, an input tape and an output tape (which may be identical to the input tape, if desired). Time is divided into discrete units and, between ticks of the clock, the automaton remains in the same state. At each tick, the automaton enters a new state that depends on its current state and its input symbol. Normally we express the rules that govern this behavior in a table or a state-transitiuon diagram (Fig. 1). The figure shows a simple finite automaton represented in both ways.

The state-transition diagram consists of three nodes labeled with state names and transition arrows between them. The corresponding table consists of two columns (one for each possible input symbol) and three rows (one for each state). Below the diagram and table is a schematic drawing of the automaton, basically a simple visual context in which to imagine its operation (see Fig. 1).

The finite automaton pictured here has three states and always writes the same input symbol as it reads, making only one tape necessary. For example, in state zero, if the automaton happens to be reading a 1, it enters state zero, according to the state-transition diagram. (Simply follow the arc labeled 1.) According to the table, it does the same thing. (Simply examine the entry in column 1 and row 0.) Once the transition is complete, the clock advances by one tick and the input tape shifts past the read-head by one square.

The input symbols do not have to be fed to a finite automaton one cell at a time. For example, inputs might consist of triples, as in 010, 011, 111, etc., or even longer strings. In such an automaton, for example, there might be a transition from state 2 to state 5 if the input was 011, but the transition might well be to other states for the remaining seven possible inputs. Finally, although care is normally taken not to confuse tape symbols with state names, we are about to enter a context where they are identical.

Definition and Examples of Cellular Automata

Although many variations exist, the basic cellular automaton consists of a large rectangular grid of squares (called cells), a clock that ticks, and a finite automaton. We imagine that each cell has a copy of that finite automaton in it. Although the same finite automaton inhabits each cell, the automata so embedded do not have to be in the same state. The input for each automaton is not on a tape, but in the neighborhood of surrounding cells. Depending on how the `neighborhood' is defined, the inputs will be strings of four state labels or eight of them. An example of this particular kind of finite automaton is provided later.

In a cellular automaton all cells typically begin in state 0, except for a finite number that are in other states. The nonzero patterns that occur while a cellular automaton is running are called `configurations'. At each tick of the clock, many of the cells enter a new state and a new configuration develops. It is natural to refer to the sequence of configurations that develop as `generations'.

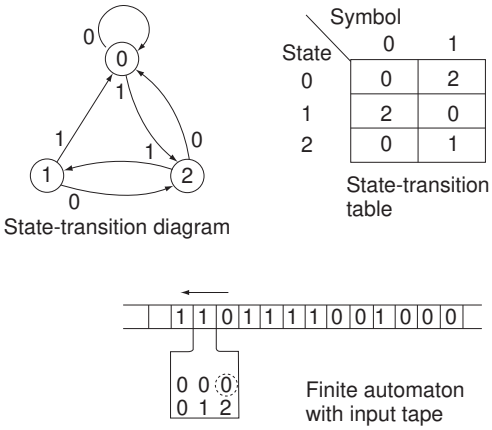

Fig. 1 Table and diagram for a finite automaton.

Perhaps the most famous cellular automaton to date is the one discovered by Cambridge mathematician John Horton Conway. He called it the Game of Life because it produced lifelike phenomena, as we shall presently see.

Conceptually, the space of Conway's Life is a two-way infinite grid of cells each of which can be in one of only two states, `alive' or `dead'. We will give these states the rather less exciting names of `0' and `1'. In this particular cellular automaton, each cell is considered to have eight neighbors, the four cells adjacent to the sides of the square plus the four cells adjacent at the corners. A cell in state 0 at a given tick of the clock will remain in state 0 at the next tick unless it has three living neighbors presently. In that case it will enter state 1 at the next tick, coming `alive', so to speak. A cell that is currently in state 1 will remain in state 1 at the next tick unless it has fewer than two neighbors in the state or more than three. Conway likens these rules to starvation (fewer than two living neighbors) or overcrowding (more than three).

These relatively simple rules astonished the mathematical and computing communities when first published in the journal *Scientific American* in 1970. No one would have predicted that such simple rules could lead to such complicated (and lifelike) behavior.

Fig. 2 shows a simple behavior of the Life cellular automaton in which an initial configuration of five cells in state 1 changes from one tick of the simulation clock to the next, turning into a somewhat larger configuration of nine cells in state 1 after five ticks of the clock. One can choose a particular cell in any of these stages and verify that its state in the next generation is the direct result of the appropriate rule as applied to the current generation.

An important feature in the Game of Life is the existence of `gliders', self-perpetuating patterns that `glide' across one's screen. **Fig. 3** shows the four consecutive configurations that constitute a glider. It will be noted that with every four generations, the glider has moved one cell diagonally in a direction that is determined by the orientation of the glider.

There is even a large configuration that produces gliders, requiring 30 generations for each glider to appear.

Even in the relatively simple milieu of a square-grid cellular automaton, a huge variety of rules is possible. The kind of rule used by Conway is called totalistic because state transitions are based on simple counts of neighboring cell states. However, totalistic rules account for only a tiny fraction of all possible rules, as applied to a particular space.

Totalistic rules can be easily implemented by a finite automaton in this context. For example, the totalistic rule for a cell in state 0 to enter state 1 requires that exactly three of the eight neighboring cells be in state 1. To manage this with a state-transition table is straightforward. If we number the neighboring cells in a fixed manner 1, 2, … , 8, the set of all strings in which exactly three 1s appear yield a list of transitions that one could begin as follows:

```
input       00000111 00001011 00001101
. . .
next state      1        1        1
. . .
```

Although cellular automata are generally conceived as inhabiting an infinite grid, the practicalities of finite computer memories impose a finite grid. To rid themselves of the boundary effects that this restriction inevitably imposes, many workers use a wraparound space in which opposite borders of the (finite) grid are identified, that is, counted as neighbors.

The underlying geometry of the cellular space need not be rectilinear. The cells may be hexagonal, for example, as in a honeycomb. (This style of cellular automaton has the advantage of having only one kind of neighbor, rather than two, as in the case of the square grid.) Nor is the underlying dimensionality of the underlying space restricted to just two dimensions. For example, there is a successful version of the Game of Life in three dimensions. In this version the cells are cubical.

The simplest possible cellular automata inhabit a linear (one-dimensional) space in which each cell has two neighbors, one to the right and one to the left. The rules for such automata are much simpler than for those having higher dimensions. In fact, for a two-state linear cellular automaton there are only four possible combinations for a neighborhood of two cells. Thus, the table would have at most four entries for each state. Yet even linear cellular automata may exhibit startling properties.

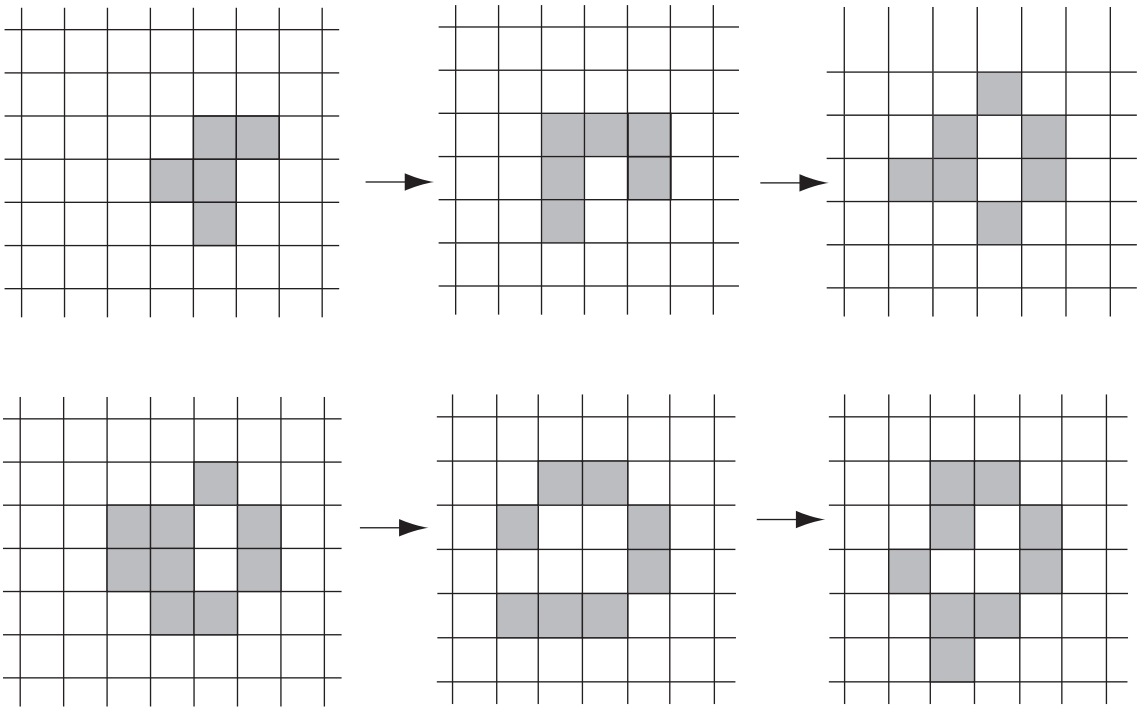

Fig. 2 Six generations.

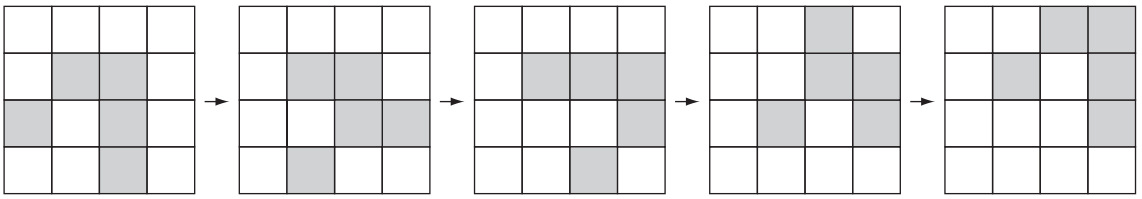

Fig. 3 Glider.

The most famous come from Stephen Wolfram, a physicist who became convinced that cellular automata amounted to a new paradigm for biological science and possibly for physics itself. Having devised a numbering scheme which encoded the many possible rule sets, Wolfram discovered Rule 30, as written according to Wolfram's scheme:

neighborhood	000	001	010	011	100	101	110	111
nextstate	0	1	1	1	1	0	0	0

The pattern of 1's and 0's, when written in reverse order, yields the binary representation for 30.

This cellular automaton, when started with an initial configuration consisting of a single cell in state 1 (the rest being in state 0), produces a succession of generations that appear to be essentially random, as in the accompanying illustration, which tracks a mere 12 generations (Fig. 4).

To this point deterministic rules have been assumed. The state of each cell depends on its own current state, as well as the states of its neighbors. The same configuration of states always gives rise to the same next state in a deterministic cellular automaton. In a probabilistic cellular automaton, the next state of a cell depends on probabilities associated with various configurations of its neighbors.

In general, probabilistic rules have the same form as deterministic ones except that the general statement would change from

Under the conditions X the next state is Y

to

Under the conditions X the next state is Y with probability p.

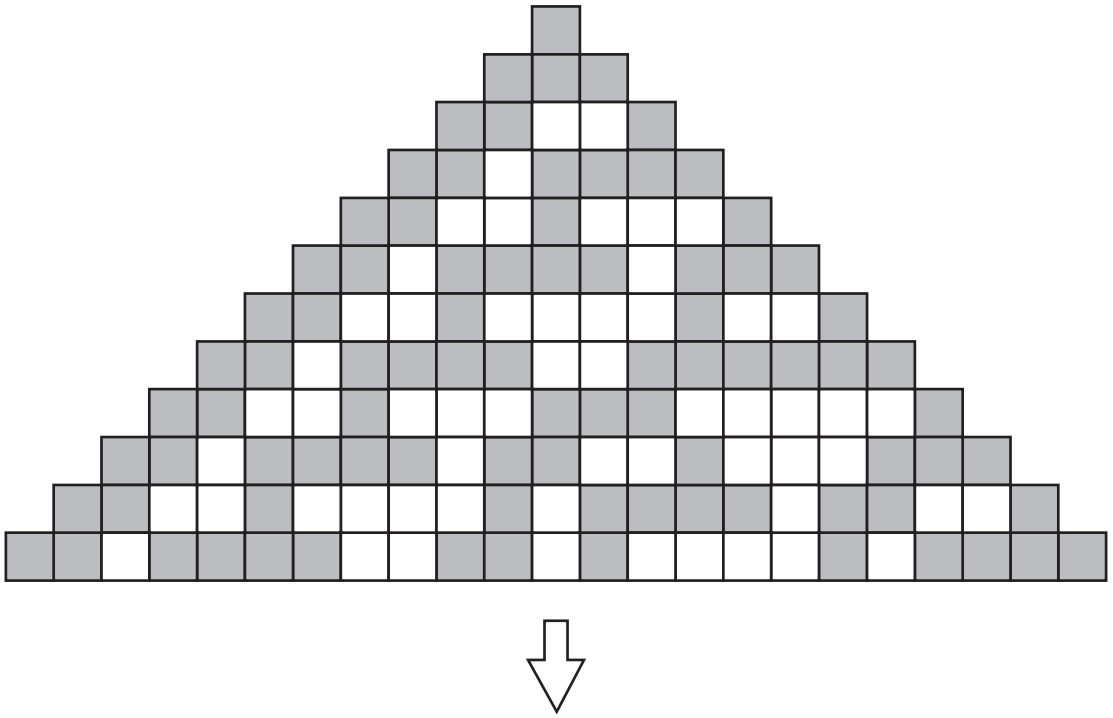

Fig. 4 Output of Rule 30.

Cellular Automata as Ecological Models

It is frequently useful, in building a cellular automaton model, to generalize the rules by making certain numbers available only at runtime. For example, the model might involve totalistic rules but with the totals treated as variables. In other words, the automaton might specify that when a cell is in a certain state, it will enter state 3 if n of its neighbors are in state 2. At run time, the user of the program may explore different behaviors by giving n a different value than he or she did last time. The probabilities used in probabilistic rules may also be made into variables, to be explored at runtime in much the same manner. Such variables, set at runtime, are called parameters of the model.

One can analyze some cellular automata readily enough to make certain predictions about their behavior without using a computer. But with a computer, one can see the rapid development of configurations through time, experiment endlessly with initial configurations, watch their fates, and adjust rules and parameters to explore certain possibilities.

History of Cellular Automata

A Strange Expectation

In the 1950s and 1960s, universities were creating computer science departments. One of the most important early subjects studied in these departments was automata theory, then being developed at the Los Alamos National Laboratory (US) and several universities, worldwide.

There has been a sense of expectation lurking in the halls of computer science from the very beginning. Leading thinkers like von Neumann and Alan Turing had pondered the lifelike properties of automata and the ability of the general purpose computer to simulate practically anything. If a soul did not lurk in the machine, then intelligence did. The field of artificial intelligence developed over the next decade into a persuasive metaphor, at least in the heady early days, with a hint of robots to come and, perhaps, new beings smarter than ourselves. This theme in computer science has had a long history, emerging two decades ago into a new field variously called artificial life or complex systems.

The Early Models

Before his death in 1957, the mathematician John von Neumann conceived of what he called the universal computer constructor, an abstract machine that was not only a fully programmable computer, but which made copies of itself, as well. The machine was designed in a cellular space of square cells that could be in any of 29 different states. von Neumann did not live to see his construction perform since he never completely specified the rules. His work, however, was taken up by the computer scientist E. F.

Codd, who reworked von Neumann's description, reducing the number of states from 29 to just 8 in the process. Codd's machine worked, at least conceptually, and von Neumann's dream was realized.

In truth, von Neumann could not be called the sole originator of cellular automata. Stanislaw Ulam, a fellow mathematician at Los Alomos National Laboratory in the United States, had devised a cellular grid to simulate the growth of crystals in a two-dimensional space. It was he who suggested to von Neumann that the dream of a universal computer constructor was best pursued in what we have now come to know as a cellular automaton.

Earlier, in 1951, Russian biophysicist Boris P. Belousov submitted a journal article that described a strange chemical reaction. When a solution of citric acid, acidified bromate, and a ceric salt was left to stand, the solution would first clarify, then turn yellow. Then it would clarify again, and so on. The paper was rejected because, according to the editor, the reaction was clearly `impossible', according to thermodynamical laws. The world of chemistry was not quite ready for lifelike properties emerging from a simple chemical soup.

Another Russian biophysicist, Anatol M. Zhabotinsky, refined Belousov's solution by replacing citric acid with malonic acid. He discovered that when the new solution was left undisturbed, it did not merely oscillate between two colors. Instead, amazing patterns consisting of concentric circles and spirals played across the surface of the mixture with no sign of ending. Zhabotinsky was ultimately able to publish his strange research, but it was not until 1989, when *Scientific American* carried an article about cellular automata that successfully mimicked the Belousov–Zhabotinsky reaction that the reaction was added to the steadily growing list of cellular automata incursions into the real world. The automaton was discovered more or less simultaneously by American David Griffeath, as well as a pair of German researchers, Martin Gerhardt and Heike Schuster.

These cellular automata are best described using an infection metaphor to express the interactions of neighboring cells. The Gerhardt–Schuster automaton has a great many states, typically 100. Cells with low state numbers are considered `healthy', while those with high numbers are considered `infected'. A weighted sum of infection in the neighborhood of a cell determines the degree of its infection at the next tick of the clock. A set of four parameters associated with the Gerhardt–Schuster cellular automaton suffices to specify the model completely. Depending on how the parameters are fixed at runtime, the cellular automaton will exhibit behavior (appropriate colors being assigned to its states) to produce a screen appearance that is virtually indistinguishable from the reaction itself. Refreshingly, Gerhardt and Schuster have issued a disclaimer that the simulation in any way `explains' the reaction. It is, they say, merely an interesting coincidence.

A Resurgence of Interest

In 1970, the journal *Scientific American* introduced Conway's Game of Life to the world in Martin Gardner's Mathematical Recreations column. Almost instantly, gliders began to flicker across the screens in graduate and faculty offices as scientists, some at least, came to appreciate the powers of cellular automata. The Game of Life was but one example. What other amazing machines awaited discovery?

Strangely, the appearance of Conway's Life came barely a year after the publication of *Calculating Space*, a book outlining the possibility that all space and physical phenomena in it were fundamentally discrete by nature. The appearance of Life gave added credibility to the book's author, Konrad Zuse. Twenty years later a kindred spirit, physicist Edward Fredkin, would maintain that the universe was one vast cellular automaton, a theme that was also being explored by physicist Stephen Wolfram.

In 1983 Wolfram began an investigation of one-dimensional cellular automata, the ones described in the previous section. He quickly discovered, while exploring the effects of different rules, that complexity would frequently arise in an unpredictable manner. In other words, it was never apparent, simply from an inspection of the rules themselves, which would produce complex and interesting generations and which would fizzle out or produce dully repeating patterns. Whatever might be the mathematical situation, Wolfram decided that the complexity he witnessed in the linear automata, produced by simple, interacting rules, had a parallel in the sunflower heads and seashells of nature. But would it be confined to occasional patterns connected with growth or would it, ultimately, hold a mirror up to nature itself? Wolfram, thinking more in the latter direction, published the boldly titled *A New Kind of Science* in 2002.

In the book, Wolfram explored elementary cellular automata, the totalistic linear automata described above. The book drew many significant parallels between patterns in nature and patterns produced by cellular automata. Perhaps the best known of these is the seashell pattern that appears on the cover of his book.

A significant question addressed by Wolfram is whether some elementary cellular automata are computation universal. Although not without significance for ecology, the question is typically asked in a computer science context. For an elementary cellular automaton to be computation universal means that the automaton is effectively capable of being programmed and is logically equivalent to a fully programmable computer. Did the marriage of humble finite automata and a cellular space boost the computing power to universality? Wolfram suspected that Rule 110, for example, was computation universal. Colleague Matthew Cook answered the question partially in 1994, proving that some of the elementary cellular automata had structures rich enough to support universality. Later, Wolfram provided the outline of a proof that Rule 110 is universal. Although the proof depends heavily on pictures and lacks mathematical rigor, Wolfram may well be correct. After all, one can prove that all sorts of simple systems are computation universal. One can, in fact, compute with ropes and pulleys, jets of water directed in a system of channels, systems of words that are assembled according to simple rules, pinball machines, and a host of other unlikely milieu.

One of the most interesting aspects of Wolfram's work with cellular automata involves a classification scheme for elementary cellular automata. When salted with an initial configuration of states, each of these automata exhibits one of four classes of behavior.

Class 1. After an initial flurry of activity, the automaton produces nothing but monochromatic generations (all cells in the same state).
Class 2. Once a class-two cellular automaton settles down, it produces strictly periodic generations. A finite set of configurations (often just one) repeats over and over again, always in the same order.
Class 3. These automata ultimately produce random-looking patterns that never repeat themselves. By the same token, they show little evidence of structure, not unlike snow on a television screen.
Class 4. Some elementary cellular automata produce a mixture of structure and randomness. These clearly interest Wolfram the most, being the most `lifelike'.

Wolfram has found interesting theoretical support for the reality of his classification system. If the state of a single cell is changed from one run to the next, the new pattern will of course be different. In class 1 automata, however, the change is rapidly `forgotten' on the way to uniform statehood. In class 2 automata, the change remains localized without affecting other areas of the pattern. Class 3 automata have a very different behavior. The effects of the change spread to the right and left at a near-linear rate, suggesting that any cell in the initial configuration can have an effect on the state of any other cell, no matter how distant, given enough time. Class 4 automata, on the other hand, show behavior that is intermediate between classes 2 and 3, with occasional bursts of long-distance communication mingled with local dieback.

Class 4 automata are poised midway between classes 2 and 3. At a metaphorical level, they seem to point to a digital future for biology and ecology. Somehow, everything alive will all end up in class 4. At a more practical level, this future can only appear if cellular automata, used appropriately, can make themselves indispensable vehicles for new knowledge that is expressed or expressible in traditional terms. Otherwise, there is a distinct danger, in this writer's opinion, that the cellular automaton will become a toy that generates the occasional `insight', ultimately to be discarded, as nobody knows what the results actually mean.

However things turn out, there are already a great many types of cellular automata employed in the pursuit of ecological insights. These have two- and even three-dimensional cellular spaces, sometimes distorted by landscapes, sometimes inhabited by finite automata but more frequently by miniature programs. The latter kind of model would be called simply and more accurately a cellular model, rather than a cellular automaton model.

Applications in Ecology

It is interesting to compare the present degree of penetration of cellular automaton models into the field of biology (including ecology) with that of a much older mathematical approach, the differential equation. A search on biosis using each term as a key phrase turned up 3993 instances of the latter, as compared with 357 instances of the former. Presumably a tenfold majority of authors still feel more at home with differential equations.

The two tools are markedly different. Differential equations describe continuous behavior, whereas cellular automata describe discrete behavior. Despite the differing conceptual frameworks, differential equations have been used in discrete situations (such as predator–prey relations) and, conversely, cellular automata have been applied in continuous situations (movement of swarms and flocks).

How Good Are the Models?

The essential question to be asked in the area of applications of cellular automata to ecology is: `How useful are cellular automata in generating insight into biological and ecological processes'? Among the most persuasive images in Wolfram's *A New Kind of Science* are those of seashells decorated with patterns that are eerily similar to those produced by some of his elementary cellular automata. Fig. 5 shows a fair rendition of a portion of one of these patterns as though it were produced by such a cellular automaton.

Of course, the surface of seashells are not marked off into tiny squares each of which is either one color or another (black and white in the case above), yet the patterns behave as if it were. On the other hand, if one tries to produce an elementary cellular automaton that actually produces patterns like the one shown here, the project will come to grief. The diagonal lines tell the story. A diagonal one-cell line amounts to a glider, that is, a structure that, in this context, moves either left or right. Although it is possible to have a right-moving one-celled glider – or a left-moving one – it is mathematically impossible to have both.

This problem illustrates the need to ensure that the `application' in question really does what most ecologists demand of their models, that they `generate insight' (a phrase which the author has encountered frequently).

An `insight', to be really useful, must go beyond merely noting a resemblance. It must lead to the discovery of a new structure or process. In the case of seashell patterns, Wolfram points out that the shell pigments are laid down by the edge of the gastropod mantle, essentially one line at a time. The cells, glands, or (as Wolfram calls them) `elements' of the mantle edge that deposit the pigments ``… have certain interactions with each other. And given this, the simplest hypothesis in a sense is that the new state of the element is determined from the previous states of its neighbours – just as in a one-dimensional cellular automaton." If an

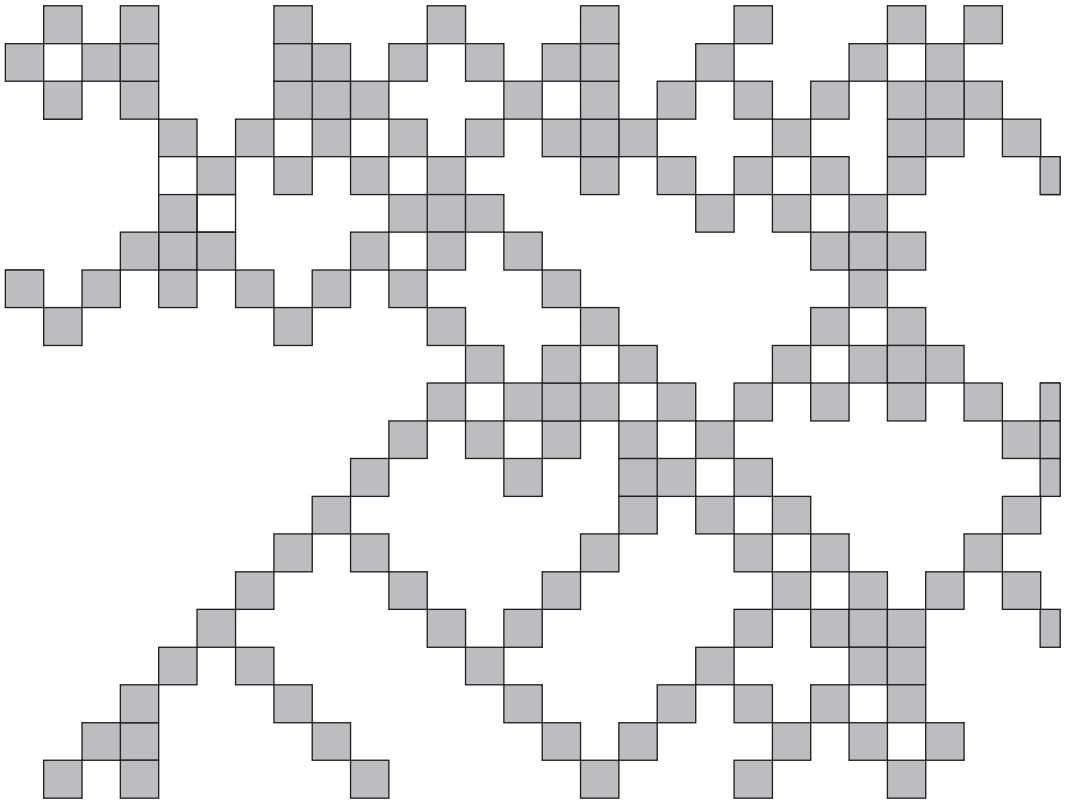

Fig. 5 Seashell pattern.

automatistic behavior is involved in such patterns, it is more complex than anything that elementary cellular automata are capable of.

A Typology of Applications

A review of the cellular automaton literature as it bears on ecology reveals a large range of applications, from abstract models with a somewhat fuzzy relationship to the real world to models that are focused on specific ecological problems with a view to eliciting new processes or structures in the underlying dynamic.

The former end of the spectrum could almost be described as solutions looking for problems. Early in the development of the subject, it became clear that certain cellular automata bore an uncanny resemblance to real-world objects or processes. Wolfram's molluskan patterns were but the tip of the cellular iceberg. A simple three-state cellular automaton captured the dynamic of the famed Belousov–Zhabotinsky (described earlier). Other cellular automata seemed to imitate the coat patterns of bi-colored animals such as zebras and leopards. Still others gave rise to `growths' that resembled root systems or rhizoids.

The most fascinating models to watch, however, were the early predator–prey cellular automata. Abstract predators occupied some of the cells, while prey occupied others. Rules could be formulated not only to allow the animals to pursue or to flee, but to reproduce. In many such models, the populations of both predator and prey oscillated in the manner predicted by the Lotka–Volterra equations. These were differential equations which operated not on discrete life forms, but continuous ones, a certain amount of predator in eternal pursuit of another quantity of prey, with both populations showing smooth, regular increases and decreases. Since the Lotka–Volterra equations were already suspected by many population biologists to capture the essence of simple predator–prey relations, the cellular model promised a more meaningful theater in which specific forms of predation could be examined.

As ecologists became intrigued with the possibilities of cellular automaton modeling, the subject took on a new and greatly expanded life. Of particular interest was the fact that thousands of interacting processes at the cellular (local) level could produce overall (global) changes or effects that might not have been predicted by simply examining the interaction rules. Such `bottom-up' or `emergent' effects include phenomena such as the complex swirling patterns of the Belousov–Zhabotisnsky reaction, the functional relationship between one variable and another, as in predator/prey models with their see-sawing populations, or long-term effects such as the disappearance of structure in Wolfram's first three classes of cellular automata.

Emergent or bottom-up properties of cellular automata not only have a fascination of their own, but motivate much of the work in this area. `What will happen if I change the density of plankton on which the prey fish subsist? Will they become extinct or

will it ultimately reduce the predator population'? It is nearly impossible to tell without adjusting the appropriate parameter and to run the model under the new conditions. Most cellular models in ecological and biological applications allow the alteration of fundamental parameters to explore emergent behavior under a great variety of conditions.

Although all cellular models share an emergent dynamism of one kind or another, the underlying spaces of the models vary in dimension. At present the great majority (90%) of applied cellular automata are two dimensional. The substrates vary from geographical areas such as grasslands to biofilms on submerged rocks, to the skin of animals, indeed any system that has a two-dimensional surface or zone connected with it. The remaining 10% involve a three-dimensional space in which animal assemblages (flocks of birds, schools of fish, myxobacterial associations, and so on), multicellular modeling (tissue growth, embryology, skeletal development), geological processes (water uptake and release, climatic effects, oil slicks), and several other areas with a paper or two each.

By far the largest number of journal articles based on two-dimensional substrates involve landscapes, with approximately equal numbers focused on urban growth/encroachment models and on vegetation dynamics in a great variety of settings. The remaining articles in this category focus on animal populations, from slugs to geese, as well as epidemiological models ranging from infections to alien plant invasions. Increasingly popular are the hybrid models, where programs replace automata, as in the example described next.

An Example Application

The black-legged tick study examined here involves an application of the cellular automaton concept that illustrates a (1) typical focus, (2) relatively successful outcome, and (3) variation in the concept that is increasingly common. An article on simulating the spread of the black-legged tick (*Ixodes scapularis*) in eastern North America by N. K. Madhav *et al*. may be placed in the epidemiology division (sensu lato) of the ecological literature.

The black-legged tick is a major vector of Lyme disease, a debilitating and ultimately fatal disease of humans. In recent decades there has been a noticeable expansion of this tick's range, offering new opportunities for human infection. Lyme disease involves a spirochete bacterium that lives in its tick hosts, then spreads to a variety of mammal and bird hosts when they are bitten by a tick. Principal vectors for the tick are the white-tailed deer, white-footed mouse, and American robin. It would be possible to predict more accurately where the tick range is most likely to expand if it were known which of these hosts played the most active role in its dispersal as a joint function of the number of such hosts and the distance they are likely to disperse the bacterium (mice: short, deer: medium, robins: long).

The study used a cellular grid to represent a large area (473 km $\times$ 473 km) within the tick's eastern range, each cell in the model representing 1 km^2. Each cell is inhabited by a process that is driven by both data and equations. Each process uses data from its own cell and neighboring cells to alter its own data. The process is also strictly deterministic. Notice that the `automaton' has departed entirely, along with its states.

The authors developed a number of hypotheses to test, including, (1) range expansion would be greater in areas dominated by hosts with larger ranges; (2) hosts with smaller home ranges would decrease the expansion of the tick range if they divert a sufficient proportion of ticks from hosts with larger ranges; (3) birds could expand the tick range if their densities and degree of infestation were high enough.

An important parameter in the model was the tick `burden' for each host in the model. Based on field data from the northeastern US, the authors calculated the mean number of ticks found on each of the host species over time. Other parameters included the average time that larvae (3 days), immatures (5 days), and adults (7 days) remained attached to their hosts, namely mice and birds for larvae, mice and birds for immatures, and deer for adults. Also important were the number of days spent by the tick at each stage of its life in seeking hosts.

Each run of the model began with a strip of cells down one side of the grid inhabited by ticks. Not to confuse the reader, each tick of the simulation clock represented one stage in the life cycle of the tick. Thus, three iterations would amount to one life cycle. The model was run for the equivalent of an 18-year period for each combination of parameter values under test.

At each iteration, this cellular model used host densities and their tick burdens in each cell, along with its four neighbors, to calculate the maximum number of ticks that can be supported in the neighborhood. This figure, in turn, yielded an estimate of the actual number of ticks feeding on a host species. The resulting engorged ticks were then distributed within the neighborhood to experience a degree of mortality, the survivors forming the basis of the next iteration.

The experiments produced some interesting results. First, the sensitivity analysis (a key component of all model building) revealed that the cellular model was highly sensitive to tick mortality. In other words, relatively small changes in the mortality parameter could produce large changes in how rapidly tick range expanded. The model was also sensitive to the home range of both mouse and deer hosts, as well as nymphal burdens. The results of the sensitivity analysis revealed the great importance of accurate estimates of certain field data, including on-host tick mortality, yearly tick burdens of host species, host behavior, and home range dynamics. In addition, accurate estimates of range expansion in the field (under appropriate conditions) would be necessary to validate the model.

The main experiment involved many runs of the model, in which each of the parameters was varied over three orders of magnitude. In this manner 125 host density combinations were tested. According to the model runs, deer density was significantly correlated with expansion of tick range, whereas with deer densities held constant at certain values, mouse densities were negatively correlated with tick range expansion. The authors sound a cautionary note that more work is needed, not only to further validate the model, but to make the cellular landscape more realistic by including geographical barriers, such as rivers.

Given that cell-to-cell interactions are represented by relatively realistic functions, the behavior of the model, though still requiring further validation, is correspondingly more realistic. Such a large proportion of work in this area involves nonautomaton modes of operation that the term cellular model would better categorize the research.

Chaos☆

Sven E Jørgensen, Royal Danish School of Pharmacy, Copenhagen, Denmark
Brian D Fath, Towson University, Towson, MD, United States

Appearance of Chaos in Models

Chaos can be explored through mathematical models or other techniques such as recurrence maps and phase diagrams. Model predictions are very sensitive to the initial conditions because the difference between predictions with slightly different initial conditions grows exponentially:

$$dN(t) = dN(0)e^{\lambda t}$$

where $d(t)$ is the difference between the two predictions at time t and $d(0)$ at time zero, and λ is the Lyaponuv exponent. Using mathematical models, the prediction uncertainty depends on the time scale of the system dynamics, referred to as the Lyapunov time. This causes long-term prediction problems because if the forecast time is doubled, then the proportional uncertainty is squared. A forecast horizon two or three times longer than the Lyapunov times is not meaningful because the system appears random. For example, for weather systems the Lyapunov time is thought to be around a few days.

An attractor is the set of numerical values to which the system evolves. These attractors can be fixed points, a finite number of points, a limit cycle, a limit torus, or "strange." Chaotic systems exhibit strange attractors, which have a fractal structure. An example of a strange attractor for the Lorenz equation is shown in Fig. 1. Note the obvious origin of the phrase, "butterfly effect."

Bifurcation and Population Dynamics

Chaos is also known in relation to bifurcation. One of the earliest models used to show this was the logistic model which describes the change in a population given its growth rate and carrying capacity. The following equation yields bifurcation:

$$N_{t+1} = N_t\left(1 + r\left(1 - {}^{N_t}/_{K}\right)\right)$$

where r is the growth rate per capita, t is the time, N the number of organisms, and K the carrying capacity. When r is above 2, the equation gives two stable fixed points; when above 2.6, four stable fixed points; when above 2.75, eight stable fixed points; and through successive bifurcations, an infinite hierarchy of stable cycles of the period $2n$ arises. Mathematically, it is clear that a high growth rate quickly pushes up against the carrying capacity causing this widely fluctuating pattern. Ecologically, chaos is rare in ecological systems because such high growth rates are not evident. Numerous researchers have demonstrated chaos in mathematical equations representing population dynamics. These studies have given support to theoretical questions of population dynamics. For example, the role of a top predator in a food chain can show chaotic behavior (Rai and Upadhyay, 2004), and the coexistence of a stable outcome for all three species in a two-prey and one-predator model occurs due to a strange attractor (Groll et al., 2017), among others. However, a few examples show that chaos may occur in insect populations and other species. A well-known field-based empirical example is the lemming population, where density (number per hectare) may fluctuate between two bifurcation values. Bifurcation pattern is also evident in seashell formation, as nicely demonstrated by Hans Meinhardt in his book *The Algorithmic Beauty of Sea Shells* (Fig. 2). Further work is needed to match the theoretical/mathematical work with empirical studies, and to explore the appearance and occurrence of chaotic behavior in population dynamics of real ecological systems.

Ecological Systems at the Edge of Chaos

A related concept that builds on chaos and complexity theory is the "edge of chaos," which is used to describe the transition zone between order and disorder. Systems operating in this region exhibit rich dynamical behavior and the concept has proven useful for understanding the evolution and adaptation of biological systems. For example, the abundance of other species determines which growth rate is optimal for any organism. If the growth rate is too high, then the resources (food) will be depleted and growth will cease. If the growth rate is too low, then the species does not utilize the resources (food) to the extent that is possible. If, in a well-

☆*Change History*: March 2018. Brian D. Fath prepared the update, revising the text in all sections and adding Figures 1 and 2.

calibrated and validated eutrophication model (state variables include phytoplankton, nitrogen, phosphorus, zooplankton, fish, sediment nitrogen, and sediment phosphorus), we vary the zooplankton growth rate, then work energy capacity will show a maximum at a certain growth rate (which is frequently close to the value found by the calibration and approved by the validation). At both lower and higher growth rates, the "average" work energy capacity is lower because the available phytoplankton is either not utilized completely or is overexploited. When overexploitation occurs, the phytoplankton and zooplankton show violent fluctuations. When the resources are available, the growth rate is very high but the growth stops and the mortality increases as soon as the resources are depleted, which gives the resources a chance to recover and so on. Somewhere poised between these extremes is a value that gives the maximum work energy capacity. In this example, when a value of the growth rate is slightly higher than the value giving maximum work energy capacity, the model starts to show deterministic chaos: a minor difference in the initial value causes exponentially increasing changes as the time increases.

Stuart Kauffman has promoted and utilized this concept to show that the rate of biological evolution, as expressed in NK fitness landscapes, is maximized near the edge of chaos. The rationale is that biological systems tend to operate at the edge of chaos to be able to utilize the resources at the optimum. In response to constraints, systems move as far away from thermodynamic equilibrium as possible under the prevailing conditions, but this will imply that the system has a high probability to avoid chaos, although the

system is operating close to chaos. Considering the enormous complexity of natural ecosystems, and the many interacting processes, it is surprising that chaos is not frequently observed in nature, but it can be explained by an operation at "the edge" of chaos to ensure a high utilization of the resources—to move as far away from thermodynamic equilibrium as possible.

Glossary

Amateur naturalist An individual with an interest in natural history who has not been formally trained in the subject.
Big data Large data sets that have been enabled by mobile devices and which, due to their immense size, often require specialized analysis techniques and devoted computational hardware and software.
Citizen science Scientific work undertaken by members of the general public, often in collaboration with or under the direction of professional scientists and scientific institutions.
Citizen scientist A volunteer participant in a citizen science project.
Do-it-yourself (DIY) science Scientific work undertaken by individuals, communities, and small organizations using the same or similar methods as traditional research institutions.
Open science The movement to make scientific research, data and dissemination accessible to all levels of an inquiring society, amateur or professional.
Typology Classification according to general type.

Introduction

The term "citizen science" has been around for just 40 years, but members of the public have done citizen science for most of recorded history—investigating scientific questions, often by noting observations of the world around them (see the glossary for the strict definition of citizen science, which only recently appeared in the dictionary). The field as grown rapidly in recent years, and encompasses an incredibly broad array of activities, common in that they include both science and the participation of volunteers—the essential components of citizen science.

Projects vary considerably, and can be classified in many ways. One of the useful ways to classify them is according to the level of participation by volunteers, the five "Cs"—contractual, contributory, collaborative, cocreated, and collegial projects. These projects vary from contractual projects in which volunteers ask questions and contract with professionals to do the research to answer them;

to contributory in which volunteers are asked by scientists to collect data; to collegial projects in which volunteers work independently of professional scientists to pursue a research project.

Recent advances in information and communications technology have facilitated rapid growth in all of these types of citizen science projects. Volunteers have unprecedented access to scientific resources and tools and can participate authentically in many research activities and at scales impossible in the past. As a result citizen science is contributing to ecology and conservation in new and exciting ways.

History of Citizen Science

Prior to the professionalization of science in the late 19th century, nearly all scientific research was conducted by amateurs—that is, by people who were not paid as scientists. These individuals were largely pursuing research because of an innate interest in particular topics or questions. Many amateurs were recognized experts in their field and conducted research indistinguishable from—and sometimes superior to—that done by most professional scientists of the time. For example, Isaac Newton, Thomas Jefferson, Charles Darwin, and many others (famous and anonymous) pursued much of their research outside the confines of academia or what we today think of as professional science. The terms "gentlemen scientists" and "naturalists" were often used to describe these individuals, at least those from upper parts of society; today they would be considered citizen scientists, following a collegial model of citizen science.

As early as the 17th century and probably earlier, some of these amateur experts as well as academic researchers had begun recruiting nonexperts to contribute natural history observations, engaging them in contributory citizen science projects. For example, in the mid-18th century, a Norwegian bishop created a network of clergymen and asked them to contribute observations and collections of natural objects throughout Norway to aid his research. These records were historical analogues to modern data collection systems, such as those used by eBird, iNaturalist, iSpot, and bioblitzes, in which volunteers record observations or collect photographs or specimens of plants and animals. Many early scientists, such as John Ray and Carl Linnaeus, used networks of volunteers to collect specimens and observations from across the known world. Such contributions have helped to build some of the most valuable collections of animals, plants, rocks, fossils, artifacts, and other specimens worldwide.

Others who have collected information and data about the natural world in the past include farmers, hunters, and amateur naturalists. For instance, wine-growers in France have been recording grape harvest days for more than 640 years, while court diarists in Kyoto, Japan, have been recording dates of the traditional cherry blossom festival for 1200 years. In China, both citizens and officials have been tracking outbreaks of locusts for at least 3500 years. Often, the people who made these observations were not intentionally participating in scientific projects, or were collecting data to address questions unrelated to their current use—but their observations and data are vital to many current scientific investigations, particularly those related to conservation and climate change.

The Professionalization of Science

Starting roughly 150 years ago, science started becoming professionalized. Many new professional scientists entered the workforce and the culture of science began changing toward that of the academic and professional laboratories and specialized scientists that we know today. Throughout this time, amateur scientists still pursued all aspects of scientific inquiry, much like gentlemen scientists and naturalists of the deeper past—amateur scientists, for example, still describe roughly 60% of all new species—but their volunteer efforts received little recognition in much of academic research. Rather, many amateur scientists were (and still are) supported by natural history clubs (e.g., New England Botanical Club, London Natural History Society, and Sapporo Natural History Society) that formed in the late 1800s or early 1900s with memberships that included mixes of professional and amateur scientists and naturalists.

During this time, advances in communications, transportation, and computing also made it easier for volunteers to contribute to large-scale data collection efforts—building on similar methods to those used by the Norwegian clergy, John Ray, and Carl Linnaeus—and for scientists and volunteers to manage and analyze the resulting data. These programs included the US National Weather Service Cooperative Observer Program (1890), Christmas Bird Count (Canada and the United States, 1900) and BirdLife Australia (initially Royal Australasian Ornithologist's Union (1901)). These surveys, and many that were developed later, yielded continental-scale datasets of biological and physical data that could not have been collected otherwise. For example, weather data gathered by volunteers for weather service agencies around the world have generated some of the most important long-term climate datasets—essential for agriculture, development planning, and assessment of recent climate change.

Recent Growth in Citizen Science

Most of the past approaches to citizen science continue today, but projects are more numerous and frequently bigger and more impactful than they were in the past. Expert amateur scientists still contribute, as they have for the entirety of the history of science; now they are supported by not only natural history and astronomy clubs, but also by do-it-yourself (DIY) laboratories and science communities (e.g., Public Labs, Genspace). Large-scale data collection projects and local and regional monitoring and research projects also still occur, many using similar methods to those used over the past 150 years or more. But mobile technologies and the

abilities to create apps and manage and analyze huge data sets have facilitated the proliferation of projects and the development of new and innovative methods. For example, projects like eBird build on methods that have been used by birders and ornithologists for decades or even centuries; but new technologies allow them to attract millions of observations and yield new insights into bird ecology and conservation.

Citizen science is also increasingly seen as a way to engage the public in science, improve scientific literacy and interest in science, and inform participants about particular topics, such as butterfly ecology, astronomy, molecular biology, or climate change. This is a major departure from most of the history of citizen science, when projects were set up mainly to achieve scientific objectives. Instead, many are now being organized primarily as means to improve participants' scientific literacy and understanding of the topics they are studying.

Characteristics and Classification of Citizen Science

In this section, we introduce some key characteristics of citizen science—namely, its unique feature that it can simultaneously contribute to research, learning, and problem solving. We also present an established citizen science project classification scheme.

Research

Citizen scientists contribute wide-ranging research that spans scales from observations of individual organisms (or even genes) to ecosystem-level assessments and analyses of images of landscapes taken by satellites. As mentioned earlier, citizen science has contributed to much of our understanding of the abundance and distribution of species, their evolution, and the functioning of ecosystems. Recent advances in technology, project design, and data standards have made the research potential of citizen science even greater. Project managers can more easily and accurately gather and curate data, and analytical tools and techniques enable easier cleaning and post-processing of huge volumes of citizen scientist-generated data. The Zooniverse suite of online citizen science projects, bird-focused projects like eBird and Project FeederWatch, and phenology projects such as those hosted by Canada's NatureWatch, are actively using big data from citizen science to contribute to solid ecological research.

Learning

A desire to learn is often a motivating factor for participants. Likewise, many citizen science project managers aim to increase the science literacy of participants. Learning through citizen science is unique because participants gain knowledge and skills, *and* contribute to authentic scientific research. This type of learning by doing is difficult to achieve in many traditional educational models. Participants of all ages can learn through citizen science activities. Youth may gain deeper understandings of the scientific method and careers in science, and their learning can be tailored to meet educational standards. Participation in citizen science may move adults to take action, alter their habits, and share what they have learned. Large institutions, such as natural history and science museums, can host citizen science activities to support learning opportunities for people of all ages and interests.

Problem Solving

Citizen science can directly contribute to solving problems—for example, by restoring habitat or removing invasive species—and can provide critical information or motivate changes in actions—for example, by informing air quality policies, increasing stewardship behavior, advocating for particular species or ecological communities, or inspiring volunteers to influence policy or vote for environmentally-friendly ballot measures. Governments are beginning to officially recognize the ability of citizen scientists to affect change and have started to provide incentives to support citizen science and encourage participation.

Classification of Citizen Science Projects

Shirk et al. (see Further Reading) established a system to categorize citizen science projects according to the level of involvement by volunteers. The scale ranges from minimal involvement in "*contractual* projects, where communities ask professional researchers to conduct a specific scientific investigation and report on the results" to a much greater degree of project management and leadership in "*collegial* contributions, where non-credentialed individuals conduct research independently with varying degrees of expected recognition by institutionalized science and/or professionals". The largest and most well-known citizen science projects exist in the second tier of this categorization, "*contributory* projects, which are generally designed by scientists and for which members of the public primarily contribute data." Many of the "grand challenges" in ecology, such as climate change and species and habitat conservation, are best supported by contributory projects, which can collect environmental data across large geographic scales. Many data collection activities require minimal training and equipment, and they can be deployed at a national or international scales year after year. Certain projects have goals that require greater volunteer involvement than occurs in contributory projects; this involvement can include participation in developing research questions, study design, data analysis and interpretation, and communication. These "collaborative" or "co-created" projects generally require more training or prior knowledge on the part of

the citizen scientists to be successful and are generally not designed to involve multitudes of people. With careful consideration, such projects can achieve deeper community engagement, improved resiliency and greater longevity.

Role of Information and Communications Technology

Information and communications technology facilitates citizen science across broad geographic scales, aids in the standardization of data collection, and broadens the appeal of citizen science to new audiences through the use of apps, games, and tools that run on mobile devices and the internet. Apps are ideal for citizen scientists monitoring light pollution (e.g., Germany's Verlust der Nacht, "Loss of the Night"), phenology (e.g., Chicago Botanic Garden's Project Budburst), or studying water quality for plankton health (e.g., the Secchi Disk Foundation's global Secchi Disk project). The ability to store and process large files also opens up opportunities for volunteers to help with the transcription of historical data sets and analysis of thousands of image files, creating valuable data for ecological research that would not be possible with professionals and automated technologies alone. Technology can also assist citizen scientists in contributing to research in a more substantial way. Web-enabled tools, such as the Collaborative Science online program developed for Virginia Master Naturalists, can help citizen scientists understand the complexities of research, and more deeply participate in data analysis, mapping, and other activities. And technologies, such as do-it-yourself kits or "hacks" for studying air quality or plant health (such as used by the Public Lab community) can allow the public to tackle research questions important to public health or other local problems that professional researchers are not interested in or cannot devote the time to. For example, community-based monitoring of water quality has grown substantially in recent years, supported by relatively easy-to-use monitoring and data management technologies, as well as the support of organizations, such as Canada's community-based environmental monitoring network.

Contributions to Ecology, Biodiversity and Conservation

Results from historical and newer citizen science have contributed tremendously to research in ecology, biodiversity, and conservation in ways often overlooked and at a variety of spatial and temporal scales (genes to global, and instantaneous to 1000 years or more). All three of these areas of research owe much of their most fundamental insights to the participation of amateurs and volunteers, whether to collect data and specimens, identify species new to science, or tackle key conservation issues.

Ecology

Citizen science is remarkably well-suited to studying the ecology of landscapes, macro-systems, urban areas, populations, communities, and ecosystems, as well as the particular areas of phenology, rare and invasive species, and disease. Landscape ecology and macroecology are relatively new subdisciplines of ecology that conduct research on large geographic scales. Large observational datasets composed of citizen science data have contributed to the development of these subdisciplines of ecology. For example, participants in the UK Breeding Bird Survey monitored the population changes of 224 common bird species in 3619 km^2 across the nation. And many of the specimens in museum collections and in large ecological databases, such as the Global Biodiversity Information Facility (GBIF), resulted from volunteer-collected data. These data sets are core to much of the work of macro-ecology.

For urban ecology, citizen science fills key roles, such as allowing sampling on private property, which is usually the majority of land in urban environments. The concentrations of people in urban areas also makes citizen science involvement in urban ecology studies—such as pollinator use of urban gardens, bird use of urban habitats, or searches for rare or underappreciated species—particularly appealing. For example, Garden Wildlife Watch is a nationwide, web-based citizen science project in Japan which monitors private gardens and the birds observed in them. Statistical analysis has revealed that larger gardens and gardens with clusters of trees and hedges support significantly more birds than other gardens, which allows researchers to make recommendations to gardeners who want to attract birds or provide important urban habitats for them.

Phenological data from citizen science projects have informed our understanding of how species are responding to climate change. In fact for much of history, volunteers led the study of phenology on their own, and now their long-term research and data sets provide much of the evidence we have describing one of the most sensitive biological responses to climate change (i.e., changes in phenology) on every continent and in the oceans around the world. For example, the UK Phenology Network revealed 250-year changes in first flowering dates for 405 plant species. Cherry blossom records from Japan show climate driven changes in flowering times, unprecedented in the flowering record (which extends back to the 9th century). More recent efforts, such as studies of the effects of climate change on winter birds in Yokohama, Japan (1986–2008) showed that birds decreased their average stay in Yokohama by about 1 month as annual temperatures warmed over the study period.

Citizen science can also be surprisingly important for studying the ecology of disease and invasive species. Data collected by FeederWatch, a project of the Cornell Lab of Ornithology and Bird Studies Canada, helped to reveal the impact of an emergent infectious disease, mycoplasmal conjunctivitis, that caused a wave of mortality in populations of house finches across the United States. And many areas rely on volunteers to help map species invasions through programs, such as Vital Signs and iMapInvasives; these mapping projects are key to managing the spread of invasive species, which can harm native biota.

Biodiversity Science

Citizen scientist contributions to biodiversity science come largely in the form of observations of the presence or absence of organisms. By and large, these projects require participants to go outside and either seek out a target organism or record the variety of life they see. Records of these observations are then shared with researchers, usually through an online portal. Biodiversity projects often require a vast quantity of observational data, making citizen science a good fit to help with data collection. In fact, most of the data submitted each year to GBIF, a primary global biodiversity database, comes from citizen science.

A distinguishing factor of observational projects is that they create *new* data. For example, a citizen scientist who records a salamander at their local park and uploads the observation to a database has, ideally, submitted a unique data point; the exact day, time, organism, or location have not been recorded before. En masse, these data provide information on distributions, range shifts, migration patterns, etc. However, these data are not always verifiable. Researchers compiling biodiversity data from citizen scientists usually employ tools to detect outliers and wrong information. Fortunately, machine learning, improved algorithms, and programmatic data analysis enables researchers to clean data efficiently and accurately.

Much biodiversity citizen science also occurs online. The two most common types involve volunteers deciphering images from camera traps and augmenting existing information with text transcription, georeferencing, or annotation. In these projects, citizen scientists are generally not creating new data per se, but are instead providing basic analysis of information, as is the case for projects where participants state the animals they see in a camera trap image. Or, they are making analog information digital by transcribing text (e.g., field notes or museum specimen records) or georeferencing textual locality information into approximations of latitude and longitude. Here, the data generated by citizen scientists is secondary to the primary data. This has implications for project design, methods, and downstream analysis as the original image, text, specimen, or other data source exists for data verification, as necessary.

Conservation

Citizen science also contributes greatly to conservation in three main ways: (1) by addressing key conservation-related science, like the science describe earlier in this article for ecology and biodiversity; (2) by involving volunteers in implementing key conservation actions, such as habitat restoration or the removal of invasive species; and (3) by encouraging citizen science participants to improve stewardship actions or get involved in decision making processes. The latter two of these really distinguish conservation citizen science from the ecology and biodiversity examples used earlier.

Many conservation projects would not be successful without the participation of volunteers—funding is frequently too limited. Thus, conservation organizations and government agencies frequently turn to citizen science to help with at least parts of their science-based restoration projects. For example, Earthwatch Institute has for a long time (since the 1970s) helped to recruit citizen science volunteers to participate in conservation-oriented research projects around the world, including the science-based restoration of mangrove forests in Kenya, clean-up of penguins and other species after an oil spill in South Africa, and restoration of sarus cranes to wetlands in Vietnam.

Many conservation organizations and government agencies also rely on citizen science specifically as a way to encourage volunteers to participate in decision making processes. The theory is that by participating in a project, volunteers will learn more and feel more invested in a particular issue and will want to get involved in decisions related to management and policy. The evidence that this type of causal relationship occurs—that is, that participating in citizen science increases participation in decision making—is still relatively weak, but there is anecdotal evidence and it is an area of active research.

Examples and Models of Citizen Science

Citizen science projects around the world have developed unique strategies to address specific themes and goals. Some projects engage thousands of participants to collect data across continents, while other projects enlist small groups of participants to focus on solving local issues.

The Cornell Lab of Ornithology, founded in 1915, works with partners to operate some of the most successful citizen science projects in the world. Most of their project focus on birds. Their largest projects, such as eBird, Great Backyard Bird Count, Nest Watch, Feeder Watch, YardMap, and Celebrate Urban Birds (many of which were created and are run in partnership with other organizations, such as Audubon and Bird Studies Canada), together have over 300,000 participants. They collect millions of observations each year and have led to key scientific insights (dozens or hundreds of scientific publications) and have informed management and policy. Most of the Cornell Lab of Ornithology's projects could be categorized as contributory projects and are designed to answer research questions initiated by scientists. Participants follow guidelines to provide high quality observational data, then scientists analyze the results, publish their findings, and provide policy suggestions. However, local organizations can use the methods and online data entry and data management infrastructure to design and implement their own projects, such as looking for spatial or temporal mismatches between species, monitoring for particular rare or invasive species, or identifying crucial conservation areas that are important to protect.

Other citizen science projects have found success through combined support from government agencies, NGOs, and scientific organizations. Monitoring Site 1000 is a citizen science project for monitoring biodiversity at about 1000 sites in Japan. It was

started in 2003 and is now a national project with about 2500 participants and with varied stakeholders including the Japanese Ministry of the Environment and more than 200 local NGOs. This project is a collaborative project with local NGOs and local citizens engaging in both data collection and dissemination of results. The United Kingdom and many countries of the European Union have similar government-supported citizen science monitoring schemes. And the United States government also recently issued policies explicitly encouraging the development of citizen science to support science, including key areas of ecology.

Zooniverse is one of the world's largest platforms of citizen-contributed research. Its online-only approach has proven to be an effective way of mobilizing data from a wide range of research-based topics including ecology, astronomy, history, and literature. Intriguingly, their approach frequently engages people in areas of science that they have not historically been interested in. People who participate in their online astronomy projects, for example, may not regularly participate in amateur astronomy. Similarly, their ecology-related projects, such as "Snapshot Serengeti" which asks participants to classify animals captured on camera trap footage, may attract new people to ecology and conservation.

Nonscience Outcomes

In addition to scientific outcomes, citizen science can benefits participant learning. By participating in research projects, volunteers may increase their awareness of local environmental issues, knowledge of scientific methods, and understanding of scientific topics. Participants can also develop scientific skills through learning data collection techniques, and may become interested in careers in science. Some of these benefits can be considered scientific literacy outcomes.

Some citizen science projects aim to influence the behaviors of participants. Evidence for these effects is limited, but it is an area of much research. Participants in some citizen science projects have gone on to improve wildlife habitat, contribute to publications, and apply for grant funding. Citizen science experiences can be transformative for some participants, but making this a consistent outcome is difficult to do and to measure.

Many citizen science projects also aim to influence policy, either through the science they produce or through the advocacy of their participants. The National Audubon Society's Christmas Bird Count, for example, engages thousands of participants each year, has contributed to more than 200 peer-reviewed papers, and has affected change in conservation policy, such as suggestions for reductions in hunting of American black ducks (*Anas rubripes*). Monitoring Site 1000 of Japan and citizen science projects in other countries have helped monitor progress toward achieving the Aichi Biodiversity Targets as a part of the Convention on Biodiversity.

Designing Citizen Science Projects

In the fields of ecology and environmental science, citizen science project managers consider four major axes when designing projects: (1) initiator of the project (professional scientists or the public); (2) scale (local or global) and duration (short or long term) of the project; (3) types of questions being asked, ranging from pattern detection to experimental hypothesis testing; and (4) goals, which include research, education, behavioral change, problem-solving, conservation and policy-making.

Information to implement projects is available through national and international citizen science organizations. New resources are being developed all the time—the field is moving quickly. Here we provide some of the major sources of information that will help lead to others.

The Citizen Science Association (CSA) was recently developed to facilitate communication and best practices. The CSA organizes a biennial conference, publishes a journal of citizen science research and ideas, *Citizen Science: Theory and Practice*, and hosts an email listserv where practitioners, researchers, and educators can exchange ideas and ask and answer questions related to citizen science. The European Citizen Science Association and Australian Citizen Science Association also promote citizen science and support the work of citizen science practitioners. CitizenScience.org, run by the CSA and Cornell Lab of Ornithology, provides a toolkit for project development and references for the professional network. CitSci.org supplies tools for creating, among other things, customized data-entry forms for volunteers. SciStarter provides tools, information about citizen science, and an extensive list of current citizen science projects. The Public Laboratory for Open Technology and Science offers citizen scientists a community atmosphere where citizens can collaborate with experts and access scientific resources.

Future of Citizen Science

As mentioned earlier, citizen science contributes to research, learning, and solving problems. It is also contributing to the "socialization" or "democratization" of science and to "open science" efforts. However, the full potential for citizen science has yet to be realized. New models, approaches, and collaborations will be helpful for researchers and society alike. Specifically, we highlight the following three areas for future work: new typologies, increased use of citizen science data, and social science.

New Typologies

Citizen science typologies to date have focused primarily on the integration of the public in scientific research. Typologies focusing on different aspects of citizen science could provide additional insights to evaluate and improve existing projects and forecast desirable future directions for the field of citizen science. One such typology focuses on project goals, such as action, conservation, investigation, virtual, and education. Projects with different goals require different approaches to design and management. Another typology focuses on mechanisms by which scientific and social aspects of the projects converge—for example, science-driven, policy-driven, and transition-driven models of citizen science. This typology could facilitate insights to increase the value of socio–ecological outcomes from citizen science projects. The transition-driven model, in particular, could be useful for tackling complex problems for which there are no ready-made solutions, where existing knowledge may be incomplete, or where perspectives are incompatible or conflicting.

Use of Data

Much of the data obtained from citizen science projects are not well analyzed. A recent review found that only 12% of biodiversity-related citizen science projects contribute data to peer-reviewed scientific articles, despite the fact that a third of these projects have verifiable, standardized data that are accessible online. It is not obvious why the data are not being analyzed—whether from lack of access or a lack of scientist time, interest, and trust. Newly developed machine learning methods may be able to help solve this problem. They require relatively little active scientist involvement relative to typical statistical data analyses, and may help researchers rapidly work through large quantities of citizen science data.

Social Science Approaches

Most ecology-related citizen science projects focus on natural science questions; social science approaches, questions, and insights are seldom included in the design and implementation of projects. This can be a serious shortcoming; insights from social science can help project organizers in many ways. For example, social science can help project managers understand and accommodate the concerns of volunteers or identify factors that influence volunteers' willingness to participate.

Glossary

Adjacency matrix Matrix representing species interactions. If two species *i*and *j* interact, the intersection of the matrix at *i*, *j* will be 1, and 0 if not.

Assembly rules Ecological processes leading to a specific species' composition of a community, for example, competition, predator–prey interactions, arrival history, etc.

Degree The degree of a node is its number of links (e.g., interactions per species). At higher level, the degree distribution represents the cumulative distribution of links per node within the network or a subnet of the network.

Ecological interactions Every type of contact between two species that alters the fitness of one or both species. Interactions can be directed or undirected, weighted or unweighted. They usually fall into one on these five main classes: competition, predation, parasitism, mutualism, and commensalism.

Ecosystem functioning Biotic and abiotic processes that sustain ecosystems, including flues of energy and nutrients between the components of ecological systems and the resulting stocks, for example, biogeochemical cycles.

Graph theory Mathematical framework used to represent the relationship between the objects of a network.

Network structure General shape of a network emerging from the organization of the interactions between its components. It is commonly described in ecology using connectance, link distribution, topological indices (such as nestedness, modularity, centrality), etc.

Nodes/links, vertices/edges Following graph theory, species are represented as nodes (or vertices), and interactions between them are represented by links (or edges).

Phylogenetic signal Tendency of phylogenetically close species to have similar traits (and as a consequence, similar interactions).

Unipartite/bipartite network The graphical representation of the entire adjacency matrix offers an unipartite network representation (see Fig. 1), where the hierarchy between nodes and their position into the network is not always visible. On contrary, a bipartite or k-partite network is a hierarchical representation of the network (Fig. 2), where nodes are separated depending on their position or function into the network (e.g., pollinator–plant as bipartite network).

Introduction

Interactions between the components of any ecological systems are organized nonrandomly. The species that form a community for example do not interact at random. The resulting organization of interactions between species drives some properties of the community such as stability, productivity, and the ability to resist extinctions, all of which eventually feedback on the organization of the system. The constant interplay between the organization of interactions and system dynamics constrains its structure. Studying the structure of ecological systems provides insights on the fundamental rules and processes that govern ecosystem formation, maintenance, and functioning.

The organization of interactions in a community is best represented as a network. *Graph theory* is a field of mathematics developed to analyze the structure of such systems. Every community can be abstracted by a *graph*, which is a representation of the system components and their arrangement (Fig. 1A). These components are called *nodes* and are linked together by *edges*. In an ecological system, nodes can be individuals, populations, communities or landscape patches and edges can represent trophic interactions, energetic flues and more generally every kind of interactions. Both nodes and edges can carry additional information such as weight (e.g., species abundance, intensity of the gene flow between two populations, etc.), location in space and time, and labels (e.g., species identity). Specific information can be attached to edges, modifying the characteristics of the graph, for example, the environmental dependence of an interaction. Graphs can be *directed* (i.e., interaction goes from A to B) or *undirected*, *weighted* (i.e., different strength of interaction among the network) or *unweighted* (Figs. 1 and 2). This information is summarized in the *adjacency matrix*, typically named *A* (Fig. 1B). The adjacency matrix *A* can be used to answer various ecological questions. Using it directly allows to follow direct interactions and the network structure, and using the inverse of *A*can be useful to obtain indirect interactions, and even more (Montoya *et al.*, 2009).

In this article, for simplicity, we will focus mostly on *Species Interaction Networks* (SIN). Ecological systems such as landscape, genetic or nutrient networks are not represented here, but they can be studying using the same framework as defined further.

*These authors contributed equally to the work.

 doi:10.1016/B978-0-12-409548-9.10564-0

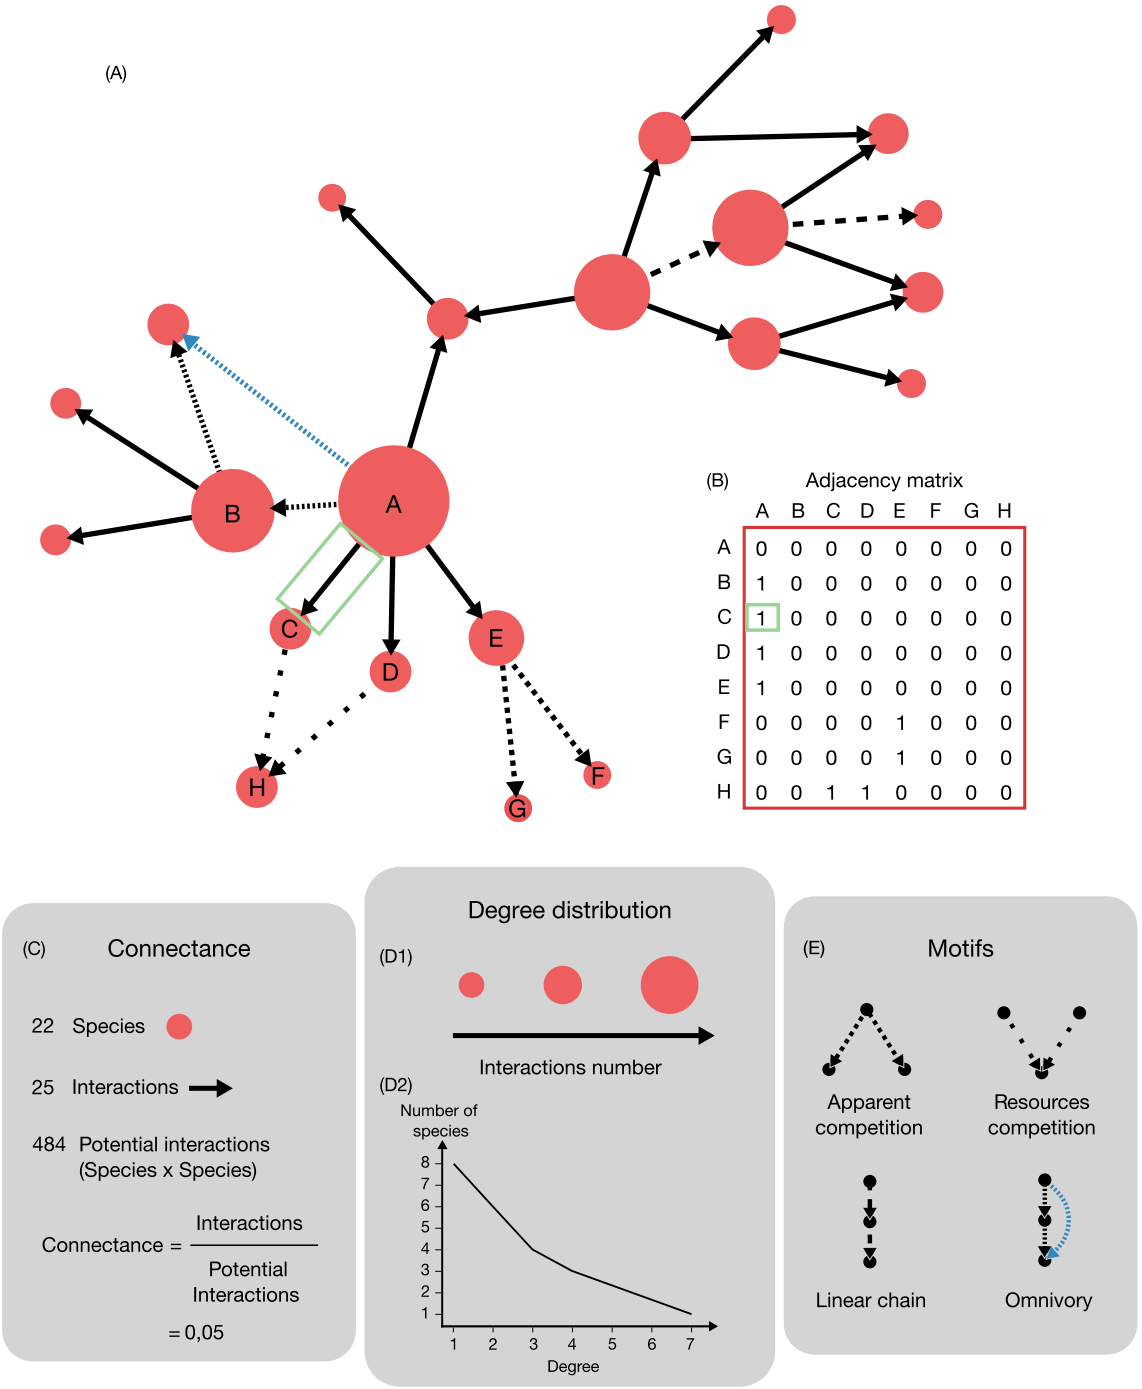

Fig. 1 Graphical representation of an ecological network (A), where species are represented by *circles* and their directed interactions by *arrows*. The representation is formalized in the adjacency matrix (B). In an unipartite representation as this one, each species is represented both as a column and a row. 1 indicates an interaction between two species (e.g., the *green square* in (B)), and 0 indicates the absence of interaction. This matrix facilitates computation of characteristics such as the connectance (C) and the degree distribution (D). (C) Represents the level of connection into the network and is calculated as showed in the figure. (D) Represents the distribution of interaction per species. The *circles* size is relative to the amount of interactions a species have (D1). This distribution is nonrandom and generally follows a power-law distribution (D2). The network can be split into subnets composed of 3 species, called motif (E). Among the 13 different possible motifs, we only represented the most commonly found in natural communities.

Describing and understanding the structure of SIN is an active, and growing, field of ecological research. We provide here an overview of some of the most prominent findings and areas of research from the last decade. Starting from a discussion of some invariant properties of the structure of species interaction networks, we will then discuss how this structure affects community

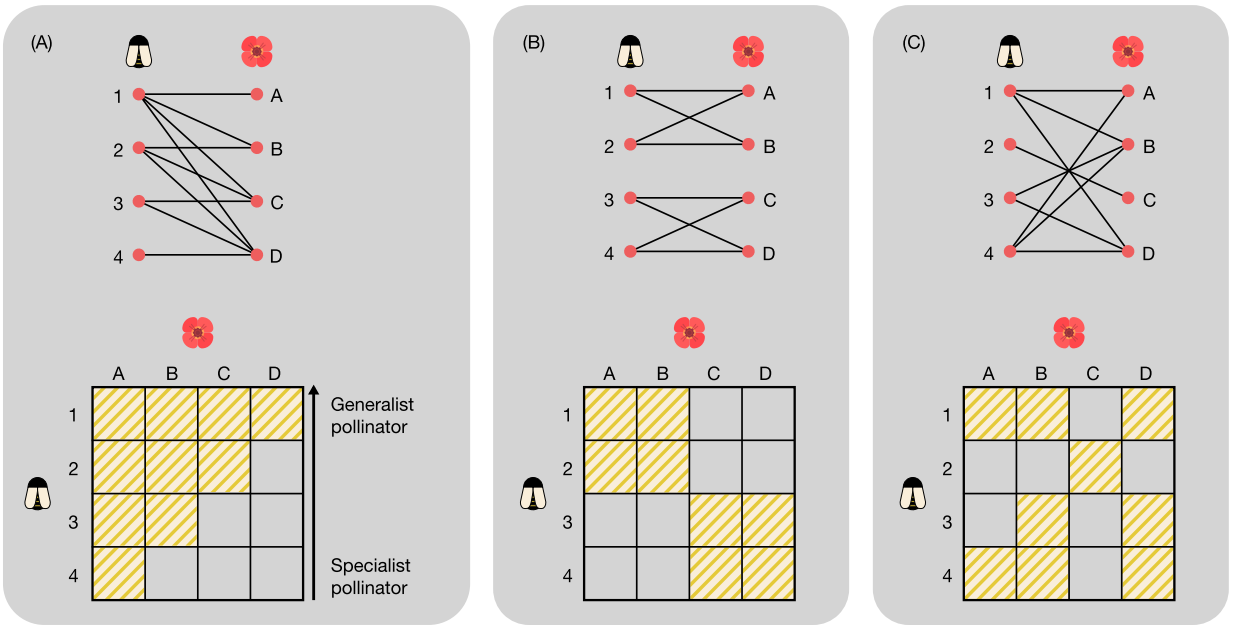

Fig. 2 Network topology, example of a fictional plant–pollinator network. (A) shows a perfectly nested network, where specialists pollinators are visiting plants embedded into the diet of more generalist pollinators. (B) Shows a perfectly modular network, where subgroups of species interact more strongly with each over than with the rest of the network. (C) Shows a random network. Two representations are possibles. Top: Bipartite representation using nodes and edges; Bottom: Ordered interaction matrix. Here, we used striped *yellow squares* instead of 1 for presence of interaction and empty squares in absence of interaction.

dynamics and properties. We will follow by a discussion of the ways ecological networks can be studied under familiar concepts from ecological theory, and finally how this approach scales up to larger temporal and spatial scales.

Invariants in Ecological Networks

One striking particularity of ecological networks is their consistency: even though they depict interactions between different organisms across all sorts of ecosystems, they all tend to look the same (Jordano *et al.*, 2003). Remarkably, even when interactions among species themselves vary, the overall network structure tends to remain unchanged (Kemp *et al.*, 2017). Most ecological networks have a very specific and similar *degree distribution* (Williams, 2011) (**Fig. 1**D), whereby most species have a small number of interactions, and a small proportions of species have a large number of interactions. In food webs, which represent interactions between prey and their predators, there is a well-described relationship between the number of species and the number of interactions. The number of interactions (L) increases proportionally to the number of species (S) raised to some exponent, or $L \propto S^k$. Martinez (1992) suggested that this exponent is approximately equal to 2, that is, the number of interactions is proportional to the squared number of species. Brose *et al.* (2004) showed that this relationship holds even across space; it is possible to estimate how many interactions a species will establish across its entire range. In other instances, networks may differ on some aspects of their structure, despite obeying to a shared underlying principle. For example, Fortuna *et al.* (2010) showed that in networks with a low connectance (**Fig. 1**C), nestedness (the degree to which the diet of specialists and generalists overlaps—**Fig. 2**) and modularity (the tendency of species to form densely aggregated clusters—**Fig. 2**) are positively correlated. In networks with higher connectance, this becomes the opposite: networks with a large number of interactions are either nested (and not modular) or modular (and not nested). In the recent years, it emerged that many aspects of network structure covary with connectance (Poisot and Gravel, 2014; Chagnon, 2015), suggesting that simply knowing how many species there are, and how many interactions they establish, is already very informative about the network structure.

Another remarkable generality of network structure is the distribution of particular interconnection between three-species subsets. Milo (2002) found that networks (not just ecological but other types of networks such as neuronal or electronical networks as well) can be characterized by the over or under representation of some of these three-species subsets, which they called motifs (**Fig. 1**E). Motifs can be more broadly defined as specific arrangements of interconnection between three (or more) nodes. The frequency at which they occur in a network can be computed and compared to randomized networks in order to reveal significant aspects of the structure. Three-species motifs represent the simplest building blocks of networks, and more importantly typical interaction modules found in communities. As such, they offer the possibility to integrate and test theories developed with simple modules in larger, more realistic networks (e.g., omnivory, McCann *et al.*, 1998, Holt, 1997). Food webs, for example, are characterized by an over representation of linear food chains and omnivory and an under representation of apparent and

exploitative competition (**Fig. 1**A and E) (Bascompte and Melián, 2005; Camacho *et al.*, 2007). Stouffer and Bascompte (2010) found that realistic motif distribution promotes stability in food webs, with over-represented motifs being more stable in isolation and correlated with higher stability in large realistic communities, and conversely. Motifs can also be used to characterize species role in networks. From the 13 different three-species motifs emerge 30 unique positions for species to occupy in these motifs, representing how the species is embedded in its community. The different positions a species will occupy, and the frequency with which it will occupy these different positions in networks are called species motif role (Stouffer *et al.*, 2012). These roles have been shown to be evolutionary conserved in food webs (Stouffer *et al.*, 2012) and to have less variability in time than expected in host–parasitoids bipartite networks (Baker *et al.*, 2015).

Another invariant network property relates to evolutionary history. Phylogeny is a key determinant of ecological network structure, being related to species position and interactions into the community. Phylogenetically close species tend to inherit traits from their common ancestors (e.g., body size, habitat, defensive strategy, metabolic type, phenology), increasing their propensity to interact with the same group of species or with similar species, a phenomenon called *phylogenetic signal*. This conservatism of interactions has been found to hold across different types of interactions such as antagonistic or mutualistic interactions (Fontaine and Thébault, 2015). However, depending in the species role (e.g., host or parasite, pollinator or plant) the link organization will be different, leading to an asymmetrical structure for pairwise interactions. For instance, closely related hosts tend to share parasites, while closely related parasites, because of competition for resources, tend to have different hosts (Krasnov *et al.*, 2012). The conservatism of interactions is consequently unequal all over the network. Following the logic that closely related species interact with the same group of species, Rezende *et al.* (2009) showed that phylogenetic structure of ecological networks explains almost entirely the formation and composition of modules and the connections between them. The species connecting modules together are indeed usually phylogenetically close. Cattin *et al.* (2004) also found, using a niche-hierarchic model, that diet is constrained by the phylogenetic origin of consumers. The nested structure of trophic networks is then influenced by the phylogenetic signal of interacting species and their traits compatibility. In contrast, the nested structure of mutualistic networks would be a consequence of trait complementary between species (Rezende *et al.*, 2007). For now, mechanisms underlying the nestedness–phylogeny relationship remain to be further investigated. Moreover, because of species plasticity, phylogeny alone does not fully explain the structure and evolution of ecological networks.

From Structure to Properties

The relationship between ecological network structure and stability is a long-lasting object of research in community ecology. MacArthur (1955) and Elton (1958) first proposed that diverse communities should have a more stable dynamic than simple ones because disturbances are more easily spread through highly connected nodes. May (1972) countered this hypothesis using a mathematical model based on random ecological networks and proposed there should be a limit to ecosystem complexity. This counter-intuitive proposition sparkled live debates still lasting today (McCann 2000; see Allesina and Tang, 2015). Two different approaches to the problem followed: one focused on dynamical stability and the other on the resistance of communities to species lost. Despite their dissimilarities, these approaches are not totally independent (Donohue *et al.*, 2013) and revealed that species diversity has no direct influence on community stability. However, the structure of ecological network such as the distribution of interaction strength and network topology seems to play a crucial role (Yodzis, 1981).

As mentioned above, the degree distribution of ecological networks often follows a power-law distribution (Montoya and Solé, 2002), indicating that few species are highly connected to the rest of the community and a large number of species are weakly connected to others. This organization combined with the myriad of weak interactions found across ecological networks buffers species variations and stabilizes the dynamics of the entire community (Bascompte *et al.*, 2005; Jacquet *et al.*, 2016). Other aspects of community structure, such as the predator–prey body–mass ratio (Emmerson and Raffaelli, 2004; Brose *et al.*, 2006a) and network architecture (Montoya *et al.*, 2006; Thébault and Fontaine, 2010), determine the distribution and strength of interactions and together drive the stability of ecological networks (Jacquet *et al.*, 2016).

Perturbations in ecological communities such as landscape fragmentation, habitat loss, or species invasion, are the primary drivers of species loss. Extinctions may happen directly, for instance if a particular habitat is eliminated, or indirectly following a first species loss (a phenomenon referred as secondary extinction or cascades). Such extinctions are used to measure the robustness of ecological communities. Simulation experiments revealed that the likelihood of secondary extinctions increases with community size (Lundberg *et al.*, 2008), decreases with network connectance (Dunne *et al.*, 2002) and primarily affects the most isolated species in the network. The loss of a highly connected species, also called a hub, induces a higher rate of secondary extinctions than the loss of a random and weakly connected species (Solé and Montoya, 2001). Similarly, species responsible for important energy-flow in the network (carbon, nitrogen or biomass) can trigger secondary extinctions (Allesina and Bodini, 2004).

The network architecture also affects the community response to perturbations. In agreement with MacArthur's intuition, it was found that species with low *degree* also more strongly propagate perturbations following permanent changes in the environment because of their tight connections (Montoya *et al.*, 2009). Alternatively, the most connected species diffuse such perturbations through the network and even though they affect a higher number of species, their average effect on other ones is much smaller. Overall network properties also affect the response to perturbation. Thanks to their structural properties (high nestedness and connectance, Jordano *et al.*, 2003), mutualistic networks persist longer than randomly structured networks (Memmott *et al.*, 2004;

Fortuna and Bascompte 2006). On the other hand, presence of modules in the community structure limits propagation of perturbations across the rest of the network and, as such, secondary extinctions (Stouffer and Bascompte, 2010).

Eluding the consequences of biodiversity lost for ecosystem functioning is also an important field where the network approach has been useful. The hypothesis that an increase in species diversity results in an increased productivity dates back to Darwin (1859) and a formal theory for what is now called the biodiversity-ecosystem functioning (BEF) relationship was proposed in the mid 1990s. In a trophic group (i.e., a group of species that all belong to the same trophic level, e.g., producers or herbivores), increasing diversity improves resource use efficiency and translates into larger productivity (Loreau, 2010) (e.g., nutrients for producers, or producers for herbivores). Yet, when the trophic group under focus is coupled to other(s), the action of diversity on functioning is more variable (Duffy *et al.*, 2007). This makes the BEF relationship unpredictable in real-world communities (Harvey *et al.*, 2013), composed of several trophic groups that are virtually never differentiable—as intraguild predation and omnivory blur the frontier between levels. The multiplicity of the factors influencing the BEF relationship calls for a more general framework that allows the integration of the theories developed for trophic groups and for simple modules or subsystems (Gravel *et al.*, 2016). By mapping transfer of biomass and energy and/or constraints on organism through the different compartments that compose a natural community, ecological networks—and food webs in particular—offer the possibility to perform this integration. Analyses performed on simulated food-webs with fixed species richness have shown that interactions, and more specifically their structure, have a significant influence on productivity (Thebault and Loreau, 2003; Thébault *et al.*, 2007; Poisot *et al.*, 2013). The structure of interactions is indeed a reflection of community properties, essential to ecosystem functioning. It seems then essential to integrate it in BEF studies.

Mechanisms Underlying Pairwise Interactions

Ecological interactions between species should be viewed as the result of low level processes involving pairs of individuals. A pollinator is able to effectively reach the nectar in a plant because their respective traits match, they have compatible phenologies, and they occur in the same environment. A virus can infect its host because it is able to attach to the cell surface, effectively penetrate it, and hijack the cellular machinery to its benefit. Interactions that are not allowed because trait values do not match have been called "forbidden links" (Olesen *et al.*, 2011). This prompted a search for "linkage rules" (Bartomeus, 2013) in ecological networks, that is, the relationships that must exist between traits of two organisms in order for an interaction between them to exist. These can be identified from existing data on traits and interactions (Bartomeus *et al.*, 2016), and then used to generate realistic ecological networks (Crea *et al.*, 2015). González-Varo and Traveset (2016) pointed out that interactions are happening between individuals, and as a consequence, it requires to consider not only how the traits are distributed at the individual scale, but also how different behaviors may allow organisms to overcome some of the forbidden interactions.

Although traits are an important part of what makes interactions happen, they are only relevant insofar as the organisms are able to encounter one another. The importance of neutral dynamics (i.e., how abundances of different species can determine the probability that they can interact, based on how often they would get in contact by chance) is, somewhat counter-intuitively, great. Canard *et al.* (2012) revealed that realistic food webs can be predicted with only knowledge of abundances. In a host–parasite system, local abundances has also been identified as a key predictor of species interactions (Canard *et al.*, 2014). More broadly, because interactions emerge from all of these ecological mechanisms, there is a need to develop a deeper understanding of their variability (Poisot *et al.*, 2015). Beyond the fundamental advance that this represents, this would allow to model interactions based on external information instead of documenting all of them (Morales-Castilla *et al.*, 2015).

The realization of an interaction between individuals has, by definition, an effect on population dynamics. But it is also archetypical of complex system dynamics, where low level processes propagate up to higher level of organization and impact emerging properties of the community. If we consider for instance a population A, its dynamic is not the same when it multiplies in isolation—where it can grow exponentially if resources are unlimited (Malthus, 1798) or logistically otherwise (Verhulst, 1938)—or when it is embedded in a real-world community, composed of several species interacting with one another through different processes. That population can lose individuals to predation, have parasitism increase its death rate and at the same time see its establishment eased through facilitation. It then becomes necessary to account for the entire set of interactions to understand population, community and ecosystem dynamics. But the effect of interactions on dynamics is not always straightforward to elude, both in terms of directionality and intensity, as there is different types of interactions and multiple factors influencing their occurrence and strength.

Ecological networks are also spatially and temporally variable (Trøjelsgaard and Olesen, 2016). There are two drivers to this variability: changes in species composition, and changes in the way these species interact (Poisot *et al.*, 2012). Changes in species alone are able to generate variation in network properties (Havens, 1992). Spatial variation in network structure can also reflect deep-time constraints; for example, Dalsgaard *et al.* (2013) revealed that historical climate change trends have a signature on the nestedness and modularity of pollination networks. Even when the same species are present, interactions between them can vary. Carstensen *et al.* (2014) and Trøjelsgaard *et al.* (2015) investigated this phenomenon in mutualistic networks. Interaction turnover results from variations in partner fidelity (some species pairs are extremely closely associated), but also from variations in the local environment in which the species interact. Interestingly, networks overwhelmingly tend to conserve their structure even when interactions within them change. Díaz-Castelazo *et al.* (2010) surveyed a pollination network over 10 years, and found important species turnover during this period. Nevertheless, the network retained its structure because species where replaced by their

functional equivalent; a generalist pollinator often succeeded to another generalist pollinator. Conversely, species tend to retain their role in different communities: Baker *et al.* (2015) showed that species keep occupying the same position in the network across space, regardless of the species they interact with at every location.

From the Regional Species Pool to Local Structured Communities

Describing the variation in ecological network structure at large spatial scales may represent an additional layer of information compared to simple species lists. As such, ecological networks are a powerful tool to shed new light on the processes underlying species distribution (Cazelles *et al.*, 2016) and variation in some ecosystem functions (e.g., trophic regulation). Until recently, the prevailing idea was that at large spatial scales, the role of biotic interactions on distribution is very small compared to that of abiotic conditions, and as such is important only locally (Pearson and Dawson, 2003; Boulangeat *et al.*, 2012). Empirical observations of species–environment relationship are used to approximate species physiological tolerance to environmental conditions and potentially predict their range under different scenarios of climate change (e.g., Araújo *et al.*, 2006). While these species distribution models provide a useful approximation of their potential range shift (Pearson *et al.*, 2002), there is mounting evidence that biotic interactions—both positive and negative—play a critical role in shaping communities not only at local scales (Boulangeat *et al.*, 2012), but also at macro-ecological scales (Davis *et al.*, 1998; Araújo and Luoto, 2007; Heikkinen *et al.*, 2007; Gotelli *et al.*, 2010; Araújo *et al.*, 2011).

It was proposed that the role of interactions in shaping species distribution could be approximated from knowledge of species cooccurrence (Araújo *et al.*, 2011). This very active field of research has been recently pushed by the development of joint species distribution models (JSDM), which account simultaneously for the effect of the environment and codistribution (Pollock *et al.*, 2014). But there are limitations to this approach. For instance, it does not allow to distinguish between cooccurrence caused by biotic interactions and correlated responses to unmeasured environmental variables (Pollock *et al.*, 2014). Conversely, the lack of association between species is no evidence of absence of interaction (Cazelles *et al.*, 2016). Further work is therefore needed to move from correlative species distribution models (SDM) toward more theoretically sound models. In particular, developing methods allowing to include prior information about the underlying ecological network when estimating (J)SDM could shed light on the fundamental processes underlying species distribution and thus making more accurate predictions (Cazelles *et al.*, 2016). Additionally, Poisot *et al.* (2017) recently showed that biotic interactions respond to environmental conditions on their own, independently of species.

Ecological networks also offer an ideal framework to study the conditions for the maintenance of biodiversity in communities. The competitive exclusion principle states that the number of coexisting species should be equal or smaller than the number of resources. This stands in contradiction with the existence of ecological communities containing species that overlap in some extent in their resources or consumers. Phytoplanktonic communities are often considered to illustrate this paradox (Hutchinson, 1961), as they exhibit a high biodiversity while species are competing for a limited number of shared resources (e.g., light, nitrate). Species coexistence mechanisms (Chesson, 2000) are based on species traits that either decrease fitness differences (equalizing mechanisms) and/or increase niche differentiation between species (stabilizing mechanisms).

The coexistence theory and the representation of ecological communities as networks of interactions has brought new perspective on species coexistence. Martinez *et al.* (2006) for instance showed that the global nonrandom structure of the food webs improve community persistence (i.e., species coexistence). The distribution of motifs in food webs (Stouffer and Bascompte, 2010, see section *Invariants in ecological networks*) as well as species' role within motifs (Stouffer *et al.*, 2012) are related to community persistence. In mutualistic networks for instance, the nested structure minimizes interspecific competition and increase the number of coexisting species (Bastolla *et al.*, 2009; Sugihara and Ye, 2009). Interactions structure also tend to impact species coexistence into communities, as highlighted by Bascompte *et al.* (2006), the fact that one species A depends strongly on another species B as resource for food or pollination, and the other species, B, only weakly depends on A, also called asymmetry of dependences, increases coexistence of species. As an other example, using food web structure Brose *et al.* (2006b) showed that the allometric scaling of metabolic rates of species improve community persistence. All these types of approach, whether they are based on motifs, species' role or allometric scaling, have highlighted the importance of network structure in species coexistence.

Ecologists have also questioned the way communities are formed and the hypothetical set of rules embedding their assembly. The network approach allows to explore in details the different processes influencing ecological communities assembly. Capitán *et al.* (2009), for instance, characterized the sequence of species arrival in a community with an assembly graph. It allows to follow step by step every possible path in community assembly from 0 to $x$species among several trophic levels, and to highlight underlying mechanisms. Verdú and Valiente-Banuet (2008), for instance, found that nested community provides generalists species which facilitate the presence of other species into the network. At the same time, Olesen *et al.* (2008) observed that newly arriving species tend to interact more easily with already well-connected or generalist species. Such results could let us think about the Drake's controversial idea that species arrival history would be an important factor driving community assembly (Drake, 1991). This proposition was supported by network analyses, such as in Campbell *et al.* (2011) for mutualistic networks, but still remains object of debate.

The addition of ecological networks into models of diversity dynamics fostered the development of theory of community assembly at both, fine and large spatial scales. Niche and neutral theories dominated most of community assembly research since the publication of Hubbell's book in 2001. A wide range of models have been used, most of them with very abstract and

phenomenological representations of the niche. But only recently, with the addition of trophic constraints (Gravel *et al.*, 2011) and other types of interactions (Cazelles *et al.*, 2016) to MacArthur and Wilson's (1967) model of island biogeography, that all types of interactions were considered in the process of community assembly. The model was first extended by assuming that predator could only colonize communities with prey already present, and go extinct with their last prey. This modification was sufficient to explain the observation of a sequential construction of food webs after the defaunation treatment of the famous experiment by Simberloff and Wilson (1969) and (Petchey *et al.*, 2008). The model was further use to illustrate a reciprocal feedback between colonization-extinction dynamics and local food web dynamics, where properties of the regional food web constrain the development of the local motif structure, and alternatively local dynamics influence the assembly process (Massol *et al.*, 2017). This modeling approach allows a general representation of the niche in studies of assembly dynamics (Jacquet *et al.*, 2017) and propose a unifying framework to explain the construction of local communities from a sample of the regional species pool.

Conclusion

Graph theory delivered important scientific discoveries, such as improved understanding of breakdown of electricity distribution systems or the propagation of infections in social networks. It is also a powerful tool to investigate key questions in ecology. Graph theory provides a remarkably simple way to characterize the complexity of ecological networks. Indices such as connectance, degree distribution or network topology serve as basic measurements to describe their structure. Such indices facilitate comparison between different systems and revealing commonalities and variations. Nowadays, the relatively important number of network studies leads to a myriads of ways to sample, analyze and interpret them (see Delmas *et al.*, 2017).

Studying ecological networks have however a larger purpose than just their description and classification. Basic measurements are correlated to several environmental conditions and network analysis appears to be helpful in different ecological fields. As we seen through this chapter, it can be used to study dynamics of ecological systems and their responses to changes, according to their stability over time or the BEF relationships in the system. It also highlights the understanding of mechanisms underlying ecological properties such as community assembly, coexistence and species distribution. Network studies were a key to reveal relationships between different properties of ecological network such as trait and structure.

Complex Systems

Mikhail Prokopenko, The University of Sydney, Sydney, NSW, Australia

Glossary

Allelomimesis A range of activities in which the performance of a behavior increases the probability of that behavior being performed by other nearby animals.
Autocatalysis A single chemical reaction is autocatalytic, if one of the reaction products is also a reactant and therefore a catalyst in the same or a coupled reaction.
Homeostasis The property of a system to actively regulate a specific variable, keeping it practically constant.
Order parameter A macroscopic variable used to describe and measure the degree of order across the boundaries in a phase transition system (normally ranges between zero in one phase and nonzero in the other).
Phase transition A change in a feature of a physical system, often involving the absorption or emission of energy from the system and resulting in a transition of the system to another phase.
Propagule Any material that is used in propagating an organism to the next stage in their life cycle, for example, by dispersal of plant material (stem cuttings or seeds) for plant propagation in horticulture, or transmitting a disease by infectious components generated by pathogens.
Shannon entropy The quantity is defined in the context of a probabilistic model and measures the uncertainty, or the average (expected) surprise of an entity, given an ensemble in which it is embedded. Shannon information is a measure of the reduction of uncertainty.
Small-world network A graph in which the neighbors of any given vertex (node) are likely to be neighbors of each other (in other words, the average clustering is high), and most nodes can be reached from every other node by a small number of hops (formally, the average shortest path length is small). Small-world effect explains how strangers are linked by a short chain of acquaintances.
Stigmergy A mechanism of indirect coordination, through the environment, between agents or actions.
Tipping point (environmental) A threshold beyond which some (typically accumulated) small changes may force an (eco-) system to rapidly and often irreversibly change to a new state, with significant effects on biodiversity at a regional or global scale.

Introduction

A complex system typically contains a large number of individual components (often referred to as agents) that interact with each other and the surrounding environment. The number of agents is usually sufficiently large so that no specific feature controls or dominates the overall dynamics of the system, but not large enough to make individual features completely irrelevant. The agent interactions follow simple rules dependent on the agents' perceptions of their local conditions. For example, pheromone-depositing ants foraging for food indirectly interact with each other through their environment. The ants employ a form of autocatalytic behaviour called allelomimesis: the probability with which an ant chooses a trail, and therefore, deposits new pheromone there, increases with the number of ants that chose the same path in the past. As more ants, attracted by the pheromone, cross the same area and lay more pheromones, making the "chemical" path even more attractive. As pheromone slowly evaporates, shorter paths, which keep being reinforced by attracted ants, become more prominent than longer ones, and an optimal path emerges. The process is thus characterized by (i) positive feedback loops, making shorter paths stronger in terms of the deposited pheromone, and (ii) nonlinear dynamics of the pheromone concentration, which is increasing with the number of ants traversing the formed paths and decreasing due to the chemical's natural evaporation. Feedback loops and nonlinear dynamics are two other common features of complexity.

A variant of complex systems is complex adaptive systems (CAS), in which the agents adapt or learn during their interactions. Holland (2006) defined four distinguishing attributes of CAS: (i) parallelism: a large number of simultaneously interacting agents exchange signals concurrently (e.g., the reaction cascades and cycles within biological cells are continually coordinated in order to ensure that a cell maintains its functions); (ii) conditional action: the agents' actions depend on the received signals or other local perceptions, constructing flexible behaviors that involve intricate positive and negative feedbacks; (iii) modularity: an agent's behaviour often includes different groups of rules, acting as "subroutines" or building blocks, that can be recombined to respond to novel situations; the usefulness of such modules may be confirmed or disconfirmed based on their success in dealing with the challenging circumstances (e.g., the Krebs cycle—the citric acid cycle in biological cells, which incorporates eight proteins that interact to form a loop—is a basic series of chemical reactions used to release stored energy by all aerobic organisms, ranging from bacteria to elephants); (iv) adaptation and evolution: the agents adapt in order to improve their performance over time (the adaptations, that can be structural, behavioral and physiological, help organisms survive in their ecological niche or habitat, for instance, the chameleon camouflage, birds migrations and the snakes ability to make venom).

Adaptive behavior can take many forms. One important example is homeostasis: a dynamic process of self-regulation and adaptation by which an overall system or individual agents adapt their behavior over time in order to stay close to a certain state (or a set of states). Homeostatic behavior is related to Ashby's Law of Requisite Variety which states that in order to maintain a dynamic stability under perturbation (or input), an active controller requires as much variety (the number of states) as that of the controlled system. In other words, the greater the variety within the system, the more resilient it is.

Turning our attention to the interaction aspect of complexity, we point out that the agents may interact not only with each other but also with the surrounding environment. This may play an important role in sustaining or maintaining its ecosystem, for example, bees pollinate flowers, facilitating the production of fruits or seeds. Such agent–environment interactions may have both positive and negative feedback loops, and typically create nonlinear dynamics.

There are also examples of interacting sub-systems such as predator–prey interactions which shape an integrated ecosystem. Predator–prey models, for example, the well-known Lotka–Volterra model, include a pair of coupled differential equations that describe the dynamics of two populations, one of which (the predator) grows at the expense of the other one (the prey). Under some simplifying assumptions, these models are able to demonstrate the coupled dynamics which are characterized by (i) oscillations in the population sizes of both predator and prey, and (ii) a time lag between the prey and predator abundances: the peak of the predator's oscillation follows the peak of the prey's oscillation. However, as predators consume the prey, the prey's abundance greatly diminishes causing the predator population to reduce. This eventually removes immediate threats to the prey, swinging its population up and resetting the coupled cycles. From the evolutionary perspective, predators and prey can influence one another's evolution, and such co-evolution need to be modeled on longer (slower) time scales than the dynamics of population sizes.

The "mass-action" models, such as the Lotka–Volterra model, have a broad range. They can describe chemical reactions, as well as the compartmental models of disease spread in mathematical epidemiology, in which the population is split into different compartments, such as susceptible to the infection; infected; recovered, and so on, interacting with each other over time. The "mass-action" models conceptually differ from agent-based models which are more applicable to studies of complex systems. The agent-based models attempt to explicitly represent behaviors of individual agents and their local interactions, including their short-term adaptations and the long-term evolutionary changes, and so the resultant global dynamics are not specified directly, for example, by some differential equations, but are expected to emerge.

Emergence

In general, the global dynamics of a complex system which result from the agents' interactions are emergent: they cannot be predicted, or explained, as an aggregation of the agents' individual dynamics. In other words, the interactions among the constituent microscopic parts (at the bottom level) bring about macroscopic phenomena (at the top level) that cannot be understood by considering any single part alone. These macroscopic features often display synergy ("the whole is more than the sum of the parts"). Continuing with the ant colony example, we note that an optimal path, or a network of paths, connecting the colony nest with food sources, emerges as a result of the pheromone-depositing ants navigating around various obstacles present in the environment. The result of this distributed process cannot be reduced to the local actions. In other words, the optimal path is an emergent property of the distributed behaviour of the ants, constrained by the locations and shapes of the obstacles.

Another example of emergent behavior is given by swarms of animals. Animal groups in nature often exhibit spatial aggregation, for example, schools of fish, swarms of locusts, herds of wildebeest, and flocks of birds (Parrish and Edelstein-Keshet, 1999). Such aggregations may provide individuals with protection, mate choices, foraging, habitat assessment, migratory routes, etc. (Camazine et al., 2001). Being a typical case of complex systems, an aggregated flocking behavior results from the local behaviors of individual birds which try to stay in close proximity, while avoiding collisions and flying in the same general direction. Again we point out that complex large-scale patterns and structures emerge within swarms and flocks through individual decisions, based on perception of the individuals' local conditions. Interestingly, these local perceptions propagate through the collective as waves or cascades. Formation of signaling waves is a widespread phenomenon observed in animal groups, rapidly transferring information over long ranges (Potts, 1984). Information cascades in collective systems often create a positive feedback loop, due to a rapid autocatalytic

response to changing conditions. This heightened adaptive response allows the group to be sensitive even to weak or ambiguous external stimuli.

Emergent behaviour is related to tangled hierarchies exhibiting Strange Loops (Hofstadter, 1989):

> "an interaction between levels in which the top level reaches back down towards the bottom level and influences it, while at the same time being itself determined by the bottom level."

Emergence is often confused with self-organization and the primary difference between these two concepts lies in their relation to the levels of system. While feedback loops are possible both within and across the levels of the system, it is important to distinguish between (i) emergence, which assumes another level of description where the emergent properties can be used for better predictions by an external observer, and (ii) self-organization which occurs within a complex system, that is, within one level, affecting the functioning of the system itself (Prokopenko et al., 2009).

Self-Organization

Self-organization is typically defined as the evolution of a system into an organized form in the absence of external pressures explicitly guiding the local behavior of the sub-systems. For example, an eco-system may develop spatial structures in order to deal with diminishing resources. The prefix "self" should not be taken literally: it only indicates the absence of centralized ordering or explicitly defined external template prescribing the internal dynamics. In general, we deal with open systems, exchanging energy, matter and/or information with the surrounding environment, and assume that the systems contain components and constraints which are defined prior to the organization itself (Prokopenko et al., 2009). Camazine et al. (2001) offered the following definition in the context of pattern formation in biological systems:

> "Self-organization is a process in which pattern at the global level of a system emerges solely from numerous interactions among the lower-level components of the system. Moreover, the rules specifying interactions among the system's components are executed using only local information, without reference to the global pattern."

Another definition is offered by Haken (2006) from a more generic perspective:

> "A system is self-organizing if it acquires a spatial, temporal, or functional structure without specific interference from the outside. By "specific" we mean that the structure or functioning is not impressed on the system but that the system is acted upon from the outside in a non-specific fashion. For instance, the fluid which forms hexagons is heated from below in an entirely uniform fashion and it acquires its specific structure by self-organization."

This physics-based view is related to the approach pioneered by Kauffman (2000) who suggested that the underlying principle of self-organization is the generation of constraints in the release of energy. According to this standpoint, the constrained release allows for such energy to be controlled and channeled to perform some useful work. This work in turn can be used to build better and more efficient constraints for the release of further energy and so on. The ability to constrain and control the release of energy may allow a system to produce behaviors which, although possible, would be extremely unlikely in its non-organized state (Kauffman, 2000; Prokopenko et al., 2009).

An interesting form of self-organization is stigmergy. Grassé (1959) introduced the term "stigmergy" ("previous work directs and triggers new building actions") to describe a decentralized pathway of information flow in social insects. Stigmergy is a mechanism of indirect coordination among agents acting in the environment, where local traces left in the environment by their decentralized actions stimulate the performance of subsequent actions, by the same or a different agent (which is exactly the case of pheromone-depositing ants). Thus, stigmergy allows the environment to structure itself through the activities: the state of the environment, and the current distribution of agents within it, determine how the environment and the distribution of agents will change in the future (Bonabeau et al., 1998). Emphasizing the role of constraints in controlling the release of energy within a self-organizing system, we point out that an optimal path formation may happen by chance even with a random exploration of the landscape, but is much more likely when stigmergy is present.

One of the modern research themes in complex systems is Guided Self-Organization (GSO). The main objective of GSO is to leverage the strengths of self-organization (such as simplicity of the local behaviors, parallelization, adaptability of the agents, robustness, resilience and scalability of the overall system), while still being able to direct the outcomes of the self-organizing process. In other words, GSO approaches differentiate between the concepts of "control" and "constraint": rather than trying to precisely control a transition towards the desirable outcomes, one puts in place specific constraints on the system dynamics in order to mediate agent behaviors, interactions and adaptations. Thermodynamically, a spontaneous increase in order within a self-organizing complex system must be offset by a production and export of entropy to the external environment. Thus, GSO attempts to harness the order-inducing potential of self-organization by guiding the system towards a desired regime or state, while "exporting" the entropy to the system's exterior.

Critical Dynamics

Self-organization, and complexity in general, is strongly related to critical phenomena: the spatiotemporal behaviour of dynamical systems at an order/disorder phase transition: the critical regime separating the two phases is often referred to as the "edge of chaos."

A system is said to exhibit the property of chaos if a slight change in the initial conditions results in large-scale but bounded differences in the result (in other words, the system is sensitive to initial conditions; such outcomes are often referred to as the butterfly effect). Importantly, there are transitions separating ordered and chaotic regimes, and by varying control parameters (for instance, the system composition and the strength of internal interactions) it is possible to trigger these phase transitions. Following Ginzburg-Landau theory of phase transitions developed in physics, Haken (2006) introduced order parameters in explaining structures that spontaneously self-organize in nature. In an ordered phase, the system becomes low-dimensional as some dominant variables "enslave" others, making the whole system act in synchrony (e.g., a laser: a beam of coherent light created out of the chaotic movement of particles).

Phase transitions are often related to symmetry breaking. An example is a ferromagnetic system undergoing a second-order phase transition: (i) in the high-temperature phase the system has no net magnetization, is "disordered" and has a complete rotational symmetry (isotropy); (ii) at low temperature, the system becomes "ordered," and the net magnetization defines a preferred direction in space (anisotropy), breaking rotational symmetry. The low-temperature ordered phase is therefore less symmetrical and can be fully described by an order parameter—the magnetization vector. In this example, the temperature is a control parameter. But in a large complex ecological system, temperature can also be an order parameter, summarizing the effect of the sun, air pressure, and other atmospheric variables.

A well-studied model in the field of complex systems—random Boolean networks, used to simulate Gene Regulatory Networks—also exhibits a phase transition between ordered and chaotic dynamics, separated by a critical regime. The nodes of a random Boolean network may approximate interconnected genes with binary states, which switch on and off dependent on the input signals received along the network links from the connected neighbors. The "logic" of switching the nodes states on and off mimics the process of gene expression, and one of the main questions is whether the overall network, starting from a particular state or responding to a local perturbation, settles into a stable configuration, or keeps changing. A fundamental result is that, at relatively low connectivity (i.e., a low average number of network links) or dynamic activity (i.e., an extremely biased probability of state changes to either zero or one), a perturbed network remains in an ordered stable phase. This phase is characterized by high regularity of states and strong convergence of similar global states in state space, providing an analogue of high stability of the genotype. Alternatively, at relatively high connectivity and/or activity, the network never settles and ends up in a chaotic phase, characterized by low regularity of states and divergence of similar global states: an analogue of high adaptability of the genotype. In the critical regime (the edge of chaos), there is a balance between stability and adaptability.

A generic measure that has been found useful in studies of critical dynamics in complex systems is Fisher information. It quantifies the amount of information in an observable variable about a control parameter, and thus estimates sensitivity of the observed variable to changes in this parameter. Thermodynamically, Fisher information is proportional to the gradient of the corresponding order parameter, diverging when the system undergoes a phase transition at a critical point. Calculating this measure requires only appropriately defined probability densities and so the method can be applied to a wide range of systems, especially those in which computation of the order parameter is problematic.

Critical regimes are typical in proximity of various tipping points, occurring when a small change (or a number of previously accumulated changes) triggers a strong or even catastrophic response, amplified by positive feedbacks (Scheffer et al., 2009), for example, tipping points in climate and ecosystems such as the Amazon rainforest "die-back" and El Niño/Southern Oscillation effect. An example of a positive feedback intensifying the effects of the initial perturbation is a loop moving from deforestation reducing regional precipitation to increasing risk of fires to extending forest die-back to causing droughts.

Even robust and homeostatic systems may not withstand pressures accumulated in the lead up to a tipping point. A transition beyond a tipping point may be irreversible, but if the system which has undergone the transition is adaptive, then it may recover, and the speed of the recovery is dependent on the system's resilience. Resilience, thus, is the capacity of systems to survive and adapt despite acute shocks and chronic stresses they experience—it captures the ability to pull together and bounce back after a crisis. Resilience is directly related to self-organization, reflecting the degree to which a complex adaptive system is capable of self-organization while absorbing recurrent disturbances such as hurricanes or floods and retaining essential structures, processes, and feedbacks (Adger et al., 2005).

Entropy and Information in Adaptation and Evolution

Complex systems can also be viewed as distributed information-processing systems, with information being a crucial currency for animals and species from both a behavioral and evolutionary perspective. Behaviourally, many decisions benefit from a reduction in uncertainty: a school of fish reshapes to evade a predator, slime mold parallelizes its search for food, animals optimize their assortative mating choices, and so on.

Shannon entropy is a measure of potential knowledge, or if applied to a sequence, a measure of how much information a sequence could hold. For example, as argued by Adami (2002), Shannon entropy may quantify our uncertainty about the genetic

identity of a randomly selected individual. Shannon information is a nonlinear form of correlation, with respect to the system that the information is about. Without such reference, it is only potential information (i.e., entropy).

Following information-theoretic interpretation of Adami (2002), adaptation may then be seen to increase mutual (Shannon) information between a system and its environment. From this standpoint, the variation decreases the amount of information encoded in the system, whereas the selection acts to increase the information. The information loss due to variation must be less than the increase in mutual information due to selection. Assuming that the generations are coupled by inheritance with variation under selective pressure, the adaptive process reduces to evolution. In general, the evolution should increase the amount of information which a population (more precisely, its genome) contains about its niche, measured by "physical complexity" (Adami, 2002).

A similar idea about the relevant biological information is expressed by Haken (2006): the information "acquires its meaning only with respect to the surroundings and, in a way, with respect to its value for the survival of the whole species." Haken (2006) concludes that

> "by the interplay of mutation and selection new types of molecules and their corresponding phenotypes are then generated and in this way we observe the creation of new information. But whether this information is useful or not can be checked upon only by the interaction of the particular species with its environment."

In general, the increase in organization can be measured quantitatively as a decrease of Shannon entropy, exported by the self-organizing system into its surroundings (sometimes referred to as negentropy: the entropy that the system dissipates to keep its own entropy low). The systems which continuously export entropy in order to maintain their organization are called dissipative structures.

A recently developed framework of information dynamics systematically quantifies information processing in complex systems (Lizier et al., 2014), relating it to critical phenomena and phase transitions. This methodology suggests that discovering and quantifying information flows in complex systems could be a key to guiding the system dynamics towards desirable outcomes. Importantly, rather than trying to quantify the level of system's complexity with a single general-purpose measure, the information dynamics framework includes several dimensions, capturing different aspects of distributed processing within the system: memory, communications (interactions) and modifications. Memory refers to the storage of information by some agent(s) and can affect the future computation. Communication is understood as the transfer of information between one agent and another. Modification is the fusion of stored and/or transferred information into a new form. Within the space formed by these basic axes, the complexity of different systems may be measured and compared in terms of their specific components.

These three information-processing components originate in the field of distributed computation, but have been identified in many complex systems, ranging from natural to technological, where a system is seen as "computing" when it updates its states while moving along a global dynamic trajectory. For example, "ecological memory" can be seen in the biological legacies persisting after tipping points, various crises and disturbances, through mobile species and propagules that colonize and reorganize disturbed sites and refuges (Adger et al., 2005). The aspect of "ecological interactions" between species reflects diverse dependencies in ecological communities and food webs, exemplified by oppositional relationships such as predation and competition, as well as symbiotic relationships such as mutualism. Finally, "ecological modifications" are immediately evident in agricultural expansions and intensifications altering the quantity and quality of global water flows, deforestations or plant successions replacing forests with tundra, and ecological niche constructions, when organisms alter either their own environment or that of other species.

The concept of information modification is strongly related to the notion of synergy. Understanding and quantifying synergy, as well as modeling of critical phenomena, require a systematic consideration of system dynamics from a thermodynamic perspective which elucidates the analysis of phase transitions and synergistic interactions. Information thermodynamics is an emergent field of research attempting to treat dynamics of complex systems, while measuring and contrasting the entropic and energetic costs of manipulating information.

Complex Networks

Sometimes, a complex system is modeled as a network where the nodes represent the components and the links their interactions. Network topology is the specific type of an arrangement of the nodes and edges, for example, a star topology, in which each node (vertex) is connected to a central hub with a node-to-node link (edge), or a random graph topology, which is generated by a probability distribution, so that a possible link occurs independently with a given probability. Network representations create the possibility of studying phenomena at multiple scales under the same formalism, relating topological and dynamics properties.

In models of complex networks it is possible to study various propagation, diffusion or contagion processes, when a single event or disruption triggers a cascade of failures. For example, the emergence of a new pathogen in a remote village can give rise to a devastating global epidemic; the introduction of an exotic new species can eventually contribute to a chain of food-web disruptions and wide ecosystem collapses.

In complex networks, the ability to function effectively arises not from individual network nodes, but rather from the way they interact. This means that a complex network, like any complex system, cannot be completely understood by examining each of its parts in isolation. Specifically, for complex networks, the topology and function of such networks are tightly coupled (Newman,

2003): the function is constrained by the structure and the structure evolves due to function. Research into the structure, function, evolution, and design of complex networks has wide-ranging applications, from epidemiological modeling to understanding of food webs.

In a food-web network the nodes represent species in an ecosystem and a directed link indicates that one species preys on the other. This implicitly captures the flow of energy or carbon flow within the system, in the direction opposite to predation. As the structure of a food web typically affects the population dynamics, considering a network representation enhances the canonical predator–prey models. One complexity measure which has been found to be particularly useful in studies of food webs and their stability is "connectance": the fraction of all possible links that are realized in a network.

Complex networks is a vigorous field of research, comprising studies of network properties (such as the small-world effect, scale-free distributions, centrality); models of network growth (for instance, preferential attachment giving rise to scale-free topologies); mixing patterns such as assortativity (exemplified by the tendency where highly connected nodes are more likely to make links with other highly connected links representing assortative mating choices); community structure and modularity (for instance, communities in food webs might reflect subsystems within ecosystems); dynamic processes taking place on networks (e.g., epidemiological processes, spread of cascading failures or food-web disruptions, percolation, reaction-diffusion), network motifs (such as a diamond food-web motif with a predator consuming two prey species which in turn compete for a shared resource), and so on.

In random and small-world Boolean networks, the ordered phase of dynamics is typically dominated by information storage (representing "memory"), while the chaotic phase is dominated by information transfer (which includes both the "interaction" and "modification" components of distributed computation). Interestingly, the small-world topology allows the information dynamics to attain a balance, with both memory and information transfer approaching their maxima near the small-world transition between ordered and random graphs.

A very-well studied topology is scale-free networks, in which a relatively small number of nodes are connected to a tremendous number of neighbors, while the vast majority of other nodes have only a very few connections (formally, the distribution of connections follows a power law). Importantly, this feature is preserved at many levels of magnification, as zooming into any part of the network does not change the profile of the observed distribution of connections. Scale-free networks are robust to random node failures but become fragmented after coordinated attacks targeting the nodes with the highest number of neighbors (the hubs).

Food webs are not generally classified as small-world or scale-free networks. Nevertheless, food-web topology is consistent with some patterns found within those networks classes, and such patterns can be used to explore and predict functional responses of ecosystems to structural changes (Dunne et al., 2002).

Conclusion: Complex Versus Complicated

Complex systems should not be confused with complicated systems which may also contain a large number of components and conditional interactions. The two terms share a common Latin origin: complexus originates from complectⷭ ("to entwine or encircle"), derived in turn from com- ("together") and plectere ("to weave"), while complicātus is a form of complicāre ("to fold together') which augments com- ("together') with plecāre ("to fold'). So the etymological difference reflects the distinction between (flexibly) weaving and (rigidly) folding some parts together.

This difference becomes even quite apparent when one compares (complex) natural organisms which have evolved their adaptive and self-organizing responses with (complicated) engineered machines which conform to precise blueprints and operate under predefined protocols. The machines, and engineered structures in general, are designed and assembled to repeatedly perform within some well-defined cycles, by exploiting their design and operational constraints which are not generated anew but only reset, by a precise channeling of the external energy. On the contrary, the stability and resilience of biological and ecological systems are explained by their capacity to self-organize and homeostatically re-establish itself, while re-using the external energy and information in composing new internal constraints. These two approaches deal with the question of robustness in significantly different ways: (i) traditionally engineered systems are well-tested and validated for a wide range of known conditions, but may crumble at an encounter with a new situation or when an individual component fails, (ii) complex adaptive systems are able to re-combine the distributed information-processing behaviors of their constituent agents in innovating new solutions, often even beyond tipping points. Nevertheless, when faced with accumulated and chronic adverse pressures, even an adaptive system may undergo a shift to a post-critical phase incompatible with its primary purpose, highlighting the need for more accurate and predictive analysis and modeling of complex systems. Understanding and managing complexity at multiple scales improves our ability to maintain and restore ecosystems with timely and precise interventions.

Cybernetics

AM Makarieva, Petersburg Nuclear Physics Institute, St. Petersburg, Russia

Introduction

The word 'cybernetics' originates from the Greek word for 'steersman'. Cybernetics can be broadly defined as a field of knowledge seeking to offer a general mathematical approach to the study of complex systems irrespective of their nature (e.g., artificial or living). In this context, under complex systems, one understands the systems composed of elements exchanging energy, matter, and information with one another and with the environment, that is, systems where various control (feedback) processes operate (Fig. 1).

To give a simple example, stability of a system quantity x over time t can be described as $dx/dt = -kx$, where parameter k can, in general, depend on both x and t. If the value of k is positive, any disturbance $\Delta x = x - x_0$ of the initial value x_0 of this parameter will exponentially diminish with time, returning the system to the initial state, $\Delta x = \exp(-kt)$. At negative k, any slight perturbation will exponentially amplify, destabilizing the system. Such formal description does not depend on the nature of either parameter x or the positive or negative feedback processes in the system that are responsible, respectively, for the system's instability or stability (homeostasis).

Established in the 1940s and the 1950s with works of Norbert Wiener, William Ashby, and others, the notion of cybernetics became well-known in the 1970s and the 1980s, the time marked with intensive research and large expectations associated with the idea of creating artificial intelligence. Cybernetics studies in life sciences can be exemplified by the models of organic evolution like the Eigen's hypercycle; there is much modeling research in the fields of neurophysiology and sociobiology.

While generality of a scientific approach is obviously an important scientific merit, the overall success of the approach is determined by its concrete applications within particular fields. Ecology, the science of interactions among organisms and between the organisms and their environment features high complexity and has the problem of homeostasis versus change at its very heart. To apply the cybernetics approach in ecology, it is important to establish the correspondence between the major notions of cybernetics like information exchange, communication, control processes, etc., and measurable characteristics of the organism, ecosystem, and biosphere. This article describes the essential aspects of ecological cybernetics. Among the subsequent sections, the first section discusses the origin of information fluxes in the biosphere. In the second section, information stores and exchange fluxes within the biosphere, on the one hand, and within the modern civilization, on the other hand, are described and compared. The third section discusses control processes operating at the biota–environment interface, which allow life to persist on Earth for practically infinite time periods of the order of billion years, thus maintaining homeostasis of the living matter.

Solar Energy and Information

According to the second law of thermodynamics, closed systems ultimately reach the state of maximum entropy. The apparent high degree of orderliness of ecological systems and the persistence of this orderliness through time indicates that there is a continuous external input of order (information) into ecological systems. The source of this information is the solar energy, the primary source of energy for life on Earth. Both solar radiation and thermal radiation of Earth consist of particles – photons. Mean energy of one photon is proportional to absolute temperature measured in degrees kelvin. Absolute temperature of Sun is about $T_S = 6000$ K. Absolute global mean surface temperature of Earth is about $T_E = 288$ K (i.e., about 15 °C). Mean energy of one solar photon is about $T_S/T_E = 6000/288 \approx 20$ times larger than the mean energy of one thermal photon of Earth. According to the law of energy conservation, the cumulative energy of all solar photons coming to Earth is equal to the cumulative energy of thermal photons emitted by the Earth into space. It means that the number of thermal photons emitted by Earth into space is about 20 times larger than the number of solar photons reaching Earth's surface. Consequently, one solar photon decays on average into 20 thermal photons. Decay of solar photons gives rise to all ordered, information-rich processes on Earth, of which life is most powerful (Table 1).

Information capacity of a system is characterized by the available number N of memory cells. If a cell's memory can be characterized by only two possible values of a certain variable, the total number of possible combinations of these values in all memory cells is 2^N. The system possesses the maximum possible amount of information equal to N bits when the values of the measured variable are defined in all N memory cells. If states of N_1 cells remain unknown, the amount of information reduces to $N - N_1$. If the measured variable remains undefined in all memory cells, the information becomes zero while the entropy of the system reaches its maximum.

Solar photons interact with molecules of vegetation covering the Earth's surface. These molecules can be viewed as elementary memory cells of the ecosystem. Solar photons can excite molecules, that is, impart a certain amount of energy to

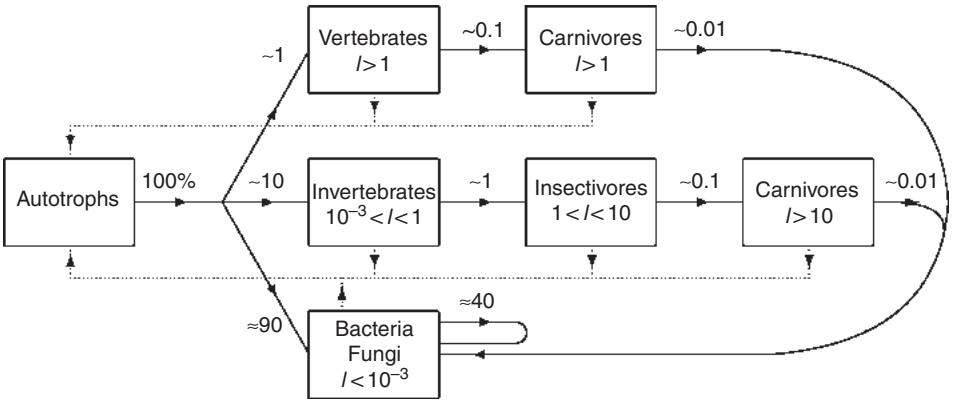

Fig. 1 Natural terrestrial ecosystem represented as a cybernetic system. The division into blocks is made on the basis of the trophic level and body size l (cm) of the organisms. Feedback loops between the system's blocks are exemplified by the fluxes of organic carbon (solid arrows) coming in and out of each block and fluxes of inorganic carbon (dotted arrows) coming out of the heterotrophic blocks into the autotrophic one. For heterotrophic blocks $dM/dt = P_{in} - P_{out} - R$, where M is the store of organic carbon in live biomass within the block, P_{in} is the incoming organic carbon, P_{out} is the organic carbon produced within the block and transferred to the next trophic level, and R is respiration (decomposition of organic carbon). 'Carnivores' indicate vertebrate-feeding heterotrophs, 'insectivores' indicate invertebrate-feeding heterotrophs. Numbers near solid arrows indicate the flux magnitude in terms of the percentage of ecosystem net primary productivity (100%). Table 1 Solar power and some routes of its dissipation on Earth

Power source/sink	*Power*	
	10^{12} W	*Relative to the solar power*
Total solar power coming from Sun to Earth	1.7×10^5	1.0
Physical processes		
Wind power	2×10^3	10^{-2}
Oceanic waves	10^3	6×10^{-3}
Natural biota		
Transpiration	3×10^3	2×10^{-2}
Photosynthesis	10^2	6×10^{-4}
Modern civilization		
Energy consumption	10	6×10^{-5}
Consumption of the net primary production of the biosphere	9	6×10^{-5}

molecules and increase their energy above the average thermal level. A good approximation is to assume that molecular memory cells are characterized by two states – excited (a definite state) and nonexcited (indefinite state) compared to the average chaotic thermal level. During the process of decay, solar photons are able to excite molecules until their own energy becomes equal to the average energy of thermal photons of the Earth's surface. Each solar photon possesses an amount of energy equal to that of about 20 thermal photons of Earth. Consequently, one solar photon can excite about 20 molecules, that is,. impart information to about 20 molecular memory cells. Such consideration makes it possible to estimate the amount of information (in bit s^{-1}) coming from Sun to Earth per unit time. It is roughly equal to the number of thermal photons emitted from the Earth to space, because each thermal photon is emitted from an excited molecule, which represents a memory cell containing one bit of information. The number of Earth's thermal photons emitted to space in a unit of time is equal to the power Q ($Q \approx 2 \times 10^{17}$ W) of solar radiation reaching the Earth divided by the energy ε of one thermal photon, which is determined by the Earth's temperature T_E, $\varepsilon = k_B T_E$, where $T_E \approx 288$ K, k_B is Boltzmann constant, which is proportional to the reverse Avogadro number ($k_B = 1.4 \times 10^{-23}$ J K^{-1} molecule^{-1}). As far as one molecule represents a memory cell with two possible states, dimension molecule^{-1} in Boltzmann constant corresponds to bit^{-1}. The information flux F coming from Sun to Earth is $F = Q/(k_B T_E) \approx 10^{38}$ bit s^{-1}.

If one solar photon possesses energy equal to that of $T_S/T_E \approx 20$ thermal photons, the maximum number of molecules it can excite is $T_S/T_E - 1 \approx 19$, because after 19 acts of excitation its energy becomes equal to that of one thermal photon. After that it cannot impart any additional energy to molecules, and, therefore, cannot excite them. So, only $(T_S/T_E - 1)/(T_S/T_E) \times 100\% = (T_S - T_E)/T_S \times 100\% \approx 95\%$ of Earth's thermal photons come from excited molecules and characterize information

flux coming from Sun to Earth. The ratio $(T_S - T_E)/T_S$ describes the well-known Carnot efficiency of the solar radiation on Earth. If the Sun's temperature were equal to that of Earth, solar photons would have the same energy as thermal photons of Earth and could not excite any molecules on the Earth's surface. In such a case the information flux from Sun to Earth would be equal to zero.

Stores and Fluxes of Information in the Natural Biota and Civilization

Stores of Information

The maximum rate of information processing by the human brain in about 10 bit s^{-1}. Information is acquired most actively during the first 20 years of life of the individual, that is, during about 6×10^8 s. The amount of information acquired later in life does not change the order of magnitude of the total store. The amount of information stored in memory of an adult human can be estimated at about 6×10^9 bit.

An upper estimate of the total amount of cultural information of the modern civilization can be obtained multiplying the current population number of Earth ($\sim 6 \times 10^9$ people) by the average individual memory store of information ($\sim 6 \times 10^9$ bit), which gives a value of about 10^{19} bit. This is a gross overestimate of the real value, because most part of memory information is the same in all contemporary people. The unique nonoverlapping information of the civilization is stored in memories of specialists (professionals) – scientists, craftsmen, writers, musicians, artists. Working specialists constitute not more than about 10% of the whole population (multiplier 10^{-1}). Each field of knowledge can normally exist with no less than 100 specialists working in this field and sharing the same memory information (multiplier 10^{-2}). The real value of information store of the modern civilization can be obtained multiplying the upper estimate by 10^{-3}, which gives about 10^{16} bit.

Genetic information of most species of the biosphere is written in polymer double-strand molecules of DNA, which represent various sequences of the existing four different monomer units – nucleotide base pairs (bp). Human genome contains $G = 3 \times 10^9$ bp, that is, 3×10^9 memory cells each of which can be characterized by one of the four different values. The store of genetic information in the human genome is equal to $\log_2 4^G = 2G = 6 \times 10^9$ bit. The stores of genetic and nongenetic (memory) information in humans are of the same order of magnitude.

To quantify the store of the genetic information of the natural biota as a whole it is necessary to multiply the information content of an average genome by the total number of species in the biosphere, which is equal to about 10^7 species. The average genome size can be taken equal to 10^9 bp, which is the average genome size of insects that constitute the majority of species in the biosphere. The total amount of genetic information stored in the natural biota is of the order of 10^{16} bit and coincides in the order of magnitude with the information store of the modern civilization (Fig. 2a).

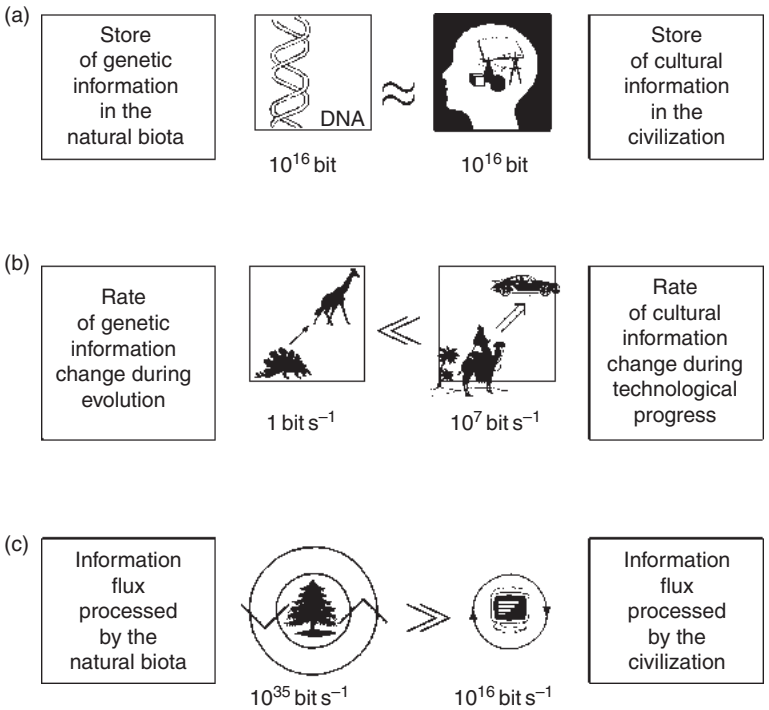

Fig. 2 Stores of information (a), rates of their change (b), and information exchange fluxes (c) in the natural biota and modern civilization. Reproduced from Gorshkov VG, Gorshkov VV, and Makarieva AM (2000) *Biotic Regulation of the Environment: Key Issue of Global Change*. London: Springer-Praxis, with kind permission from Springer Science and Business Media.

The amount of information that can be stored in a modern PC is of the order of 10^{11} bit, that is, it greatly exceeds the amounts of genetic and individual memory information of one person. The cumulative memory capacity of modern computer technologies is large enough to store both the cultural information of the modern civilization and the genetic information of the natural biota.

Fluxes of Information Exchange

Species composition of the natural biota changes with evolutionary transitions of old species to new related ones. The genetic information of the biosphere changes in the course of evolution. Closely related species differ from each other in about 1% of their genetic information. The average species life span is about 3 million years. Thus, 1% of the genetic information changes in a single act of speciation approximately every 3×10^6 years. A complete turnover of the genetic information of the natural biota, 10^{16} bit (Fig. 2a), takes about 3×10^8 years, that is, about 10^{16} s. The rate of evolution (i.e., the rate of change of genetic information of the natural biota in the course of evolution) is approximately equal to 10^{16} bit/10^{16} s = 1 bit s^{-1} (Fig. 2b). This extremely low rate of information change has been sufficient to ensure sustainable development of the biosphere, that is, to support evolution of the natural biota in such a manner that the latter has been able to compensate directional adverse environmental changes of cosmic and geophysical nature during the whole period of life existence, that is, during nearly 4 billion years.

The rate of information change during technological progress of the civilization is determined by the ability of people to generate and assimilate new cultural information. The present-day population of Earth can assimilate no more than $6 \times 10^9 \times 10$ bit $s^{-1} = 6 \times 10^{10}$ bit s^{-1}. The present-day rate of technological progress depends on the average time of renewal of modern technological systems, which is of the order of 10 years, that is, about 3×10^8 s. Given that the store of information of the modern civilization is of the order of 10^{16} bit, the modern rate of civilization progress is about 10^{16} bit/3×10^8 s $\approx 3 \times 10^7$ bit s^{-1}. (This estimate is obtained under the reasonable assumption that the most part of cultural information of the modern civilization is represented by information stored in memory of specialists dealing with modern technologies.) The ratio of the amount of newly generated information to the amount of assimilated information for modern people does not exceed $3 \times 10^7/6 \times 10^{10} \approx 10^{-3}$.

The information rate of the progress of the modern civilization, 3×10^7 bit s^{-1}, exceeds the information rate of evolution, 1 bit s^{-1}, by more than 7 orders of magnitude (Fig. 2b). This provides an explanation for the unprecedented (as compared to all other extant and extinct species) potential of *Homo sapiens* to destroy the natural environment.

An estimate of the total information flux going through all modern computers can be obtained multiplying the average information flux in one PC, $\sim 10^8$ bit s^{-1}, by the total number of people owning computers. Assuming that at present there is one PC for every hundred of people we obtain that the total flux of information in computers of the modern civilization is of the order of 10^{16} bit s^{-1}. This figure will hardly ever increase by more than 6 orders of magnitude (by providing computers for all people on the planet and ensuring a 4-orders-of-magnitude increase of information flux in each PC), that is, up to 10^{22} bit s^{-1}.

Even the present-day global computer information flux, 10^{16} bit s^{-1}, exceeds the assimilation capacity of the brain of modern people, 10^{10} bit s^{-1}, by a factor of million. Computers work on the basis of programs designed by people and speed up significantly the processing of information. But this only makes sense while people are still able to check and control the outgoing flux of information. All the information that is generated by computers and other mass-media devices (TV, cinema, video, theatre, music, etc.) above that threshold represents informational pollution of the environment. Informational pollution affects all the five organs of sense of people, and, among various types of pollution, presents the most dangerous threat to the mental health of humans.

In humans, metabolic power of existence in adults is equal to $q = 140$ W. The body temperature of humans is approximately equal to $T_b \approx 37\ ^\circ C = 310$ K. The average thermal energy of molecules in the human body is equal to $k_B T_b$, where k_B is the Boltzmann constant ($k_B = 1.4 \times 10^{23}$ J K^{-1}). Thus, $k_B T_b$ gives the order of the average amount of energy necessary to excite a molecule, that is, the additional energy committed to a molecule as compared to the average thermal level. Assuming that one molecule corresponds to one memory cell with two possible states (excited and nonexcited), that is, 1 molecule $\approx$ 1 bit, we obtain that the information flux going through all living cells of the human body is equal to $q/k_B T_b \approx 3 \times 10^{22}$ bit s^{-1}. This value exceeds the asymptotic information power of possible future computers and by more than 12 orders of magnitude exceeds the assimilation capacity of the modern humanity.

Human body contains about 10^{14} living cells. Thus, every living cell processes on average about $3 \times 10^{22}/10^{14} \approx 10^8$ bit s^{-1}, which is equal to information flux realized in a modern PC. The biosphere contains about 10^{28} living cells. Thus, the natural biota of Earth as a whole processes about $10^8 \times 10^{27} = 10^{35}$ bit s^{-1}, which is about 20 orders of magnitude more than the information flux of all computers of the modern civilization. Unlike in computers, molecular memory cells of living cells are directly coupled with the environment. Thus, the whole flux of information processed by the biota is used for correct interaction with the environment in control processes aimed at environmental and ecological homeostasis.

Energy consumption of the modern humankind is equal to 10^{13} W, which is only an order of magnitude less than the photosynthetic power of the natural biota (Table 1). But, due to the huge difference in the rates of information processing between the natural biota and civilization, any kind of anthropogenic energy use is inevitably characterized by a remarkably low efficiency, that is, low information content of most processes generated by the humankind with help of energy use.

The humankind spends a large portion of its energy on transport, that is, moving macroscopic objects – cars, trains, people, etc. Motion of a macroscopic object is totally determined by only four variables – its mass and three coordinates of the velocity vector. Motion of macroscopic objects can be fully described by a very small amount of information coded in corresponding macroscopic

memory cells. It is in principle possible to efficiently convert the kinetic energy of moving macroscopic objects to gravitational or electric energy that could be further used for generation of complex correlated molecular processes similar to those taking place in a living cell. But the kinetic energy of transported objects does not generate any ordered, information-rich processes. It is spent on friction, and finally dissipates converting to heat.

Macroscopic motion can be found in natural ecosystems as well (e.g., locomotive animals). However, in stable ecosystems, the amount of energy allocated by the natural biota to this less-efficient channel of energy use does not exceed 1% of the total biotic energy consumption. Meanwhile humans spend on transport more than one-third of the consumed energy. The remaining part of anthropogenically utilized energy is spent even more wastefully with respect to the information content of the generated processes (e.g., heating of buildings).

The total amount of energy consumed by the humankind (**Table 1**) does not characterize the amount of work that can be done by humans in order to stabilize the environment. Of critical importance is the total flux of information that can be processed by the modern civilization. And, as far as information fluxes are concerned, the modern civilization is inferior to the natural biota (**Fig. 2c**), which uses this flux to maintain ecological and environmental homeostasis.

Control Processes in Ecological Systems

Life is based on biochemical reactions that convert inorganic substances stored in the environment into organic ones and back. The existing power of the biochemical fluxes of synthesis and decomposition of organic substances is such that, were not these feedback processes rigidly correlated, the environment could change completely in time periods of several tens of years, reaching a state where life would be impossible.

For example, the global amount of atmospheric CO_2 is of the order of $M^- \sim 10^3$ Gt C (1 Gt$=10^9$ t). The mean global rates of biochemical synthesis P^+ and decomposition P^- are of the order of $P^+ \sim P^- \sim 10^2$Gt C yr^{-1}. If the rates of synthesis and decomposition were not correlated, that is, if they coincided by the order of magnitude only, their relative difference would be of the order of unity, $|P^+ - P^-|/P^\pm \sim 1$. In such a case, if synthesis exceeded decomposition, $P^+ > P^-$, the global biota would use up the entire store of atmospheric carbon on a timescale of $M^-/P^- \sim 10$ years. This would render further photosynthesis and existence of life impossible. The amount of organic carbon in the biosphere (living biomass, humus, and oceanic dissolved organic carbon) is of the same order of magnitude, $M^+ \sim 10^3$Gt C. If the rate of decomposition exceeded the rate of synthesis, the global biota would be able to destroy itself completely in equally short periods of time.

The fluxes of synthesis and decomposition cannot be correlated with each other directly. Synthesis and decomposition of organic matter represent independent biochemical processes that are generally performed by different species under different environmental conditions (temperature, humidity, etc.). While primary productivity is limited by the incoming solar radiation, there are no physical limitations on the rate of decomposition, since the latter is ultimately dictated by the population numbers of heterotrophic organisms. Characteristic ecosystem values of P^+ and P^- are determined by the individual design of every species, population abundance, and overall numbers of autotrophic and heterotrophic species inhabiting Earth. The values of P^+ and P^- cannot coincide with an infinite precision *a priori*.

For example, even if the mean global rates of synthesis and decomposition coincided, say, with a high accuracy of 1%, $\alpha \equiv |P^+ - P^-|/P^+ \sim 0.01$, such a biota would completely destroy its environment (or self-destroy) in $M^\pm/|P^+ - P^-| = M^\pm/(\alpha P^+) \sim 10^3$ years, that is, nearly instantaneously on a geological scale. The life span of the biota is short for any realistic accuracy of the coincidence of P^+ and P^-. To extend the biotic life span to the documented several billion years of life existence, $T \sim 10^9$ years, one has to demand that the living organisms and their ecological communities are designed such that the mean rates of synthesis and decomposition performed by them coincide to the accuracy of $M^\pm/(p^+T) \sim 10^{-8}$, which is improbable.

Correlation of the ecological fluxes of synthesis and decomposition of the organic matter is achieved indirectly, via continuous sensing of information about the current state of the environment that is performed by living organisms. The biota reacts to any environmental change as soon as its relative magnitude reaches some critical value, biotic sensitivity ε_b. As long as the magnitude of the environmental change remains lower than biotic sensitivity, synthesis and decomposition of organic matter by the biota may proceed in a noncorrelated manner at different rates. As soon as some environmental parameter changes by ε_b, the biota initiates compensating negative feedback processes and keeps them going until the disturbance is diminished to a level below ε_b, when the biota no longer notices it. The optimal state to which the ecosystem ultimately returns (the state of ecological homeostasis) is thus defined to an accuracy of ε_b. For example, if the amount of inorganic carbon in the atmosphere changes by $\varepsilon_b \sim 1\%$ (e.g., increases), the biota can enhance the rate of biochemical synthesis (that takes away CO_2 from the atmosphere) or reduce the rate of biochemical decomposition (that would further add to the atmospheric CO_2 amount) until the perturbed concentration relaxes to its optimal value. The same principle can be used to control temperature, humidity, and all other environmental parameters.

The huge information fluxes processed by the natural biota (**Fig. 2c**) are necessary for sensing the environment, reading the data about its state, and ensuring regulatory ecological processes aimed at compensation of possible environmental disturbances. This biotic regulation of the environment is equivalent to an operating system where the characteristic rate of information processing exceeds the maximum possible rate of automatic control provided by all computers of the modern civilization by 20 orders of magnitude. Biotic regulation is based on genetic programs of biological species of the biosphere. It can be viewed as an automatically controlled operating system where the program of automatic control has been tested for reliability in an experiment lasting for several billion of years (during the whole period of life existence).

The relative degree of unsteadiness in the work of a computer is defined as the ratio of the rate of human-induced changes in the computer program to the total flux of information processed by the computer. The relative unsteadiness of the regulatory program of the natural biota is fantastically low, 1 bit $s^{-1}/10^{35}$ bit $s^{-1} = 10^{-35}$. (Rate of program change corresponds to the rate of information change in the course of evolution, 1 bit s^{-1}. The total information flux processed by the natural biota is equal to 10^{35} bit s^{-1}). It means that each working regulatory program is maintained by the natural biota in a steady state for the maximum possible periods of time.

Genetic information of the natural biota changes completely every 3×10^8 years. Thus, during the whole period of life existence (3.8×10^9 years) there were no more than 12 completely different programs of biotic regulation of the environment. A working program of biotic regulation is presumably unique for each particular epoch. Evolution of the biotic regulatory program is possible due to acting geophysical and cosmic processes; that is, directional changes in parameters that cannot in principle be controlled by biota (e.g., solar activity) may lead to a situation when the old regulatory program is no longer the most effective one. As a result, there opens a possibility for a new more effective regulatory program of the biota to establish in the result of genetic modifications (i.e., appearance of new species) in the old program. New regulatory programs appearing in the course of evolution are exposed to a thorough experimental testing.

The humankind is unable to create a technological system equivalent to the natural biota, where each micron of the Earth's surface is controlled by dozens of independently functioning unicellular and multicellular organisms, each living cell processing an information flux similar to that of a modern PC. The genetic program of the natural biota cannot be substituted by any technological program of automatic control (even if this technological program is characterized by fluxes of energy and information similar to those in the natural biota), because search for appropriate technological decisions and their testing is performed by human beings and can take billions of years. Technological solutions of ecological problems can be only successful on a local scale. Globally, the only promising strategy for the modern humankind is therefore strategy of preservation of the remaining natural biota and gradual restoration of its global regulatory potential.

Ecological Data Archiving and Sharing

William K Michener, University of New Mexico, Albuquerque, NM, United States

Glossary

Archive A collection of data and information that is permanently stored in a data repository; also can be used as a verb to represent the process of preparing and storing data and information for the long-term in a repository.

Data curation The management, organization, quality checking and preservation of data.

Data life cycle The sequence of stages that data undergo in a research project from planning, through acquisition, quality assurance and quality control, documentation, analysis and visualization, and preservation and dissemination.

Data repository A location for long-term storage of data and metadata.

Data sharing The process of making data available for use by others.

Digital object identifier (DOI) A persistent identifier used to uniquely identify objects such as data sets or data packages (e.g., data and metadata).

Meta-analysis Combining the results of many research studies using statistical approaches; often used in synthesis efforts to reach broader generalizations.

Metadata Information about data that enables discovery, interpretation and use of the data (e.g., Who collected the data and how can one access and use the data?, Why were the data collected?, How, when and where were the data collected?).

Open science An emerging movement designed to make science (and data) more broadly accessible, transparent and reproducible.

Reproducibility The capability to independently reproduce one's own work or that of another researcher.

Workflow The sequence of tasks or operations followed in an analytical program including reading, processing, and visualizing data.

Introduction

Data sharing refers to the act of making data available for use by others. Data may be shared in many different ways. One mechanism is to physically copy and transfer data from the creator to others upon request. This transfer may be done via various media including paper copies, floppy disks, tapes, and hard drive(s)—an approach that remains necessary for transferring very large volumes of data. Another mechanism that is frequently used today is to email data files or upload data to a data or file-sharing service and provide a link so that others may download the data. Both mechanisms require the active and continual involvement of the data creator.

Increasingly, data creators voluntarily or are required by funders and journals to upload and share their data via a data repository. In this case, the data contributor initially prepares and submits the data and accompanying documentation (or metadata) to a data repository that may reformat, organize, preserve and advertise the existence of the data. Once the data are submitted by the contributor and accepted by the data repository, then the data repository, alleviating the need for further engagement by the contributing researcher, supports subsequent requests for data.

Data repositories are also often referred to as data centers or data archives and they may be associated with funding agencies, journals, professional societies, universities and other research, governmental and non-governmental organizations. Their role in preserving and sharing data is discussed further below.

Data Sharing: Perceived Impediments and Benefits

Researchers perceive that there are both impediments to and benefits derived from sharing data (Michener, 2015a; Tenopir *et al.*, 2011, 2015). Commonly expressed barriers to data sharing by data creators include concerns that potential new discoveries based on the data will be scooped by others and the belief that some individuals may misinterpret and misuse the data. Although such concerns are normally unfounded, there are real costs associated with organizing and preserving high quality data and metadata as well as making the data discoverable, interpretable and usable by others. Many researchers find data sharing to be challenging because of their lack of training in data management, absence of institutional support for data management, and paucity of user-friendly data management tools.

As data sharing has become more commonplace, attitudes and perceptions are changing and the majority of researchers—along with research sponsors and professional societies—recognize that there are many benefits that accrue from data that are preserved and shared. For example, the nature and pace of science expand and accelerate as researchers and others are able to discover and re-use relevant data, integrate data from different sources, and ask new questions. This benefit is particularly important as many of the

"grand challenges" addressed by ecologists require multi-, inter-, and trans-disciplinary perspectives as well as pertinent data that can support research efforts that bridge domain and disciplinary boundaries. Likewise, broad-scale studies, meta-analysis and major synthesis efforts normally depend upon the accessibility of large amounts of data from many different sources.

In addition to directly supporting science, data sharing can also benefit data creators and the public. Data creators (i.e., researchers) receive credit when their data are used and appropriately cited in new research studies. Further, studies have demonstrated that a researcher's publication citation rates increase when the underlying data are also made available. Public trust and the trust of research sponsors increase when findings can be reproduced and verified by others who access the data and run associated code and workflows.

Evolution of Data Sharing and Archiving Norms

Large national and multi-national efforts have played a major role in the evolution of data sharing and archiving practices (see Michener, 2015a). The International Biological Program (IBP) operated from 1964 through 1974 and was one of the first multi-national efforts to focus on ecosystem experiments, modeling and synthesis. IBP was viewed as a scientific success based on the significant publications and new theories that resulted. Although IBP drew attention to the need for cross-site data in synthesis and modeling studies, very little data from the program can be discovered today as there were no agreed upon standards for sharing, documenting and archiving data.

Attitudes towards data management and sharing changed with the emergence of the US Long-Term Ecological Research (LTER) Program in 1980 and the International LTER Program in 1993. Both Programs promoted data sharing and good data management practices and policies at the site and network levels. Consequently, the data underlying thousands of publications are preserved, well documented and available for further use.

More recently, ecological synthesis centers, ecological and ocean observatories, data aggregators such as the Global Biodiversity Information Facility, and community-based research networks and data federations have promulgated standardized data sharing and archiving policies and practices for the ecological and biodiversity sciences. Many research sponsors now require that researchers include a data management plan that describes how data will be managed, archived and shared as part of their research proposal. Furthermore, many leading professional societies and scientific journals associated with the ecological and evolutionary sciences established the Joint Data Archiving Policy (JDAP) in 2010 to ensure that data underpinning scientific publications are archived and shared (Box 1) (also see Whitlock, 2011). Most present-day ecologists and environmental scientists have an expectation that data will be preserved and shared including the data they have created (Tenopir *et al.*, 2015). Well-managed and shared data and code provide the foundation for open science where science is made more transparent and findings are reproducible (Hampton *et al.*, 2015).

Effective Practices for Sharing Data

Five practices can facilitate effective data sharing (Michener, 2015a). First, creating and following a data management plan from the inception of the research is recommended and, in many cases, required by research sponsors. A comprehensive data management plan covers all aspects of the data life cycle (**Fig. 1**) and fully describes how data will be treated and managed during the research as well as after the project has been completed (Michener, 2015b).

Second, researchers can promote the appropriate sharing, use, and attribution of their data by establishing or adopting and following reasonable data sharing and attribution policies. The Creative Commons Organization (CC) offers numerous free licenses to researchers that provide standardized ways for others to share and use their creative work based on conditions chosen by the researcher(s). CC conditions establish whether the data must be attributed to the originator, conditions under which the data can be shared with others, and whether the data can be modified or used for commercial purposes. Data archives also frequently have established guidelines for how data should be shared and cited. The Dryad Digital Repository, for example, provides recommendations for how to cite data products that are acquired from the repository (Box 2).

Third, data should be sufficiently described or documented so that others may discover, interpret and appropriately use the data. Such documentation is referred to as metadata and allows users to understand all facets of the data including who collected the data, as

Box 1 Joint Data Archiving Policy (created by a group of professional societies and publishers in 2010 and available through the Dryad Digital Repository)

"[Journal] requires, as a condition for publication, that data supporting the results in the paper should be archived in an appropriate public archive, such as [list of approved archives here]. Data are important products of the scientific enterprise, and they should be preserved and usable for decades in the future. Authors may elect to have the data publicly available at the time of publication, or, if the technology of the archive allows, may opt to embargo access to the data for a period up to a year after publication. Exceptions may be granted at the discretion of the editor, especially for sensitive information such as human subject data or the location of endangered species."

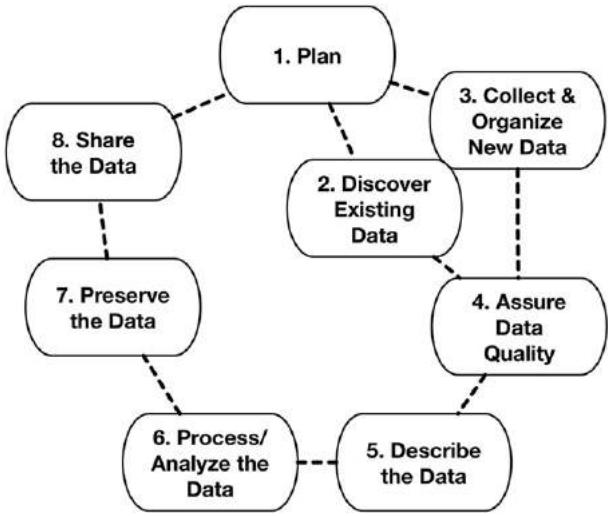

Fig. 1 A good data management plan encompasses the entire data life cycle: (1) starting with planning how the data will be managed, used and shared; (2) describing how existing data will be used and (3) how new data will be collected and organized; (4) summarizing the quality assurance and quality control procedures that will be employed to ensure data quality; (5) listing the metadata standards and supporting software tools that will be used to describe the data; (6) outlining anticipated data processing activities, algorithms and workflows that will be used to process and analyze the data; (7) describing how and where data will be preserved; and (8) providing plans for disseminating and sharing the data. Adapted from Michener, W. K. (2015b). Ten simple rules for creating a good data management plan. *PLoS Computational Biology* **11**, e1004525. https://doi.org/10.1371/journal.pcbi.1004525.

Box 2 Recommended guidelines for citing data that have been acquired from the Dryad Digital Repository

"How do I cite data from Dryad?

When citing data found in Dryad, **please cite both the original article as well as the Dryad data package**. It is recommended that the data package be cited **in the bibliography** of the original publication so that the link between the publication and data is indexed by third party services. Dryad provides a generic citation string that includes authors, year, title, repository name and the Digital Object Identifier (DOI) of the data package, for example

Westbrook JW, Kitajima K, Burleigh JG, Kress WJ, Erickson DL, Wright SJ (2011) Data from: What makes a leaf tough? Patterns of correlated evolution between leaf toughness traits and demographic rates among 197 shade-tolerant woody species in a neotropical forest. Dryad Digital Repository. https://doi.org/10.5061/dryad.8525

Dryad also assigns a DOI to each data file, which should only be used in contexts where the citation to the data package as a whole is already understood or would not be necessary (such as when referring to the specific file used as part of the methods section of an article).

If you are using a large number of data sources, it may be necessary to provide a list of the relevant data packages/files rather than citing each individually in the References. The list can then be submitted to Dryad so others who read your publication can locate all of the original data."

well as where, when, how and why it was collected (Michener *et al.*, 1997). Numerous metadata standards (Ecological Metadata Language (EML) for ecological and environmental data; Darwin Core for biodiversity data; Dublin Core for high-level descriptions of data and other resources; and ISO 19115 and others for geospatial data) and metadata management systems have been created to simplify the process of creating and managing standardized metadata (see Corti *et al.*, 2014; Goodman *et al.*, 2014; Hampton *et al.*, 2015; DataONE; Global Biodiversity Information Facility; and International Organization for Standardization for more information).

Fourth, effective sharing, interpretation and use of data typically require that the data and algorithms and workflows used to process the data be preserved and accessible to users. Hundreds of data repositories (also referred to as data archives and data centers) have been developed to serve different research communities. Repositories can be characterized by their hosting institution (e.g., university, funding agency, governmental or non-governmental organization, research network, etc.) and disciplinary focus (e.g., Arctic data, long-term ecological research data, or general purpose repository such as the Dryad Digital Repository). The Registry of Research Data Repositories provides a searchable catalog of hundreds of research data repositories worldwide ranging from general use to highly specialized disciplinary archives. Some repositories are free or inexpensive and offer a relatively small number of services, whereas others are fee-based and may offer numerous value-added services such as data curation, data quality

checks, peer-review, and advertising. Many repositories also provide access to metadata authoring tools and support the preservation of code, software tools, and associated resources in addition to the data and metadata.

Fifth, data products often are more broadly disseminated and cited when they are published as a data paper in a high-profile journal like *Scientific Data*. Several such data paper journals exist and, like traditional journal articles, the data papers normally undergo peer-review and are assigned a digital object identifier that allows them to be more easily cited and discovered. Another approach for promoting discovery and dissemination of data is to deposit the data and metadata in a trusted data repository that is associated with a data aggregation service or repository federation like DataONE, GBIF and VertNet. DataONE is one example of a federated repository network where researchers can discover ecological and other types of data associated with any one of a large number of member repositories by searching a single data portal. Likewise, VertNet and GBIF make it possible to discover vertebrate data and other species data that are associated with numerous museum and biological collections that are distributed worldwide.

Effective Practices for Creating Preservation-Ready Data

Data products or data packages (i.e., data and metadata) are ready to be submitted to an archive for long-term preservation once the data are logically and consistently organized, files and variables (i.e., file elements) are stable and appropriately named and defined, data quality is assured, and metadata is clear and complete. The following practices will help ensure that data are interpretable and usable by both the data creators and other researchers long after the data were collected and archived (from Olson and McCord, 2000; Cook *et al.*, 2001, 2017).

Logically and Consistently Organize the Data

It is good practice to organize similar types of measurements and observations in a single data set. For instance, a study of forest primary production may be most logically organized in three or more distinct data sets: (1) *tree data* including elements such as tree identification number, diameter (e.g., diameter at breast height), date and time the tree was measured, and other relevant data that are collected at some routine interval (e.g., monthly, seasonally, annually); (2) *site characteristics data* including location, forest or ecosystem type, geology, soils, and other relevant data that may only be collected once or at very infrequent intervals; and (3) *environmental data* including air and soil temperature, precipitation, soil moisture, and other relevant data that may be collected at relatively high frequency (e.g., minutes to hourly). In contrast, organizing all of the primary production data from this study in a single data set leads to many empty fields in the data as the three different types of data are collected and recorded at widely varying intervals with different instruments and, possibly, by different individuals. Likewise, parsing a data set like the *environmental data* set into daily or weekly data sets can lead to a large number of files—each of which must be individually named, quality assured, documented, managed, and preserved, thereby creating an undue management burden on the data creator and subsequent users.

Use Descriptive and Consistent File Names

Descriptive file names that follow consistent naming conventions enable data creators and users to more easily discover, organize and manage, analyze, and protect and preserve the data. For instance, organizing the *tree data* from the primary production example presented above into a series of files named "treedata_a.txt", "treedata_b.txt", …, "treedata_m.txt" provides little indication of what data are contained in the files other than the possible association with trees. Better file names uniquely and precisely relate to the file contents. For example, "Konza_trees_dbh_2014.csv" might reasonably be expected to include tree measurements (dbh—diameter at breast height) from the Konza site in 2014 that are stored in comma separated variable format. Assuming a consistent naming convention is followed, a file named "Konza_trees_dbh_2015.csv" would be expected to contain similar types of data from the following year (i.e., 2015).

Use Stable and Accessible File Formats

The long-term usability of data depends on storing the data in file formats that can be read long into the future. Companies fail; proprietary formats fall out of favor; and data, consequently, can become difficult or impossible to read and use. Appropriate file types include those that are non-proprietary and are neither encrypted or compressed. Several suitable file formats that are widely used by researchers are listed in Box 3.

Use Descriptive and Consistent Variable Names

Variable names such as "var_1", "var_2" through "var_n" may be understood initially by the data creator but convey no meaning to other potential users and typically become unusable even by the data creator as time passes and memory fails. It is good practice to use concise, but descriptive variable names such as "date_measured", "site", "tree_number", "scientific_name", "UTM_easting", "UTM_northing", "soil_moisture_10cm", and so on. If species names are variables, a common convention is to provide the first

Box 3 Stable file formats recommended by DataONE.

- ASCII formatted files are preferred for many types of data; tabular data should ideally be stored using ASCII comma-separated variables format (.csv).
- Geospatial data in raster format can be stored in a variety of formats including: GeoTIFF/TIFF; ASCII Grid; binary image files; NetCDF; and HDF or HDF-EOS.
- Image (vector) data can be stored as shapefiles, ENVI vector files (.evf), or ESRI Arc/Info export files (.e00).

Table 1 A data set or file in which each row represents a single observation

Location_name	*Date*	*Measurement*	*Value*	*Unit*
PawleysStation1	20170113	Max_air_temp	24	Deg_C
PawleysStation1	20170114	Max_air_temp	26	Deg_C
PawleysStation1	20170113	Precip_total	7	mm
PawleysStation1	20170114	Precip_total	0	mm

Table 2 A data set or file in which each row contains all measurements that were recorded at the same time

Location_name	*Date*	*Max_air_temp*	*Precip_total*
Units	YYYYMMDD	Deg_C	mm
PawleysStation1	20170113	24	7
PawleysStation1	20170114	26	0

letter of the genus, followed by an underscore and the complete species name (e.g., "C_florida" for *Cornus florida*); however, caution should be exercised since some abbreviated variable names could apply to two or more species.

Clearly Define Variables in the File and Their Associated Units

In addition to using descriptive variable names, it is good practice to also associate variables with their units directly in the file. This can easily be done in one of two ways. First, a data set or file can be constructed so that each row represents a single, well-defined observation such as in Table 1. In this case, each sensor measurement is clearly labeled and the values are associated with a specific measurement unit.

Another way to structure a data set is to include all measurements that are taken at the same time in the same row as in Table 2. This table contains the same information as Table 1, but is smaller in size since the information about measurement units is only listed once in the second row of header information. Such organization requires that the units of measurement be consistent throughout the file; thus, a new data file would need to be created if the measurement methods changed and observations were recorded in different units.

Assure the Quality of the Data

Errors of commission and omission are common in environmental and ecological data. For example, erroneous data can be introduced as a result of human transcription errors, sensor and instrument malfunction, power fluctuations, and environmental contamination (e.g., moisture, dust and temperature extremes that exceed operational guidelines). Such errors of commission can often be detected using graphical and visualization approaches (e.g., X-Y scatterplots, time series analysis, plotting sampling locations, and quality control charts), range checks (e.g., comparing new measurements to the range of values previously recorded and flagging those that exceed specific thresholds), and various parametric and non-parametric statistical methods. Of course, many errors of commission are best prevented before they occur through personnel training, establishing and following routine maintenance schedules, and following documented and standardized field and laboratory methods. Errors of omission may be difficult or impossible to detect and include failure to document unusual environmental conditions and other factors that may affect data quality. It is good practice to examine data frequently and routinely plot the data to look for both errors and anomalies that may indicate an interesting pattern or process. Data creators and users benefit when attention is paid to data quality throughout the project and when those efforts are well documented in the data files and metadata as appropriate.

Provide Complete and Understandable Metadata

A table of rows and columns of numbers (i.e., data) is meaningless unless there is sufficient metadata present (e.g., column headers and other information about the data) that allows one to understand how the data are organized and what the data represent. Some of this information may be included in a table header that defines the table's elements, units of measurement, format, and so on (see **Tables 1** and **2**). Much more information, however, may be required if the data are to be correctly interpreted, used and cited far into the future. Users will likely wish to know why the data were collected, who collected the data, what methods were used to collect and process the data, when and where the data were collected, how the data are organized and formatted, and how the data have been quality-assured. In addition, users may benefit from knowing whether the data have been analyzed and used in subsequent publications as well as how to best cite the data if they use it in a publication.

Protect Data and Metadata Throughout the Research Project

Accidents happen. All to often, valuable data are lost due to carelessness, theft (e.g., laptop computer), computer malfunctions, storage media degradation, and anthropogenic and natural disasters (e.g., fires, tornadoes, hurricanes, frozen and burst pipes). A good practice is to store data and metadata on three or more storage devices (e.g., desktop, ancillary mass storage device, cloud) in at least two geographically separated locations (e.g., office, home, commercial cloud-based mass storage facility).

The Role of Data Archives

The data archiving process generally consists of several steps that are illustrated in **Fig. 2**. First, the data creator or data contributor identifies and engages with a suitable repository (e.g., one identified by searching the Registry of Research Data Repositories; see Pampel *et al.*, 2013). Initial engagement with the repository may range from reading online policies and guidelines to meeting virtually (email, phone or videoconference) or in-person with a repository representative where fees (if any), requirements and best practices can be discussed. Following repository guidelines, the data creator prepares the data, metadata and supplemental files (e.g., software code, appendices, videos) and submits them to the data repository. Second, the repository initiates data curation activities whereby the files are quality-reviewed and errors or issues are noted. This stage is iterative and may require several exchanges between the curator and the data creator until all issues are resolved and the files are deemed ready for archival. Third, the repository archives the data, metadata and associated files, and normally associates a unique identifier (e.g., DOI) to the complete data product. Fourth, the repository links the data product with additional value-added services such as indexing that may enable rapid search and discovery by repository users, as well as analytical and visualization tools that may allow users to see where the data were collected or peruse statistics generated from the data (e.g., means, ranges). Some repositories may offer additional online or in-person support to users who wish to acquire and make use of the data. Fifth, a user discovers, reviews and, if deemed appropriate, may download and use the data.

The archiving process can vary considerably among data repositories. Many institutional repositories (e.g., universities, agencies) allow users to self-submit data and metadata and only require that the user be affiliated with the institution (e.g., faculty member, student, employee, fundee). Institutional repositories may provide online guidance and help desk support, and they may restrict data submissions to particular file types and sizes. Other repositories may provide higher levels of data curation. For example, the Dryad Digital Repository (Dryad) and the Oak Ridge National Laboratory's Distributed Active Archive Center for Biogeochemical Dynamics (ORNL DAAC, Cook *et al.*, 2017) verify that: (1) the correct files have been received by the repository; (2) the documentation adequately describes the files; (3)

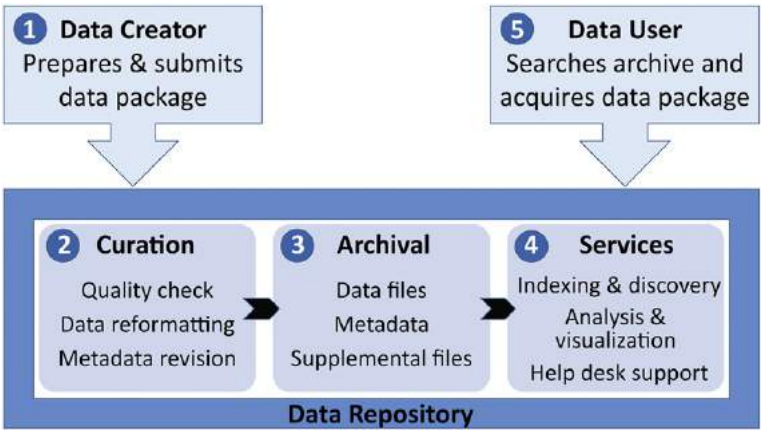

Fig. 2 The data archiving process starts with a data creator (1) who initially prepares and submits data and metadata; continues at the data repository where varying levels of data curation (2) may take place, the data package is archived (3), and ancillary services (4) add value to the data; and ends with data users (5) who may discover and potentially acquire the data for subsequent use.

files, parameters and units are appropriately named and defined; and (4) file content is consistent (e.g., variable formats are consistent throughout the file). To the extent possible, curators associated with Dryad and the ORNL DAAC will attempt to verify that values for parameters within the files are reasonable and may assist users with reformatting and reorganization if necessary.

Large government- or agency-supported repositories (e.g., ORNL DAAC) and publishers of data journals (e.g., *Scientific Data* and the publishers affiliated with Dryad) may also require that the data and metadata be peer-reviewed and undergo additional quality checks before the data products are accepted and disseminated. Dryad, for example, provides password-protected access so that peer-reviewers of journal articles may also simultaneously review the data and metadata; the data and metadata are only formally accepted and published in the archive when the journal article is accepted for publication (note that some journals affiliated with Dryad allow up to a one-year embargo on the data before they become publicly available).

Promoting Data Discovery, Use and Attribution

The data that can be most readily discovered and used are those that are well organized and documented, stored in a trusted and widely used data repository, and associated with a persistent unique identifier such as a DOI that facilitates indexing and discovery. DOIs provide a mechanism for permanently and unambiguously identifying a digital object, making it possible to easily access, cite, and use specific data products. Many data repositories assign DOIs as part of the archiving process. DOIs for data products are acquired from institutional members of organizations like DataCite and Crossref—global registration agencies for research data and related scholarly products.

Data discovery and use can also be promoted by archiving data in repositories that are associated with data aggregators and data repository federations that enable precise search and discovery of data. Data aggregators and federations (e.g., GBIF, DataONE) make it possible for users to discover and access particular data products that may be stored in one of many similar types of repositories without having to search each individual repository.

Appropriate citation of data is facilitated when the data repository and data contributor(s) provide specific recommendations for how the data should be cited; such guidance may be provided on the repository website and in the metadata associated with the data. Data creators can also promote discovery and citation by citing their own data products in the journal articles and other scholarly publications they produce that are based on the data. Of course, it also helps when the data creator can be uniquely identified since most personal names are not unique (e.g., J. Smith, B. Jones, W. Lee). Unique identifiers can easily be acquired from ORCiD—an organization that provides individual researchers with a free nonproprietary alphanumeric code that uniquely identifies them and can be associated with publications, data, proposals, and other scholarly contributions.

Conclusion

New scientific discoveries and knowledge emerge when the existing corpus of data, information and knowledge is archived, discoverable and interpretable. Like journal articles, data can be important products of the scientific enterprise and, thus, deserving of preservation, dissemination and re-use. Data sharing perceptions and practices have evolved over the last several decades. Large national, international and multi- and interdisciplinary research programs have been important in shifting cultural attitudes positively towards data sharing. Presently, many research sponsors, institutions and publishers require that data be well documented, archived in a data repository and available for further use. Five practices facilitate effective data sharing: (1) creating and following a data management plan that covers all aspects of the data life cycle during and after conclusion of the research project; (2) establishing and adopting a reasonable data sharing and attribution license or procedure; (3) comprehensively documenting project data following community standards and best practices; (4) protecting and making available data, metadata, and algorithms and workflows via a trusted community data repository; and (5) disseminating and advertising the existence of the data including, for example, publishing the data in a peer-reviewed data journal. Preparing a preservation-ready data product for submission to a repository requires that the data contributor logically, consistently and clearly name and describe the data package, including the variables, files and associated algorithms and workflows. Furthermore, the data should be quality assured, completely and comprehensively documented, and protected throughout the research. Data repositories often have specific data organization and submission guidelines and play an important role in preserving and disseminating data that serve as a valuable scientific resource for decades to come.

Ecological Indicators: Connectance and Connectivity☆

Marcel Holyoak, University of California, Davis, CA, United States

Glossary

Gene flow The movement of genes from a population (subpopulation, etc.) in one location to another, involving movement of individuals and their survival, successful reproduction, and survival of the offspring.

Genetic heterozygosity Variation in genetic material (DNA, RNA etc.) of organisms within a population (subpopulation, etc.) that indicates the presence of different genotypes and serves as future material for evolution and can enhance fitness under varied environmental conditions.

Habitat matrix or matrix The area between habitat patches that are suitable for an organism to survive in and complete at least a part of its life cycle.

Landscape The composition of an area of land including all of its elements and their spatially-explicit layout. An analogous term is a seascape for seas.

Metacommunity A population of communities in which individuals potentially move between local communities.

Metapopulation A population of populations. Individuals move between habitat patches, recolonizing them and replacing local populations that have gone extinct, which prevents regional (metapopulation-wide) extinction.

Introduction

Studies have reported that habitat loss and fragmentation are leading contemporary causes of imperilment for plants and animals. Very frequently habitat loss proceeds in ways that habitat fragments are left, reduced size and smaller more isolated areas of habitat that can be occupied by organisms. Humans also regularly erect barriers to movement in forms such as fences, roads, canals, dams, and urban areas. The extent to which the capacity of organisms to move through a landscape will be reduced is likely to depend on how an organism moves and its behavior and ecology as they relate to movement. For instance, how an organism reacts when it reaches an edge between two ecosystem types, the physical capacity of an organism to move, and whether it requires resources during movement. Anthropogenic changes in landscapes also often occur at the same time as increases in human activity or altered physical conditions, which potentially alter organismal movement. This entry reviews types of changes in habitat connectivity and their consequences. This is followed by a description of how we measure habitat connectivity, and a section on how habitat corridors are being used to attempt to reduce the effects of fragmentation.

Table 1 summarizes and defines some of the common terms used for connectivity. Habitat connectivity is defined as the degree to which a landscape facilitates or impedes movement of organisms among habitat or resource patches. The term is used synonymously with landscape connectivity. (This article does not review food web connectance, which refers to the density of trophic links in a food web—see food chains and food webs). Habitat connectivity includes elements of both the physical structure of habitat and the movement ability and behavior of the organisms in question. Structural connectivity denotes the physical structure of habitat, and is evaluated using measures of habitat extent, subdivision, and contagion, or some combination of these. By contrast, functional connectivity refers to the potential for movement of organisms among habitat or resource patches, and depends on the organisms' perception of, and reaction to, their environment, as well as on their ability to move and costs of movement. Therefore, functional connectivity may vary between species or between individuals of the same species. Functional connectivity is either a potential measure or an actual measurement of the number and frequency of individuals moving between locations. For some species, physical carriage (vectoring) of organisms by natural currents (e.g., stream flow or oceanic currents) or winds may influence functional connectivity. Both structural and functional connectivity may vary among natural environments and as a result of human activities that alter the composition and patterning of the environment and/or an organism's movement behavior. Some studies have defined connectivity on a purely structural basis, and others have used the presence of habitat corridors as an indicator of connectivity. A relevant question when reading papers about connectivity should be which kind of definition of connectivity are the authors referring to, and are parts of the movement of organisms among locations left out.

Habitat connectivity can also influence the flux of materials across ecosystem boundaries, which is considered under the topic ecosystem subsidy (Polis *et al.*, 1996). Here, the overlap between subsidy and habitat connectivity is considered. Ecosystem subsidy is defined as the transport of a donor controlled resource (prey, detritus or nutrients) from one habitat to another where it is utilized by a recipient plant or consumer. Transport here involves physical fluxes and flows, including river flows, winds, and

☆*Change History*: March 2018. M Holyoak updated the Introduction to reflect advances since 2007. Added Table 1 as an overview of terms used to describe connectivity. Updated section 2.4 on graph theoretic approaches to include more about network methods and metrics.

This is an update of M. Holyoak, Connectance and Connectivity, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 737–743.

Table 1 An overview of the various definitions of connectivity

Term	*Definition*
Connectivity	A generic overarching term that includes all of the types of connectivity below
Habitat or landscape connectivity	The degree to which a landscape facilitates or impedes movement of organisms among habitat or resource patches
Structural connectivity	The physical structure of habitat or resources across a landscape (seascape, etc.). Hydrological connectivity (below) is a specialized form of structural connectivity
Functional connectivity	Actual or potential movement of organisms between two or more locations
Genetic or population connectivity	Gene flow between populations (subpopulations etc.) resulting from movement and demography
Hydrologic connectivity	The connectivity of streams, rivers and similar water bodies as determined by physical factors like network topology, stream length, depth, width, any flows (etc.)

oceanic currents. A network of channels or rivers joining lakes or ponds fits naturally into ideas of structural connectivity. However, transport via winds and oceanic currents are not usually considered in landscape studies of structural connectivity, which usually involve the quantification of static (or occasionally dynamic) landscape patterns. Ecosystem subsidy is therefore dependent on connectivity, but the literature for patterns with fluxes and flows is largely separate from the landscape ecology literature about habitat connectivity. Studies of ecosystem subsidy typically investigate processes at ecosystem and community levels such as fluxes of nutrients and levels of biomass in different trophic levels. By contrast, landscape ecological studies of habitat connectivity are more frequently motivated by maintaining species diversity and population persistence. Hence connectivity in a broad sense influences processes at levels from individuals up to entire ecosystems, and at the ecosystem level it is termed ecosystem subsidy.

The prime importance of the movement of organisms to biodiversity is revealed by a variety of kinds of ecological and evolutionary studies. Below we briefly review the importance of island biogeography studies of species diversity, metapopulation studies of the population dynamics of one or a few species, and studies of inbreeding in relation to isolation.

MacArthur and Wilson's (1967) equilibrium theory of island biogeography theorizes that the level of species diversity on habitat islands arises as a balance between the processes of colonization and extinction of species. Colonization is related to distance from a large mainland area of habitat such that more isolated habitat islands should contain fewer species than islands that are closer to a large mainland area of habitat. Extinction of species is related to island size, such that smaller islands can hold fewer species than large islands. Hence, smaller more remote islands should contain fewer species than larger and more connected islands. Furthermore, there is a turnover of species and colonization is required to maintain species diversity. There is a broad range of empirical evidence supporting this theory in a diverse array of taxa. These ideas were brought to the attention of conservation biologists by Wilson and Willis, who in 1975 published a figure laying out the idea that islands closer together and those connected by habitat corridors support more species than islands that are less connected. The ideas both from the equilibrium theory of island biogeography and from Wilson and Willis's figure have been broadly applied to habitat islands of many kinds both aquatic and terrestrial, and have been influential in perpetuating the importance of habitat connectivity. The role of movement in colonization was also modified by James Brown and Astrid Kodric-Brown in 1975, who included the idea that movement may be from one island to another, both as a source of colonization and in a "rescue effect" where immigration might prevent populations of individual species from going extinct on individual and maintain species diversity on individual islands (and regionally).

Instead of exploring the effects of colonization and extinction on species diversity, metapopulation theory relates these processes to the regional population dynamics of one or a few species (reviewed by Hanski, 1998). Metapopulation studies show how reduced connectivity increases extinction rates of local populations and reduces rates of recolonization of vacant habitat patches. The net effects of such dynamics depend on whether species have their own independent dynamics, as represented in single species models, or whether species can be driven locally extinct by predators or competitors. As shown in **Fig. 1** the isolation of increasingly small habitat patches can only reduce the likelihood of regional persistence for single or non-interacting species, whereas interacting species can actually benefit from moderate reductions in connectivity. For example, in predator and prey metapopulation models a voracious predator might drive its prey species extinct from large well-connected areas of habitat. Reduced connectivity might reduce the ability of predators to reach areas containing prey, thereby weakening the net effect of predators on prey by providing prey with a refuge from predation. If connectivity is reduced too much, prey may be hindered from reaching habitat areas from which they have been driven extinct, so that local extinction rate exceeds the recolonization rate and eventually prey are driven extinct and predators would starve to death. In predator and prey metapopulation models the dynamics of prey at extremely low levels of connectivity are similar to those of single species. There is a moderate amount of evidence supporting such dynamics for predators and prey, but mostly from microcosms and other highly manipulable systems. Metacommunity models of many competing species show similar effects of reduced connectivity, with the added prediction that species that are the worst at dispersing should be least able to withstand reductions in connectivity even if they are strong competitors in local communities.

The isolation of a habitat patch refers to the rate of immigration into that habitat patch. Hence, isolation and connectivity are inversely related. Mortality during dispersal may add to isolation. In the absence of immigration populations are expected to suffer

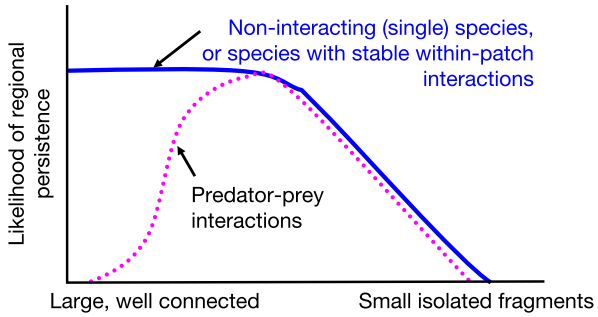

Fig. 1 The influence of habitat subdivision on single species and interacting species where one species can drive another extinct within a habitat patch (e.g., a predator and prey, or a dominant and subordinate competitor species). In highly connected habitat patches the predator is capable of driving the prey species regionally extinct whereas a single species can persist. At extremely low levels of connectivity in small habitat fragments all species go extinct regardless of their interactions. Overall the figure illustrates that the degree to which species interact may alter how they are influenced by changes in connectivity and habitat patch size.

from several effects. Small populations are likely to have reduced genetic variability as a result of the small number of individuals present. This may be compounded by the accumulation of deleterious mutations through inbreeding leading to mortality and reduced reproductive capacity in a population. Small populations are also more likely to go extinct, such that a metapopulation with lots of small populations in a region may experience a regional reduction in genetic diversity, which may exasperate the effects of small population size through reducing the potential for gene flow. Populations with low heterozygosity may have a reduced potential for future evolution. A metaanalysis (quantitative review) by Derek Spielman, Barry Brook, and Richard Frankham of over 170 threatened taxa from the IUCN-World Conservation Union Red List showed that on average threatened taxa had a 35% reduction in heterozygosity compared to non-threatened relatives. Several empirical studies indicate that the loss of heterozygosity is frequently associated with a reduction in reproductive rates through inbreeding. Furthermore, computer simulation models that involve reasonable assumptions suggest that this 35% level of loss of heterozygosity could cause 24%–78% reductions in the median time to population extinction because of reduced reproduction (estimates vary depending on assumptions about the extent of juvenile mortality caused by inbreeding). Habitat loss and fragmentation are the prime causes for imperilment of taxa (at least in the U.S.), and therefore reductions in connectivity are likely to be involved in these effects. It is important to realize that in severe cases reduced connectivity likely produces genetic changes that can impact populations before purely demographic processes cause these populations (or species) to go extinct. Hence, both demographic and genetic changes are important to understanding the effects of habitat fragmentation and reduced habitat connectivity.

Implicit in the idea of measuring connectedness is that there is a sharp demarcation between habitat and non-habitat. By contrast many organisms are not strict habitat specialists and may use different landscape elements to different extents. A step towards recognizing that species may not sharply demarcate habitat from non-habitat while still simplifying the landscape is to recognize the matrix that lies between habitat patches. Differentiating between species that use the matrix and those that do not may improve the predictability of analyses that look at species diversity in relation to connectivity because connectivity is only relevant to species that do not use the matrix as habitat. The same is true of metapopulation studies that investigate patch occupancy in relation to connectivity. A review by Jayme Prevedello and Marcus Vieira in 2010 examined whether the composition of the habitat matrix affected abundance or species richness in 104 empirical fragmentation studies. They found that although the composition of the matrix affected abundance or species richness in 95% of studies, effects were highly species specific, and the effect size was on average smaller than that of patch area and isolation (which is a habitat connectivity metric).

Measuring Connectivity

There are a variety of ways of quantifying the structural and functional connectivity of a landscape. Structural connectivity is usually quantified from aerial photographs, maps, or remote sensing data (GIS–geographic information systems data, satellite imagery). Many metrics require that an image is rasterized by overlaying a grid of cells, with each cell having a defined size or grain. The impression of structural connectivity may vary with the grain size that is chosen, with coarser grains making it more likely that small gaps between habitat areas will be overlooked because large cells average across the gaps. Similarly, organisms may have a particular spatial scale at which they sample or are affected by the environment, and move through it either in a conscious way or by the action of diffusion or a vector. The grain of our sampling a landscape to measure connectivity should be sufficiently fine that it is congruent with the scale selected by the study organism. However, this is often not known prior to commencing a connectivity analysis and therefore analyses at multiple scales are of value to identify the grains that have the highest ability to describe the movement or occupancy patterns of a species across a landscape.

There is a distinction between connectivity measured between pairs or landscape elements, or other portions of a landscape, and connectivity across an entire landscape. Often movement is measured between pairs of points, or along particular paths (e.g.,

for radio-tracked animals) and these data are then analyzed in relation to habitat type or the occurrence of particular landscape elements (rivers, roads, etc.). A typical approach is to start with pairwise measures of connectivity between two points and then repeat such measurements across a landscape. However, there are no general guidelines available to set the spatial scale at which connectivity should be measured.

It is useful to further consider functional connectivity, which can either be based on potential or actual measurements. Potential connectivity comes from combining structural connectivity with information about the movement behavior, distance and costs in the organism in question. Actual connectivity is that which is measured. Be it potential or actual, functional connectivity can be based on strict adjacency (touching) of habitat, a threshold maximum dispersal distance, or some other function of distance. Common forms include a decreasing function of distance, reflecting that movement frequency (or potential) is inversely related to distance, or a resistance-weighted distance function that incorporates the different costs of traversing various paths.

A useful framework for classifying connectivity metrics was presented by Justin Calabrese and Bill Fagan (2004), and this framework is used here to organize connectivity measures. Furthermore, the description of the advantages and disadvantages of different metrics, as well as the data requirements to estimate them draws heavily on their work. Six classes of metrics can be distinguished.

Nearest Neighbor Distance Metrics Using Patch Occupancy Data and Interpatch Distances

The crudest measures of connectivity are based on the distance from a given habitat patch to other occupied habitat patches, which might provide immigrants. This is an index of isolation, and is turned into an index of connectivity by taking its inverse. Indices of this type use only the distance to the nearest habitat patch, ignoring all other patches that might provide immigrants, and variation in the size of source populations in different patches. Metaanalyses and simulations both confirm that nearest neighbor metrics are crude estimates of connectivity and that they have lower predictive ability than the more sophisticated measures discussed below. Measures could be converted from structural measures to potential connectivity by converting links from distances to binary presences or absences, or probabilities using known movement distances and a dispersal kernel (describing the probability of dispersal as a function of distance), respectively. Nearest neighbor distances are the most widely used of the different kinds of connectivity metrics, despite their low predictive ability.

Spatial Pattern Indices Using Spatially Explicit Habitat Data

A variety of metrics can be calculated from a map portraying the spatially-explicit layout of habitat areas. These include things like the number of patches, patch sizes, patch perimeter to area ratios, fractal dimension, contagion and indices of patch shape. Such indices are readily calculated with software packages such as “Fragstats” and reflect the popularity of analyzing GIS data. However, simulated analyses of the ability of these indices to predict connectivity suggest that they are inconsistent when the characteristics of a landscape are varied. Empirical work is needed to establish relationship between actual connectivity and structural connectivity measured using spatial pattern indices.

Scale-Area Slope Indices Using Spatially Incomplete Data

Records of individuals at either random locations on a landscape or from a systematic survey of points on a landscape can be used to quantify the occurrence of a species across a landscape and how this varies with spatial scale. Specifically, a grid can be overlaid and the presence and absence of the species in each cell recorded. As grid cells are made larger (or adjacent grid cells summed) the number of records can be plotted as a function of cell size; specifically, the map area occupied by a species can be plotted against the size of the cells sampled and a power function can be fitted using regression. Such plots will have shallow slopes if species are uniformly distributed across space, which is taken as an indicator of highly connected landscapes. Conversely steep slopes are likely to result from aggregated distributions and these are presumed to arise because of limited movement. The slope is called the scale-area slope and is a measure of connectivity. Such approaches cannot distinguish whether steep slopes are because habitat is aggregated in its distribution across the landscape or whether habitat is uniformly distributed and the organisms are restricted in their movement for some reason other than habitat connectivity. The approach also assumes that proximity is the major determinant of connectivity, an assumption that had predictive power for the long-term dynamics of populations of fishes in desert springs and streams in the southwestern United States. The validity of the approach for other study systems requires evaluation.

Graph-Theoretic Measures Using Dispersal Data and Spatially Explicit Habitat Data

Graph theoretic measures of connectivity use spatially explicit habitat data and known biological information about dispersal to estimate potential connectivity. The approach consists of using a habitat graph that summarizes habitat patch arrangement (as “nodes”) and patch information in a concise way. One common way to convert a graph to measures of potential connectivity is to use either fixed dispersal distances to create links if the metric is less than the maximum dispersal distance or to do this probabilistically if a dispersal kernel is available. A dispersal kernel is a function describing the probability of dispersal as a function if

distance, and can be combined with structural landscape data by using random draws to decide whether a patch is connected or not depending on the appropriate probability of dispersal for the distance in question. Pairwise metrics such as the maximum distance able to be traveled in a random direction are then scaled up to the entire landscape. Three main types of approaches are in use, based on network analysis, percolation theory and the correlation length of spanning clusters, which are described below.

Networks and their application to connectivity are introduced in detail by Bronwyn Rayfield and colleagues in a 2011 review paper. A network consists of a weighted collection of nodes (locations), with weighting either being by population size at each node or the strength of links between nodes. The related subject of circuit theory considers the resistance of different links to flow, and emphasizes and analyzes the many ways in which circuits can be connected. Network analyses are more widely used in analyses of habitat connectivity, and building on available mathematical and statistical tools have gone from simple undirected equally weighted links to inclusion of factors like habitat suitability, different matrix permeability (see next paragraph), and movement behavior. Link weights can be assigned to reflect habitat characteristics (structural connectivity) or actual movement (functional connectivity). Analyses can consider either single (or least cost) pathways or multiple pathways through networks. In turn, metrics can be calculated for various properties at different scales from elements (nodes) within networks to whole networks or collections of "meta-networks". Rayfield and colleagues break down metrics into route-specific quantities, route redundancy, route vulnerability to breakage from loss of links or nodes, and area of connected habitat. There are a large number of such metrics and readers should refer to the literature on network analyses of connectivity for further details.

Percolation is most easily understood for a rasterized grid of habitat and non-habitat cells and is a measure of the probability that habitat cells are contiguous. Percolation theory comes from mathematics and was developed in physics before being applied to landscape ecology. The main concept is the existence of a percolation threshold, defined in the following way. Suppose p is a parameter that defines the average degree of connectivity between cells (in a grid) of a landscape classified into habitat and non-habitat. When $p = 0$, all patches are totally isolated from every other sub-unit. When $p = 1$, all habitat cells are connected to (touching) their neighbors. At this point, the landscape is connected from one side to the other, since there are paths that go completely across the system, through spanning clusters. Now suppose, starting at $p = 1$, habitat cells are randomly removed, so that p, the measure of average connectivity, decreases. The percolation threshold is that value of p, usually denoted p_c, at which there is no longer an unbroken path from one side of the system to the other. Measures of structural connectivity based on percolation can be changed into functional connectivity by allowing gaps between habitat cells of certain distances, corresponding to the organism's maximum movement distance across non-habitat.

The correlation length for a rasterized habitat patch map is based on the average extensiveness of connected cells. The correlation length is the average distance one might traverse across a landscape without leaving what is defined as habitat from a random starting point and moving in a random direction.

An advantage of graph-theoretic approaches is that they can be used to calculate how an individual patch contributes to landscape-scale connectivity. However, such approaches are data-intensive, requiring both movement data (maximum dispersal distance or a dispersal kernel) and spatially explicit landscape data representing habitat and non-habitat areas. Atte Moilanen in 2011 cautioned against using graph-theoretic measures in conservation and management because of their low ability to predict ecological patterns related to connectivity.

Buffer Radius and Incidence Function Metrics Using Spatially Explicit Patch Occupancy Data, Patch Area, and Dispersal Data

Building on the idea of nearest neighbor distances a buffer radius calculates the number of occupied habitat patches or total number of individuals of a species within a given distance. The metric uses more information than nearest neighbor distances, potentially improving its accuracy and can also be calculated at multiple spatial scales. The spatial scale of relevance will depend on typical movement distances and consequently movement data could greatly improve the utility of buffer radius connectivity metrics. A related idea is captured in Ilkka Hanski's (1998) incidence function model approach, which includes an explicit function of the number of individuals in habitat patches at different distance and these are weighted by distance in a power function. The approach can also be adapted to use information just on patch occupancy, or patch area as a surrogate measure, if the number of individuals per patch is not known. The approach has been tried and tested with a variety of taxa and appears to work well when organisms occur in discreet patches and are limited in their dispersal ability. As a minimum information on patch occupancy, or colonization are required and this needs to be complete spatially, without missing (uncensused) habitat patches in the study area. Such approaches are mainly limited by the high data requirements and limited areas that can be censused.

Observed Movement Rates Requiring Individual Movement Data

A broad range of metrics of movement are collected by ecologists and biologists. Common forms of measurement are tracking individuals using radio-telemetry, satellite tagging, radiotelemetry, or other methods, mark-release-recapture, mass mark-recapture, observations of colonization of habitat patches over some period of time, and indirect estimates from genetic data. Using genetic data requires making assumptions about effective population size and the equilibrium of dynamics, and the neutrality of genetic markers. Rolf Ims and Nigel Yoccoz reviewed the different measures of measuring movement and discuss the advantages and disadvantages of different metrics. The most accurate measures are those that are most labor-intensive to collect and these will necessarily be spatially limited.

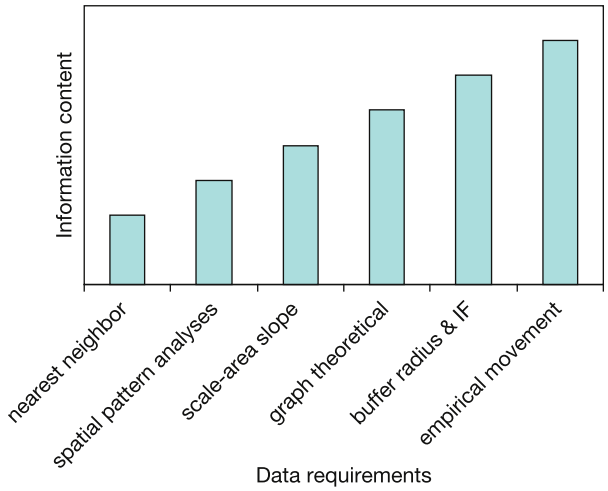

Fig. 2 A representation of the information contained in different metrics of connectivity as a function as the amount of data required for their measurement. IF = incidence function model approaches. Altered from Calabrese, J.M. and Fagan, W.F. (2004). A comparison-shopper's guide to connectivity metrics. *Frontiers in Ecology and the Environment*, **2**, 529–536.

Measuring Connectivity: Putting it All Together

The preceding discussion should have highlighted that connectivity metrics differ in their ease of measurement and the amount and type of data required to use them. There is a tradeoff between the ease of measurement of connectivity metrics and the amount of detail they capture. This is illustrated in Fig. 2. Hence, we face a choice between metrics in which we are uncertain about their utility or accuracy and investing the time and resources to measure metrics that are more information-rich. The choice of metric is likely to depend on the spatial scale of the problem which we are attempting to solve, be it a conservation strategy for a region, or the need for a migration route for deer across a highway, and so on. It should be noted that the metrics that have been discussed can often be improved by including additional information. Most commonly information about the number of individuals within patches is used, or patch size a surrogate for information about local population size. Alternatively immigration and emigration may scale differently with patch size, such that individuals are more likely to remain in or colonize smaller or larger habitat patches. Movement can also be adjusted for variation in the type of habitat being crossed or landscape features present in the area traversed. Such modifications to metrics have been shown to improve the accuracy in specific studies, but their general utility is unknown.

Corridors

Corridors are continuous strips of habitat connecting areas of habitat that would otherwise not be connected. They are one of the major ways in which we attempt to improve habitat connectivity. However, corridors serve many purposes that are related to connectivity, from facilitating the movement of individuals, enhancing social structure (e.g., for primates), population viability (e.g., for spotted owls in the Pacific Northwest of the U.S.), and community structure to improving ecosystem properties. Furthermore, corridors can be natural (e.g., riverine vegetation) or constructed (e.g., wildlife crossings on roads), deliberate or inadvertent (e.g., road verges), and vary in scale from highway crossings to ambitious international projects such as connecting the Greater Yellowstone area in Montana and Idaho to the Yukon and Alaska with a forest corridor to facilitate the movement of large mammals. Constructed corridors are often greenbelts or greenways in urban and suburban areas that serve recreational purposes, enhance ecosystem functioning (e.g., groundwater infiltration), or are low value areas, such as those subject to flooding.

When first conceived of, corridors were viewed as being non-selective pathways that facilitate movement. The reality is that certain species may benefit from corridors of a particular type, depending on width, length, habitat composition within them, the surrounding habitat matrix, and what they are connecting; all of these things are measured relative to the requirement of the species and individuals in question. Corridors may also be selective in terms of factors like the ages, social status or other traits of the individuals dispersing. Increasing connectivity through the use of corridors is not always good. For example, weedy plants are often spread along highway corridors, introducing nonnative invasive species that are selected for factors like rapid generation times, high movement capacity, being able to benefit from disturbance (e.g., open ground for germination) and high competitive ability. The spread of a disease, pathogen, predator, dominant competitor or nonnative invasive species may also occur and impact either particular species or whole communities and ecosystems. Nonetheless, the negative effects of isolation on population viability, genetic diversity, species diversity and community structure are generally severe so that the weight of evidence suggests that improving connectivity is usually desirable. It is clear that long term studies of the community-wide effects of altering habitat connectivity are especially desirable. Fig. 3 shows an aerial view of a long-term ecological experiment where Nick Haddad and colleagues manipulated the connectivity of pairs of habitat patches consisting of clearings within pine forest in South Carolina.

Fig. 3 False color aerial photograph showing a large-scale habitat fragmentation experiment conducted by Nick Haddad and colleagues. Three treatments are shown: pairs of patches connected by a habitat corridor (100 m by 100 m patches connected by a 25-m–by–150-corridor; an unconnected patch (of 137.5 m by 100 m) and winged patches that have the same total habitat area (100 m by 100 m, with two 25-m–by–75-m wings). The amount of edge habitat is also broadly similar in a connected patch and a winged patch.

The experiment controls for the amount of habitat edge and the increase in habitat area caused by having corridors by using winged patches that are of similar area to patches connected by corridors except the corridors do not connect to other patches. Nick Haddad and colleagues showed that connecting patches using corridors increased the interpatch movement rate of a diverse suite of taxa, including butterflies, small mammals, and bird-dispersed plants. In the same study system Ellen Damschen and colleagues demonstrated that by the end of a 5-year period after initiating the experiment the connected patches contained an average of 20 more plant species than unconnected patches.

Summary

Connectivity has important links to a broad range of population processes, genetic variability (and evolutionary potential), species diversity and community structure. Connectivity can be defined through structural and functional means, and functional connectivity can be further subdivided into potential and actual measurements. Connectivity can be measured between pairs of patches or across entire landscapes and many scales between. A complex diversity of metrics has been used to measure connectivity, with different metrics exhibiting different degrees of reliability, to the extent that this is known. Different metrics also differ in whether they require movement data or not, and spatially explicit landscape data or information on neighboring patches only. A key idea is that connectivity can be manipulated using habitat corridors, although such corridors are often constructed and their long-term consequences are less often explored.

Ecological Informatics: Overview

F Recknagel, University of Adelaide, Adelaide, SA, Australia

Introduction

Ecological informatics (ecoinformatics) is an interdisciplinary framework for the management, analysis, and synthesis of ecological data by advanced computational technology. Management of ecological data aims at facilitating data standardization, retrieval, and sharing by means of metadata and object-oriented programming. Analysis and synthesis of ecological data target elucidating principles of information processing, structuring, and functioning of ecosystems, and forecasting of ecosystem behaviors by means of bioinspired computation and hybrid models.

Ecological informatics currently undergoes the process of consolidation as a discipline. It corresponds and partially overlaps with the well-established disciplines of bioinformatics and ecological modeling but is taking its distinct shape and scope. In **Fig. 1**, a comparison is made between ecological informatics and bioinformatics. Even though both are based on the same computational technology, their focus is different. Bioinformatics focuses very much on determining gene function and interaction, protein structure and function, as well as phenotypes of organisms utilizing DNA microarray, genomic, physiological, and metabolic data (**Fig. 1a**). By contrast ecological informatics focuses to determine genotypes of populations by utilizing genomic, phenotypic, and environmental data as well as structure and functioning of ecosystems by utilizing community, environmental, and climate data (**Fig. 1b**).

A comparison is made between ecological modeling and ecological informatics in **Fig. 2**. Even though both rely on similar ecological data they adopt different approaches in utilizing the data. While ecological modeling processes ecological data top down by *ad hoc* designed statistical or mathematical modeling methods, ecological informatics infers ecological processes from ecological data patterns bottom up by computational techniques. The cross-sectional area between ecological modeling and ecological informatics reflects a new generation of hybrid models that enable to predict emergent ecosystem structures and behaviors, and ecosystem evolution. Typically hybrid models embody biologically inspired computation in deterministic ecological models.

Feature Areas

Current research in ecological informatics focuses at four major feature areas:

1. understanding information processing and evolution in ecosystems;
2. computational management of ecological data;
3. computational analysis and synthesis of ecological data; and
4. hybrid modeling of ecological data.

Great efforts are undertaken to address feature area (1) by studying both intraspecific population adaptations to changing climate and habitat conditions as well as interspecific population relationships controlled by infochemicals and allelopathy.

The feature area (2) aims at standardized archiving of highly complex and fragmented ecological data in order to allow ecological data sharing. The ecological metadata language EML (http://knb.ecoinformatics.org/software/eml/) is an example for developing computational tools based on metadata concepts that will facilitate ecological data warehousing at global scale.

The feature area (3) is being largely stimulated by both the availability of complex ecological data including genomic and phenotypic data, and the development of bioinspired computational techniques. The study of population genomics in their natural habitats without the need for isolation and lab cultivation of individual species has led to the new research area of ecogenomics (also called metagenomics) that promises to determine the impact of environmental and climate changes on biodiversity. Bioinspired computational techniques prove to be superior in unraveling highly complex ecological data, coping with distinct nonlinearities and inducing predictive models by learning from temporal and spatial patterns. The next section illustrates applications of artificial neural networks (ANNs) and evolutionary algorithms for ecological informatics.

Research on hybrid modeling in the feature area (4) promises ecosystem models with improved accuracy and generality. Cao and Recknagel provided a case study for multiobjective optimization of process and parameter representations in process-based ecosystem models by the embodiment of evolutionary algorithms in ordinary differential equations for food web dynamics and nutrient cycles in lakes.

Ecological Informatics by Computational Analysis and Synthesis of Ecological Data

Artificial Neural Networks

ANNs are computer programs designed for inducing problem solutions (models, knowledge) from complex data by means of principles of information processing similar to biological neurons in the human brain. A biological neuron consists of three major components: the cell body, dendrites, and the axon (Fig. 3a). Connections between neurons are formed at synapses. Information is represented and transmitted by chemically generated electrical activity within the cell. Both excitatory and inhibitory inputs to the neuron enter through synaptic connections with other neurons. Input potentials are summed up within the cell body. If the total input potential is sufficient (e.g., meets a certain threshold value), the neuron acts. Ultimately an action potential is generated and propagated down the axon toward the synaptic junctions with other nerve cells.

The design of ANNs (Fig. 3b) has been inspired by the structure and functioning of biological neurons. The dendrites which are acting as input receptors were represented by input units. The cell body that acts as information accumulator was represented by activation units adjusting and summing up the weights of inputs, and the input–output transfer function. The axon that acts as the biological output channel was represented as the output.

ANNs gain adaptive capability by undergoing training similar to neural learning where two basic training modes are distinguished: supervised and nonsupervised. The supervised training aims at the optimal approximation of the calculated output Y_c to the observed (desired) output Y_o. An iterative adjustment of input weights takes place in order to minimize the error $(Y_o - Y_c)$. After training, the generalization of the supervised ANN is assessed by feeding it only with input values, not observed output values, and testing how close calculated outputs match observed outputs. The two most common methods for assessing generalization are the 'split-sample validation' and the 'cross-validation'. The 'split-sample validation' means that part of the data is reserved as a test set, which must not be used in any way during training. The test set must be representative for the problem to be modeled by the ANN. After training, the ANN is run on the test set, and the error on the test set provides an estimate of the generalization error usually expressed by the root mean square error (RMSE) or the correlation coefficient r^2. The disadvantage of split-sample validation is that it reduces the amount of data available for both training and validation. By contrast, 'cross-validation' allows use of all the data for training. In k-fold cross-validation, the data is divided into k equal-sized subsets. The net is trained k times, each time leaving out one of the subsets from training, but using only the omitted subset to compute the generalization error. If k equals the sample size, this is called 'leave-one-out' cross-validation. The disadvantage of cross-validation is that the ANNs need to be retrained many times.

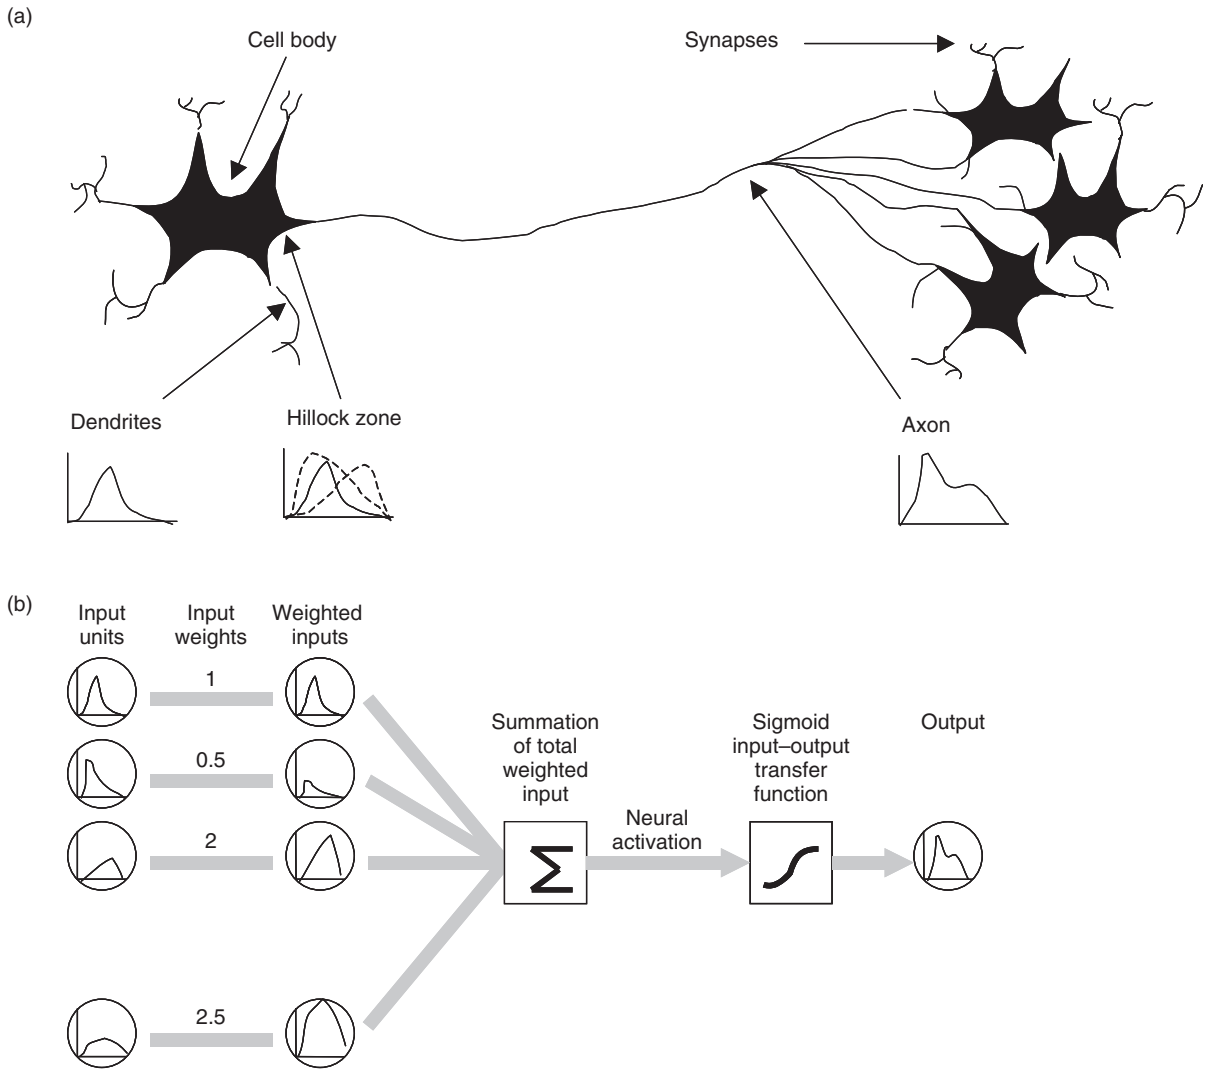

Fig. 3 Conceptual structures of biological and artificial neurons.

Depending on using external inputs only or feedback inputs as well, supervised ANNs are differentiated into feedforward or feedback ANNs (see **Figs. 4a** and **4b**). By contrast, nonsupervised ANNs process external inputs only without adjusting calculated outputs to known outputs (**Fig. 4c**).

Supervised feedforward ANN

The supervised feedforward ANN proves to be a universal approximator of multivariate nonlinear functions and is usually implemented as multilayer perceptron with back-propagation training. The multilayer perceptron represents input units as input layer, adjusted and accumulated input weights as hidden layer(s), and outputs as output layer. The back-propagation algorithm performs the iterative adjustment of input weights (activation units) in order to minimize the approximation error ($Y_o - Y_c$).

Supervised feedforward ANNs are widely applied in ecology either using cross-sectional data to predict discrete ecosystem states or using time-series data to predict continuous ecosystem behavior. Successful applications by means of cross-sectional data have been demonstrated for fish communities in streams, macroinvertebrate communities in streams, river salinity, primary productivity in esturaries, chlorophyll *a* concentrations in lakes, coastal vegetation, and bird populations.

Successful applications by means of time-series data have been demonstrated for marine fish and zooplankton communities, river hydrology, macroinvertebrate communities in streams, freshwater phyto- and zooplankton communities.

The majority of the supervised feedforward ANNs documented achieved forecasting results that were superior to conventional modeling techniques such as multiple linear regression. Even though supervised ANNs do not provide explicit mathematical representations of the underlying ANN model, most of the authors have conducted sensitivity analyses in order to identify inputs as key driving forces of the predictive ANN.

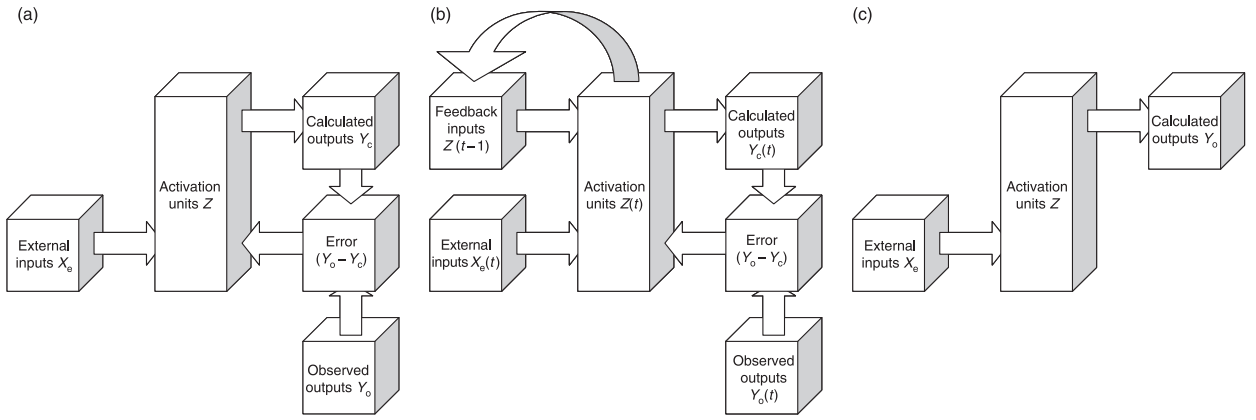

Fig. 4 Basic types of ANNs: (a) supervised feedforward ANN; (b) supervised feedback ANN; (c) nonsupervised ANN.

Supervised feedback ANN

Supervised feedback or recurrent ANNs are designed to use not only external inputs for training but also activation levels of the previous training iteration which are constantly fed back (see **Fig. 4b**). Their functioning can be compared with ordinary differential equations that calculate the current system state $Z(t)$ by taking into account current external inputs $X_e(t)$ and the system state $Z(t-1)$ of the time step before:

$$dZ(t)/dt = f(X_e(t), Z(t-1), P)$$

where P represents constant parameters.

Supervised feedback ANNs prove to be very powerful for modeling time-series data where the fed-back activation levels provide extra training information on the system state of the time step before.

Fig. 5 shows an example for a supervised feedback ANN that has successfully been trained and tested by split-sample validation for the forecasting of the algal populations *Microcystis* and *Stephanodiscus* in River Nakdong in South Korea. The weekly measured limnological data of the river study site were interpolated to daily values. The interpolated data from 1995 to 1998 were used as training set, and the interpolated data of 1994 were used as testing set. In order to achieve a 4-day-ahead forecasting, a 4 days time lag was imposed between the measured inputs and the measured outputs of the training data set. The design of the feedback ANN considered the following 18 external input variables: irradiance, precipitation, discharge, evaporation, water temperature, Secchi depth, turbidity, pH, DO, nitrate, ammonia, phosphate, silica, rotifera, caldocera, copepoda (see also for input sensitivity in **Fig. 5**), 21 hidden activation units, and the two output variables: *Microcystis aeruginosa* and *Stephanodiscus hantzschii*.

After 2100 training iterations, an RMSE of 0.001 7 was achieved and the generalization of the trained ANN was tested based on testing data of 1994. **Fig. 6** shows the visual comparison between the observed and the 4-day-ahead predicted data for *M. aeruginosa* ($r^2 = 0.68$) and *S. hantzschii* ($r^2 = 0.73$). The results indicate a high degree of accuracy in the forecasting regarding both the timing and the magnitudes of populations dynamics of the two algal species, which have their distinctive seasonal patterns.

This application has demonstrated that supervised feedback ANNs achieve a high generalization degree and forecasting accuracy after training by time-lagged time-series data. The typical rapid growth and blooming of the blue-green algae *Microcystis* under warm and calm conditions in mid- and late summer as observed in River Nakdong in 1994 was well reflected by the predicted data in **Fig. 6a**. By contrast diatoms tend to be abundant at moderate temperatures and turbulent conditions. Both observed and predicated data for *S. hantzschii* in River Nakdong correspond well by showing population densities in the highest range, in spring and autumn (**Fig. 6b**).

This case study has also convincingly demonstrated the benefits of sensitivity analyses in order to gain insights and test hypotheses regarding ecological relationships between input and output variables. Results in **Fig. 7** compare the input sensitivities of the two different algal populations that have been interpreted in great detail by Jeong *et al.* The most obvious differences between *M. aeruginosa* and *S. hantzschii* can be seen in their preferred water temperature, pH, and silica levels that comply with ecological theory.

Successful applications have also been demonstrated for time-series modeling of macroinvertebrate communities in streams and phytoplankton communities in freshwater lakes and rivers.

Nonsupervised ANN

Nonsupervised ANNs are designed to identify unknown input patterns based on similarities between inputs. So-called self-organizing maps (SOMs) developed by Kohonen are the most popular nonsupervised ANNs which can be applied to ordination, clustering, and mapping of complex nonlinear data.

The principal approach of nonsupervised ANNs according to Kohonen is represented in a simplified manner in **Fig. 8**. It shows that the neurons of the nonsupervised ANN learn to distinguish between similar and dissimilar features of the normalized input data, which are mapped as clustered inputs. The term nonsupervised in this context means that the learning algorithm is not

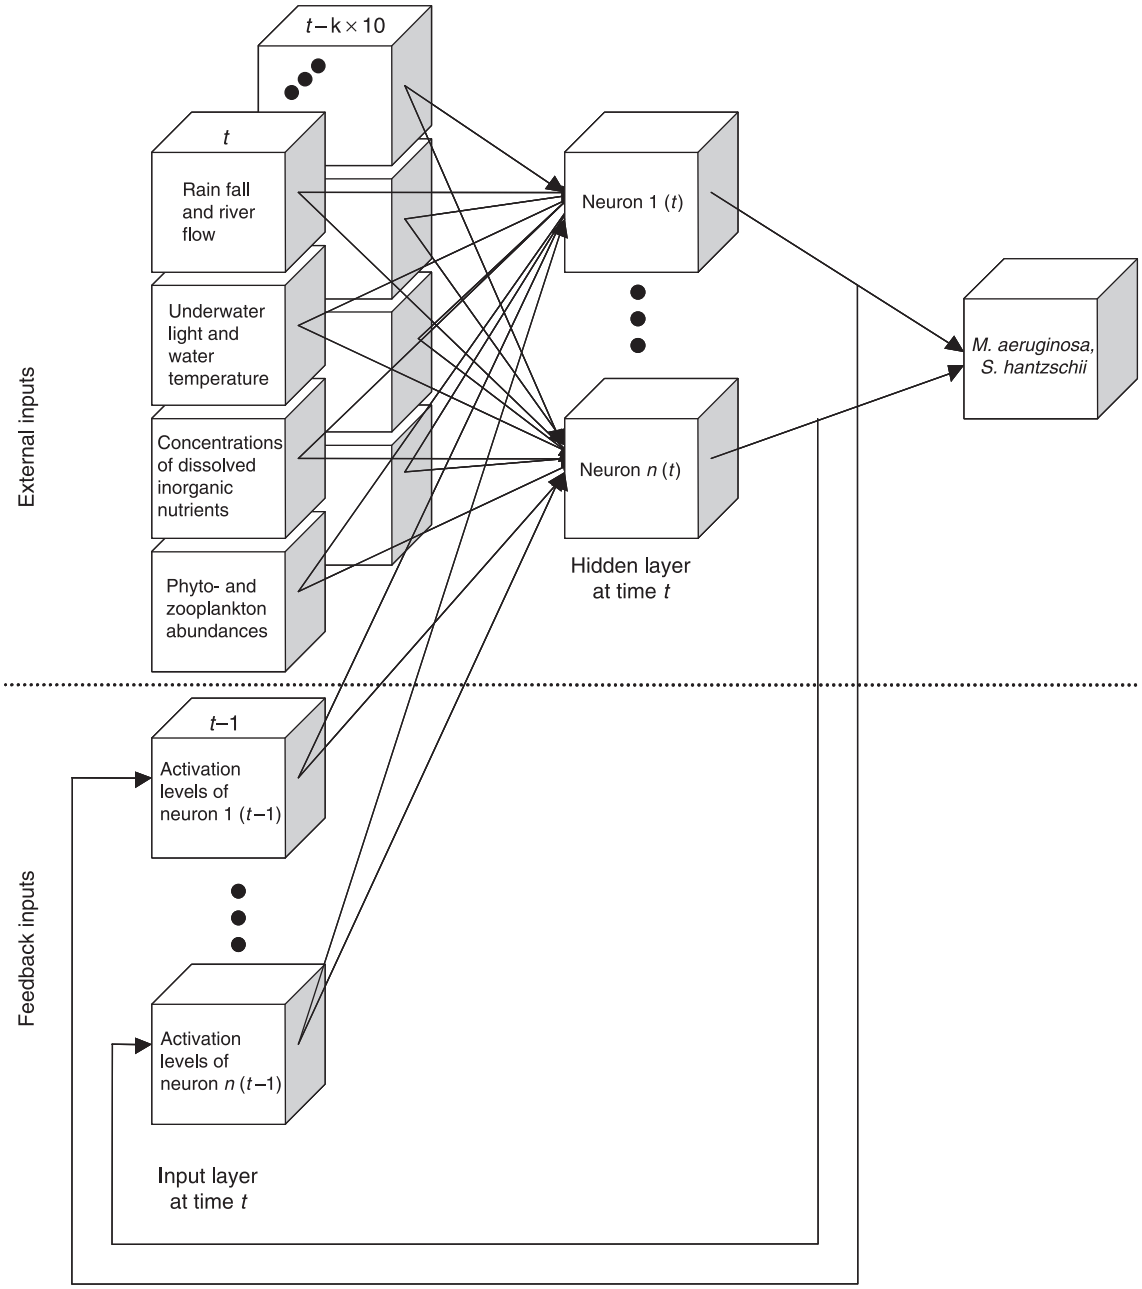

Fig. 5 Supervised feedback ANN for 4-day-ahead forecasting of population densities of *Microcystis aeruginosa* and *Stephanodiscus hantzschii* in River Nakdong (South Korea). Modified from Jeong K-S, Recknagel F, and Joo G-J (2006) Prediction and elucidation of population dynamics of the blue-green algae *Microcystis aeruginosa* and the diatom *Stephanodiscus hantzschii* in the Nakdong River–Reservoir System (South Korea) by a recurrent artificial neural network. In: Recknagel F (ed.) *Ecological Informatics: Scope, Techniques and Applications*, 2nd edn., pp. 255–273. Berlin: Springer.

guided by known output patterns but learns the patterns from features of the inputs. Those features can be expressed by Euclidean distances, which are calculated between the inputs and weights. Similarities between inputs in terms of Euclidean distances can be visualized and partitioned by the unified distance matrix (U-matrix) and the K-means map.

In order to illustrate opportunities of applications of nonsupervised ANN to ecological time-series data, **Figs. 9–12** show results of a case study carried out for limnological data of Lake Kasumigaura in Japan. **Fig. 9** represents seasonal clusters for Lake Kasumigaura as mapped by the U-matrix and K-means partitioning using the SOM Toolbox of MATLAB 5.3. The U-matrix map in **Fig. 9a** visualizes the relative distances between neighboring data of the input data space as shades of gray. The light areas in the U-matrix visualize neighboring data with distances in the shortest range belonging to a region or cluster. The black colors represent the distances in the longest range between neighboring data and denote borders between clusters. The K-means algorithm

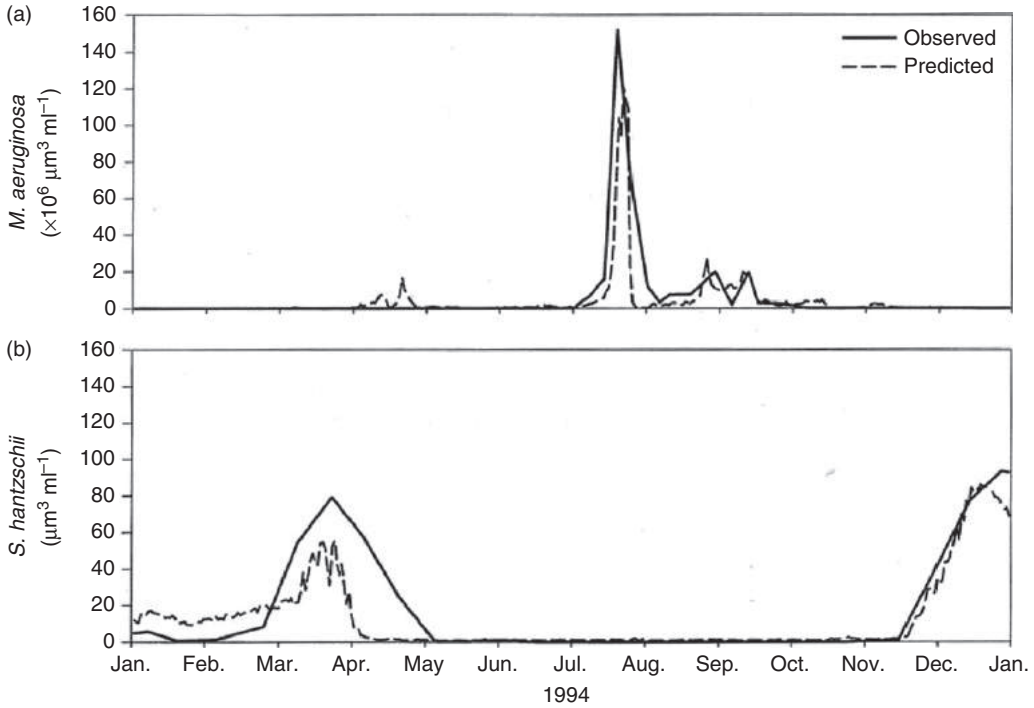

Fig. 6 Four-day-ahead forecasting of population densities of *M. aeruginosa* and *S. hantzschii* in River Nakdong (South Korea) by means of a supervised feedback ANN. Modified from Jeong K-S, Recknagel F, and Joo G-J (2006) Prediction and elucidation of population dynamics of the blue-green algae *Microcystis aeruginosa* and the diatom *Stephanodiscus hantzschii* in the Nakdong River–Reservoir System (South Korea) by a recurrent artificial neural network. In: Recknagel F (ed.) *Ecological Informatics: Scope, Techniques and Applications*, 2nd edn., pp. 255–273. Berlin: Springer.

partitions the input data space into a specified number of clusters based on the U-matrix. **Fig. 9b** represents the corresponding partitioned map for five seasons.

Fig. 10 visualizes seasonal distributions of abundances of the blue-green algae *Microcystis* and *Oscillatoria* in Lake Kasumigaura based on data of the years 1984–86 (left column) and 1987–89 (right column). **Fig. 11** represents the seasonal distributions of concentrations of NO_3-N and PO_4-P in Lake Kasumigaura in correspondence with the time periods differentiated in **Fig. 9**. **Fig. 10** highlights that while *Microcystis* declines in cell numbers by more than 50% between 1984–86 and 1987–89, *Oscillatoria* doubles in cell numbers. It also shows that seasonal dominance of two algal populations for the early and the late 1980s shifted for *Microcystis* from late summer to autumn, and for *Oscillatoria* from early summer to late summer. Takamura *et al*. pointed at changes of NO_3-N/PO_4-P ratios as possible explanations for the succession of the two blue-green algal populations during the 1980s in Lake Kasumigaura, that are indicated by the component planes in **Fig. 10**. From the early to the late 1980s, the NO_3-N concentrations increased by 50% while PO_4-P concentrations dropped to 50%, causing a significant change of the NO_3-N/PO_4-P ratios (from 8.5 to 32).

A combination of input sensitivity curves by supervised feedback ANN with component planes by nonsupervised ANN proves to be an informative approach (e.g., for hypothesis testing). While component planes allow to map nonlinear relationships of output variables with predefined input ranges in a qualitative manner (see **Fig. 12**, top), input sensitivity curves draw numerical relationships of output variables over the whole range of input variables as learnt from training data. Both the component planes and sensitivity curves in **Fig. 12** confirm theoretical assumptions that the diatoms *Cyclotella* have a preference of low to medium water temperatures typically occurring in spring and autumn, while the population growth of *Microcystis* reaches rates in the highest range at high water temperatures in mid- and late summer.

Successful applications of nonsupervised ANNs have been demonstrated for cross-sectional data of macroinvertebrate communities in streams and vegetation types.

Successful applications of nonsupervised ANNs have been demonstrated for time-series data of plankton communities in lakes and rivers.

Evolutionary Algorithms

Evolutionary algorithms (EAs) are adaptive methods for finding problem solutions (models, knowledge) based on principles of biological evolution by natural selection, genetic variation, and 'survival of the fittest' (see **Fig. 13**). Holland provided the theoretical framework for the development of genetic and evolutionary algorithms that are being widely used for pattern

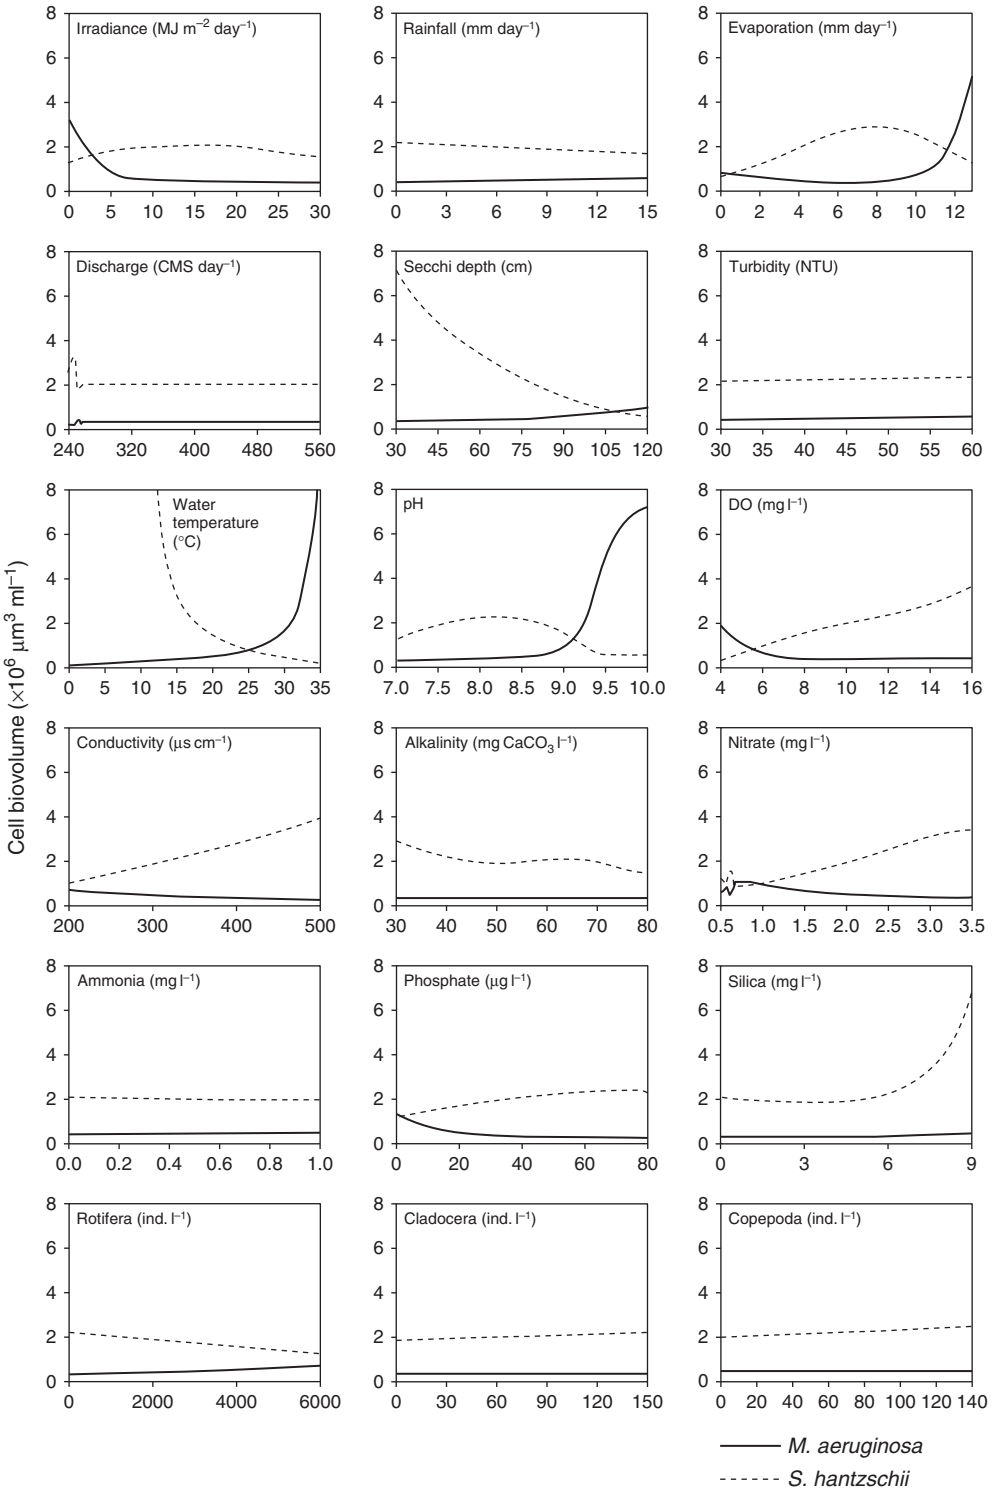

Fig. 7 Input sensitivity curves for the population densities of *M. aeruginosa* (solid lines) and *S. hantzschii* (dotted lines) in River Nakdong (South Korea) by means of a supervised feedback ANN. Modified from Jeong K-S, Recknagel F, and Joo G-J (2006) Prediction and elucidation of population dynamics of the blue-green algae *Microcystis aeruginosa* and the diatom *Stephanodiscus hantzschii* in the Nakdong River–Reservoir System (South Korea) by a recurrent artificial neural network. In: Recknagel F (ed.) *Ecological Informatics: Scope, Techniques and Applications*, 2nd edn., pp. 255–273. Berlin: Springer.

recognition, forecasting, knowledge discovery, optimum control, and parallel processing. Useful guides for history, current developments, and applications of genetic and evolutionary algorithms are provided by Goldberg, Mitchell, and Bäck *et al*.

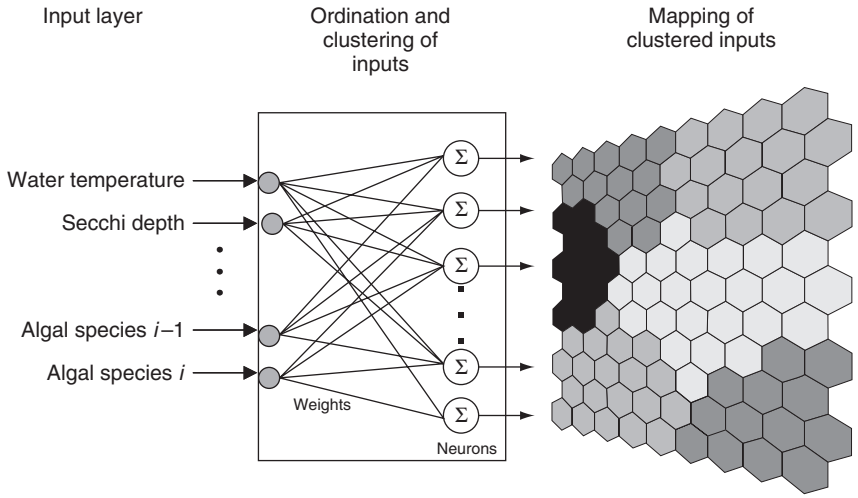

Fig. 8 Conceptual diagram of the structure and functioning of nonsupervised ANN.

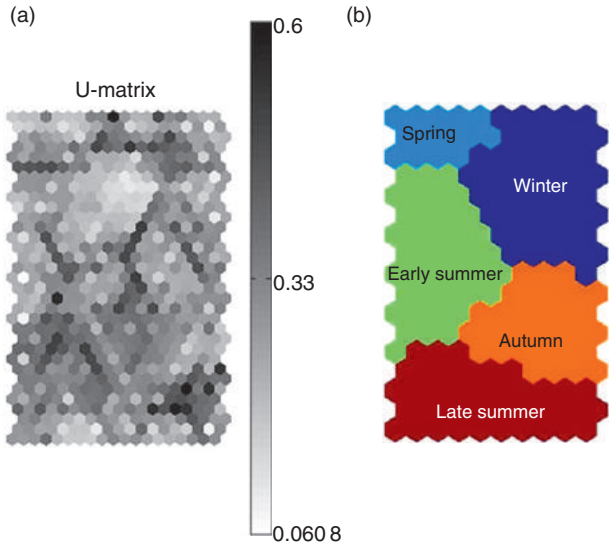

Fig. 9 Ordination and clustering of seasons of Lake Kasumigaura by means of nonsupervised ANN visualized as unified distance matrix map (U-matrix) (a), and as partitioned map (K-means) (b); the seasons were defined as follows: winter from 1 December, spring from 15 March, early summer from 1 June, late summer from 1 August, autumn from 1 October.

Successful implementations of EA as tools for solving complex economic and engineering problems have stimulated their application to solving ecological problems, which exhibit highest complexity. They allow to induce predictive models from ecological data sets similar to supervised ANN but rather than lacking an explicit model representation as typical for ANNs, EAs are distinctively designed for assembling the explicit model represented as multivariate functions or rule sets. Therefore EAs serve as powerful tools for knowledge discovery as well.

The hybrid evolutionary algorithms (HEAs) have been *ad hoc* designed as flexible tool for inducing predictive multivariate functions and rule sets from ecological time-series data. The conceptual framework of the application of HEA to rule discovery in limnological time-series data is represented in **Fig. 14**. It indicates that similar to supervised ANN, the training of HEA aims at the optimal approximation of the calculated output Y_c to the observed (desired) output Y_o. However, by contrast, HEA iteratively adjusts the rule structure and parameter values rather than input weights in order to minimize the error $(Y_o - Y_c)$.

The detailed algorithm for the rule discovery and parameter optimization by HEA is shown in **Fig. 15**. HEA uses genetic programming (GP) to generate and optimize the structure of rule sets and a genetic algorithm (GA) to optimize the parameters of a rule set. GP is an extension of GA in which the genetic population consists of computer programs of varying sizes and shapes. In standard GP, computer programs can be represented as parse trees, where a branch node represents an element from a function set (arithmetic operators, logic operators, elementary functions of at least one argument), and a leaf node represents an element from a terminal set (variables, constants, and functions of no arguments). These symbolic programs are subsequently evaluated by

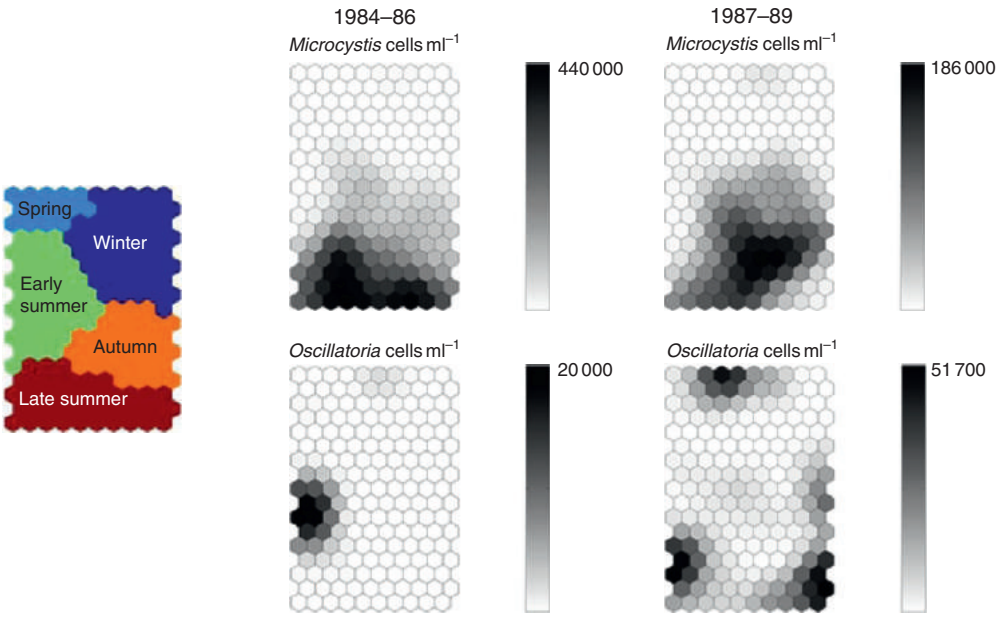

Fig. 10 Component planes for seasonal abundances of *Microcystis* and *Oscillatoria* populations in Lake Kasumigaura for the years 1984–86 (left column) and 1987–89 (right column).

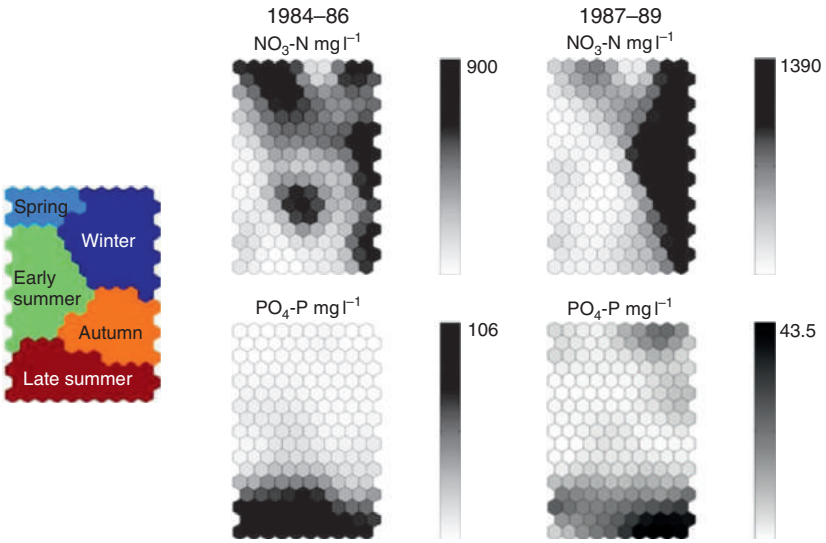

Fig. 11 Component planes for seasonal concentrations of PO_4-P and NO_3-N in Lake Kasumigaura for the years 1984–86 (left column) and 1987–89 (right column).

means of 'fitness cases'. Fitter programs are selected for recombination to create the next generation by using genetic operators, such as crossover and mutation. This step is iterated for consecutive generations until the termination criterion of the run has been satisfied. A general GA is used to optimize the random parameters in the rule set.

Figures 16 and **17** illustrate the structure, input sensitivity, and *k*-fold cross-validation of a rule-based agent for 7-day-ahead forecasting of *Microcystis* biomass developed by HEA.

The rule in **Fig. 16a** is the result of using 42 years of merged limnological data of the South African lakes Hartbeespoort, Roodeplaat, and Rietvlei for the training of HEA. The sensitivity analysis in **Fig. 16b** indicates that both water temperature and Secchi depth are key driving variables for low biovolumes of *Microcystis* of up to 14 $cm^3\ m^{-3}$ reflected by the THEN branch of the rule as well as for high biovolumes of up to 350 $cm^3\ m^{-3}$ reflected by the ELSE branch of the rule. As a result of *k*-fold cross-validation, the parameters p_1 and p_2 have been evolved to water temperature functions which provide the agent an extra mechanism for adaptation to lake-specific seasonal conditions.

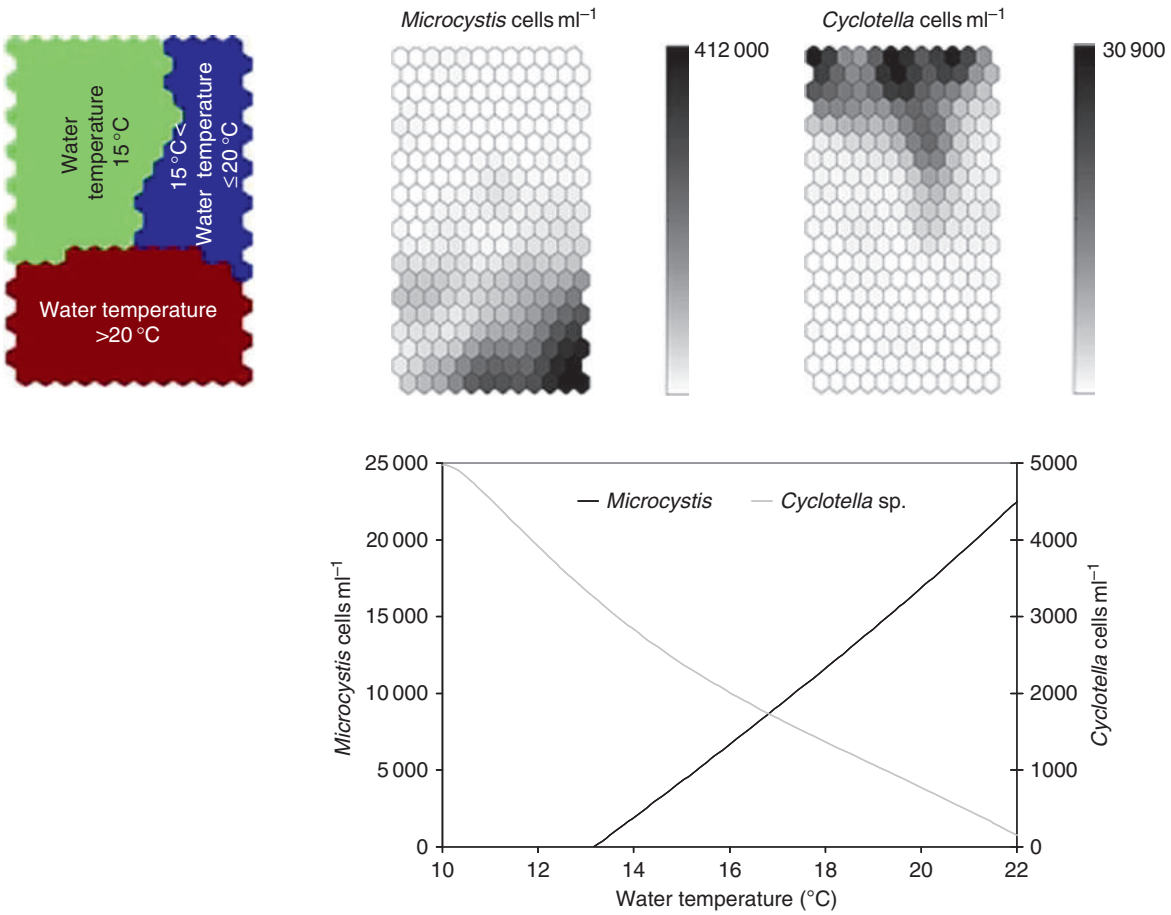

Fig. 12 Component planes for water temperature preferences of *Microcystis* and *Cyclotella* populations (top) and water temperature sensitivity curves for *Microcystis* and *Cyclotella* populations (bottom) in Lake Kasumigaura for the years 1984–93.

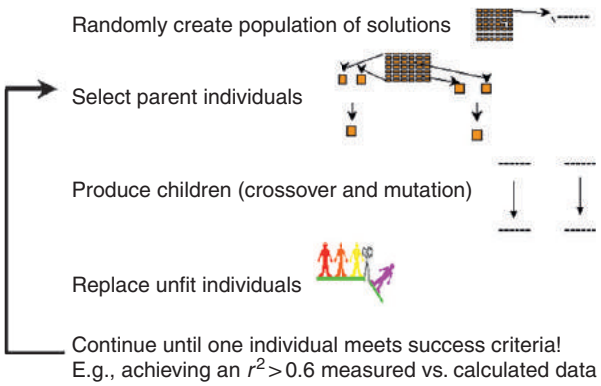

Fig. 13 Conceptual diagram for the design of evolutionary algorithms. Modified from Morrall D (2006) Ecological application of genetic algorithms. In: Recknagel F (ed.) *Ecological Informatics*, 2nd edn., pp. 69–83. New York: Springer.

The *k*-fold cross-validation of the rule-based agent for *Microcystis* achieved r^2 values of 0.31 for Lake Hartbeespoort, 0.34 for Lake Roodeplaat, and 0.75 for Lake Rietvlei (Fig. 17).

Successful applications of EA have been demonstrated for cross-sectional data of fish populations as well as macroinvertebrate communities in streams, and for time-series data of plankton communities in lakes and rivers, and biological wastewater treatment.

Future Directions

Making informed decisions on preserving biodiversity and sustainable environments in spite of pollution, eutrophication, and climate change is of vital importance for the habitat Earth in the twenty-first century. Ecological informatics is challenged to

contribute ecological understanding and tools for integrating, analyzing, and synthesizing the wealth of ecological knowledge and data for making an informed decision at local, regional, and global scale.

It is anticipated that at the next stage ecological informatics will distinctively focus on: (1) integrated analysis of genomic, phenotypic, and ecological data in order to better understand biodiversity and ecosystem behavior in response to habitat and climate changes; (2) facilitating data sharing by www-based generic data warehouses tailored for ecosystem categories at global scale; and (3) implementing hybrid model libraries generic for ecosystem categories at global scale by object-oriented programming and interactive www-access.

Emergent Properties

F Müller, University of Kiel, Kiel, Germany
SN Nielsen, Danmarks Farmaceutiske Universitet, Copenhagen, Denmark

Introduction

Many biologists will recognize the statement that "the whole is more than the sum of the parts" as a commonly used (but hardly understood) phrase. This formulation refers to the idea that there are systems which possess additional qualities or quantities, beyond easily measurable or predictable physical parameters. The resulting properties have been described on many levels of the biological hierarchy, from simple physical systems, like laser beams, to the organization of the whole biosphere within the Gaia concept of J. Lovelock. The emergent property at one level is in general finding its causality at the subsystem components and the interaction between them. For example, an organized form of cell functions, stemming from self-organized transformations of cellular compounds, known as hypercycling may be considered as an emergent entity; at the physiological levels we are, for example, dealing with the mating behaviors of organisms as results of hormone interactions. Similarly, motion, feelings, or intelligent behavior occur as a consequence of special couplings of neurons. In addition, the patterns in the development of ecosystems may not be predictable from knowledge of organisms alone. Therefore, emergent properties are not unusual phenomena, but simply consequences of hierarchical organizations.

The concept of emergence found its way into ecology through the proposal of E. P. Odum, who suggested that the study of emergence should lead to a 'new integrative discipline'. This idea was due to the fact that studies of complex systems had shown that the investigations of the details alone were not adequate in predicting ecosystem function and behavior. Neither were they sufficient to explain a more advanced pattern like behavior and performance of ecosystems, for example, during the succession from young systems toward more mature states.

The History of the Concept

The concept of emergent properties originates in the nineteenth century, finding the primary roots back in Kantian philosophy. The term was coined by G. H. Lewis as far back as 1875. A common definition from that time states that "emergence is the denomination of something new which could not be predicted from the elements constituting the preceding condition."

Throughout the last century, several scientists have addressed the concept from a more philosophical point of view, resulting in the appearance of different descriptions and explanations. The definitions have, in general, been referring to subjective arguments, such as surprise, unexpectancy, thus being clearly observer dependent. This has strongly influenced the present approaches, and this comprehension has often been connected with a flavor of mysticism. Thus, the seriousness of the concept has often been underestimated.

During the last decades, the use of the term emergent properties has found widespread use in biological sciences, especially, because it is clearly connected with the growing implementation of the system approach in ecology. The need for a holistic concept was due to the failure of the traditional reductionistic research strategies to explain the properties of ecosystems by the knowledge of the behavior and the properties of the ecosystem constituents alone. Ecosystems are highly complex middle-numbered systems dominated by nonlinear relationships between their constituents. In such systems, things are bound to happen that are not easy to predict from the basic knowledge of the system, no matter how extensive this knowledge is.

Highly relevant to biology and ecology is the question when an emergent property appears. This leads to the distinction of 'primary' and 'secondary' emergence, primary emergence being the first time an emergent property appears. To be conserved the property can be reproduced again and again but in this case it is nominated as a secondary emergence. Recent approaches to emergence have come up with three further notions of emergence: 'computational emergence', 'thermodynamic emergence', and 'emergence relative to a model'. The computational emergence deals with the patterns produced by different computer programs, for example, cellular automata systems developing complex distributions out of simple rules from game theory. Thermodynamic emergence covers the establishment of highly complex, self-organized structures and their relations to the nonlinear, far from equilibrium thermodynamics. Emergence relative to a model defines emergence as the deviation of the actual behavior of a physical system in comparison with an observer's model of it.

Summarizing these historical notions of emergence, the following features can be stated:

- Emergent properties are properties of a system which are not possessed by component subsystems alone.
- The properties emerge as a consequence of the interactions within the system.
- Two fundamental types of interactions are found that may be characterized as intra- and inter-connectedness, that is, connections within and between levels, including controls. This point does not consider the direction of the intra-level interactions. Emergence is based on both, upward and downward causation.

- The historically emerged properties are considered 'new' with reference to their primary appearance.
- These new properties appear at one level of a system and are not immediately deducible from observation of the levels or units of which the system consists.

Emergence and Hierarchy

Emergence has been described at many levels of the biological hierarchy. As argued above, the reason for emergence is to be found in the hierarchical organization of the system and the quantitative and qualitative characters of the 'linkages' within the structure. As biological structures are often complex, this makes it hard to determine the actual cause of emergence.

Hierarchy theory states that middle-numbered systems – such as ecosystems – can be comprehended if they are investigated on different levels of integration. Broad scale levels can be assigned to high spatial extents, and low typical frequencies, filtering the signals from lower levels. These scale levels are spatially smaller and their typical frequencies are higher. They are not able to filter constraints from the higher levels, but their potentials and interactions are building up the material basis and the coordination functions of the higher level. Emergent properties are created by both types of nonlinear interactions. Therefore, the properties of specific levels can be termed 'hierarchical emergent properties'. Of course, the interesting question is how these properties emerge. Some examples might be helpful to illuminate this question.

Prebiological Emergence

Several examples of emergent properties can be found in physical and chemical sciences. They form an important prerequisite for protobiology and evolutionary processes. Within the area of physics some examples are nearly classical: Water (e.g., its wetness), which is a simple molecule with a rather complex behavior, that is unpredictable from knowledge about oxygen and hydrogen alone, has often been used to demonstrate emergent properties. Similarly, the sense of colors by the eyes is not predictable by knowing a certain wavelength of light.

Two famous chemical examples related to self-organized behavior of systems may also be mentioned, the Bénard cells and the Bhelusov–Zabotinsky (BZ) reaction. In the case of Bénard cells, during specific conditions, hexagonal, convective cells (the emerging structures) form a fluid when a thermal gradient is imposed on the experimental setup containment. In the BZ-reaction a special ratio of chemicals causes a mixture to perform a pulsing pattern in colors with a period of about one minute. The structure of these physico-chemical processes, gradients resulting in convective cells, pulsing patterns, together with other observations like the occurrence of Turing structures in chemical fluids, spontaneous formation of lipid coacervates, might be crucial to our understanding of the emergence of life.

Protobiological Emergence

The appearance of the earliest life forms has often been referred to as a primary emergence. Although many of the properties occurring during this phase of evolution have been repeated, over and over again their appearance still qualifies them as emergent properties. As examples, the emergence of life, emergence of animals, or the emergence of bird feathers from reptile scales can be mentioned to characterize situations of primary emergence.

Many examples found in the literature deal with the formation of the earliest cells. Biochemical cycles, the organization and exchange of information by DNA or RNA and the compartmentalization of material within membranes are but a few examples. Molecular complementarity, defined as "nonrandom, reversible coupling of the components of a system," has been argued to be a widespread mechanism in biological systems and important for the understanding of the processes lying behind emergent properties. The seemingly (self)organization of molecules observed in prebiotic systems, such as Turing structures and auto-catalytic hypercycles, can be seen as emergent properties already at a very low level of organization.

Emergence in Biological Systems

Emergent properties really come into play when biological systems reach higher levels of complexity. This becomes evident already when cells or groups of cells communicate with each other as in the case of hormones and natural neural networks. Organs are composed of cells, their individual functions are important only to the organism as a whole. A heart, kidneys or lungs, are vital but their function is not existent when they are on their own. Organisms interacting as populations or societies provide properties which cannot be explained by properties of the individual organisms alone. They all go together in what we consider as ecosystems and thus are a part of the biosphere.

Cellular level. In regarding the outcome of interacting cells many studies have been concentrating on the organization of neuronal systems, which result in unexpected properties like the ability to move, to sense, to be intelligent, and to emote. The sensory systems, being connected to visual, auditory, or other communicative processes are all playing a major role in how successful living organisms are in performing specific life strategies. Reliable senses, and responding the right way to the received

stimuli are crucial to the existence of many life forms, in processes like finding food, knowing when and where to escape, or creating bonds with other members of the species, for example, during reproduction.

Neural networks, like in our brains, consisting of a huge number of interconnected neurons, are so complex that unforeseen patterns in responses are bound to occur and have also been reported to exist. During the evolution of the brain, emergent properties, together with new cell types, local and large circuits have added up to the increasing complexity of brain function. Motor control, the control and coordination of motor activity are taken care of by our brain passing on signals to the limbs or organs involved.

Organ level. Numerous cells, often during morphogenesis differentiated in certain, specialized directions, form organs, take up a particular task of the organism, like for instance liver cells secreting enzymes, or kidney cells filtering and cleaning the coelom. Although the formal 'layout' for this functionality is existent in the genetic material of all cells, the eventual determination occurs during the development of the organism and the actual function of the organs may be viewed as emergent. The brain as an organ may serve as an example of this emergence: Here differentiated cells, with highly specialized physiological properties, go together and create activity patterns that are far more complex than expected from knowing the physiology of neural cells alone. The whole becomes more than the sum of the parts.

Organism level. Complex behavior occurs among the individual organisms that cannot be determined exclusively by internal factors. The sending, reception and interpretation of signals from interagent organisms, the relationship(s) to the outside, and thus semiotics play an important role, creating patterns impossible to foresee if only the subsystems are known. For example, in trees, the formation of branches and leaf mosaics have been studied in a number of recent investigations with modeling approaches as well as the allocation of resources between above- and belowground biomass and the related physiological mechanisms. A modeling study of this problem indicates a 'complex integrated growth pattern' which may only be understood as an emergent property as it is claimed to have no direct or indirect mechanistic basis related to subcellular activities. In a similar manner it was shown that whole-plant behavior is an emergent property arising from a rule-based model of the system. Communications between individuals, that is, their social interactions within a population, are important to the function of the organism as a whole and are indistinguishable from the emergence of ethological features. Stressing the importance of communication, may lead to an interpretation of the communicative process as an emergent interpretation of signs, which is described within the discipline of semiotics.

Population level. Populations are composed of individual organisms, interacting in various ways, differing in quantity and quality, throughout the biological system. The interactions may vary in character according to the complexity. At the one end of the spectrum, we find the single cell organisms interacting mostly on a material basis (matter fluxes). At the other end, there are colonial organisms forming complex societies, where brains, senses, memory, and thus informational interaction become dominating. Emergent properties as a result of individual level behavior and interactions in populations of social insects have been argued in several studies. For instance, the distribution of food to larvae of the fire ant has been argued as emerging from interactions between individuals, workers, and larvae. Cellular automata models were used to study the short time oscillations in ant colonies. The nonlinear dependencies describing the relationships between, and the movement of, individuals explain this behavior. The resulting oscillations were found to be emergent properties of the colony.

Ecosystem level. Ecosystems are inherently complex as they are composed of an embedded hierarchy of all the previously mentioned subsystems in close interaction with abiotic factors. Emergence is to be expected, but surprisingly few reports exist at this level, before all analyzing microcosms, forest ecosystems, predator–prey relationships, food webs, and the organization of aquatic communities.

Ecosystem behavior is often analyzed through modeling studies. The relation to emergent properties becomes clear when looking at recent efforts of structural dynamic modeling, where the changes in ecosystem composition and structure over time are analyzed. Another example is the work of B. C. Patten on the propagation of matter–energy through the ecosystem network, leading to the discovery of the importance of 'indirect effects, quantitative and qualitative utilities' of the system, results that are highly surprising and unexpected, and as such are emergent properties. Both examples link to higher-level information expressions such as ascendency, different kinds of entropy or information derived descriptors like exergy.

The ability of the ecosystem to perform with systematic directional changes in some macroscopic characters, not predictable from knowledge about the single ecosystem members alone, has been discussed since 1967 on the basis of the 24 principles of ecosystem development during succession in the second edition of E. P. Odum's *Fundamentals of Ecology*. Many other factors, known as indicators, orientors, or goal functions have been presented since then (**Table 1**).

How Emergence Emerges

The concept of emergent properties refers very clearly to, and must be seen in tight connection with, at least two other concepts often occurring in literature on modern ecosystem theory, the concepts of hierarchy and self-organization. In connection with hierarchy, the emergent properties are seen as outcomes of ecosystem organization where supersystems are formed with subsystems as constituents and where the properties are observable at the supersystem level only. Here the emergent property is an outcome of a certain way of organization. To exemplify this point, we might look at the following hierarchical features:

1. Individual level: individual nutrition budgets – foraging strategies.

Table 1 Some ecosystem orientors

Immature state	*Mature state*
Properties of the dominating species	
Rapid growth	Slow growth
R-selection	K-selection
Quantitative growth	Qualitative development
Small size	Large size
Short life spans	Long life spans
Broad niches	Narrow niches
Properties of production	
Small biomass	Large biomass
High P/B ration	Low P/B ratio
Low respiration	High respiration
Small gross production	Medium gross production
Properties of nutrient flows and cycles	
Simple, rapid, and leaky	Complex, slow, and closed cycles
Small storage	Large storage
Extrabiotic	Intrabiotic nutrient distribution scheme
Small amounts of detritus	Large amounts of detritus
Rapid nutrient exchange	Slow nutrient exchange
Short residence times	Long residence times
Minor chemical heterogeneity	High chemical heterogeneity
Loose network articulation	High network articulation
Low diversity of flows	High diversity of flows
Undeveloped symbiosis	Developed symbiosis
Properties of the community	
Low diversity	High diversity
Poor feedback control	Developed feedback control
Poor spatial patterns	Developed spatial patterns
Thermodynamic and integrative system properties	
Poor hierarchical structure	Developed hierarchical structure
Close to equilibrium	Far from equilibrium
Low exergy storage	High exergy storage
Small total entropy production	High total entropy production
High specific entropy production	Small specific entropy production
Small level of information	High level of information
Small internal redundancy	High internal redundancy
Small path lengths	High path lengths
Low ascendency	High ascendency
Poor indirect effects	Developed indirect effects
Small respiration and evapo-transpiration	High respiration and evapo-transpiration
Small energy demand for maintenance	High energy demand for maintenance

The features, that are optimized throughout natural successions, provide several characteristics of emergent properties: They are only observable at the ecosystem level (which is the typical and the lowest logical level to describe, e.g., cycling phenomena), and they are based on self-organized processes. They can not be explained on the basis of knowledge of the parts alone, and the emergence-creating processual linkages between the sub systems are non-linear processes. From the hierarchy-based viewpoint also the additive features (e.g. size, biomass, life spans) can be categorized as emergent properties because their extensions are dependent on the scale of observation and because they also are based on internal system interrelations.

2. Population level: species nutrition efficiencies – intraspecific food competition.
3. Ecosystem level: nutrient cycling – food webs.
4. Landscape level: lateral nutrient transfers – food webs including large scale predators.

On the other hand, the ability of biological systems to arrange themselves in a special manner, for example, in a hierarchical way, is in itself a property which emerges as a consequence of the properties of its constituents, but the organization and the function for sure cannot always be foreseen. Thus, the capability of self-organization can be seen as an emergent property itself (**Fig. 1**).

The existence of emergent properties is based on the system's organization (built up by structures and functions) whereby the interrelations (energy, matter, water and information flows, communications) play an important role. Some conditions of the system's state add up to the increased chances that emergent properties will appear. For example, instabilities seem to be important

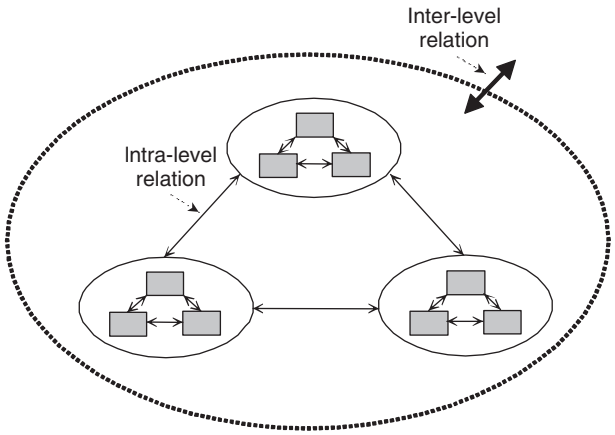

Fig. 1 Biological entities are often organized in a hierarchical manner, whereby the emergent properties of a certain level are based on the interrelations between the lower levels, while both are constrained from the highest level linkages.

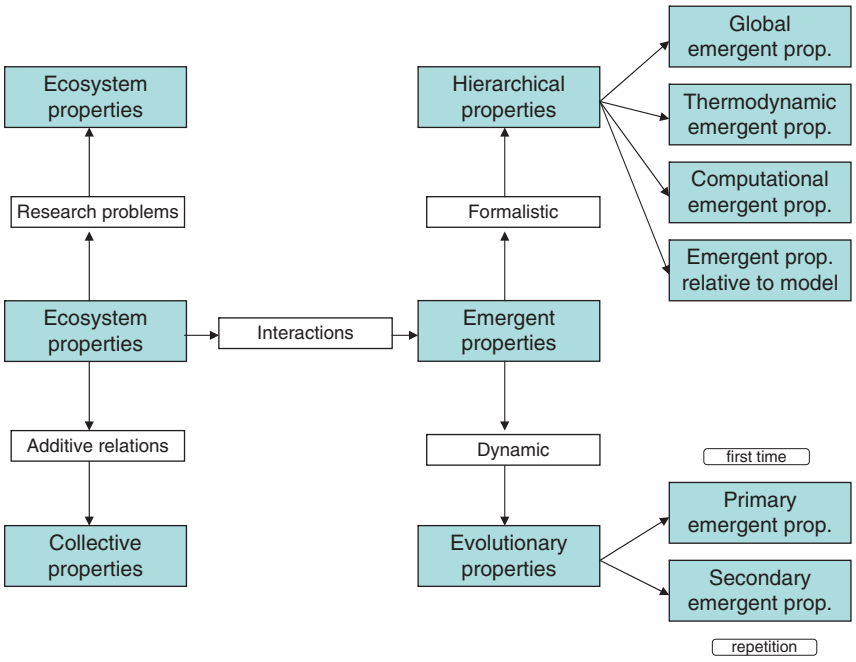

Fig. 2 An attempt to form a typology of emergent properties.

conditions that support emerging processes, especially referring to evolutionary emergence. Stable periods may lead to the emergence of new structures through bifurcations. As systems move toward the state of minimum dissipation they are, at the same time, moving toward bifurcation points with possibilities of further evolution to occur. Similarly broken symmetries, complementarity has been proposed as a global mechanism.

Classification of Emergent Properties

From the presentation of the concepts above it can be seen that emergence and emergent properties will not easily find a clear, consistent and unifying definition for covering all the cases described. The widespread and 'loose' use of the concepts over a vast range of areas at first glimpse simply shows confusion. However, it is possible to establish some typology of the areas where, and the ways in which, the concepts have been used, following Fig. 2.

First, emergent properties might appear through evolution of the systems, primary emergence, hereafter only being repeated. This characteristic may be called 'evolutionary emergence'. As structures are integrated, new organizational forms, as previously mentioned often hierarchical, occur ('hierarchical emergence').

Taking the view that emergent properties do exist and that the reductionistic approach to science will not (dis)solve the problem so it eventually disappears may allow us to establish a schematic relationship between the various categories of ecosystem properties.

One major line follows a direction of research problems, the search for the unexplained and not understood. This lies close to using emergent properties as research strategies, while the extreme leads to the reductionist approach. This is more or less the situation at the second line, where properties are 'collective' and additive, that is, that the properties are the sum of the whole, and may be explained at subsystem level, provided sufficient knowledge exists. At the other end, the attitude that only holistic studies will lead to increased understanding might be taken.

Along the third line, we find the core of emergence, and following the above points the respective features may be divided in an evolutionary line and in a hierarchal line. Here emergence is basically represented as a function of time and space. The evolutionary process was described above and deals with primary and secondary emergence. The organizational, hierarchical line includes four areas described in the previous sections: 'global emergent properties' as a function of local rules and local interactions, 'thermodynamic emergent properties' dealing with emergence as a consequence of mainly the second thermodynamic law, the emergence of (dissipative) structures as a result of thermodynamic gradients. 'Computational emergence' is also based on global patterns emerging form local rules. As mentioned above, emergent properties also appear as a result of models being used to analyze the problem, which is called 'emergent property relative to a model'.

Quantifying Emergence

Several authors argue that in any attempts to formalize or quantify the concepts, true emergent properties should be observer independent. This does not necessarily mean that emergent properties should be observation-independent. Observations undertaken by different methods result in differences in acquired knowledge. This means that emergent properties can be defined as the differences in knowledge gained by the observation of a system by two different methods. This is partly reflected by the computational emergence.

It is this observer dependency that leaves a way open for the quantification of emergent properties. Emergent properties could then be expressed in a semiquantitative way by the use of an 'index' derived of Kullback's measure of information (Fig. 3). This involves moving the normal reference frame in information theory assuming the *a priori* knowledge of the system to be zero, which is not necessarily the case.

Rather in ecology, we do possess some knowledge about the system and what we usually refer to are the deviations in what we observe in the systems or models of systems compared with our expectations built on previous knowledge. The way of quantifying emergence has to be built on the use of computers and models. If our knowledge gained hitherto is synthesized and treated in a computer model (from traditional ecological science) is p^{*}, and the outcome of an experiment or observations of a system differs by p^{**} the emergent properties can be calculated by the following:

$$\text{Emergence} = \sum p^{**} \ln \frac{p^{**}}{p^{*}}$$

which correlates emergence to the concept of exergy. Emergence now is a consequence of information gained between observations.

The question is if emergence in this manner will, at the end, dissolve itself and disappear as knowledge increases, which refers to the above debate of reductionism versus holism.

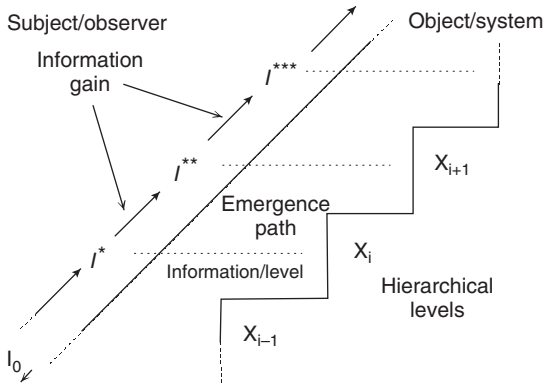

Fig. 3 Quantification of emergence, based on Kullback's measure of information, might be carried out from quantifying the difference between actual observed, *a posteriori*, behavior or composition of a system and what may be predicted from *a priori* knowledge about subsystems. The analysis may be carried out at various levels of hierarchy, differing in emergence value.

Many of the concepts used to characterize ecosystems are based on various numerical treatments of data observed in the ecosystem. Since the concepts are immediately deducible (calculable) from certain knowledge about the components of the ecosystem, for example, numbers, species, biomass etc. such concepts cannot be coined as emergent property but rather as a 'collective' property of the system. An interesting corresponding analog in this context are the macroscopic properties from thermodynamics such as entropy and parallels in formulation of formulas. Reductionism cannot win the debate since it will be impossible to achieve enough knowledge. If not for anything else, then for thermodynamic reasons, since the achievement of more and more detailed knowledge becomes more and more expensive in terms of not only energy but also dissipation.

Meanwhile, what strikes is that such a traditional, vertical organization of systems is not mandatory in order to produce emergent behavior. Vertical, here, refers to levels being either higher or lower in the hierarchy. Rather only parts are needed, of which none have actual regulatory functions and therefore should be evaluated or ranked higher than the other(s). Emergent properties can occur also in horizontally organized systems, emergence appearing alone as a consequence of interactions at the same level. The study of these intra-level relationships and their consequences to the higher levels in the hierarchy may be important to investigate in the future.

Goal Functions and Orientors

H Bossel, University of Kassel (retd.), Zierenberg, Germany

Introduction

The global ecosystem is made up of an ensemble of interacting local and regional ecosystems, each composed of biotic and abiotic subsystems. The evolution of these systems is constrained by physical and system laws and by the basic properties of their environment, including the constraints of exergy (energy that can be usefully transformed into work), material, and information flows. Sustainability (persistence) of a system in its environment therefore requires respecting these constraints. Conversely, the very fact of its persistence demonstrates that a system has successfully adapted to its operating conditions. Evolution has forced it to respect physical and system laws and the basic properties of its environment. To an observer, the system's behavior appears to be guided by a particular attractor state, or by attention to a number of orientors.

System Concepts

System Organization

'System' is anything that is composed of system elements connected in a characteristic system structure (Fig. 1). This configuration of system elements allows it to perform specific functions in its environment. These functions can be interpreted as serving a distinct system purpose. The system boundary is permeable for inputs from, and outputs to, the environment. It defines the system's identity and autonomy.

When we talk about a viable system, we mean that this system is able to survive, be healthy, and develop in its particular environment. In other words, system viability has something to do with both the system and its properties, and with the environment and its properties. And since a system usually adapts to its environment in a process of coevolution, we can expect that the properties of the system's environment will be reflected in the properties of the system; for example, the form of a fish and its mode of motion reflect the laws of fluid dynamics of its aquatic environment.

Systems are termed complex if they have an internal structure of many – qualitatively different – processes, subsystems, interconnections, and interactions. Besides assuring their own viability, the individual systems that are part of a complex total system specialize in certain functions that contribute to the viability of the total system. Viability of subsystems and the total system requires that subsystem functions and interactions are organized efficiently (or at least effectively). In the evolution of complex systems, two organizing principles in particular have established themselves: hierarchy and subsidiarity. They can be found in all successful complex systems: biological, ecological, social, political, technological.

Hierarchical organization means a nesting of subsystems and responsibilities within the total system. Each subsystem has a certain degree of autonomy for specific actions, and is responsible for performing certain tasks contributing to the viability of the total system. For example, body cells are relatively autonomous subsystems, but contribute specific functions to the operation of particular body organs, which in turn contribute to the viability of an organism.

Subsidiarity means that each subsystem is given the responsibility and the means for keeping its own house in order, within the range of its own abilities and potential. Only if conditions occur that cannot be handled by the subsystem would the suprasystem

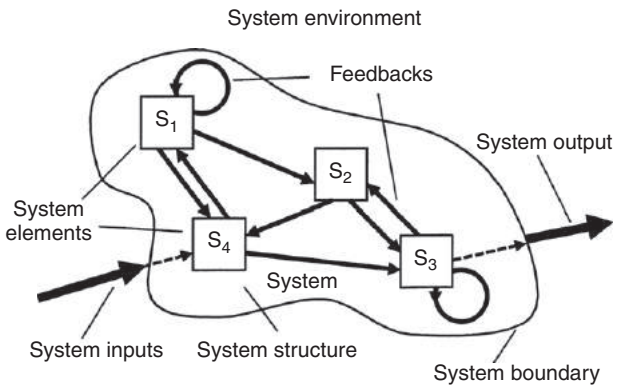

Fig. 1 System notation.

 doi:10.1016/B978-0-444-63768-0.00691-0

step in and help. The principles of hierarchical organization and subsidiarity require that each subsystem has a certain measure of autonomy. In its particular environment, each subsystem must be viable. The total system can only be viable if each of the subsystems supporting it is viable. Each subsystem reflects the properties of its individual environment; its behavior is informed (oriented) by that environment.

Note that this way of looking at complex systems is recursive. If necessary, we can apply the same system/subsystem dichotomy of viable systems again at other organizational levels. For example, a person is a subsystem of a family; a family is a subsystem of a community; a community is a subsystem of a state; a state is a subsystem of a nation, etc.

It is not enough to be concerned with the viability of individual systems. There are no isolated systems in the real world; all systems depend in one way or another on other systems. Hence their viability, and ultimately the viability of the total system are also preconditions for sustainable development. This means that a holistic system view must be adopted.

Evolution of Systems, and Emergence of Orientors and Goal Functions

The adaptation of a system to its environment is reflected in its structure, including its nonmaterial, cognitive structure. This system structure determines its behavior, and hence the adaptive response to its particular environment. System structures of material systems are dissipative; they require exergy and material flows for their construction, maintenance, renewal, and reproduction.

The dissipative structures of the global ecosystem are constructed and maintained by a finite rate of exergy input (mostly solar energy) and a finite stock of materials. The global ecosystem is therefore forced to recycle all of its essential material resources. The development of local ecosystems is constrained by the local rate of exergy flux (solar radiation input) and by the local rate of material recycling (weathering rate, absorption rate, decomposition rate, etc.) that it produces.

Evolution favors those species or (biotic) subsystems of the ecosystem that have learned to use available resources more efficiently and effectively than their competitors. This learning is embedded in their genetic code, and it is manifest in the dissipative structures they construct. Both will increase in complexity as a species evolves. At the ecosystem level, species evolution will cause increasingly better use of (exergy and material) resources. Species as well as ecosystems as a whole therefore tend to progress toward more complex dissipative structure producing more complex behavior.

Interacting species in a common ecosystem coevolve in the direction of increasing fitness of each individual species. Evolution of ecosystems therefore proceeds in the direction (arrow of time) of specialization, speciation, synergy, complexification, diversity, maximum throughflow of exergy, and more efficient use of material resources. This development becomes manifest in the corresponding emergent properties: exergy degradation, recycling, minimization of output, efficiency of internal flows, homeostasis and adaptation, diversity, heterogeneousness, hierarchy and selectivity, organization, minimization of maintenance costs, storage of available resources. These properties can be viewed as orientors, propensities, or attractors guiding system evolution and development. They are not limited to ecosystems; they are a general feature of living systems, including human organizations. When quantified and used in models, we refer to them as goal functions.

In particular, ecosystems will therefore build up in the course of their development as much dissipative structure as can be supported by the available exergy gradient. Available opportunities will eventually be found out by the processes of evolution, and will then be utilized. The ability to respond successfully to environmental challenges can be 'interpreted' as intelligent behavior, although it is strictly the result of nonteleological evolutionary development.

System Orientation in a Complex Environment

Basic concepts can be introduced by visualizing a simple animal with limited vision in a simple environment. The animal requires exergy for self-organization, motion, harvesting food, and maintenance. The environment provides food in certain locations, usually associated with obstacles that must be avoided since they have an exergy cost.

In a stable environment where sufficient (regenerating) food is distributed in a completely regular pattern, evolutionary adaptation would eventually lead to optimization of an animal's movements in a regular grazing pattern, with a single objective, optimum exergy uptake and use. The regular grazing pattern reflects the complete certainty of the next step, which the animal learns by accumulating and internalizing experience in a cognitive structure aiding its limited vision.

In more complex and diverse environments the animal, because of its limited vision, may not know for several steps which situation it will encounter next. It will therefore have to develop decision rules that have greater generality and are applicable to (and will be reinforced by) different motion sequences with different outcomes. In addition to the requirement of harvesting and using exergy resources effectively and efficiently, another objective is now implicitly added, to secure food under the constraint of incomplete information, that is, a security objective. Note that this is an emergent property that is not explicit in the reward system (which still rewards only food uptake). Failure to heed this implicit security objective will reduce food uptake and may endanger survival. On the other hand, the pressure to play it safe will occasionally mean giving up relatively certain reward. With other words, efficiency is traded for more security, and both are now prominent normative orientations (goals, values, interests) incorporated in the cognitive structure.

Orientation theory deals in a more general way with the emergence of behavioral objectives (orientors) in self-organizing systems in general environments. The proposition is that if a system is to survive in a given environment – characterized by a specific normal environmental state, sparse resources, variety, unreliability, change, and the presence of other systems – it must be able to physically exist in (be compatible with) this environment, effectively harvest necessary resources, freely respond to

environmental variety, protect itself from unpredictable threats, adapt to changes in the environment, and interact productively with other systems. These essential orientations emerge in the course of the system's evolution in its environment.

Properties of Environments

There is obviously an immense variety of system environments, just as there is an immense variety of systems. But all of these environments have some common general properties. These properties will be reflected in systems. These reflections, or basic orientors, orient not just structure and function of systems, but also their behavior in the environment. The term orientor is used to denote (explicit or implicit) normative concepts that direct behavior and development of systems in general. In the social context, values and norms, objectives and goals are important orientors. Ecosystems and organisms tend toward certain attractor states whose specific characteristics can be viewed as orientors. Orientors exist at different levels of concreteness within an orientor hierarchy. The most fundamental orientors, the basic orientors, are identical for all complex adaptive systems. Orientors are dimensions of concern; they are not specific goals. Their satisfaction can be determined by observation of corresponding indicators, which can also be used to define goal functions for model studies.

In addition to the physical constraints of exergy and material flows, ecosystem and species development is determined by the 'general properties of the environment':

1. *Normal environmental state*. The actual environmental state can vary around this state in a certain range.
2. *Scarce resources*. Resources (exergy, matter, information) required for a system's survival are not immediately available when and where needed.
3. *Variety*. Many qualitatively very different processes and patterns occur in the environment constantly or intermittently.
4. *Reliability*. The normal environmental state fluctuates in random ways, and the fluctuations may occasionally take it far from the normal state.
5. *Change*. In the course of time, the normal environmental state may gradually or abruptly change to a permanently different normal environmental state.
6. *Other systems*. The behavior of other systems changes the environment of a given system.

Basic Orientors

If evolution enforces fitness of (natural) systems, then persistent systems must reflect the properties of their environment in their structure. More generally, the basic properties of the environment require corresponding basic system features. Since the basic environmental properties are independent of each other, a similar set of independent system features must exist, and it must find expression in the concrete features of the system structure.

There is a one-to-one relationship between the properties of the environment and the 'basic orientors of systems' (Fig. 2):

1. *Existence*. Attention to existential conditions is necessary to insure the basic compatibility and immediate survival of the system in the normal environmental state.

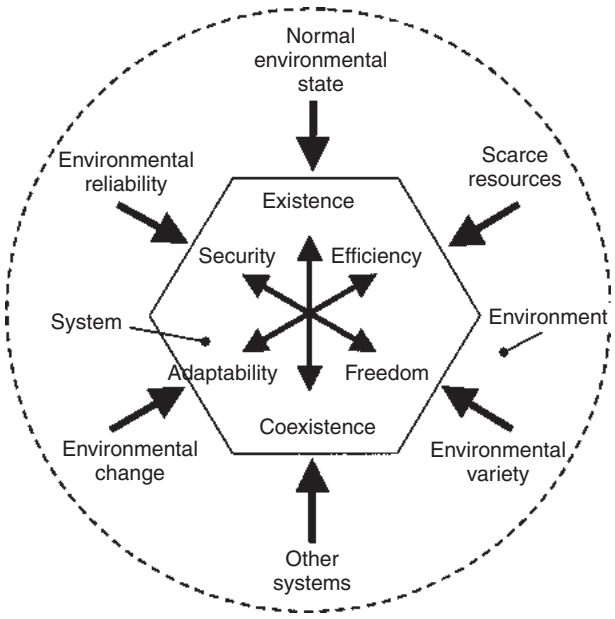

Fig. 2 A tentative typology of emergent properties.

2. *Effectiveness*. In its efforts to secure scarce resources (exergy, matter, information) from, and to exert influence on its environment, the system should on balance be effective.
3. *Freedom of action*. The system must have the ability to cope in various ways with the challenges posed by environmental variety.
4. *Security*. The system must have the ability to protect itself from the detrimental effects of variable, fluctuating, unpredictable, and unreliable environmental conditions.
5. *Adaptability*. The system should be able to change its parameters and/or structure in order to generate more appropriate responses to challenges posed by changing environmental conditions.
6. *Coexistence*. The system must modify its behavior to account for behavior and interests (orientors) of other systems.

Obviously, the system equipped to secure better overall orientor satisfaction will have better fitness, and will therefore have a better chance for long-term survival and sustainability. In persistent systems or species, these orientors will be found as emergent objectives (or system interests).

Properties of Orientors

Each of the basic orientors stands for a unique requirement. Attention (conscious or unconscious) must therefore be paid to each of them, and the compensation of deficits of one orientor by over-fulfillment of other orientors is not possible. Fitness forces a multicriteria response, and comprehensive (conscious or unconscious) assessments of system behavior and development must also be multicriteria assessments.

In the assessment and orientation of system behavior, we deal with a two-phase assessment process where each phase is different from the other.

Phase 1. First, a certain minimum satisfaction must be guaranteed separately for each of the basic orientors. A deficit in even one of the basic orientors threatens long-term survival. The system will have to focus its attention on this deficit.

Phase 2. Only if the required minimum satisfaction of all basic orientors is guaranteed is it permissible to try to raise system satisfaction by improving satisfaction of individual orientors further.

Adequate satisfaction of each of the basic orientors requires, on a lower level, system- and environment-specific satisfaction of thermodynamic, structural, functional, ecophysiological, and system orientors. Network analysis suggests complementarity of different formulations of extremal principles as orientors describing ecosystem development.

Characteristic differences in the behavior of otherwise very similar systems (animals, humans, political, or cultural groups) can often be explained by differences in the relative importance attached to different basic orientors (i.e., emphasis on freedom, or security, or effectiveness, or adaptability) in phase 2 (i.e., after minimum requirements for all basic orientors have been satisfied in phase 1).

The basic orientor proposition has three important implications:

1. If a system evolves in a normal environment, then that environment forces it to implicitly or explicitly ensure minimum and balanced satisfaction of each of the basic orientors (and of lower-level orientors contributing to this satisfaction).
2. If a system has successfully evolved in a normal environment, its behavior will exhibit balanced satisfaction of each of the basic orientors.
3. If a system is to be designed for a normal environment, proper and balanced attention must be paid to satisfaction of each of the basic orientors.

The third implication has particular relevance for the creation of programs, institutions, and organizations in the sociopolitical sphere, among other things. Note that for a specific system in a specific environment, each orientor will have a specific meaning. For example, security of a nation is a multifacetted objective set with very different content from the security of an individual particular organism. However, the systems theoretical background for satisfaction of the security orientor is the same in both cases.

Orientors as Implicit Attractors

Better orientor satisfaction (better fitness) for more participants in a system requires more dissipative structure, which requires more exergy throughput as well as exergy accumulation. Since the exergy flow of ecosystems is limited (capture of solar radiation by photoproduction), increasingly better utilization is to be expected in the course of system development. This saturates at maximum exergy flow utilization for the ecosystem as a whole. Ecosystems as a whole therefore move in the direction of using all available exergy gradients. For organisms in the ecosystem, this implies development tendencies (orientors, propensities, attractors) toward specialization (using previously unused gradients), more complex structure (greater use efficiency), larger individuals (less maintenance exergy required per biomass unit), mutualism, etc. For species development, this translates into a principle of maximum exergy use efficiency. On the basis of these principles, prediction of development trends in ecosystems is possible.

The selection for better fitness in evolutionary processes favors systems (organisms) with better coping ability. Aspects of the behavioral spectrum of a system that improve coping ability (basic orientors) can be understood as implicit goals or attractors: existence, security, effectiveness, freedom, adaptability, coexistence. In the developmental stage of ecosystems, emphasis is on the basic orientors: existence, effectiveness, and freedom; in the mature stage it shifts to security, adaptability, and coexistence (see **Table 1**, where orientor concepts have been linked to E. P. Odum's classical model of ecological succession).

Table 1 Orientor concepts in the context of ecological succession

	Developmental stage	*Mature stage*
	Basic orientor emphasis	
	Existence	Coexistence
	Freedom	Security
	Effectiveness	Adaptability
Ecosystem orientor	*Orientor emphasis (goal function)*	
Growth and change	High	Low
Life cycle	Short, simple	Long, complex
Biomass	Low	High
Energy conservation	Low	High
Nutrient conservation	Low	High
Nutrient recycling	Low	High
Specialization	Low	High
Diversity	Low	High
Organization	Low	High
Symbiosis	Low	High
Stability; feedback control	Low	High
Structure	Linear, simple	Network, complex
Information	Low	High
Entropy	High	Low

The existence of these implicit goals does not imply teleologic or teleonomic development toward a given goal (where the final state is specified). These attractors do not determine the exact future states of the system at all; they only pose constraints on choices (or evolutionary selection). The process and its rules are known, the product is unknown. The spectrum of (qualitatively different) possible future development paths and sustainable states remains enormous. The shape of the future, and of the systems that shape it, cannot be predicted this way. All one can say with certainty, however, is that (1) all possible futures must be continuous developments from the past, and (2) paths with better orientor satisfaction are more likely to succeed in the long run (if options to change paths have not been foreclosed).

In many systems, in particular ecosystems, specific attractors or functional orientors are often more immediately obvious than the basic orientors that cause the emergence of these orientors in the first place. These orientors can be viewed as appearing on a level below the basic orientors in the hierarchical orientation system (see **Table 1**). They translate the fundamental system needs expressed in the basic orientors into concrete attractor states linking system response to environmental properties. In models and ecosystem analyses, measures of ecosystem integrity can be based on corresponding ecosystem goal functions. Ecosystem attractor states emerge as general ecosystem properties in the coevolution of ecosystem and environment. They can be viewed as ecosystem-specific responses to the need to satisfy the basic orientors. Major ecosystem orientors are optimization of use of solar radiation, material, and energy flow intensities (networks); matter and energy cycling (cycling index); storage capacity (biomass accumulation); nutrient conservation, respiration, and transpiration; diversity (organization); hierarchy (signal filtering).

The emergence of basic orientors in response to the general properties of environments can be deduced from general systems theory, but supporting empirical evidence and related theoretical concepts can also be found in such fields as psychology, sociology, and the study of artificial life.

Orientor Guidance in System Development, Control, Adaptation, and Evolution

Environmental influences partially determine system behavior. The magnitude of their effect on behavior depends on the influence structure of the system.

Sometimes systems can be controlled by controlling the inputs from their environment. However, the feedbacks in the system itself are usually more important for system control and adaptation of behavior to environmental conditions. Feedback means that the system state influences itself. Behavior-changing internal feedbacks are possible on several hierarchical levels in complex systems with different typical response characteristics and time constants (typical response times). These possibilities are also shown in **Fig. 3**.

Response time	*Level*	*Response*
Immediate	Process	Cause–effect
Short	Feedback	Control
Medium	Adaptation	Parameter change
Long	Self-organization	Structural change
Very long	Evolution	Change of identity
Always	Basic orientors	Maintaining integrity

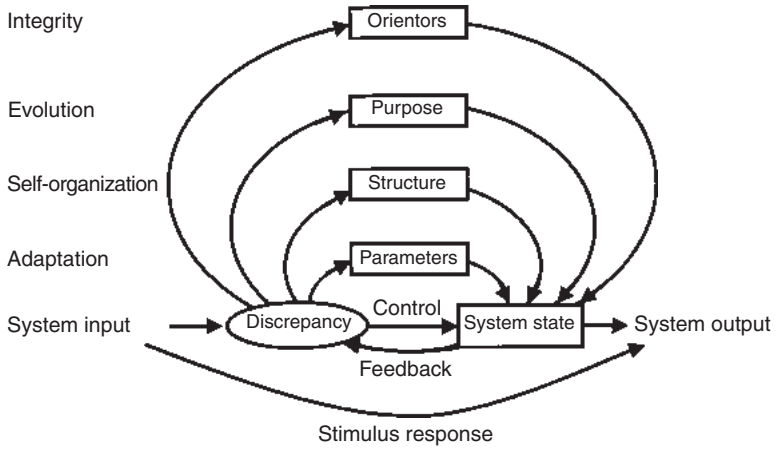

Fig. 3 System response can be caused by different processes with very different time constants: stimulus–response, feedback control, adaptation, self-organization, evolution, maintaining system integrity.

The simplest type of system response is the cause–effect relationship. It occurs at once as in for example, stimulus–response reflex. It is the only type of system behavior which can legitimately be described by relating the output directly to the input. Unfortunately, it is often assumed that the same simple relationship is also applicable to other types of system response (such as the following), and this erroneous assumption often leads to fundamental mistakes.

On the next higher level we find responses which are generated by feedback in the system, involving at least one state variable or delay – such as an empty stomach causing hunger and the search for food. Control processes belong to this category. The response time is short, and influence structure and system parameters remain invariant.

On the next higher level we find processes of adaptation. In this case the system maintains its basic influence structure, but parameters are adjusted to adapt to the situation, possibly changing the response characteristics in the process. For example, a tree may adapt to the gradual lowering of the groundwater level by growing its roots to greater depth. This constitutes a parameter change (root length and root surface). The fundamental system structure of a tree, in particular, the function of the roots, has not changed in this case.

On the next higher level we find processes of self-organization in response to environmental challenges. This means structural change in the system. Processes of this kind have a longer response time and can only be conducted by systems having the capability for self-organization. Adult organisms or technical systems rarely or never belong to this category; on the other hand, this characteristic is often found in the development of organisms, social systems, organizations, and ecosystems.

A system may also change its identity in the course of an evolutionary process. This means that its functional characteristics, and hence its system purpose, change with time. Adaptations of this kind take place as a result of reproduction and evolution of living organisms. It is characteristic of this process that the system change coincides with a possibly drastic shift in system identity (change of goal function and of system purpose). An evolutionary example is the development of flying animals (birds) from water-dwelling reptiles.

All of these system responses to challenges from the environment in essence constitute attempts to maintain system integrity (possibly over many generations and over a long time period) even if it means changing system identity, that is, system purpose. From this observation it can be deduced that a system must orient its development with respect to certain basic criteria (basic orientors) to assure its long-term existence and development in an often hostile environment. This orientation may be implicit (forced upon the system) or explicit (actively pursued by the system). It does not require conscious decision or even cognitive ability, although resulting action may appear to an observer as intelligent or even goal- or value-oriented behavior.

Simulation of the Evolution of System Orientation

Animats and Genetic Algorithms for Orientation

Orientation theory is not just a conceptual framework for understanding system evolution and behavior under the exergy availability constraint. It also allows quantitative and comparative analysis of system performance under different environmental conditions.

Genetic algorithms are models of biological adaptive processes that are being widely and successfully applied to a wide spectrum of adaptation and optimization problems. In particular, these algorithms have been used to simulate learning and adaptation of artificial animals (animats) in simulated environments containing food and obstacles. They can be used to demonstrate the emergence of basic orientors in self-organizing systems having to cope with complex environments.

The animat model incorporates essential features of a simple animal in a diverse environment. Being an open system, an animal depends on a flow of exergy from the environment. In the course of its (species) evolution, it has to learn to associate certain signals from the environment with reward or pain and to either seek or avoid their respective sources (exergy gain or exergy loss). This learning phase (of populations) will eventually lead to the establishment of cognitive structure and behavioral rules which are approximately optimal in the particular environment (with respect to maximization of reward, minimization of pain, and securing survival). These behavioral rules incorporate knowledge which enables intelligent behavior.

The animat is designed to simulate this process. It can pick up sensory signals from its environment (containing food and obstacles), and classify them with available rules to determine an appropriate action (direction of movement). After a successful move, the strength of rules leading up to it is increased by sharing in the reward (i.e., exergy gain). New rules are occasionally generated by either random creation, or by genetic operations (crossing-over and recombination). They are added to the existing rule set, and compete with the other rules for reward. Unsuccessful rules are not reinforced and lose strength and influence in the rule set.

The training process consists of placing the animat at a random empty location in an environment with specific environmental properties, and allowing it to move around searching for food. A collision with an obstacle causes a loss of exergy and throws the animat back to its previous position. Rules leading to success are rewarded. A genetic event of rule generation may occur with a prescribed probability. Random rules are created in unknown situations. The process is repeated for a large number of steps (typically 10 000). Eventually, a set of behavioral rules develops which allows optimal behavior under the given set of conditions.

Note that this optimal behavior has not been defined in terms of an objective function guiding the evolution of the set of behavioral rules. The rule set develops solely from the reinforcement of rules which lead to food or avoid collisions. An explicit exergy balance accounts for all exergy losses associated with movement, collisions with obstacles, and rule generation, and exergy gains due to uptake of food. The development of the rule set is then driven by the requirement to optimize exergy pickup in the given environment (with specific resource availability), while allowing for environmental variety, variability, and change specific for that environment. Neglect of these properties is penalized by lack of fitness, and threat to survival, and causes disappearance of deficient rules. Other criteria besides efficiency will therefore be reflected in the set of behavioral rules. Since these were not expressly introduced, we must recognize them as emergent value orientations or objective functions.

The animat experiment contains all components necessary for a study in the basic orientor framework. Animat fitness depends on the ability to maintain a positive exergy balance in the long term. This exergy balance is therefore at the core of the orientor satisfaction assessment. At each step, exergy uptake (by food consumption) and exergy losses (by collisions with obstacles, motion, and learning of rules) are recorded and used to compute the momentary exergy balance. Attention to all orientors is mandatory to ensure a positive exergy balance even under adverse environmental conditions.

Quantitative measures must be defined for characterizing the different properties of the environments used in the animat experiments. Animat performance in different environments is compared by using measures of orientor satisfaction. These have to be defined using relevant parameters of animat performance.

Emergence of Basic Value Orientations, Anticipation, and Individual Differences

Since the animat's training depends on a number of random factors, each animat develops a different cognitive system (classifier set and decision rules), even though final performance may be similar. In order to show general tendencies despite these individual differences, mean values over large populations were obtained. These dealt with (1) results of the training process in two (otherwise identical) environments having different variety and variability, and with (2) performance of animats after transfer from their training environment to environments challenging them with more variety, or variability, or change.

One remarkable result from these experiments is that individuals achieve comparable performance in a given training environment with very different cognitive systems, and in particular with different orientor emphasis. While this may not provide any particular advantage in the training environment, it may provide distinct fitness advantages if the animat is moved to a different environment. Three particular types of individuals stand out: generalists (type F) stressing freedom of action, specialists (type E) focusing on effectiveness, and cautious type (type S) emphasizing security. **Fig. 4** shows the different orientor stars for these three types.

The ability to develop a cognitive system reflecting its environment makes the animat a suitable vehicle for investigating goal function emergence and value orientation. Genetic algorithms are very effective processes that seem to capture the essentials of real processes found in the evolution of organisms and ecosystems. In the animat, they very effectively build up a cognitive model (or goal function) that enables anticipatory behavior; since rewards flow back to earlier rules leading to later pay-off, the activation of the initial rules in a pay-off chain means that the system suspects possible pay-off and anticipates the near future, that is, it has an internal model of the results of its actions under the given circumstances.

In the animat experiments (and similarly, in real life), implicit and (more or less) balanced multidimensional attention to the basic orientors emerges from the simple one-dimensional mechanism of rewarding success in the given environment. Thus, in the course of its evolutionary development in interaction with its environment, the system evolves a complex multidimensional behavioral objective function from the very unspecific requirement of fitness. Conversely, this also means that balanced attention to the emergent basic orientors is necessary for system viability and survival – they would not have emerged unless important for the viability of the system.

Balanced attention still leaves room for individual differences in the relative emphasis given to the different orientors. Individuals belonging to the populations used in the animat experiments evolve significant differences in value emphasis

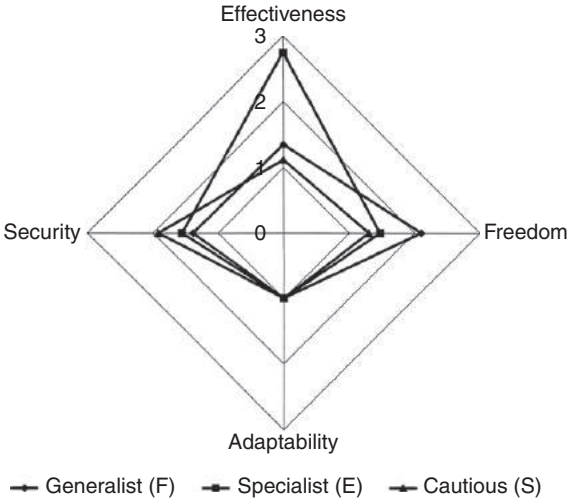

Fig. 4 In an identical training environment, different lifestyles may evolve. Generalists stress freedom of action, specialists focus on effectiveness, while cautious types emphasize security.

(e.g., specialist, generalist, cautious type). These individual variations, while not significantly reducing performance in the standard training environment, provide comparative advantage and enhanced fitness when resource availability, variety, or reliability of the environment change. They also result in distinctly different behavioral styles. However, pathological behavior will follow if orientor attention becomes unbalanced (e.g., dominant emphasis on one orientor).

Training of animats in different environments, the performance of animat individuals in environments that differ from their training environments, and the simulation of adaptive learning in a changing environment, lead to some general conclusions that are in full agreement with everyday observations and general systems knowledge:

- Generalists have a better survival chance than others if moved to an environment of greater variety.
- Cautious types have a better survival chance than others if moved to a less reliable environment.
- Training in more unreliable and/or more diverse environments increases satisfaction of the security and/or freedom of action orientors at the cost of the effectiveness orientor.
- Training in an uncertain environment teaches caution and improves fitness in a different environment.
- Learning caution (better satisfaction of the security orientor) takes time and decreases effectiveness, but increases overall fitness.
- Investment in learning (exergy cost of learning in the animat) pays off in better fitness; the learning investment is (usually) much smaller than the pay-off gain.

Animat individuals not only develop behavior that can be interpreted as intelligent, they also develop a complex goal function (balanced attention to basic orientors), or value orientation. Serious attention to basic values (basic orientors: existence, effectiveness, freedom, security, adaptability, coexistence) is therefore an objective requirement emerging in, and characterizing self-organizing systems. These basic values are not subjective human inventions; they are objective consequences of the process of self-organization in response to normal environmental properties.

Hierarchy Theory in Ecology

TFH Allen, University of Wisconsin, Madison, WI, USA

Need for Hierarchy Theory

In ecology we need a body of theory to address relationships that are consequences of changing levels of analysis, which call for altered definitions. For instance, the contemporary fracas over definitions of plant competition could benefit from recognizing differences in the scope and type of the framework used by the respective partisans. With distinctions between levels of analysis made clear, each school may test their respective hypotheses in peace aware of which theories actually compete and when they merely address some other level of discourse. The contentious literature surrounding overcompensation of plants in response to losses to grazing was significantly a matter of pulse versus press consumption in relation to different timescales for assessing recovery. The Clements/Gleason debate over the proper definition of plant community might not have lasted the body of the twentieth century had hierarchy theory been available at the onset of hostilities when Nichols attacked Gleason's paper at the 1926 International Congress of Plant Sciences. Hierarchy theory's focus on level of analysis offers such clarification. It lays subtle distinctions bare, so that definitions work for the ecologist instead of ecologists working for their definitions.

If big, slow things were always on top, such that hierarchical levels were only a matter of scale, the problem would reduce to a straightforward technical scaling issue. Not to underestimate the challenges of scaling in engineering, but that technical setting does not need something as grand as a theory to deal with hierarchies. But in ecology, scaling is complicated by higher ecological levels giving lower levels meaning. In ecology, the move upscale to be more inclusive often changes significance more than it invokes a change of size, and so we do indeed need a special body of theory to deal with difference of quality, not just quantity. Differences in scale quickly become large enough to cause qualitative change in perception, which forces a change in the level of analysis. Thus scale is soon embroiled in values, judgment, and arbitrary choices, not just as an inconvenience, but as a necessity for proper understanding. While scaling as an engineering technicality actively ignores such messy issues, hierarchy theory explicitly includes value-based decisions of the observer in creating hierarchies.

To control for observer values, technical measurement and analysis in science keeps its criteria constant across the local discourse. But large discoveries precisely amount to the recognition of a change in value. New scientific ideas indicate a specific change in the preanalytic stage, before deciding what might be relevant data. In the terms of Russell and Whitehead (made accessible by Gregory Bateson), new scientific ideas amount to the definition of new logical types. Hierarchy theory's central activity is recognizing logical type. Logical types are tied to some new level of inclusivity, a new hierarchical level with its own meaning. Notice how left and right sides are possessed by organisms at their own level of existence. Meanwhile, the notions of up and down refer to a larger discourse that includes an environment, which is shared by many organisms. As a result, a mirror switches the image left and right, but with no switch in up versus down. The larger scope invoked by the idea of up introduces a new logical type, even though left and right may often be simply at right angles to up and down. If left and right contrasted with up and down can be problematic, ecosystems are a nightmare. While exquisitely holding criteria constant in formal scientific calibration will help, it is insufficient for large discoveries, which turn on recognizing when a new type is necessary to solve some puzzle.

Ecology in particular invites many logical types because its hierarchies are so rich. A new type invokes new aggregation criteria, which come explicitly from observer decisions. Consider the difference between a community conception of vegetation as opposed to the process-functional conception that prevails in ecosystem modeling. A forest can be considered as a collection of trees on a tract of land. Alternatively those same tree trunks may be aggregated as a separate class from the leaves (**Fig. 1**). If leaves in a forest are the production system independent of species, then the boles are part of the carbon storage function. This assignment has the peculiar effect of unifying the tree trunks with soil carbon in a single carbon storage compartment. A community focus aggregates trees set in an environment of soil and atmosphere. Meanwhile a flux-process conception splits the trees into at least two parts, one of which aggregates with the soil. But the soil was part of the environment in the community conception. Thus the same pieces of soil and plant biomass are aggregated into different higher units, depending on the type of system that is recognized as being in the foreground by the observer. Note how forests under either conception may be called forest ecosystems, suggesting that one use of hierarchy theory is to untangle alternative meanings in commonplace ecological terminology. The difference between a process-focused ecosystem and a community is a change in logical type.

Hierarchy and Hypothesis

Hierarchy theory is a body of thought that relates chosen levels of analysis to defined levels of organization, all in the context of scaling. It advises the scientist of subtle but crucial distinctions that follow from observing and making analytical decisions. A significant part of hierarchy theory is observation in relation to conceptions of order in complex systems that would otherwise

 doi:10.1016/B978-0-444-63768-0.00692-2

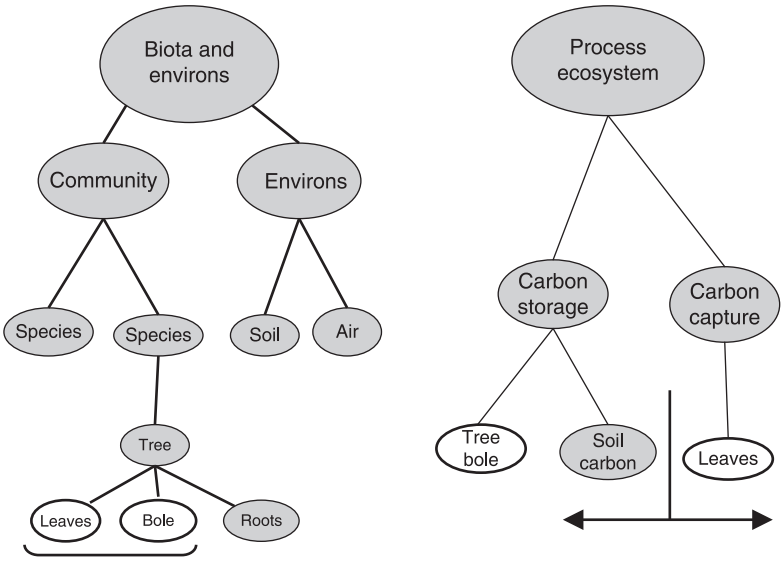

Fig. 1 A community conception leads to an expected situating of whole trees in an environment. But a process-functional ecosystem conception of that same forest can lead to a hierarchy where tree boles are separated from the leaves, and then united with soil elements in a carbon storage compartment. Each respective hierarchy takes its form from the purpose for which it is intended.

invite confusion. It is a metatheory that guides the generation, fine-tuning and testing of other bodies of thought, themselves more easily recognizable as theories in the conventional sense. Some theories in ecology are associated with answering questions taken as given. Such theory is validated in testing hypotheses. Other ecological theories may fine-tune questions, perhaps clarifying what is meant by competition, so that worthwhile hypotheses may be generated. By contrast, hierarchy theory applies in the pre-analytical stage, when the questions are being framed rather than when clarified or answered. In the preanalytical stage, the boundaries of things are established, and structures are assigned to types or classes. With the discourse laid out unambiguously by hierarchy theory, other theories may come into play, testing explicit hypotheses with measurement and models. Thus hierarchy theory does not have its own hypotheses *per se*, but rather opens the way for subsequent testing of specific hypotheses. Like multivariate description in ecology, hierarchy theory focuses on hypothesis generation and clarification. From a small number of first principles, it highlights what would be otherwise taken for granted and then forgotten in the muddle that ensues. Hierarchy theory is explicit, as it positions the tacit next to the focal. Its precision is in thought and choosing definitions, more than action in quantitative experimentation.

Hierarchical Levels

Entities in a hierarchy are recognized as belonging to levels. Levels are sets, but the sets become levels because of robust asymmetry between them in a hierarchy. Mathematically, the asymmetry between levels makes hierarchies partially ordered sets. Hierarchy theory is the set theory that may precede network theory. A level of analysis assigns entities to levels, and is often explicit about their relationship to other entities assigned to other levels. There is a distinction between levels of observation and levels of organization. Levels of observation are ordered relative to each other on matters of size and scale. Meanwhile relationships between levels of organization follow from definitions chosen by observers, sometimes as a prelude to actual observation. For instance, organisms are subsumed by populations only by a definition. Hidden in the definition is a requirement for equivalence between population members. Meanwhile, a host and its parasite, while both organisms, are generally not assigned to the same population, in part because of inequivalent size. Host versus parasite is the basis of a hierarchy employing levels subtly different from those in the population/organism distinction. Hierarchy theory places entities in levels, taking care to be explicit about the definitions that lead to those levels, and the criteria that create order and linkage.

Scale versus definition has potential for generating different sorts of hierarchies. Some hierarchies focus on size and containment, while others are control hierarchies where upper level entities simply control lower levels. A Watt governor may be placed at a higher level in a control hierarchy, while being smaller than the whole steam engine it controls. Whether it is a scalar or a control hierarchy depends on the use for which the hierarchical conception is intended, something for which the observer must take responsibility. Time against space plots are popular in landscape ecology. But such hierarchies can miss out on the interesting situations where large space maps onto short time spans, or long time spans map onto small places (**Fig. 2**). The globe is large enough to be the context of continental movement over hundreds of millions of years, but at the same time the rotation of the globe is also responsible for diurnal phenomena, at the fast end of ecological happenings. Surfaces arise when narrow space applies to large differences in time constants (strong temporal connection within, but weak connections across surfaces). Ecotones

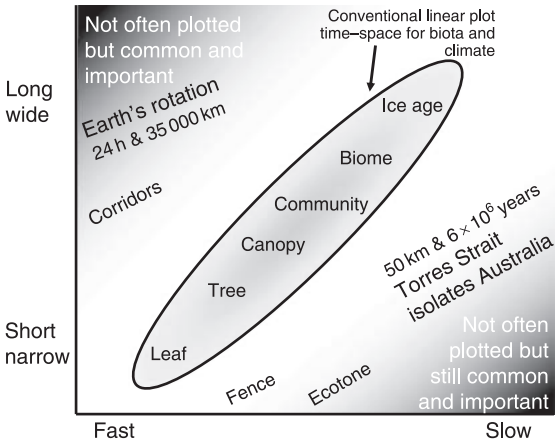

Fig. 2 A common graph appearing in landscape ecology plots increases in time against space, focusing on the quasi-linear pattern of larger things seen as behaving over longer time periods. But such plots ignore potential control systems and their hierarchies. Local intransigence can control large entities (Wallace's realms where Australia's fauna is isolated from Asia by the narrow Torres Strait, separating millions of years of evolution). Barriers and surfaces occur at the lower right, while communication channels and corridors appear upper left.

would be a case in point, because there is rapid exchange and fast process inside the abutting ecosystems or communities areas, while the exchanges across the narrow ecotone may be remarkably slow. Thus ecotones are spatially small, while representing slow exchanges that might cause the ecotone to move in a process of gradual encroachment. Conversely, in a communication channel, small differences in time constants apply along the long connection. Corridors would be an example here, where there is rapid movement along the extended length of the corridor. In ecology, these special places, such as ecotones and corridors, are at least as interesting as situations where time and space widen in concert. Complexity in hierarchies arises from the challenge of mapping between levels, as scale and definition entwine.

History of the Field

Hierarchy theory has its roots in economics and business administration of the 1960s, suggesting that the world appears nearly decomposable. We can decompose wholes into parts, but only to a degree, in that parts communicate and leak onto each other. Complete decomposability would deny upper-level structures' existence. Completely decomposed, the parts would not to be able to communicate with each other in making the larger whole. Parts have strong connections within, but weak connections between, and those weak connections may be precisely what links hierarchical levels (Fig. 3).

While some practitioners in subsequent studies have sought real hierarchies in an external world, much of the early literature of business administration hierarchies is agnostic about the ultimate reality of hierarchical structure. In this spirit, hierarchy theory in social organizations operates largely in the realm of epistemology, as a theory of observation and analysis. The discourse generally takes the position that hierarchies appear somewhere between the material world and human understanding. If there are complex

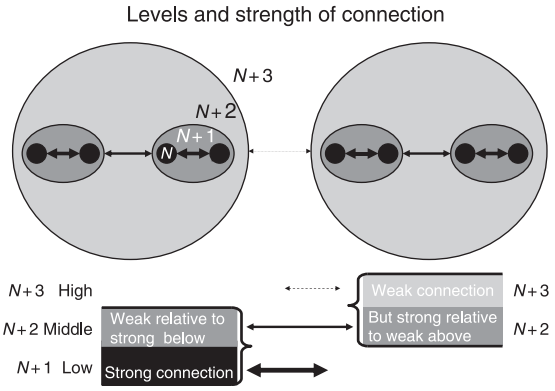

Fig. 3 In nested hierarchies, the bonds that unite members of the lowest level N are strong, as they make entities of level $N+1$. The bonds that create level $N+2$ are weaker. Nevertheless, these weaker bonds appear as the strong bonds making the entities at level $N+2$ when seen from level $N+3$. If the two largest units in the figure are molecules, then the entities at $N+1$ are atoms. Breaking their atomic bonds releases huge amounts of atomic energy as subatomic particles, N, are freed. Atomic bonds are stronger and release more energy when broken, compared to breaking the chemical bonds that make molecules, the $N+2$ entities.

material systems that are not hierarchic, we might expect to have great difficulty in observing or understanding them. There appear to be points of passage of information up hierarchies, where details are explicitly lost. A military command is a favorite hierarchic example of a human organization. There, details of how an individual soldier observed local enemy concentrations fall away as the intelligence passes up the command. Setting the detail aside allows the top brass to make sweeping decisions, without being encumbered by a blizzard of local happenings. Not only must the general in command let go of details of grains so as to get a handle on the wide extent, but so too must the observers of hierarchical structure. To understand what a general is doing, the observer of a command structure needs to integrate away the details inside the army. By the late 1960s, the notion of hierarchy had moved beyond administration systems, and was being taken up across a range of disciplines.

In the following decade, hierarchy theorists from physics addressed hierarchical complexity after Heisenberg, invoking dualities, uncertainty, and complementarity between dynamics versus structure. Important developments have turned on the tension across the dilemmas presented by dual structures, as in the holon, a generalized entity in a hierarchy. Holons have been equated with the concept of system, with the advantage that holon does not appear in common parlance. The holon can therefore escape the reification and slovenly usage in the vernacular where the model is mistaken for the materiality. Conceptual developments suggest that what is inside a given holon is chosen by an observer. This emphasizes that holons are abstractions more than material objects; a point forgotten when 'system' is used for 'holon'. In the holon, the tension is between system and subsystem. But the subsystem is a system in its own right, thus offering some sort of dual existence that invites contradiction.

The concept of the holon takes the whole to be a surface that integrates the parts to give a unified signal to the rest of the universe. At the same time, the holon is the surface that integrates the external environment for the parts to experience. In ecology, the environment falls away at the level of the holon when viewed from the perspective of the parts. A forest raises humidity and lowers temperature, thus allowing survival of some of its parts, tree seedlings that are its future. The parts are protected. Conversely, viewed from the context of the hot, dry environment surrounding the forest, the contributions of each tree to the water vapor inside the forest are lost in a more general flux of water from the canopy. Thus, loss of information occurs with movement both up and down the hierarchy. While the environment is too large to catch the details of the working of the parts, the parts themselves cannot span wide enough to see large, slow differences in the larger context. In all this, we see again the tension embodied in hierarchical discussions between scale, organization, and uncertainty in observation.

Earlier, five general principles for ordering ecological hierarchies were recognized:

(1) As to frequency of behavior, higher-level holons operate at a lower frequency, taking longer to exhibit returns in behavior than holons at lower levels.
(2) Higher levels in a hierarchy constrain lower levels by displaying intransigent constancy. Deans constrain faculty by not changing the budget, except once a year.
(3) Higher levels in a hierarchy will be contextual to lower levels. The environment would be seen as operating at a higher level.
(4) With regard to bond strength, higher-level holons are held together by weaker forces than those that integrate lower-level holons (e.g., chemical vs. nuclear bonds) (**Fig. 3**).
(5) As to containment, if higher-level holons consist of lower holons, which they contain, then the hierarchy is said to be nested. Not all the criteria apply to all hierarchies, but all five principles may apply simultaneously.

The distinction between nested and non-nested hierarchies matters (**Fig. 3**). In nested systems, upper-level entities contain and consist of lower-level entities. In non-nested hierarchies, containment is not a criterion, but principles (1)–(3) can still apply. In nested hierarchies, containment applies even if aggregation criteria between levels change type. Western medicine generally uses nested hierarchies for the human condition. Thus organelles may be aggregated into cells by biochemical interaction. Meanwhile, nesting of organs inside the whole body may invoke fluid mechanics as a principal on which parts make the whole person. When whole humans nest inside groups, relationships may be in epidemiological terms. In Western medicine, there are regular changes in aggregation criteria from biochemical, through fluid dynamic, to epidemiological. Despite inconstant criteria for linking levels, the nesting keeps such hierarchies straight. But in non-nested hierarchies, such as food chains or pecking orders, the top dog neither contains nor consists of the subordinate individuals. Because there is no nesting to maintain order, non-nested hierarchies embody only one specific rule for moving between levels. As a result, the criteria for moving up a food chain must be consistently 'is eaten by', or conversely going down it is 'eats'. In this way, the hierarchy is consistent top to bottom. Because of their robustness to changes in aggregation criteria, nested hierarchies are particularly useful for exploration before firm criteria connecting levels have been established. Concomitantly, non-nested hierarchies are for mature ideas, where focused sets of relationships are organized and abstracted in a control system.

In thermodynamic studies of ecological emergence, nested hierarchies are essential, because otherwise the bookkeeping of energy flow between the system and its environment would not sum. In complexity theory, self-organized emergence is a matter of thermodynamic gradients being applied to material systems that are pushed away from equilibrium. Thus, nested hierarchies apply when self-organization is invoked, when holons emerge at a new level without any plan. Planned systems often yield to a non-nested conception. A surprising and important new turn in applied ecology of human management systems links non-nested human socioeconomic hierarchies to nested thermodynamic hierarchies. The whole system is embodied in energy flow and control through the twinned social and biogeochemical hierarchies.

These thermodynamic approaches develop self-organizing holarchic open systems (SOHOs), using the term holarchy for nested hierarchies. The word holarchy appears in part to sidestep the political unacceptability of hegemonic hierarchical control.

Using the SOHO approach, the full power of hierarchy theory in solving real time problems has been developed by Waltner Toews and colleagues at NESH, a Canadian centered, complex systems group. They solved some critical problems in Peru, Kenya, and Nepal. For instance, a Kathmandu sewer had children playing around slaughterhouse waste. By linking the social hierarchy to the ecological process hierarchy, NESH identified that a street cleaner caste was being blamed for things out of their control. Blaming scapegoats had led to inaction and paralysis, but once the street cleaners were no longer held responsible, the SOHO thermodynamic methodology achieved significant rehabilitation as the social and ecological hierarchies began to function in concert.

The earliest explicit introduction of hierarchy theory into ecology in the 1970s spoke of decomposability as an issue in some of the biomes studied in the International Biological Program (IBP). At that time, terms, such as 'environ', 'creaon', and 'genon' were coined as extensions of the concept of holon. Environ addresses the environment acting as an integrated whole for its residents. The inward direction toward the holon pertains to the creaon, whereas the outward direction pertains to the genon generating new things and experiences for the environment and its residents. Holon remains the central concept. The first fully integrated treatments of hierarchies in ecology turned on epistemological implications of scale and dynamics. Following shortly, evolutionary ideas focused on the structural elements in hierarchies, in a more ontological spirit. The structural elements were cast as a triadic view of holons, where the level above and the level below, as well as the level of the holon in between, are all required for an adequate treatment. Recently, two more crucial levels were added: the level above the context keeps the context of the holon stable, while the level below the parts provides stability for the material of which the parts are made.

Scale and Type

Scale problems invited hierarchy theory into the discipline. Ecologists have long been aware of scale, investigating the properties of quadrats in obtaining estimates of vegetation in the 1950s. Then change in variance across quadrat size was used to measure aggregation of plants on the ground. Hierarchy theory remains associated with scale today. The observation protocol brings attention to a universe of a certain extent, while making a second distinction, the finest grain at which observation units are distinguished from one another. Grain and extent together characterize the scalar level in question in many ecological hierarchies. Grain and extent are connected. Wider extents require coarser grains, if the mass of data are to be remembered, analyzed, and understood. Modern computational power has widened the gap between grain and extent, where remotely sensed areas are captured in billions of pixels. Even so, explicitly linking items in the grain across the extent becomes difficult, and generally impossible as the extent widens by much.

In contrast to linking across scales, it is possible to unify ecology across types of ecological system that correspond to the main subdisciplines of ecology: organism; population; community; ecosystem; landscape; biome; and biosphere. These types for ecological subdisciplines are explicitly not scale based, and so are not required to be assigned to level in the order given in the previous sentence. When scale is parsed away from type, the various approaches to ecology achieve a sharper depth of focus, offering clear relief between types of investigation. The subdisciplines of ecology are not scalar levels. If they are levels at all, they are type-based levels of organization, with the different types related to one another by asymmetric relationships made explicit in the definitions. As a separate issue, a typed level of organization itself contains scale-based hierarchies, as in fractal landscapes. In that scaled universe, the ecosystem modeling strategy may apply across a range of sizes, where local processes are part of more global processes. Communities too may be variously inclusive of species across narrow or wider areas. Under the organism criterion, examples are found from redwood trees to mites. An ecological hierarchy may change the scale and type at the same time, but it is fraught with conceptual danger. Indeed, hierarchy theory is often invoked to clean up the mess in the aftermath of scale and type being mixed together. There is no prohibition changing both together, but only so long as the relationships at each new level are explicit. This matters because most descriptions of ecological material precisely do change type across widening scalar levels, although most of them do not follow the textbook ordering from organism to biosphere. For instance, in a forest community, a rotting tree trunk may be considered an ecosystem, whose upper surface is landscape, on which grows a community of bryophytes.

The copious variety of materials, entities, and sizes in ecology invites hierarchy theory into ecology. Indeed, it is in ecology that hierarchy theory has been used most often to significant effect, as in the NESH studies mentioned above. Hierarchy theory can capture a rich set of scaled examples across a mixture of types. Ecology is a multiple-scaled labyrinth of types. Hierarchy theory is the ball of string that we can trail behind, so that ecological scientists do not get lost.

Panarchy

L Gunderson, Emory University, Atlanta, GA, USA

Panarchy is a conceptual model of how ecological systems change across scales of space and time. From the perspective of systems ecology, ecosystems are self-organized systems that cover a broad range of spatial and temporal scales. The interactions among biotic and abiotic components generate ecosystem dynamics that are both slow and fast as well as small and large. Panarchy theory attempts to explain qualitatively different types of change, by linking theories of hierarchy (how structures and processes are organized across scales) with a heuristic of adaptive cycles (how structure and process change within a given scale range).

The remainder of this article is structured into three parts. The first section defines terms of scales and dimensions in ecological systems. The second section contrasts two theoretical descriptions of hierarchy and panarchy. The third section describes cross-scale interactions.

Scale and Ecosystems

Scale has at least two meanings that relate to measurement of objects in ecological systems. One meaning of scale is the unit of measurement in any dimension. Much of ecosystem ecology is measured along dimensions of space and time. As such, meter and foot are different scales of measurement in space, and seconds and years are similar units in time. Ecosystem structures and processes are measured using multiples or fractions of these units. For example, the diameter of a tree is measured using scales of meters, centimeters, and millimeters. The other definition of scale has to do with ratios among measured units and is derived from the Latin word *scalaris* for ladder. For example, if the scale of a map is 1:250 000, then 1 cm on the map equals 250 000 cm on the ground. Both of these meanings suggest that relationships among units are set, so conversions can be made among units. The second meaning of scale, related to relationships among ecosystem components, is germane to panarchy, but requires defining two more terms.

Two other concepts are useful in understanding scales in ecological systems: grain and extent. Grain is defined as the unit of the smallest resolution of measure for a given system dimension. The resolution of a successional study may be a day or week in the time domain, at an area of a square meter in the spatial domain, depending upon what is being measured (species composition within a meter quadrat). The extent defines the bounds of measurement of a system under study. Continuing the successional study example, some long-term studies of forests may be multiple decades or even a century in extent. For two-dimensional spatial data, such as a map, the extent is also called the window of the map. In temporal data, the grain is usually defined as the minimal time unit, such as minute, day, or year, and the extent is the period of record used in analysis. Therefore, scale ranges can be determined by two components: the grain and extent.

One of the key features of ecological systems is that the components (structures and processes) cover large ranges of scales in both space and time. For example, the Atlantic Ocean ecosystem covers thousands of kilometers from the equator to almost the poles. Biological entities in the ecosystem range from the microbes whose volumes cover fractions of cubic micrometers to masses of *Sargassum* that cover thousands of cubic kilometers. In the time domain, the processes in the Atlantic Ocean vary from milliseconds to millenia.

One way of examining how ecological systems vary over scales of space is to map key structures and processes along dimensions of space and time. Ecosystem components can be mapped using the grain and extent to define ranges in these two dimensions. Across a range of scales in forested systems, leaves, branches, and trunks make up trees, trees make up stands, stands make up forests, forests make up landscapes, and landscapes comprise biomes (**Fig. 1a**). This can be identified as a vegetation hierarchy. Atmospheric hierarchy is comprised of similar structures (thunderstorms, frontal waves, El Niño Southern Oscillation) that cover ranges of scales.

A cross-scale examination of ecosystems leads to three observations. The first is that as the grain and extent of observation change, different objects (structures and processes) cover distinct scale ranges. For example, aerial photographs of forest stands cannot capture the detail of leaves (at smaller grains), nor spatial biome patterns (at larger extents). The second observation is that scalable processes and structures cover different extents in space and time. Some processes such as forest fires range from scales of a square meter to thousands of square kilometers. Other processes such as changes in carbon dioxide concentration in the atmosphere cover 20 or so orders of magnitude, from the cubic centimeters of cylinders in millions of internal combustion engines, to fossil-fuel-powered plants to regional-scale land clearing. The third observation is that ecological systems are comprised of self-organized processes that are not scale invariant; that is, they are not self-similar across scales (as measured by a constant fractal dimension). While many physical systems are self-similar or scale invariant, ecological ones are not because of the interaction between biotic and abiotic elements. Hence ecological systems are discontinuous in dimensions of space and time. These three observations lead to theories of cross-scale structures, described as hierarchy and panarchy theory.

 doi:10.1016/B978-0-444-63768-0.00695-8

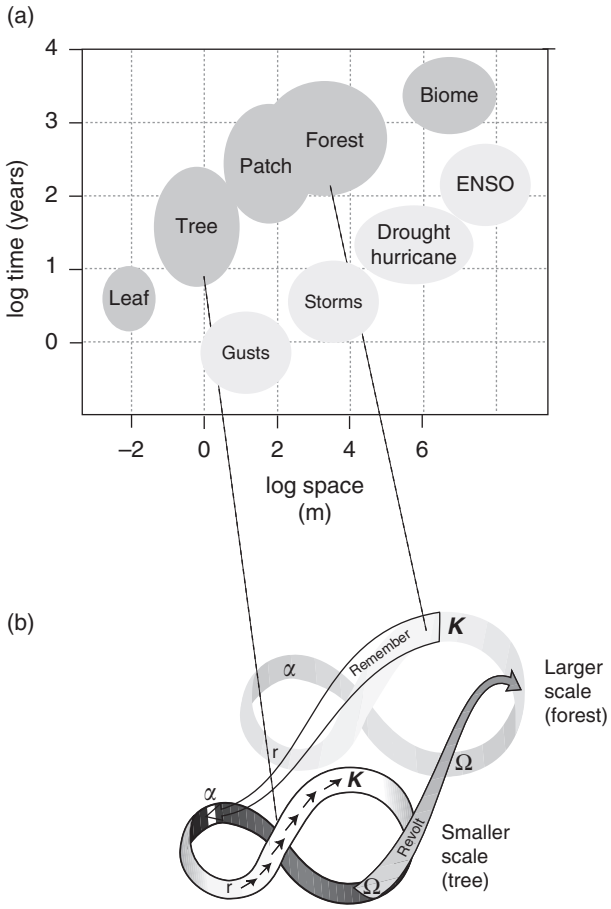

Fig. 1 (a) Cross-scale structures in a terrestrial ecosystem. Each object represents approximate grain and extent in spatial and temporal dimensions. Vegetation panarchy consists of leaves, trees, patches, forests, and biomes, while an atmospheric one is comprised of small, fast dynamics of wind gusts to global dynamics suggested by El Niño Southern Oscillation (ENSO) fluctuations. (b) Two levels of a panarchy, indicating dynamic systems within scales and cross-scale linkages or connections. Within a scale, systems undergo four phases of change. Initially, systems begin with a rapid phase (r phase) of growth. Growth slows as the system becomes connected and structure accumulates in the K phase. As the system is perturbed, rapid phases of creative destruction (Ω) and reorganization (α) occur. At key times, the release or creative destruction can spread to larger and broader scales. The up-scale connection or 'revolt' occurs when smaller-scale releases intersect with broader-scale vulnerability. Following release phases, often the system relies on larger- and longer-scale processes during periods of reorganization. The down-scale 'remember' connection facilitates renewal by drawing on the potential that has been accumulated and stored in a larger, slower cycles. National- or international-scale relief efforts following destructive storms or tsunamis are examples of remember connections.

Hierarchy and Panarchy

One major conceptual framework for understanding ecological cross-scale structure and dynamics is hierarchy theory. Ecologists in the 1970s and 1980s built on the seminal work of Herbert Simon to develop a theoretical base that emphasizes a pattern of aggregations (hierarchical levels, or 'holons') that are nearly separable across scales. Hierarchical levels can be identified by a stronger set of interactions within a hierarchical level than between levels. These hierarchical levels correlate to scales, and each level has characteristic spatial and temporal domains; that is, each level has a characteristic turnover time and spatial domain, as indicated in Fig. 1.

The interaction of hierarchical levels across scales has been the subject of much debate and is based on the interaction between slow (and broad) structures and processes and those that are fast and small. These interactions can be characterized in two ways: (1) hierarchical control and (2) panarchical relations. Hierarchical control is demonstrated when slow, broad features constrain and control the small, fast ones. This is an example of top-down control, when variables such as geology and soil types interact with climatic variables (temperature, photoperiod, rainfall) to determine the suite of plant and animal species that thrive. Much empirical evidence supports hierarchical or top-down controls. Panarchy theory was proposed to suggest that both top-down and bottom-up interactions occur; that is, while top-down control does exist, there are many bottom-up or cascading phenomena that occur. Many disturbance dynamics, such as forest fires or forest pest outbreaks are not the result of top-down control or control by slower variables, but examples where faster, smaller variables appear to control the system for periods of time. The interaction of processes and structures at different scales is one of the conceptual foundations of panarchy theory.

A critical feature of such hierarchies is the asymmetry of interactions among hierarchical levels. The larger, slower levels constrain the behavior of faster ones. In that sense, therefore, slower levels control faster ones. If constraint and control were all that mattered, then systems would have little, if any, opportunity for change and experimentation. For example, a forest stand moderates the climate within the stand to narrow the range of temperature variation that individual organisms experience. But missing in this representation is the dynamic of each level that is organized in the four-phase cycle of birth, growth and maturation, death, and renewal. That adaptive cycle is the engine that periodically generates the variability and novelty upon which experimentation depends. As a consequence of the periodic, but transient phases of creative destruction (Ω stage) and renewal (α stage), each level of a system's structure and processes can be reorganized (**Fig. 1b**). This reshuffling allows the possibility of new system configurations and opportunities from the incorporation of exotic and entirely novel entrants that had accumulated in earlier phases.

The adaptive cycle is a metaphor of temporal change in ecological systems. It suggests that systems at specific scale ranges exhibit four distinct and usually sequential phases of change in the structures and function of a system. As systems begin to form (such as primary or secondary succession in ecosystems), systems exhibit a growth phase. The growth phase is characterized by relatively rapid accumulation of structure (biomass and complexity). During this phase, competition is a scramble for resources, as winners are able to obtain and quickly convert raw materials to structure and organization. The first phase is also called the r phase, in reference to the specific growth rate parameter in an exponential growth model. Over time, structure accumulates and the system becomes more diverse and more connections appear among the system components. Gradually, system net growth slows, as more of the acquired resources and energy are allocated to system maintenance rather than growth of new structure. The accumulated structures and resources are conserved, hence the designation of the next phase is the conservation phase. This is also called the K phase in reference to the carrying capacity parameter in the logistic equation. During this phase, the system becomes increasingly connected, less flexible, and more vulnerable to external disturbances. These two phases, r to K, correspond to ecological succession and have been described as optimizing growth and energy throughput. These phases also represent system maturation and increasing vulnerability to external variations or disturbances.

Variation in inputs external to the system intersecting with increasing internal vulnerability leads to the next phase of the adaptive cycle. External disturbances generate a sudden release of accumulated capital or structure. This phase is called a period of creative destruction or the omega (end) phase. In pyric communities, for example, fuel slowly accumulates since the time of the last fire. As fuel accumulates, the system becomes more vulnerable to sources of ignition at small scales with an increasing probability of fire. Forest fires, grass fires, pest outbreaks are examples of the Ω phase, in which the structure is quickly destroyed. The collapse or release during the Ω phase is quickly followed by a reorganization (α) phase, where a new system emerges, leading to the growth phase of a new cycle. The new r phase may be very similar to the previous r phase, or it may be quite different. This pattern of rapid, then slowing growth, swift destruction and reformation, has been observed in many systems. These include ecological examples, such as pest outbreaks and fires in temperate forests; and social-ecological systems such as water management history of the Everglades, and aboriginal cultures in the eastern and western US.

In summary, many (but not all) systems exhibit a sequential series indicated in the adaptive cycle as it proceeds from an exploitation phase (r phase) slowly to conservation (K phase), very rapidly to release (Ω phase), rapidly to reorganization (α phase), and rapidly back to exploitation.

The dynamics conceptualized in the adaptive cycle are for systems at a particular scale range; that is, the dynamics of growth, conservation, destruction, and renewal can be observed for specific ranges of structures (**Fig. 1b**). Most plant leaves exhibit the phases on an annual cycle, growth senescence, fall, and the emergence of new buds. This cycle is driven in large part by external variation in seasonal cycles of insolation and temperature. Patches of forest go through these phases of succession on cycles of decades, as indicated by periodicities of fire or pest outbreaks. The blend of the adaptive cycle heuristic with older hierarchy theory forms the nucleus of panarchy theory.

Cross-Scale Interactions

A panarchy has three ingredients, (1) subsystems of adaptive cycles that represent system dynamics at a specific scale range, (2) dynamic systems that occur at different scale ranges (hierarchical levels), and (3) coupling of those systems across scales. All of these structures are posited to change in phases described by the adaptive cycle, but at a given scale. Panarchy links these structures across scales, and suggests that interactions can go from smaller, faster levels to broader, slower levels (or up-scale connections). Panarchy also suggests that the slow and broad processes and structures influence those that are faster and smaller (i.e., the subsystems and down-scale influences). But these connections are ephemeral, becoming dominant at certain times and dormant at others.

There are potentially multiple connections between phases at one level and phases at another level. The two most significant are the connections labeled as 'revolt' and 'remember'. **Fig. 1b** indicates two levels of a vegetation panarchy, each at distinct scale ranges or domains, and linked by cross-scale connections of revolt and remember.

Up-scale linkages or connections have been named 'revolt', suggesting that small events can cascade up to larger scales. Most of the time, the larger, broader variables control the smaller and faster processes. This is classic hierarchical control. However, when a level in the panarchy enters an Ω phase of creative destruction and experiences a collapse, that collapse can cascade up to the next larger and slower level by triggering a crisis, particularly if that level is at the K phase where resilience is low. One example is in the

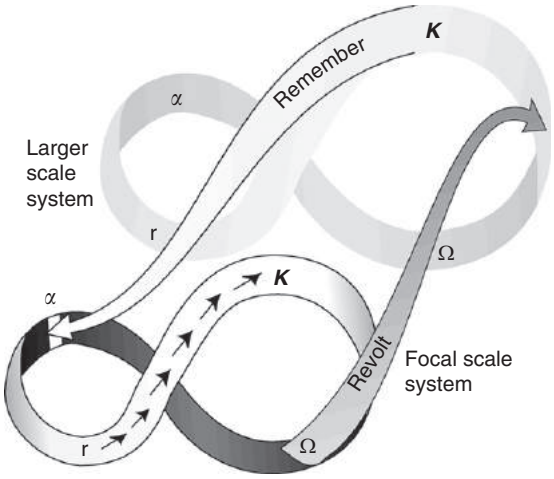

Fig. 2 Two key cross-scale connections of a panarchy are revolt and remember. The revolt pathway depicts how small-scale (local and fast) variables can interact to create an upscale cascade. Revolt dynamics have been described for forest pest, forest fires, and disease outbreaks. Resources in the form of capital, connections, and memory from larger systems often help in the recovery of focal scale collapse, as indicated by the remember pathway.

dynamics of fire-prone ecosystems. The lighting of a match in a forest, or a strike of lightning is a small, local phenomena. Under many conditions the local fire is either quickly extinguished or never begins a fire. However, under certain conditions (such as extreme droughts or low humidity), local ignitions can create a small ground fire that spreads to the crown of a tree, then to a patch in the forest, and then to a whole stand of trees. Each step in that cascade moves the transformation to a larger and slower level. A societal example occurs when local activist groups succeed in efforts to transform regional organizations and institutions, because they had become broadly vulnerable. Hence part of the connotation of revolt is used to describe how fast and small events overwhelm slow and large ones. And that effect could cascade to still higher slower levels if those levels had accumulated vulnerabilities and rigidities.

The down-scale interactions in panarchy are captured by the phrase 'remember'. As shown in **Fig. 2**, this type of cross-scale interaction is important at times of change and renewal. Once a catastrophe is triggered at a level, the opportunities and constraints for the renewal of the cycle are strongly organized by the K phase of the next slower and larger level. After a fire in an ecosystem, for example, processes and resources accumulated at a larger level slow the leakage of nutrients that have been mobilized and released into the soil. The options for renewal draw upon the seed bank, physical structures, and surviving species that form biotic legacies that have accumulated during the growth of the forest. It is as if this connection draws upon the accumulated wisdom and experiences of maturity – hence the choice of the word remember.

Panarchy theory describes at least three categories of change in complex ecological systems. These categories include gradual or incremental change, adaptive change, and transformative change. Incremental changes occur slowly and predictably, as systems mature. Adaptive change occurs after disturbances, when the system has the potential to change into a qualitatively different state. Alternative states in ecosystems occur when resilience of the system is exceeded. That alternative state occurs at one level of the panarchy. Transformational change occurs when multiple levels of the panarchy change as a result of cross-scale linkages and lead to fundamentally new types of structures, processes, and controls.

Summary

Panarchy is a term to describe cross-scale interactions in ecological systems. Other concepts such as hierarchy theory, bottom-up or top-down control are part of the systems ecology lexicon. Panarchy was proposed as a way of synthesizing these concepts. The derivation of the word hierarchy is from terms that suggest 'sacred rules'. As such, hierarchy suggests rules that are inviolate and top down. Much ecological research suggests the widespread presence of these relationships, where the broad and slow constrain and control the small and the fast. In contrast the derivation of panarchy was from Pan, the Greek god of nature. Panarchy in this sense is thus proposed as 'nature's rules'. It blends system dynamics at a particular scale domain that suggests that at least four phases of changes (growth, conservation, release, and reorganization) are observed in many systems. During the growth and conservation phases, internal controls dominate system dynamics. The release and reorganization phases are when cross-scale connections emerge, and the system becomes linked to dynamics and processes occurring at other scales. Panarchy also suggests that three types of changes occur in ecological systems. Incremental change occurs during growth to conservation phases of a system at a single scale. Adaptive change occurs as result of four-phase dynamics at a single scale, when the system can change structure and processes as a function of ecological resilience. Transformational change occurs when multiple levels of panarchy all undergo state changes.

Population Dynamics: Stability☆

Peter A Henderson, Pisces Conservation Ltd., Lymington, United Kingdom and University of Oxford, Oxford, United Kingdom

Glossary

Density-dependence An effect in which the intensity changes with the increasing population size.

The abundance of all organisms varies through time and across space and many populations can occasionally undergo dramatic exponential change. No population can remain at a stable equilibrium in which the number of individuals is constant because deaths and births cannot be in perfect balance. However, many populations do not show the explosive increases in number that their reproductive potential would allow, nor the violent collapses that their pathogens or predators could potentially inflict. This constraint on abundance can be viewed as a form of stability and has been long recognized.

Before examining how populations may be stabilized, it is informative to briefly examine typical time series to see the way populations do change through time.

Common Patterns of Dynamic Behaviour

Populations can show a wide range of dynamic behaviors and a great variety of dynamics can occur contemporaneously within a single community. To illustrate this point all of the examples of different dynamic behaviour shown below are for species living together in Bridgwater Bay in the Bristol Channel, England between 1981 and 2018.

Seasonal Variation

The most common form of variability observed in the natural world is a seasonal change in numbers. Seasonal changes in abundance occur in both temperate and tropical latitudes. Whereas temperate changes relate to seasonal variation in sunlight, temperature, snow cover and wind, tropical seasonality is frequently related to rainfall or flooding. **Fig. 1** shows the clear seasonality in occurrence of the dab, *Limanda limanda*, a small flatfish which is only present in Bridgwater Bay during the autumn and early winter. The population is dominated by small fish only a few months old which are the size of a postage stamp. For the rest of the year dab lives in deeper, cooler waters.

Not all species show a single seasonal peak.

It is important to remember that many species are annual and for part of the year exist as resting stages such as eggs or pupae.

Random Variation Without Trend

Many populations show seemingly random between year fluctuations in abundance. For example, **Fig. 2** shows the abundance of whiting in Bridgwater Bay over a 37-year period. Note that whiting abundance jumps up and down between years but there is no long-term increase or decrease in the average abundance.

Common causes for this noise are changes in climatic conditions or food availability during the breeding season. However, for many species the cause may be far from apparent and quite likely multifactorial. A cursory examination of such time series might lead to the conclusion that these populations show no stability and the natural world is following a chaotic, wild, dance. However, there are clear indications that these are not the steps of a random sequence because the population does not progressively move to ever higher or lower levels of abundance with time. As shown in **Fig. 7**B, the level of temporal variability stabilizes as the time series lengthens, if it were a random walk it would continue to increase with time. Such populations may be considered stable because the fluctuations, however violent, are all around a long-term mean abundance that does not change. In fact Bulmer's test (Bulmer, 1975) when applied to the 37-year whiting abundance time series indicated significant levels of density-dependence ($R = 0.625$ which is smaller than $R0.5 = 1.53$). Essentially, after each perturbation the population tends to move back toward the same mean level.

☆*Change History:* March 2018. Peter A Henderson. The time series graphs were revised and increased in length (years of observation). A new section 'Density and Dependence and Stability Within a Single Community' was added.

This is an update of P. Henderson, Stability, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3334–3341.

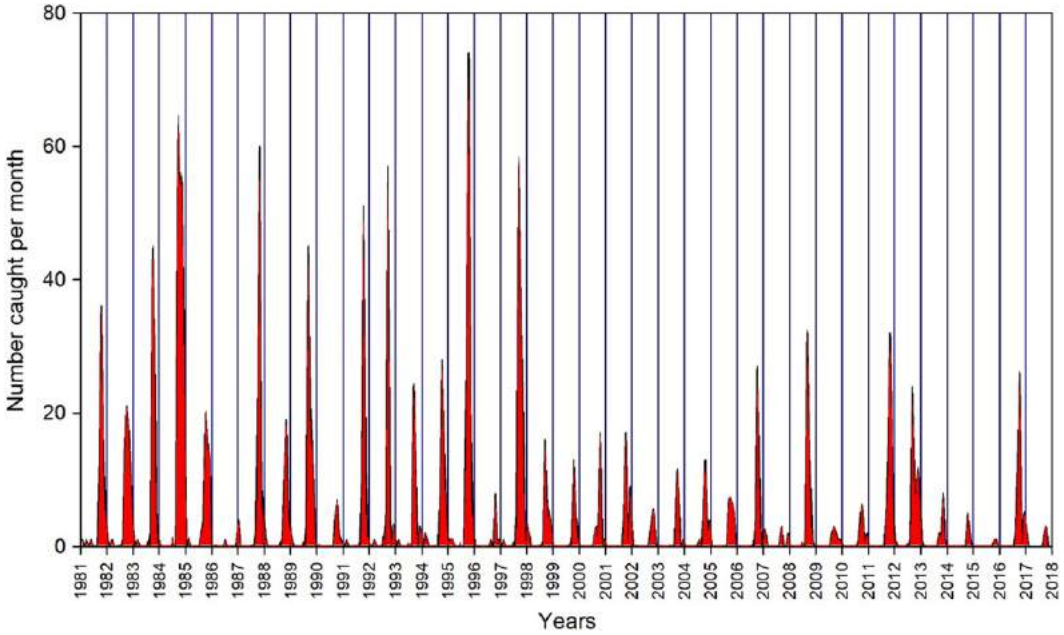

Fig. 1 The seasonal variation of the flatfish, *Limanda limanda*, in Bridgwater Bay, England. The time series was derived from monthly sampling and clearly shows an annual peak in abundance every autumn. The decline from 1999 is related to climate warming as this species avoids warmer waters.

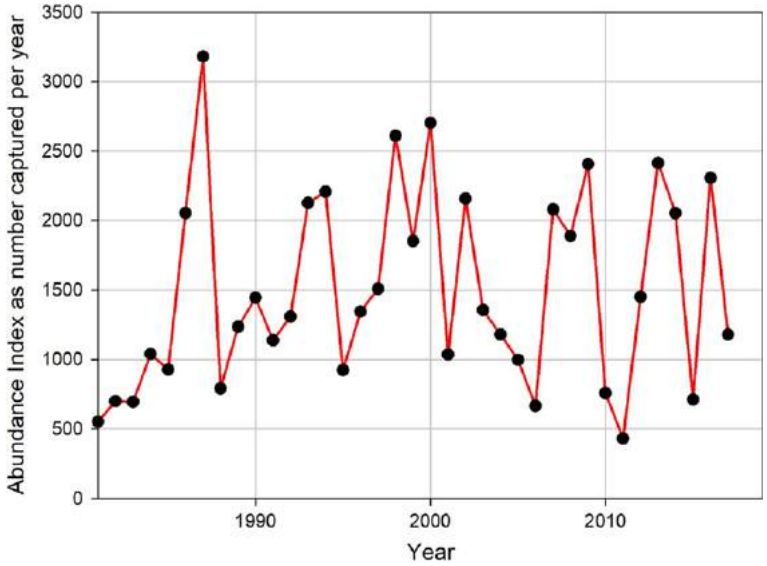

Fig. 2 The annual variation in abundance of whiting, *Merlangius merlangus*, a gadoid fish, in Bridgwater Bay, England. This species shows considerable between-year variation in number without any long-term trend (difference sign test, statistic = 0.56, $n = 37$, $P = 0.5741$).

Population Outbursts

Some populations maintain a generally low population size, but occasionally undergo abrupt bursts in number. Such behaviour is frequently observed with pest species, which in some years may be almost undetectable yet a few years later are present in huge numbers. Fig. 3 shows the between year abundance of the gurnard, *Eutrigla gurnardus*, a small bottom feeding fish. In 1992 there was a sudden peak in abundance, followed by a long period of low abundance before a second, much higher, peak in 2007 and subsequent lower outbursts in 2013 and 2016.

The reasons for the outbursts are often obscure, but, possibly relate to optimal conditions during the spring for larval survival and the arrival of large numbers of juvenile migrants into the study area. Again, there are indications of stability in the system as

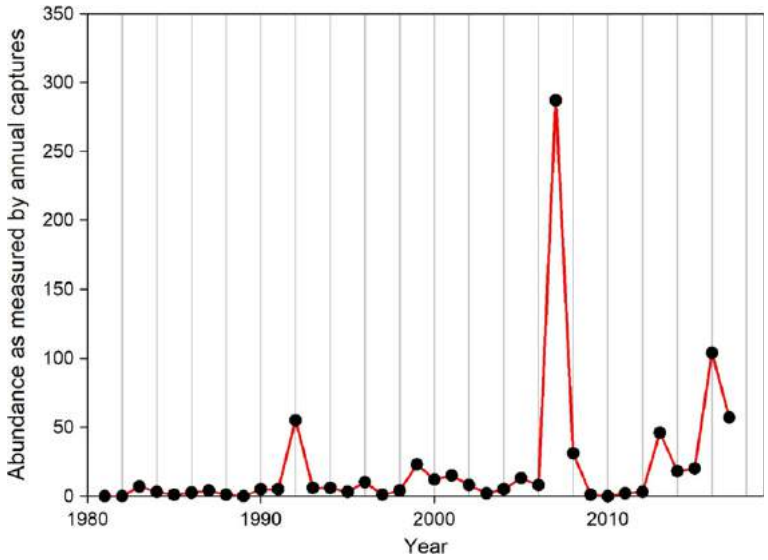

Fig. 3 The change in annual abundance of the gurnard, *Eutrigla gurnardus*, in Bridgwater Bay, England. While there is some evidence for a small upward trend in numbers, the most striking feature of this time series is the greatly increased abundances in 1992, 2007, 2013, and 2016.

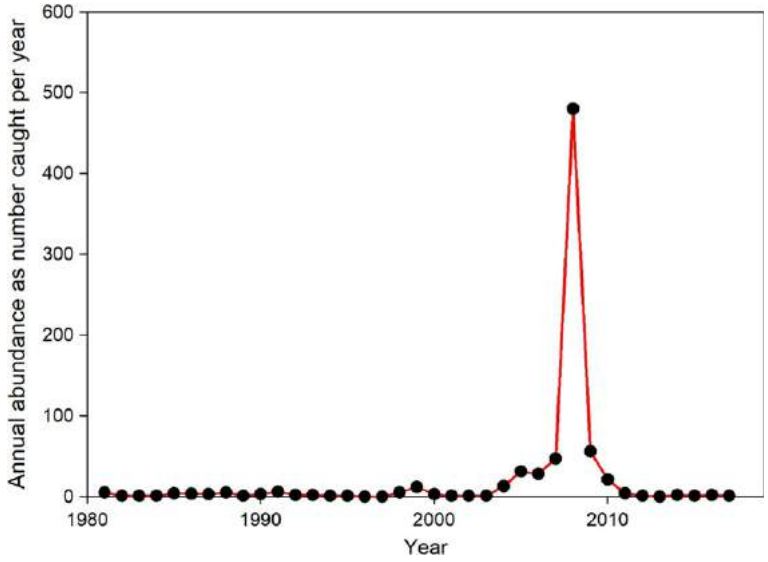

Fig. 4 The annual abundance of the snake pipefish, *Entelurus aequoreus*, in Bridgwater Bay, England showing the major outburst in abundance that occurred between 2003 and 2011.

the population explosions are contained and consumed so that the population equally quickly subsides to the basal level. Within a few years there is frequently no trace of the previous population explosion.

While the gurnard outburst described above comprised recently born individuals and can be thought of as reflecting years when reproduction was especially favorable some outbursts comprise adult age groups and do not reflect isolated incidences of reproductive success. An exceptionally clear example was the outburst of snake pipefish, *Entelurus aequoreus* in British waters between 2003 and 2011 (Fig. 4). The rise up to the peak abundance in 2008 is even faster than exponential growth and cannot be explained by reproduction alone. It appears that environmental conditions caused production from a wide region of sea to become concentrated in inshore waters. It is often the case that sudden bursts in population density are linked to migrations or environmentally forced concentrations into small regions of habitat (Fig. 4).

Exponential Increase and Decline

If the instantaneous rates of mortality and birth are consistently different for an extended period a population can show an exponential change in number. Fig. 5A and B shows that the large prawn, *Palaemon serratus*, underwent an approximately

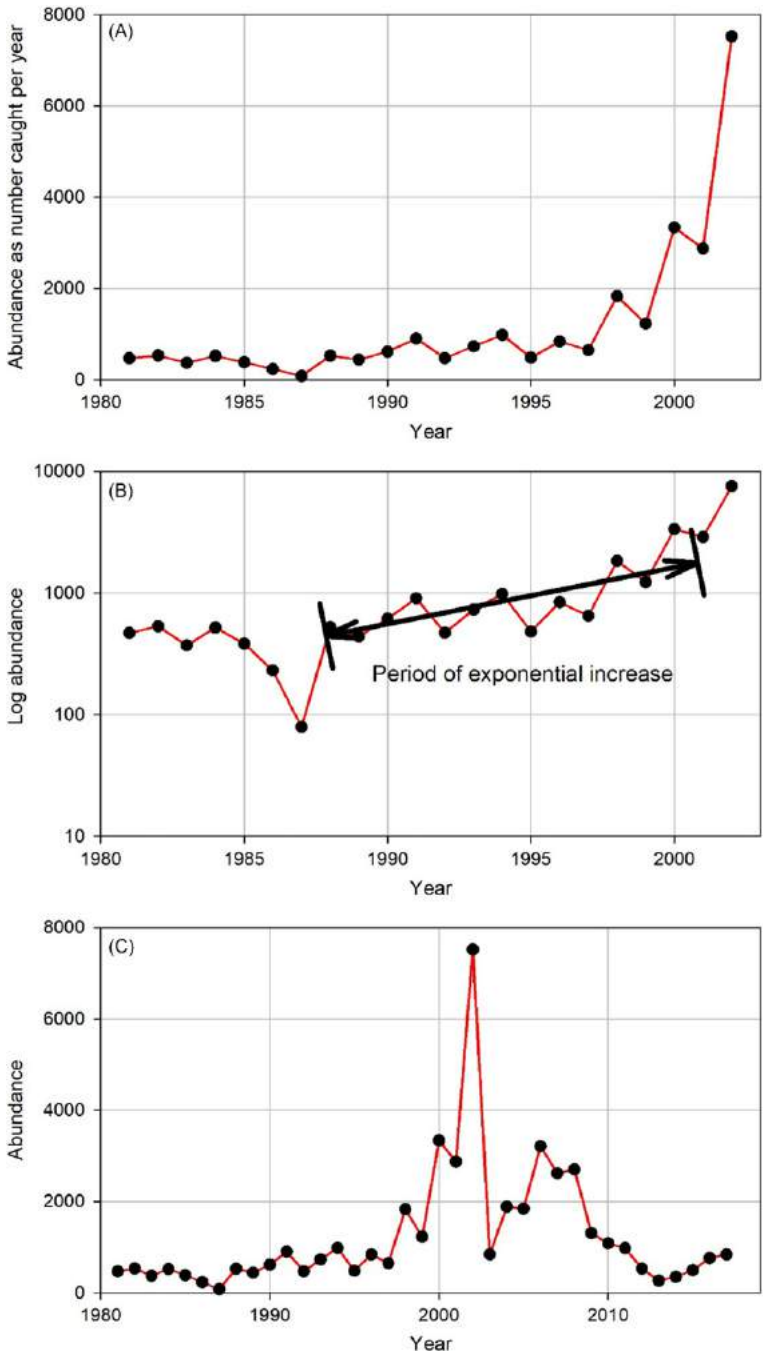

Fig. 5 The change in annual abundance of the prawn, *Palaemon serratus*, in Bridgwater Bay, England. (A) This species underwent an exponential increase in abundance between 1987 and 2002. (B) The exponential growth period is shown as a straight line in the log abundance plot. (C) The population trajectory for the longer period 1981–2017 shows that after 2002 the population then suddenly fell back in abundance.

exponential increase in abundance between 1987 and 2002 which is shown as a good fit to a straight line on the log plot (**Fig. 5**B). A major downward correction then occurred (see **Fig. 5**C), which was at some stage inevitable as any population growing exponentially must eventually experience resource limitations. The increased abundance of this prawn between 1980 and 2002 was probably linked to raised seawater temperatures allowing increased growth and a longer reproductive season. In recent years, average water temperatures in Bridgwater Bay have been declining, and the population has fallen to levels previously observed in the 1990s. It seems likely that the exponential growth phase was a short-term response as the population increased to take possession of a larger niche which has now been lost.

A clear example of exponential decline is shown by the common eel, *Anguilla anguilla* in **Fig. 6**. This dramatic decline toward possible local extinction of a fish that was once highly abundant is probably linked to a multifactorial increase in mortality rate.

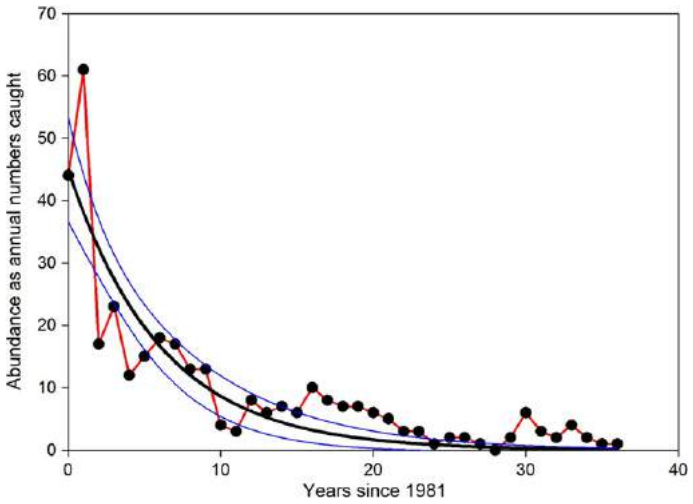

Fig. 6 The exponential decline in the annual abundance of eel, *Anguilla anguilla*, in Bridgwater Bay, England. This rate of decline has been observed at other localities across Europe. The smooth *black line* is an exponential curve fitted by regression and the two *blue lines* are the 95% confidence bands.

Man has been responsible for over-fishing, producing impediments to migration such as weirs and dams and finally introducing a deadly parasite. While such declines are becoming common because of human destruction, they can also occur naturally because of the outbreak of disease or climate change. This population decline must free resources allowing other species to increase as they use the resources previously taken by the eels.

The Balance of Nature

Our present understanding of the stability of natural populations shows a gradual, if uneven, increase in understanding that is still far from complete. That there is a balance of nature, so that all species can continue to coexist, is a common and ancient worldview and has been long held in western thought. Until the 20th century it was widely assumed that the sizes of populations were held in balance by divine power, occasional outbreaks of pests and a loss of balance, such as a plague of locusts, were seen as divine punishment. Belief in this benevolent balance gradually eroded, until C. S. Elton in 1930 could assert "The balance of nature' does not exist, and perhaps never has existed. The numbers of wild animals are constantly varying to a greater or less extent, and the variations are usually irregular in period and always irregular in amplitude." However, no 20th-century ecologist, including Elton, viewed populations as simply random variables changing without constraint for it was realized this would rapidly lead to extinction and the collapse of ecosystems. The natural world shows order that needs to be explained. The tightness of the constraints exerted by the environment, both biotic and abiotic, and the nature of the factors impacting population density are presumed to influence the degree of population stability. But, in addition, it came to be realized that the life history strategy followed by the organism also had an influence and was itself undergoing natural selection. Some species had evolved to produce large numbers of offspring and were capable of explosive growth when conditions allowed. In contrast, others produced a small number of offspring and their populations were considerably more stable. These two strategies were termed r (for reproductive rate) and k (for carrying capacity) selected. The populations of r-selected species were viewed as more variable than the k-selected species, which remain closer to their environmental carrying capacity. The distinction between r- and k-selected species is now less frequently applied in ecological arguments, in part because the distinction is too rigid. How population stability is determined and regulated remains a major area of research and is still capable of generating considerable controversy.

The Functional School and the Role of Density-Dependent Biotic Interactions in Population Regulation

The debate on how populations are regulated began in the mid-1930s when A. J. Nicholson proposed that controlling factors must act density-dependently. While a huge body of evidence has been collected demonstrating the existence of density-dependent mechanisms, the debate on their general role in determining population size and stability is still ongoing. Nicholson's key argument was that regulatory agents must increase their impact on a population as the size of the population increases. It is this change in impact with density that is termed density-dependence. Because predators, pathogens, and parasites can change their population size in response to changes in host abundance and thus change their level of impact with the host population size, they were viewed as key regulatory candidates. The core role of biotic factors in density-dependent regulation came to be a central belief of ecologists of the functional school. This view implies that populations have a long-term equilibrium size or density from which

they may be displaced by stochastic factors and toward which they are returned by density-dependent forces. However, the proponents of this view do not suggest that populations are necessarily held tightly to this equilibrium. As D. L. Lack stated in the 1954 "most wild animals fluctuate irregularly in numbers between limits that are extremely restricted compared with what their rates of increase would allow."

The Environmental School and the Role of Climate and Other Environmental Factors in Limiting Population Growth

In the 1950s a radically different view on the nature of regulation from that presented by Nicholson was proposed. In contrast to the views of the functional school, H. C. Andrewartha and L. C. Birch argued that density-independent agents such as climate and resource availability limited the growth of populations and there is only limited time when they had the opportunity to increase. Termed the environmental school, this viewpoint emphasizes constraint by predominantly physical conditions and by implication argues against the existence of long-term equilibrium population sizes. A strong argument for this viewpoint is given by T. C. R. White, "Surviving on this earth is, and always has been, especially for the very young, a struggle, a chancy business…. Nor is there an "optimum" or "equilibrium" density of a population in nature—only the maximum number that can survive each generation in a population that is pressing hard against the variable but limited supply of resources in its environment." From this viewpoint populations are constantly expanding and being pushed back by adverse events. Through time, they may occasionally expand exponentially, then, as conditions change, suddenly decline. This is a reasonable explanation for the dynamics of the Atlantic prawn graph shown in **Fig. 5**.

Combining Biotic and Physical Factors

Many ecologists take a hybrid position between the functional and environmental schools, noting the powerful influence of climate and other physical features while also acknowledging the existence of density-dependent regulation. Some have advocated a revision in terminology, arguing that, in part, the disagreement between ecologists on the nature of population regulation can be linked to poor or confusing terminology. A. A. Berryman suggests that ecology should use the vocabulary of dynamic systems theory and replace the term density-dependence by negative feedback. Negative feedback occurs whenever the rate of change of a population (dynamic variable) is inversely proportional to its current or past size (states). For a population to be regulated, a negative feedback must operate. It is clear that the individual scientist's viewpoint on population regulation is heavily influenced by field experience. Those working on large mammals or birds are far more likely to emphasize biological, density-dependent possesses than those working on single-celled organisms or small fast breeding insects. Entomologists frequently observe population explosions or collapses linked to a change in environmental conditions.

It is striking that much of the argument about population stability and the importance of density-dependence, population regulation, and species interactions such as competition has not been based on empirical observation and has been heavily influenced by simple mathematical models. This is notable, as generally ecologists put great emphasis on the importance of field observation. More recently, there has been a reduced emphasis on gaining insights from mathematical models as it came to be realized that quite simple models could produce an astonishing richness of dynamical behaviors. In effect, everyone could find a simple model to demonstrate that his or her view had a theoretical basis. For much of the 20th century the emphasis on theoretical considerations was inevitable as ecologists had too few long-term population dynamical time series to study. While all-natural populations vary in numbers in space and time, surprisingly little was and still is known about the statistics of this natural variability. The shortage of empirical data was, in part, because ecology is a relatively new science and population data was not systematically collected until the later part of the 19th century so even now we have few reliable data sets extending for longer than 100 years. When it is remembered that many larger species of animals can live for thirty or more years and large plants for hundreds of years, it is apparent that our time series cover too few generations to show the full dynamical range of long-lived organisms. In part, studies of fossils have supplied the long-term perspective required; however, such studies can rarely give reliable estimates of relative abundance. A continuous stream of new observations is now rapidly increasing the database upon which ecologists can test hypotheses and measure the degree of stability actually shown.

Measuring the Variability of Populations

Many measures of variability have been proposed, most of which are unsuitable for ecological purposes because they do not measure proportional change in density or population number. We generally require a measure of variability which gives the same result for a population which changes from 0.1 to 1, 10 to 100, or 1000 to 10,000 as in each case the population has increased 10-fold. Such a measure is then not dependent on the size of the sample. It is now recommended to use either the standard deviation of the natural logarithm of the abundances or the coefficient of variation of the abundances (CV(N)). As many time series of abundance have occasional zero values, CV(N) is the preferred measure as the logarithm of zero is undefined.

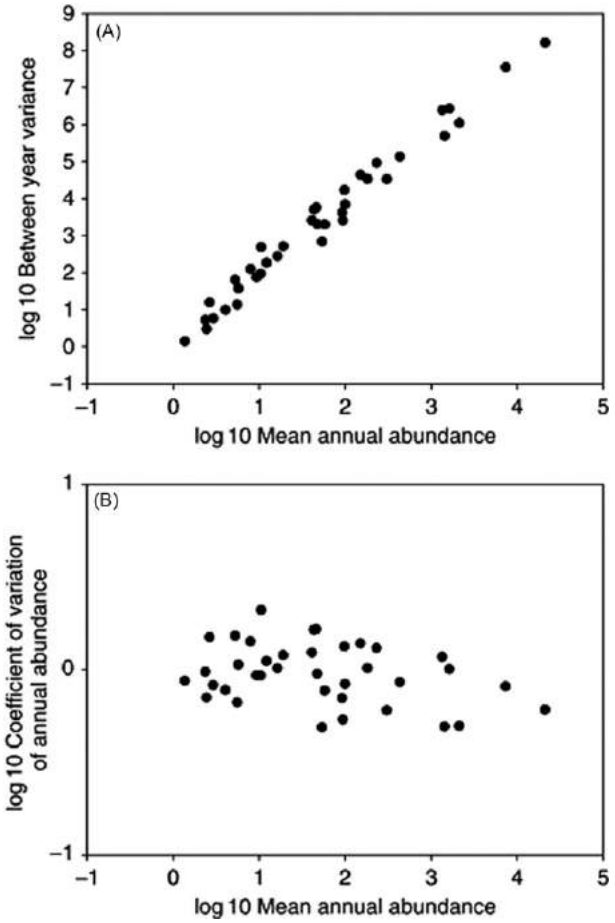

Fig. 7 (A and B) A comparison of the dependence of variance and coefficient of variation on the mean number caught per annum. The data are for the resident fish and crustaceans captured from monthly sampling over a 25-year period in Bridgwater Bay, England. These plots are based on the number caught per annum which may not be directly proportional to the actual number present. This is particularly the case for sampling methods such as trapping that can become saturated at high densities.

The merit of CV(N) over a nonproportional measure such as the variance of the time series is illustrated using as an example the 25-year variability of fish and crustaceans in Bridgwater Bay, England. Fig. 7A shows clearly that the variance is highly positively correlated with mean abundance and therefore is a useless measure of population variability as it will inevitably show that the most abundant species are the most variable. This linear relationship between log variance and log mean has long been recognized and is referred to as Taylor's power law. In comparison, the coefficient of variation of annual abundance does not always increase with the mean (Fig. 7B). In fact, the CV(N) for the Bridgwater Bay animals indicates that proportional variability tends to decrease with increasing abundance and hints at an increased stability with increasing population size (this is investigated and explained in the following section). This observation is important, as the choice of the CV(N) as the preferred measure of variation is not to remove all dependence on population size. Even if this were possible, it would be undesirable as we frequently wish to identify stabilizing density-dependent processes, which change the dynamics as mean abundance changes. The standard deviation of the logarithm of the abundances þ1 has been suggested as a measure of variability which can be used with time series that include zeros. It should be avoided as it is biased.

Having settled on the coefficient of variation CV(N) of the time series as an appropriate measure of variability, it is essential, when comparing population variability, to compare time series over the same time period. This is because the CV(N) tends to increase with the increasing length of the time series. This is illustrated in Fig. 8 using a 25-year time series of crustacean and fish data. While the common shrimp time series shows a long-term trend of increasing CV(N) (Fig. 8A), the whiting data (Fig. 8B) shows a time series for which the CV(N) initially rises with duration and then stabilizes. A tendency for the CV(N) to stabilize with time is indicative of population regulation and thus may be a general feature of time series monitored for sufficient time to display detectable density-dependent regulation. It is notable that the whiting time series showed no long-term trend in abundance and shows significant density-dependence using Bulmer's test (see Fig. 2). However, there is little empirical data on this subject and most time series have the potential to suddenly increase in variability. The jump in variability of the common shrimp population after 20 years (Fig. 7A) was linked to a sudden increase in water temperature from 1999.

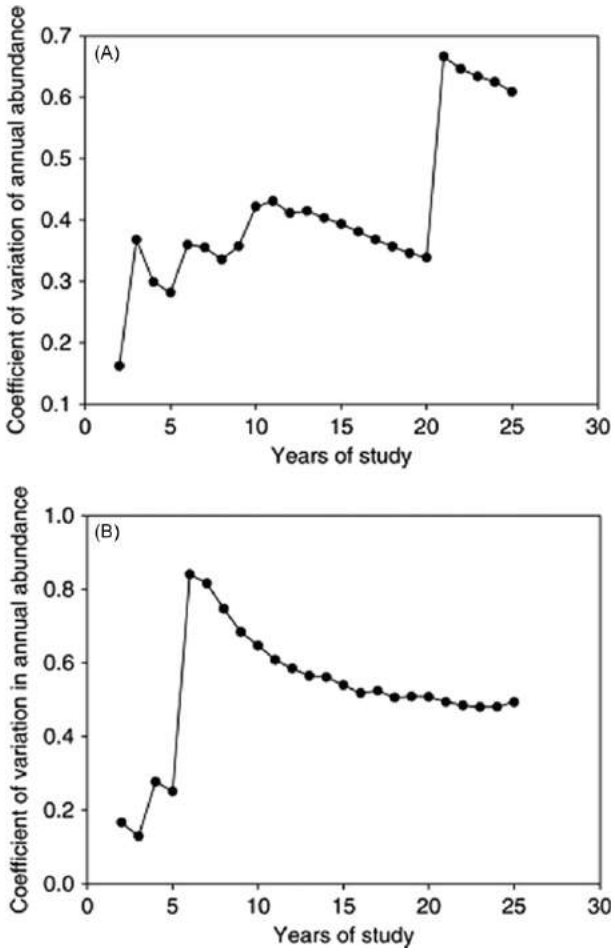

Fig. 8 (A and B) The change in the coefficient of variation with the length of the time series for (A), the brown shrimp, *Crangon crangon* and (B) whiting, *Merlangius merlangus*. The data were collected by monthly sampling over a 25-year period in Bridgwater Bay, England.

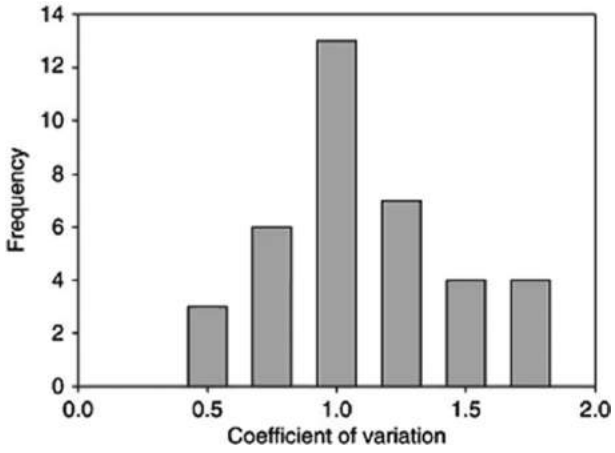

Fig. 9 The distribution of the coefficient of variation in annual abundance for the resident fish and crustacean species in Bridgwater Bay, England. The data were collected by monthly sampling over a 25-year period in Bridgwater Bay, England.

Once a measure of variability is defined and it is also noted that a time-series variability should only be compared between populations over the same time period, it is then possible to examine comparative population stability. Fig. 9 shows the frequency histogram of the CV(N) in annual abundance for all the species of fish and macro-crustaceans resident in Bridgwater Bay in the Bristol Channel, England. All the populations were monitored contemporaneously for a 25-year period commencing in 1981. It

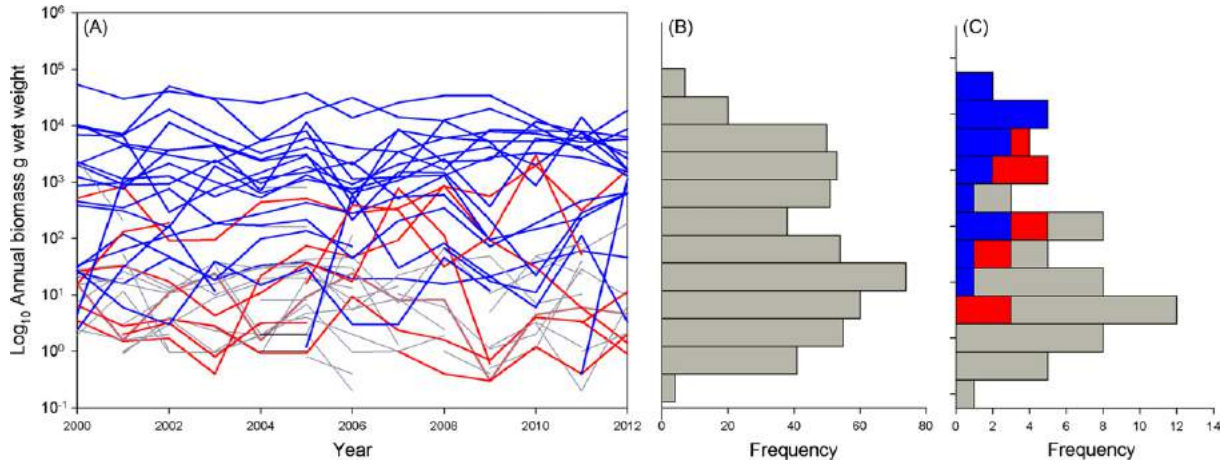

Fig. 10 Temporal variability within the fish community of Bridgwater Bay. (A) The variation in annual biomass. Core species showing density-dependence are shown in *blue*, core species with no evidence of density-dependence in *red*, and transient species in *gray*. (B) The frequency distribution of fish abundance over the 12 years combined. (C) The frequency distribution of average abundance over the 12-year period.

can be seen that CV(N) is approximately normally distributed around a mean of one with a slight skew toward higher CV(N) values. This skew would appear to be related to human impacts and climate change as high CV(N) populations are dominated by species that have been showing a trend in abundance over the entire 25-year period. Some species such as the herring, *Clupea harengus*, which has a CV(N) = 1.6, are slowly recovering from a population collapse caused by overfishing. Others, such as the gurnard, *Eutrigla gurnardus* (CV(N) = 1.4, see **Fig. 3**), have been increasing in abundance as seawater temperatures have increased. In summary, a wide range of vertebrate and invertebrate species, differing greatly in life history characteristics, display a notably small range of CV(N) between 0.5 and 1.5 over a 25-year period, suggesting that they all are tending to be constrained toward a similar level of population stability. Unfortunately, we do not have similar long-term data sets covering all the common vertebrates and invertebrates for a terrestrial ecosystem to test if this is a common feature of other communities.

It is possible to determine if the fish in Bridgwater Bay are showing a similar degree of variability to terrestrial vertebrates. B. Saether and colleagues in 2003 presented data for the CV(N) for 13 solitary birds over a 15-year time period. Values ranged from 0.08 for the sparrowhawk to 0.71 for the cactus finch with a mean of 0.31. In comparison, the 23 nonshoaling fish from Bridgwater Bay had CV(N)'s over a 15-year period of between 0.45 and 1.9 with a mean of 0.88. It is clear that North American birds have, on average, considerably more stable populations than estuarine fish. This difference is probably related to differences in reproductive behavior. Most of the fish have high fecundities and limited or negligible parental care and therefore their populations are able to respond rapidly to changes in climatic conditions. In general, the CV(N) in annual abundance varies greatly between habitats, taxonomic groups, and species because of differences in the reproductive and life history strategy and the degree of environmental variability. From an extensive study of bird population dynamics, B. Saether and colleagues in 2004 demonstrated that the stability of bird populations is clearly related to their life history strategy and concluded that "The demographic stochasticity decreased with adult survival rate, age at maturity, and generation time or the position of the species toward the slow end of the slow-fast life history gradient."

Density and Dependence and Stability Within a Single Community

An analysis of the Bridgwater Bay community shows how the views of the functional and environmental schools of population regulation are reconciled given sufficient data. Magurran and Henderson in 2003 noted that the Bridgwater Bay community comprised two groups of species they termed core and transient respectively. The core species are permanent members of the community and tend to have relatively high abundance population size in terms of biomass. In comparison, transient species are only occasionally present. These tourists tend to occur when the environment particularly favors their needs, but cannot maintain their populations in the long-term. Subsequently, in 2014, Henderson and Magurran showed that the core species, which have by far the greatest population size in terms of biomass, are under density-dependent control (**Fig. 10**). In comparison, the transient species tend to have highly variable populations often responding to physical conditions such as water temperature, ocean currents and wind. **Fig. 11** shows that for the Bridgwater Bay community population variability, as measured by the coefficient of variation, is far lower in core species under density-dependent control.

These results show that species make different contributions to the stability of a community. Species experiencing density-dependence exhibit relatively little temporal variation. These species also typically account for a large fraction of the overall abundance; in the case of the Bridgwater assemblage they represent >98% of the total biomass. Because of the stability in biomass of these core species it is inevitable that nutrient and energy flux will also be stabilized. The results demonstrated that density-

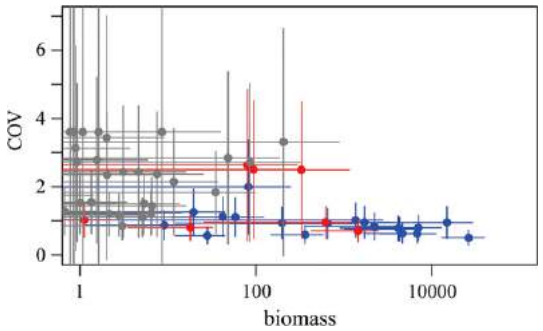

Fig. 11 Relationship between mean (±sd) coefficient of variation (COV) and mean (±sd) biomass. Core species showing density-dependence are shown in *blue*. Core species with no evidence of density-dependence in *red*. Transient species in *gray*. Note that the *blue*, density-dependent species have very low coefficients of variation in their population biomasses.

dependence is not uniform across species, operating in common species rather than rare ones. However, common species are defined as those always present at relatively high biomass. This need not imply high numerical abundance, for example the conger eel ranks 2nd in biomass but only 20th in terms of numerical abundance. When measured as the number of individuals per unit area of seabed the top predator conger eel would be considered rare, but is under density-dependent control.

This analysis leads to the hypothesis that animal communities (ecosystems) comprise a core group of resident species which have constrained populations because they are pushing against their respective carrying capacities and an often larger group of transients probing the system and ready to move in should conditions allow. The transient species abundances are influenced by environmental conditions and not generally constrained by resource availability and therefore do not exhibit density-dependent dynamics. The core species contribute the greater part of the biomass, but a far smaller proportion of total species richness. A healthy system needs both, the transients are a genuine part of a healthy system, they utilize resources which are only occasionally available and are preyed upon by the core assemblage. They must certainly be present if the system is to survive long-term as they allow adaptation to changed conditions.

Natural communities are hybrids of two dynamical behaviors, a core group, dominant in biomass terms, which display negative feedback dynamics and depressed variability (higher stability) and a larger group of species displaying quasi random abundance as they cannot establish permanent residency.

Species Richness, Stability and Regular Cycles

It has also been suggested on both theoretical and observational grounds that the species richness of a habitat may influence population stability. At present, the effect of species richness is unclear. The exceptional study of a plant community by D. Tilman and Downing has indicated that species richness actually increased stability by increasing resistance and recovery of primary productivity to drought. However, the opposite conclusion has been reached in other studies. Results from theoretical studies are equally contradictory. At present, the indications are that there is no universal relationship between the number of interacting species and individual species stability. However, it is difficult to imagine how a species rich system could maintain species number long-term if it held a dominant species that fluctuated greatly in abundance. Such a species would act like a bull in a china shop. The Bridgwater Bay fish data shows that the most abundant species are under the most powerful density-dependent constraints and have the most stable populations (Fig. 11). Within this system the dominants have remarkably orderly dynamics.

While the great majority of studied populations fluctuate with little obvious pattern and clearly respond to random climatic events, there has been great interest in those populations that show long-term oscillations. The most famous of these cyclic phenomena is the 4-year cycle of microtine rodents in boreal and artic regions first discussed by Elton in 1924. There has been considerable debate as to how these cycles form and are stabilized. One favored view is that they are caused by delayed density-dependence as time lags are frequently observed to produce cyclical or quasi-cyclical behaviour. It has been argued that in Fennoscandia, the cycle is imposed by time lags in the population response of mustelid predators and the time series of the rodents is actually chaotic. Studies in both Fennoscandia and Hokkaido, Japan, show that rodent cycles vary geographically and that cycles tend to be more apparent toward the north of the range where species richness is low. Studies on the gray-sided vole, *Clethrionomys rufocanus*, for example, show that the dynamics of this species is influenced by density-dependent, delayed density-dependent, and stochastic climatic changes. The appearance of quasi-regular cycles therefore seems to depend on the relative magnitude of the three types of influence: density-dependent, delayed density-dependent, and climatic. It is notable that as knowledge has deepened, the important role of both biotic and physical environmental factors has been recognized.

The geographical extent of species is an important factor in population stability. K. J. Gaston in a study of 263 species of British moth studied over a time period of up to 14 years concluded that there was a strong relationship between local population variability and species abundance and distribution—with the most abundant and widely distributed species showing the greatest local variability. These observations indicate that the spatial extent of a population may have a great influence on local stability.

This pattern may be related to the fact that widely distributed, well-dispersed, organisms can be opportunistic species, which take advantage of temporary niches to invade and then abandon when conditions worsen with low probability of global extinction. Spatial effects are also a key feature of pathogen population dynamics. For example, L. Ericson and colleagues report a 13-year study of the rust fungus, *Uromyces valerianae*, on the herb valerian, *Valeriana salina*, in an archipelago of islands in central Sweden. They found that the fungus populations frequently went extinct and re-colonized, producing very different and unstable population dynamics within different island populations. It is now well established that meta-population dynamics must be considered to understand the stability of many populations.

A meta-population comprises several spatially distinct populations. Stochastic variation acting on small populations almost inevitably leads to eventual extinction. However, the meta-population avoids collapse because immigrants from one population can re-colonize habitat which has been left open by the extinction. They may also reinforce a population and stop extinction. Such arguments rely on the ability of populations to exchange members. They are also favored by a lack of correlation between the abundance in different populations. This is not always the case. It has been frequently observed that insect pest outbreaks occur at about the same time over large geographical areas. The degree of spatial synchrony between forest insect populations has been used to test the differing hypotheses as to why populations fluctuate. While there is considerable difference in the degree of spatial synchronicity between insects, there is good evidence that synchrony is related to large-scale climatic variables. This in turn indicates that the notorious instability of insect forest pests is determined, at least in part, by their sensitivity to climatic conditions.

In conclusion, it is clear that populations can vary greatly in abundance through time and space. Huge though this variation can be, there is considerable evidence that populations are constrained within limits by biotic and physical factors and they do not show their full potential for explosive growth or sudden collapse. The amount of variability displayed differs between species, taxa, and habitat and is related, in part, to life history characteristics and, in part, to the variability inherent in the habitat. Populations are composed of individuals that are constrained by and respond to their physical and biotic environment. This response to the environment can have the characteristics of negative feedback control and results in sufficient stability to increase the likelihood of long-term population maintenance. However, many local populations repeatedly go extinct and re-colonization from successful populations is essential for long-term existence. Stability of existence for many species may only exist at the meta-population level.

Self-Organization

DG Green, S Sadedin, and TG Leishman, Monash University, Clayton, VIC, Australia

Introduction

Self-organization is the appearance of order and pattern in a system by internal processes, rather than through external constraints or forces. Plant distributions provide examples of both constraints and self-organization. On a mountainside, for instance, cold acts as an external constraint on the ecosystem by limiting the altitude at which a plant species can grow. Simultaneously, competition for growing sites and resources leads to self-organization within the community by truncating the range of altitudes where plant species do grow. Self-organization can also be seen among individuals within a population (e.g., within an ant colony or a flock of birds) and within individuals (e.g., among cells during development) (Fig. 1).

A growing understanding of ways in which internal processes contribute to ecological organization has provided new perspectives on many phenomena familiar from traditional ecology. Self-organization usually involves interactions between components of a system, and is often closely identified with complexity. Also associated with self-organization is the idea of emergence: that is, features of the system emerge out of interactions, as captured by the popular saying, "the whole is greater than the sum of its parts." It is necessary to distinguish between emergent features and other global properties of a system. For instance, although biomass production in a forest is a global property, it is simply the sum total of production by all the organisms within the forest. A stampede, on the other hand, is behavior that emerges when panic spreads from one animal to another within a herd.

Semantic and philosophical issues sometimes lead to confusion about self-organization. Self-organizing systems are usually open systems, that is, they share information, energy, or materials with their surroundings. However this does not necessarily mean that the external environment controls or determines the way they organize. A growing plant, for instance, absorbs water, light, and nutrient from its environment, but its shape and form are determined largely by its genes.

Also, in considering self-organization, it is important to clearly identify the system concerned, and in particular, what is external and what is internal? This issue arises in the difference between a community and an ecosystem. For a community, which consists of the biota of an area, the effect of (say) soil is an external constraint. However, for the corresponding ecosystem, which would include soils, the interactions between plants, microorganisms, and soil formation are internal processes. Defining the physical limits of an ecosystem poses similar problems. A lake, for instance, is not a closed ecosystem. Among other things, water birds come and go, removing some organisms and introducing others.

Historical Comments

Self-organization as a widespread phenomenon first came to the attention of researchers during the mid-twentieth century. The interest in self-organization comes from many different fields of study. The biologist Ludwig von Bertalanffy drew attention to the role of internal interactions and processes in creating organization within biological systems. His 'general systems theory' drew heavily on analogies to highlight the existence of common processes in superficially different systems. Meanwhile, W. Ross Ashby and Norbert Wiener explored self-organization from the perspective of communications and feedback in the control of systems. Ashby introduced the term self-organizing in 1947. Wiener coined the term cybernetics to refer to the interplay of control systems and information. In the 1950s, systems ecologist H. T. Odum collaborated with engineer Richard Pinkerton to develop the principle of maximum power, which states that systems self-organize to maximize energy transformation.

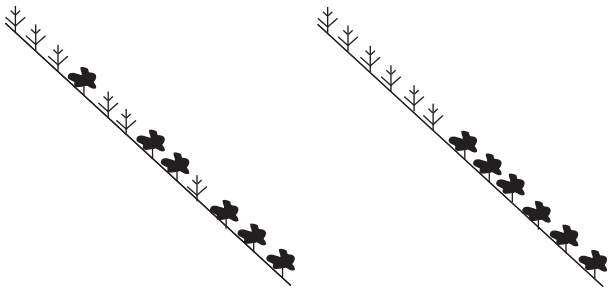

Fig. 1 Effect of competition on plant distributions on a gradient. The two plant species shown are adapted to different conditions, which are here found at either end of the slope. At left, there is no competition, so the distributions merge into one another. At right, competition truncates the distributions, leading to sharply defined altitudinal zones.

 doi:10.1016/B978-0-444-63768-0.00696-X

During the 1970s and 1980s, increasing computing power made it possible to use simulation to explore the consequences of complex networks of interactions. By the last two decades of the twentieth century, the nature and implications of biological self-organization were increasingly being explored as a part of the complexity theory. The new field of Artificial life (Alife), initiated by pioneers such as Chris Langton, Pauline Hogeweg, and Bruce Hesper, has produced a series of seminal models that demonstrate self-organization in a variety of ecological and evolutionary contexts. Around the same time, H. T. Odum introduced the systems concept of 'emergy' to represent the total energy used in developing a process.

By the 1990s, researchers were looking for broad-based theories of self-organization. John Holland stressed the role of adaptation in self-organization. He suggested that seven basic elements are involved in the emergence of order in complex adaptive systems. These include four properties – aggregation, nonlinearity, flows, and diversity – and three mechanisms – tagging, internal models, and building blocks. In contrast, Stuart Kauffman's work on autocatalytic sets within Boolean networks emphasizes ways in which self-organization may structure biological systems independent of selection. Likewise, embryologist Brian Goodwin suggested that to understand macroevolution, we require a theory of morphogenesis which takes account of physical, spatial, and temporal dynamics in addition to selection. The work of James Kay provided an interpretation of life from a thermodynamic perspective, arguing that self-organizing systems maximize the dissipation of gradients in nature. In particular, Kay argues that over time, ecosystems evolve to dissipate energy more efficiently by becoming increasingly complex and diverse.

Theories of Self-Organization

Thermodynamic Basis

In physical terms, the phenomenon of self-organization appears at first sight to be ruled out by the second law of thermodynamics, which states that in any closed system, entropy increases with time. In this sense, living systems seem to fly in the face of thermodynamics by accumulating order. However, self-organizing systems need not be closed. Open systems, including living things, share energy and information with the outside environment. In the late 1960s, Ilya Prigogine introduced the idea of dissipative systems to explain how this happens. He defined dissipative systems to be open systems that are far from equilibrium. Dissipative systems have no tendency to smooth out irregularities and to become homogeneous. Instead, they allow irregularities to grow and spread. Physical examples include crystal formation. Biological systems, including cells, organisms, and ecosystems, are all examples.

The Network Model

An important source of self-organization is provided by the interactions and relationships between the objects that comprise a complex system. Patterns of such relationships are captured by the network model of complexity.

Networks capture the essence of interactions and relationships, which is a fundamental source of complexity. A graph is defined to be a set of nodes (objects) joined by edges (relationships) and a network is a graph in which the nodes and/or edges have values associated with them. In a food web, for instance, the populations form nodes, and the interactions between them (e.g., predation) form the edges. In a landscape, spatial processes and relationships create many networks. For instance, the nodes might be individual plants and the corresponding edges would be any processes that create relationships between them, such as dispersal or overshading. In an animal social group, the nodes would be individuals and the edges would be relationships such as kinship or dominance.

Nodes that are joined by an edge are called neighbors. The degree of a node is the number of immediate neighbors that it has. A path is a sequence of edges in which the end node of one edge is the start node of the next edge, for example, the sequence of edges A–B, B–C, C–D, D–E forms a path from node A to node E. A cycle is a path that ends where it starts, for example, A–B, B–C, C–A. A network is called connected if, for any pair of nodes, there is always some path joining them (otherwise it is disconnected). The diameter of a network is the maximum separation between any pair of nodes. Clusters are highly connected sets of nodes.

The importance of networks stems from their universal nature. Network structure is present wherever a system can be seen to be composed of objects (nodes) and relationships (edges). Less obvious is that networks are also implicit in the behavior of systems. In this respect, the nodes are states of the system (e.g., species composition) and the edges are transitions from one state to another.

Sometimes, network structure plays a more important part in determining the behavior of a system than the nature of the individual components. In dynamic systems, for instance, cycles are associated with feedback loops. In disconnected networks, the nodes form small, isolated components, whereas in connected networks, they are influenced by interactions with their neighbors. Self-organization in a network can occur in two ways: by the addition or removal of nodes or edges, or by changes in the values associated with the nodes and edges.

Several kinds of network patterns are common and convey important properties.

- A random network is a network in which the nodes are connected at random. In a random network of n nodes, the degrees of the nodes approximate a Poisson distribution, and the average length (L) of a path between any two nodes is given by $L = \log(n)/\log(d)$, where d is the average degree.

- A regular network is a network with a consistent pattern of connections, such as a lattice or cycle.
- Small worlds fall between random networks and regular networks. They are typically highly clustered, but with low diameter. A common scenario is a system dominated by short-range connections, but in which some long-range connections are also present.
- A tree is a connected network that contains no cycles. A hierarchy is a tree that has a defined root node. For instance, the descendents of a particular individual animal (the root of the tree) form a hierarchy determined by birth. Trees and hierarchies are closely associated with the idea of encapsulation.
- A scale-free network is a connected network in which the degrees of the nodes follow an inverse power law. That is, some nodes are highly connected, but most have few (usually just one) connections.

Encapsulation

Encapsulation is the process by which a set of distinct objects combine to act as a single unit. Individual fish, for example, form a school by aligning their movements with their neighbors. Because smaller objects usually merge into larger wholes, encapsulation is often linked to questions of scale. Encapsulation is closely associated with the idea of emergence. The whole emerges when individuals become subsumed within a group in relation to the outside world. There are many examples in ecology. Ecosystems are communities of interacting organisms; populations are groups of interbreeding organisms; and schools, flocks, and herds are groups of animals moving in coordinated fashion. In all of these cases, the individuals may not be permanently bound to the group, unlike cells within the human body. Cellular slime molds present an intermediate case in which cells sometimes act independently but at other times aggregate to form a multicellular individual.

Various ecological theories are based on the assumption that encapsulation plays an important role in ecosystem structure and function. The concept of ecosystem compartments implies that a community is formed of distinct groups (compartments) consisting of mutually interacting species, but the interactions between the groups are limited.

Connectivity and Criticality

Criticality is a phenomenon in which a system exhibits sudden phase changes. Examples include water freezing, crystallization, and epidemic processes. Associated with every critical phenomenon is an order parameter, and the phase change occurs when the order parameter reaches a critical value. For example, water freezes, when its temperature falls to 0 °C. A wildfire spreads when fuel moisture falls below a critical level (else it dies out).

Changes in the connectivity of a network have important consequences and often underlie critical phenomena. When a network is formed by adding edges at random to a set of N nodes, a connectivity avalanche occurs when the number of edges is approximately $N/2$. This avalanche is characterized by the formation of a connected subnet, called a unique giant component (UGC), which contains most of the nodes in the full network. The formation of the UGC marks a phase change in which the network shifts rapidly from being disconnected to connected.

Any system that can be identified with nodes and edges forms a network, so the connectivity avalanche occurs in many settings and is the usual mechanism underlying critical phase changes.

The connectivity avalanche has several important implications. For interacting systems, it means that the group behaves either as disconnected individuals, or as a connected whole. Either global properties emerge, or they do not: there is usually very little intermediate behavior. Landscape connectivity provides an important ecological example of critical phase change.

Phase changes in connectivity also underlie criticality in system behavior. The degree of connectivity between states of a system determines the richness of its behavior. Studies based on automata theory show that if connectivity is too low, systems become static or locked in narrow cycles. If connectivity is too high, systems behave chaotically. The transition between these two phases is a critical region, popularly known as the 'edge of chaos'. It has been observed that automata whose state spaces lie in this critical region exhibit the most interesting behavior. This observation led researchers such as James Crutchfield, Christopher Langton, and Stuart Kauffman to suggest that automata need to reside in the critical region to perform universal computation. More speculative is their suggestion that the edge of chaos is an essential requirement for evolvability (the ability to evolve) in complex systems, including living things. Others have proposed that living systems exploit chaos as a source of novelty, and that they evolve to lie near the edge of chaos. These ideas are closely related to self-organized criticality (SOC).

Self-Organized Criticality

SOC is a phenomenon wherein a system maintains itself in a critical or near-critical state. A classic example is the pattern of collapses in a growing pile of sand. Because information theory suggests that systems in critical states are most amenable to information processing and complexity, self-organized criticality has been proposed as a component of collective behavior in ant colonies, societies, ecosystems, and large-scale evolution. SOC is characterized by events whose size and frequency distributions follow an inverse power law. However, it is often difficult to distinguish genuine cases of SOC from simple cause and effect processes that exhibit similar distributions.

For example, ecosystems might tend toward critical states through the following mechanism. If new species or mutations appear in an ecosystem occasionally, then as the variation in the ecosystem increases over time, so does the probability of forming destabilizing positive feedback loops. Such destabilizing interactions could initiate avalanches of extinctions, and the probable size of such avalanches would be related to the preexisting connectivity of the system. In this way, mutation, migration, and extinction could keep the system near the critical region, as the addition of new variation drives the ecosystem out of subcriticality, while extinction avalanches prevent supercriticality. Proponents of this idea point to extinction events, whose distribution follows an inverse power law, as supporting evidence. However, other explanations of this pattern, such as cometary impacts, are also plausible.

Feedback

Feedback is a process in which outputs from a system affect the inputs. Predator–prey systems are examples of negative feedback. For instance, any increase in the size of a predator population means that more prey are eaten, so the prey population decreases, which in turn leads to a decrease in the predator population. Reproduction is an example of positive feedback: births increase population size, which in turn increases the rate of reproduction, which leads to yet more births. Feedback loops arise when a sequence of interactions form a closed loop, for example, A–B–C–A. Feedback loops play an important role in food webs and ecosystem stability. Time delays in the response within a feedback loop often lead to cyclic behavior (e.g., in predator–prey systems).

Both positive and negative feedback are important in self-organization. By dampening changes, negative feedback acts as a stabilizing force. It is one of the principal mechanisms of homeostasis, the maintenance of dynamic equilibrium by internal regulation. In contrast, positive feedback magnifies minor deviations. An example is competitive exclusion: any small decrease in size of a competing population is likely to lead to further decreases, until it dies out (Fig. 2).

Stigmergy

Stigmergy is a form of self-organization that occurs when parts of a system communicate by modifying their environment. Many examples of stigmergy occur in the organization of eusocial insect colonies. For example, in ant colonies, objects such as food, larvae, and corpses are often stored in discrete larders, nurseries, and cemeteries. Models show that this civic order can emerge through interactions between the ants and their environment. In the model, ants pick up objects at random, and may drop them when they encounter similar objects. Over time, this process creates piles of similar objects. Positive feedback causes larger piles to grow at the expense of smaller ones (Fig. 3).

Synchronization

Synchrony can alter system-level behavior by enhancing or dampening nonlinearities. For example, when predator and prey populations are tightly coupled to one another, a stable, negative feedback relationship can result where an increase in prey causes increased predators and a subsequent decrease in prey. In this case, the ecological interaction acts like a thermostat regulating population size. However, if the two populations respond at different rates, oscillations or even chaotic behavior can occur instead. A classic example of such oscillations occurs in the interaction between populations of hares and lynxes in the Arctic Circle.

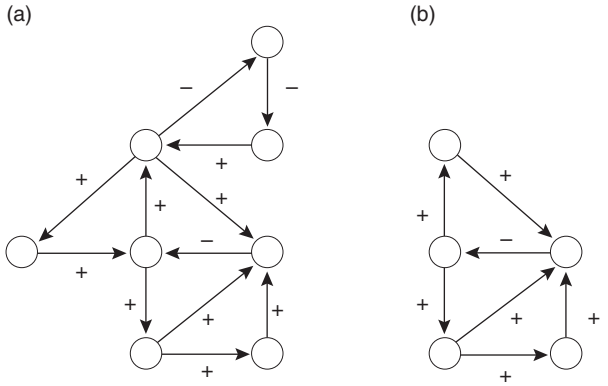

Fig. 2 The role of feedback in self-organization of a food web. In this diagram, circles represent populations and arrows indicate the influence (positive or negative) of one population on another. In a food web, circular chains of interaction between populations form feedback loops, as in the example shown here. (a) The initial food web contains both positive and negative feedback loops. Internal dynamics within the positive feedback loops leads to the local extinction of several populations. (b) The resulting food web contains only negative feedback loops, which stabilize the community.

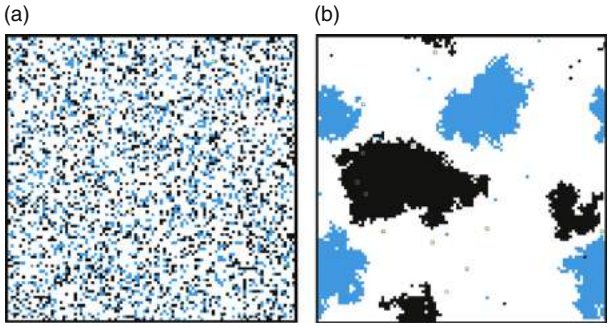

Fig. 3 The emergence of order by stigmergy and feedback in an ant colony. Given a random scatter of objects (a), ants sort objects by picking them up and dropping them again when they find a similar object. This process creates piles, which grow over time. Large piles grow at the expense of smaller ones until only a few large piles remain (b).

Synchronized breeding behavior is common and includes mass flowering in plants, mass breeding in birds, and mass spawning among marine animals such as corals and squid. In these cases, synchrony is usually achieved by individuals responding to a common environmental cue, such as a change in temperature or day length. Synchronized breeding conveys distinct advantages such as maximal exploitation of resources and satiation of predators.

Different species often have co-adapted simultaneous seasonal behavior, such as birds that breed when butterflies emerge. However, both the environmental cues, and the physiological response, may differ among these co-adapted species. For example, great tits time their egg laying by photoperiod. Winter moths are an important food source during the breeding season, and they develop more quickly at higher temperatures. As a result, recent warm springs in Europe caused by climate change have disrupted the synchronization between these species, reducing food availability for nesting great tits and potentially destabilizing populations.

In other cases, synchronous behavior arises through social contagion, where individuals imitate others. The dynamics of such behavior are similar to those seen in epidemiology. Social contagion can lead to coordinated group behavior such as flocking, as well as disparate phenomena such as synchronized flashing in fireflies, and 'fashions' in mate choice among birds and fish. The emergence of synchronous behavior in these cases is highly sensitive to the structure of social networks. Synchrony is easily achieved when networks are highly connected (i.e., individuals can perceive a large number of other individuals, or some individuals have very large influence). However, in loosely connected networks, social contagion can result in asynchronous waves or chaos.

Complex Adaptive Systems

Complex adaptive systems (CASs) consist of diverse, locally interacting components that are subject to selection. Examples include learning brains, developing individuals, economies, ecosystems, and the biosphere. In such systems, hierarchical organization, continual novelty and adaptation, and nonequilibrium dynamics are known to emerge. As a result, the behavior of a CAS is characterized by nonlinearity, historical contingency, thresholds, and multiple basins of attraction. A key question in current CAS research has been the relationship between resilience and criticality. Some authors suggest that a CAS will generally evolve toward self-organized criticality. By being maintained near the edge of chaos, such systems might maximize information processing. In this way, criticality might enhance the ability of CASs to adapt to changing environments and efficiently utilize resources, making systems become more resilient over time.

Artificial Life

The field of Alife uses simulation models to understand biological organization by abstracting crucial features and examining living systems 'as they could be'.

One of the most widespread representations used in Alife models is the cellular automaton (CA). This is a grid of cells in which each cell has a state (some property of interest) and is programmed to behave in identical fashion. Each cell has a neighborhood (usually the cells immediately adjacent to it) and the states of it neighbors affect changes in a cell's state. The most famous example is the Game of Life, in which each cell is either 'alive' or 'dead' at any time. Despite its extreme simplicity, the game showed that large numbers of interactions governed by simple rules lead to the emergence of order within a system. Cellular automata have been used to model many biological and ecological systems. In models of fires, epidemics, and other spatial processes, each cell represents a fixed area of the landscape and the cell states represent features of interest (e.g., susceptible, infected, or immune organisms in an epidemic model).

Other prominent ALife models include Tom Ray's Tierra model, which demonstrated adaptation within self-reproducing automata. Craig Reynolds' boids model demonstrated that flocking behavior emerges from simple interactions between individuals. James Lovelock's Daisyworld model showed the potential for biotic feedback and adaptation to stabilize the biosphere.

Self-Organization in an Ecological Setting

Social Groups

Relationships between individuals create several kinds of organizations within groups of animals.

Coordination between moving animals leads the formation of groups. Examples include swarms of insects, flocks of birds, schools of fish, and herds of mammals. Coordinated group movements, even in very large groups, can be achieved by individuals obeying simple rules, such as 'keep close, but not too close, to your neighbors' and 'head in the same general direction as your neighbors.'

Several mechanisms that channel aggressive behavior create social organization. In social animals, dominance hierarchies reduce the potential costs of conflict over mates and food. Adominance hierarchy emerges when interactions between individuals result in physiological and behavioral changes: for example, 'winning' a contest may elevate testosterone, causing increased dominance behavior, and evoking submissive behavior from individuals who have been less successful in the past. In this way, coherent transitive hierarchies can emerge even when all individuals were initially equal. Similarly, territoriality reduces the costs of conflict over resources by partitioning a landscape among a population. Territoriality often generates spatial patterns, such as regular distances between nests in seabird colonies. In this case, the distance between nests is defined by the maximum area that a sitting bird can defend without abandoning her nest. More complex coordinated group behaviors can emerge when individuals take on different tasks and roles within groups. For example, within ant and termite colonies, individuals can develop into a variety of castes, each with distinct roles such as foraging, nest defense, and nursing young. In honeybees, individuals take on different roles at different life stages.

In some cases, upper limits exist on the size that social groups can attain and depend on interactions between the animals. In apes, for instance, where social bonds are maintained by grooming, troop sizes tend to be 30–60 individuals. Larger troops tend to fragment. Among humans, social groups are usually much larger. The anthropologist Robin Dunbar argues that this is a consequence of speech providing more efficient social bonding than grooming, leading to a natural group size of 100–150 individuals.

In most cases, group size may be the outcome of several interacting ecological and social factors. For example, although lions hunt cooperatively, prides and hunting groups are usually larger than is optimal for hunting efficiency. Lionesses cooperate to defend cubs against infanticidal males by forming crèches. In addition, hunters are vulnerable to attack by larger groups, and territories are more effectively defended by larger prides.

The origin of cooperation among groups of cells and organisms can also be examined from the perspective of self-organization. The paradox of the evolution of cooperation is that (by definition) selfish individuals outcompete altruists, and therefore in a population of self-replicators, a selfish mutant should always spread at the expense of altruists. Nonetheless, altruism does occur among humans and cooperative behavior is often seen among animals. Such cooperative behavior can self-organize when the network structure that governs interactions among individuals results in the same individuals encountering one another repeatedly (e.g., when individuals are fixed in space, so that their only interactions are with their neighbors), or when their reproductive fate is very closely tied to that of others (as is the case for cells within a multicellular organism). Experimentally, the evolution of cooperation has been induced in bacterial populations by production of adhesive, causing individual cells to clump together. Cooperation can also evolve in marginal environments, where the evolutionary impact of competition between individuals is outweighed by the need to survive. Experimental studies of bacteria in marginal environments show that complex spatial patterns and signaling behaviors can emerge as a result of this selection. In theoretical models, the inclusion of policing behavior (punishing nonconformists) can also enforce high levels of cooperation even when interactions occur at random in large societies.

Persistence and Stability in Ecosystems

One of the most puzzling topics in systems ecology is how ecosystems emerge that are at once complex and stable. Field studies suggest that the most complex (diverse) ecosystems are also the most stable. However, this observation runs counter to expectation from systems theory. It shows that the more components a dynamic system has, the more likely it is that a destabilizing interaction (such as a positive feedback loop) will cause it to collapse and lose species. Consequently, systems theory suggests that simpler ecosystems should be more stable than complex ones. The paradox implies that the complex, stable ecosystems seen in nature are not random assemblages. Self-organization in this case involves removal of destabilizing positive feedback loops.

Communities versus Assemblages

The question of how important self-organization is in ecosystems has long been debated in ecology. Are ecosystems communities of co-adapted species, or are they simply random assemblages? Some early theorists, such as Clements, believed that the groups of species found together were specialized for living together, whereas others, such as Gleason, stressed the importance of chance and individuals.

The idea of succession concerns the patterns and processes involved in community change, especially after disturbance. A form of self-organization often associated with succession is facilitation. That is, plants and animals present in an area can alter the local environment, thereby facilitating the appearance of populations that replace them. After a fire, for example, a forest will regenerate with herbs and shrubs growing back almost immediately. The first trees to reappear will be 'pioneer' (disturbance) species, which

disperse well, grow fast, and can tolerate open, exposed conditions. These trees create shade and leaf litter, which favor slow-growing, shade-tolerant trees.

Recent theoretical work (such as Hubbell's neutral theory of biodiversity and biogeography) emphasizes the role of chance and spatial dynamics in generating ecological patterns. In these models, self-organization is trivial because all individuals and species are effectively identical, and species abundances are driven by random birth, migration, and death processes. Both neutral and self-organizing models have been successful in explaining real relative abundance and species–area curves.

Food Webs

Species interactions lead to the flow of material within an ecosystem. For animals the most common processes are eating, respiration, excretion, and egestion. For plants, they are root uptake of water and nutrients, respiration, and photosynthesis. The outputs of material from one organism often become inputs to other. This focus on 'what eats what' led Elton to identify several patterns, notably the food chain and the food web, the food cycle, the ecological niche, and the pyramid of numbers.

Self-organization in ecosystems is evident in the structure in food webs, networks that describe trophic interactions among species. Within food webs, specific patterns of interaction may be prevalent. These patterns, termed ecological motifs, are thought to represent especially stable interactions. The concept of keystone species supposes that certain species play a crucial role in maintaining the integrity and stability of an ecosystem.

Analysis of food webs suggests that a small-world structure is common. That is, most species interact with only a small number of other species, but the connectivity of the web as a whole is maintained by a few species that interact with a large number of others. This observation provides a theoretical basis for the idea of keystone species. Functionally, small world networks are thought to be robust to random loss of nodes (e.g., species), but vulnerable to attacks that target their highly connected nodes (e.g., keystone species).

Spatial Patterns and Processes

Spatial processes lead to the formation of distribution patterns. Seed dispersal, for instance, often produces concentrations of seedlings around parent plants and leads to the formation of clumped distributions. When local dispersal is combined with patchy disturbance, such as fire, the result is a distribution composed of patches. When combined with environmental gradients, such as soil moisture, local dispersal can produce zone patterns, with different species dominating different areas (**Fig. 4**).

Fragmentation is one of the most important consequences of landscape connectivity. When the density of (randomly located) objects in a landscape falls below a critical density, they are mostly isolated individuals. When the density exceeds the critical threshold, they become connected. The density at which the critical threshold occurs depends on the size of the neighborhood of the objects. There are many cases where landscape connectivity plays an important role. Epidemic processes require a critical density of resources to spread. Instances include disease outbreaks (susceptible individuals), fire spread (fuel), and invasions of exotic plants (suitable sites). Populations become fragmented if individuals cannot interact with one another. For instance, in wet years the water bodies of central Australia are essentially connected for water birds, which can fly from one body to another almost anywhere in the continent. In dry years, however, many water bodies shrink or dry up and become too widely separated for birds to migrate between them (**Fig. 5**).

Self-Organization in the Biosphere

Arguably the most ambitious ecological theory based on self-organization is the Gaia hypothesis, which postulates that the biosphere itself evolves to a homeostatic state. Lovelock suggested the Daisyworld model as an illustration of how this process

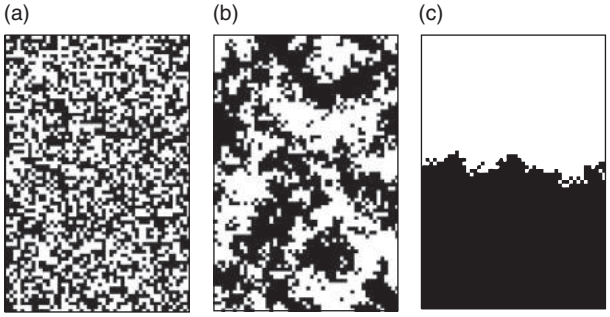

Fig. 4 Emergence of spatial patterns from dispersal. This CA model shows the hypothetical distributions of two plant populations that result in three different scenarios. (a) Global dispersal, in which seeds can spread anywhere, results in random distributions of plants. (b) Dispersal from local seed sources leads to clumped distributions. (c) The combination of local dispersal and environmental gradients (from top to bottom) creates vegetation zones.

Fig. 5 Critical phase changes in connectivity within a fragmented landscape. In this CA model, grid cells represent sites in a landscape. Gray and black cells represent vegetation and white cells have no cover. The black cells show examples of patches of vegetation sites that are connected, for example, by spread of a fire ignited in the center of the grid. Notice that only a small increase in the density of covered sites makes the difference between subcritical and supercritical.

might occur. On the hypothetical Daisyworld, black and white daisies compete for space. Although both kinds of daisies grow best at the same temperature, black daisies absorb more heat than white daisies. When the Sun shines more brightly, heating the planet, white daisies spread, and the planet cools again. When the Sun dims, the black daisies spread, warming the planet. In this way, competitive interactions between daisies provide a homeostatic mechanism for the planet as a whole.

The idea behind Gaia is that ecosystems will survive and spread more effectively if they promote the abiotic conditions required for their own persistence. If so, ecosystems might gradually evolve to be increasingly robust, and if this happened on a global scale, then the biosphere itself might behave as a self-regulating system. However, evidence for Gaian processes in real ecosystems remains tenuous and their theoretical plausibility is disputed.

Evolution

Self-organization may play a prominent role in evolution, especially in the context of landscapes, which regulate interactions between individuals. One consequence is the evolution of cooperation in marginal and viscous habitat networks, whereas randomly interacting populations are more dominated by intraspecific competition and therefore more likely to behave selfishly.

Landscape structure influences genetic diversity and speciation. In connected landscapes, genes flow freely throughout a species and speciation is inhibited. However, in fragmented landscapes, a species breaks into isolated subpopulations. Fragmentation increases the risk of inbreeding and loss of genetic diversity in these subpopulations. Divergence between population fragments may also underlie adaptive radiations, in which many novel species suddenly emerge simultaneously.

As species adapt to their environment, they are often faced by tradeoffs in allocating resources for different purposes. These tradeoffs can lead to the evolution of distinct morphs within a species, or to speciation. For example, many mangrove species face a conflict between salt tolerance and competitive ability. Mangroves grow in estuaries, where salinity varies along the gradient between land and sea. Mangroves growing landward will be under strong selection for competitive ability, while those growing closer to the sea require better salt tolerance. The tradeoff, combined with local seed dispersal, can generate discrete banding patterns in the distribution of mangrove species, where each species is displaced by a more salt-tolerant one closer to the sea.

Contingency also plays a large part in the organization of spatial distributions. Spatial dominance occurs when a particular species is overwhelmingly abundant in a local environment. In this situation, the species can resist invasion, even by a superior competitor, because its propagules are much more numerous locally than those of any other population. For the same reason, a mutation that enables a species to exploit a novel environment may result in it permanently excluding potential competitors from that environment, even after they have evolved similar adaptations.

Practical Considerations

The insights provided by theories of self-organization have many practical implications, both for ecology and for conservation. The sharp end of the conservation debate often hinges on the question of which areas and which sites to conserve. If ecosystems consist of random collections of species, then one site in a landscape is as good as another. All that matters is to preserve representative populations of each species. However, if the ecosystems consist of self-organized communities, in which the species are adapted to depend on one another for survival, then whole communities need to be conserved.

Closely related to the above issue is that the tendency for randomly constructed food webs to be unstable raises questions about the long-term viability of artificially created communities in which translocated species are introduced into new areas. Self-organization is evident even in artificial ecosystems. In biosphere 2, for instance, a closed, experimental environment designed to emulate natural ecosystems, the environment was found to favor species that collect more energy and internal processes led to unexpected problems, such as runaway depletion of oxygen levels.

The need to understand self-organization is important when considering altered ecosystems. For instance, it is usually not possible to carry out experiments to determine the long-term effects of current ecological management practices such as translocation of populations, controlled burning or allocation of reserves and wilderness areas. This problem makes simulation

modeling a potentially crucial tool of ecological theory and practice. New methods of field observation are also appearing. For instance, the need to understand landscape fragmentation has led to studies of connectivity in landscapes, both field based, and using data from remote-sensing and geographic information.

Systems Ecology☆

Todd M Swannack, U.S. Army Engineer Research and Development Center, Vicksburg, MS, United States

Introduction

This article presents a scientific overview of systems ecology. The first section defines systems ecology and provides a brief history discussing the development of the discipline. The second section defines both complex systems in general and complex ecological systems and further describes several properties of ecological systems. The concluding section provides a brief overview of the systems approach used to analyze ecological systems.

Systems Ecology

Systems ecology is the study of the complex ecological systems using the systems approach. Ecological systems are thermodynamically open, hierarchical, self-organized, and self-regulating. The systems approach, including systems analysis and simulation, is characterized by the conceptualization, quantification, evaluation, and application of a model representing the ecological system of interest. These models can Systems ecology often, but not necessarily, focuses on the development of quantitative models to simulate the dynamics of ecosystem-level processes such as energy flow and nutrient cycling. However, the distinguishing feature of systems ecology is its holistic approach to questions dealing with complex ecological systems, regardless of their specific nature.

Systems ecology is a relatively new field within ecology. Until the middle of the 20th century, ecology was mainly a descriptive science and progressed by traditional, reductionistic methods. Organisms were often the focus of ecological studies. During this time, many ecological processes were identified as relationships between organisms (e.g., pairwise Lotka–Volterra competition equations). In 1935, the concept of an ecosystem as a self-sustaining, functional unit was introduced, but this concept was not built upon significantly until after World War II. Drawing from other fields such as engineering, communications, information theory, and systems sciences, ecologists began to recognize that ecological systems could and should be treated as unique, functional entities. A new definition for ecosystems emerged in 1995—an ecosystem is a complex of ecological communities and their environment, forming a functional whole in nature. This holistic approach recognized the irreducibility and complexity of natural systems. Due to the interactions among many different abiotic and biotic components, natural systems are inherently complex. This complexity makes it virtually impossible to obtain a complete picture of a natural system by reductionistic methods alone. Methods that synthesize analytical results were needed to illuminate the properties of natural systems. Incorporating the philosophy and techniques from general systems theory, ecologists now have the tools and ability to study complex ecological systems. This holistic approach emphasizes synthesis, that is, putting analytical results gathered from the reductionist approach, together to form a picture or model of natural systems.

Complex Ecological Systems

A system consists of a defined set of objects that interact in space and time. Systems are organized collections of interrelated physical components characterized by a boundary and functional unity. Systems are subjective entities created by humans for specific purposes, generally to do work, answer questions, illustrate theory, or explain the natural world. The complexity of any system increases as the number of system components and connections among components increases. An important property of a system is that the interactions among components create emergent properties, specific to that system. These properties result from the interactions among the components, are unique to the system itself, and are more than the collective sum of the properties of the components of the system. In complex systems, cause and effect often are not closely linked in time and space. Systems properties can be studied using the principles from general systems theory.

Ecological systems are functional, complex systems, which can sustain life and are composed of both living and nonliving components from a specific environment. The size and scale of any specific ecological system depends on the point of view of the researcher and are not specified until the objectives of the study are identified.

☆*Change History*: March 2018. Todd M. Swannack (original author) did the updates. The following sections were updated/added. Network connectivity was added. Figure 2 is a new figure. Communication, confusion of a concept, difficulty picturing the system, conflicts with preexisting models sections are new. Further reading was updated.

This is an update of T.M. Swannack and W.E. Grant, Systems Ecology, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3477–3481.

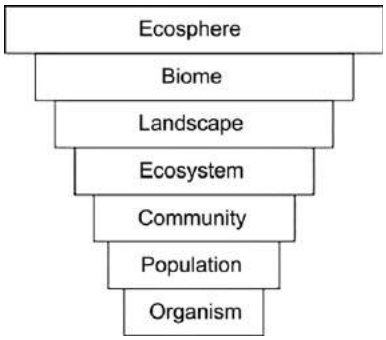

Fig. 1 Most commonly recognized ecological hierarchy. The organism is the simplest level within this hierarchy while the ecosphere is the most complex.

Open Systems

Ecological systems are thermodynamically open. Solar energy enters the biosphere and biological and ecological processes use this energy, which eventually leaves the system as unusable heat. There are two common measures of the flow of energy in a natural system, emergy and exergy. Emergy is the sum of one type of energy required to create an energy flow of another type, usually referenced to solar radiation. Exergy is a measure of the potential of a system to cause change as the system approaches equilibrium. Both emergy and exergy attempt to quantify the energy hidden in the organization and construction of living organisms. Both energy and material (e.g., nutrients in a nutrient cycle or individuals in a population) flow through ecological systems. Several properties of ecological systems result from being open systems. These properties include hierarchical organization, self-organization, and self-regulation via feedback.

Hierarchical Organization

Ecological systems are hierarchical in nature—at each level, components interact with the physical environment (matter and energy) and produce functioning systems. The most recognized ecological hierarchy, from the simplest to the most complex, is illustrated in Fig. 1. This hierarchy organizes the living systems on the planet into seven levels. Each level is composed of the levels below (i.e., populations are composed of organisms, communities are composed of populations, ecosystems are composed of communities, etc.). Energy and material can flow among levels. It is important to note that ecological systems need not be confined to the traditional ecosystem level of the hierarchy. An ecological system can be any system with biotic and abiotic components. Further, most ecological system are hierarchical and Fig. 1 may not explain all ecological phenomena well—for example, nutrient cycling does not fit well within this hierarchy; however, this is a fundamental ecological process that transcends the levels of organization diagrammed in Fig. 1. The complexity of ecological systems is a result, in part, from the interactions across these levels. At any given level in the hierarchy, interactions among components of lower levels produce emergent, irreducible properties that cannot be predicted from studying individual components of these lower levels. Ecological interactions occur across hierarchical levels, so systems ecologists have to deal explicitly with issues of scale, both spatial and temporal. In addition to emergent properties, there are functions that operate across all levels (e.g., diversity, evolution, energetics, regulation). These transcending functions can operate the same way in all levels (e.g., energetics) or can operate differently across levels—for example, evolution at the organism level involves genetic mutations and other genomic interactions and this process indirectly affects other levels of the hierarchy. At broader levels, systems principles apply, like the maximum power principle, which states evolution favors systems that maximize the flow rate of useful energy. The hierarchical structure of ecological systems creates a great deal of complexity which necessitates a holistic approach to elucidate system properties.

Order implies that the relatedness among system components is not a result of random processes. The more information required to describe a system, the higher the degree of randomness, indicating a lower degree of order. At the lower levels of the hierarchy, order is shaped, in part, by evolutionary processes occurring at the organism level. Adaptation at the individual level cascades through the hierarchy—for example, individuals evolve adaptations so they can compete (or avoid competing) with other species; competitive interactions among populations affect the spatial distribution of the populations in the community, which affects the community distribution in the landscape, etc. Evolution, along with other ecological processes, confers order within ecological systems.

Self-Organization

The interactions of components of ecological systems are nonrandom. These nonrandom interactions produce order and, as a result, ecological systems self-organize. Self-organization is when systems composed of many parts organize, achieving a

stable state in the absence of external perturbations. These systems can only maintain themselves by having a constant flow of energy (i.e., these systems are not in thermodynamic equilibrium). Ecological succession is an example of a self-organizing ecological system. During succession, the system builds up biomass and complexity. This process, termed ascendency by Ulanowicz, is the tendency for self-organizing systems to develop complexity in network flows and biomass. Ascendency is one way to measure the self-organizing complexity of ecological systems.

Self-Regulation

Self-regulation is another fundamental property of ecological systems. This concept was adapted from the field of cybernetics. Control is generally in the form of a feedback loop where part of the output of a system feeds back into the system as input. Negative feedback (when the output counteracts the input) is necessary for regulating a system. The energy required for negative feedback can be small compared to the total energy flowing through a system. Low-energy feedback components are common in natural systems. In addition to feedback, systems possess resistance and resilience, which measure the ability of a system to resist and recover from perturbations, respectively. Self-regulation implies that there is some level of stability for a given system. In natural systems, there is not a fixed level of stability, instead the interactions of material cycles and energy flow, along with feedback mechanisms, generate a self-correcting homeorhesis (i.e., evolutionary stability of a system flow). These homorhetic controls keep the variability of the system's energy and material flows altering in the same way they have done in the past.

Network Connectivity

Ecosystems can be viewed as networks because the components of the system have direct transactions between them (e.g., predator–prey, competition, nutrient sequestration, among many others). While these interactions are discrete events, when viewed as a whole, these transactions link the direct and indirect components in an interconnected web. This web represents the network structure. System level properties emerge from the network, so viewing a species or event in isolation limits the ability to observe the higher-level properties. Networks are covered in detail in the Network section of this encyclopedia. Systems analysis and network science provide the analytical tools that embrace the holistic qualities of ecosystems.

The Systems Approach

Ecological systems are inherently complex and due to their emergent properties, most ecological systems are irreducible. These two factors reveal the necessity for a systems science to analyze and interpret ecological systems. Systems ecologists, in general, are interested in the quantification of system properties. There are several approaches to the study of ecosystems:

1. analytical studies,
2. comparative studies,
3. experimental studies, and
4. modeling or simulation studies.

Analytical studies collect pieces of information and attempts are made to integrate and synthesize these into a complete picture of the system. In comparative studies information is collected for a few components of several different systems, and these components are compared across system types. Experimental studies manipulate entire ecological systems to identify patterns and processes. Modeling of ecological systems involves abstracting the real system into either a verbal description, which is often represented as a conceptual model or a series of mathematical equations (quantitative model).

Ecological models represent formal descriptions of the ecosystem of interest. Models do not contain every element of the real system but include the characteristic features that are essential to the structure and function of the system within the context of the objectives of the study. Simulation is the process of using models to represent the behavior of the real-world system. Both models and simulation are invaluable tools for studying ecological systems. Models can be used to reveal systems properties, test hypotheses, and illuminate areas within a system that require more analytical research.

Each of these methods has strengths and weaknesses; however, they all attempt to achieve an understanding of an entire ecological system. Each method views the system as a functional unit. The systems approach, a collection of techniques used to identify and elucidate systems properties, is often used to analyze the properties of ecological systems. Regardless of the specific details of each method, in general, there are essentially five stages of systems analysis: (1) define and conceptualize the system, (2) quantify the relationships among system components by creating a mathematical model of the system, (3) evaluate the usefulness of the model, (4) apply the model toward the objectives of the study, and communication (Fig. 2). The process is inherently iterative as systems are redefined as more understanding of the complexities and interactions emerge.

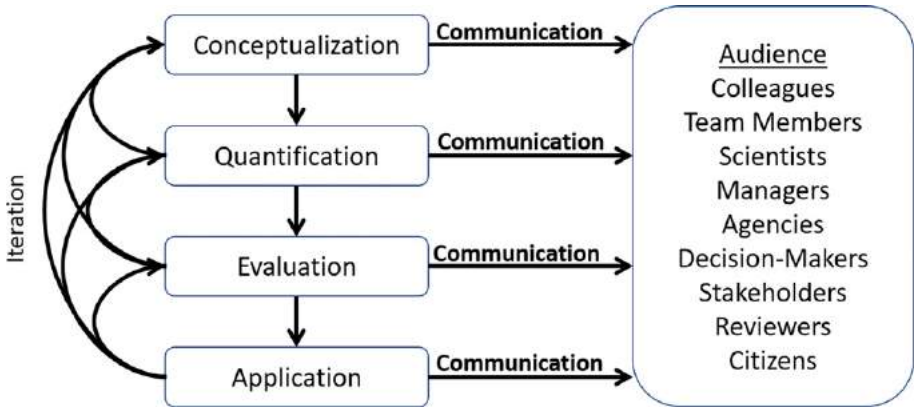

Fig. 2 Diagram of the modeling process. The process flows from conceptualization through application with communication being provided to an audience throughout the modeling process.

Conceptualization

Defining, or bounding, the system of interest is arguably the most critical stage of systems analysis. The idea is to develop a conceptual diagram of the real-world system that represents only the necessary components (i.e., enough of the components to reveal the system-level properties) and how they are related to each other. Important components are often identified by analytical, comparative, or manipulative studies. These components and their relationships are represented in a systems language using symbols that indicate the specific nature of the relationships. Two of the most common systems languages are Forrester diagrams and the energy circuit language developed by H.T. Odum. Each language uses a specific set of symbols, with each symbol indicating a specific function within the system. The major difference between the two systems languages is that Forrester diagrams allow materials and information to flow from one part of the diagram to another, while the energy circuit language is strictly used for representing how energy flows from place to place.

Quantification

The second stage of systems analysis involves translating the qualitative relationships diagrammed in the conceptual model into a series of mathematical equations. Depending on the system of interest, different types of mathematics can be used to solve the equations. Difference equations, differential equations, and matrix algebra are commonly used. The type of mathematics used depends on the objectives of the study. Due to the sheer number of components in ecological systems, analytical solutions rarely exist. Often, simulation is used as a tool to provide numerical solutions for complex models. The series of equations is solved at each time step over the entire period of simulated time. Equations are parametrized from either quantitative data gathered from analytical, comparative, or manipulative studies, or qualitative data which can come from the literature or from expert opinion.

Evaluation/Validation

The third stage of systems analysis is to evaluate the usefulness of the quantitative model in meeting the objectives of the study. This stage, commonly referred to as model validation, is the subject of much debate. This process considers the quantitative representation of the system from an array of distinct aspects, from comparing the results of the model to real-system observations to determining how sensitive model predictions are to changes in specific parameter values.

Application

The final stage of systems analysis is applying the quantitative model for its intended purpose. This stage involves designing and simulating the same experiments with the model that would be conducted in the real system. These results would be analyzed in the same way as empirical results.

Communication

As more complex models are used for large-scale planning and decision making, there is a need to clearly communicate the steps of model development to the appropriate audience. Model documentation should be focused on transparency, replicability, and

scientific defensibility. There are three main obstacles modelers face when communicating a model: confusion regarding a concept, difficulty picturing the system, and conflicts with preexisting cultural or mental models.

Confusion of a Concept

Developing a common vernacular with the desired audience is paramount for successful communication. Many disciplines use the same terminology, yet the underlying connotations of the terms can have different meanings. Overcoming this obstacle requires that modelers ask their audience how they interpret these terms. Similarly, modelers can develop a glossary of definitions for the audience. A common practice to clear up areas of misunderstanding is to develop an elucidating explanation that provides an example of the concept that lists the concept's critical features, and provides a variety of examples and nonexamples. This technique provides the audience with the opportunity to practice distinguishing the features that separate the example and nonexample.

Difficulty Picture of the System

Ecological systems models can be complex and can contain multiple feedback loops, threshold effects, and time lags. An audience can easily become confused when modelers obfuscate the concept by explaining too many details too quickly. In order to develop a useful picture of the overall system, modelers need to provide the audience with forming a general impression (i.e., big picture) of the system that they can grasp the systems components and interactions. Visual aids that depict the step-by-step construction of the model are useful for this task. Describing how the model was put together can be an onerous task, but it is crucial because it lends the process and the model more transparency. There is always more to describe about a model, but a clear presentation is the result of careful editing for a target audience.

Conflicts With Preexisting Models

Every person's intuitive understanding how the world works is framed by that person's specific life history. When a model directly conflicts with audience members' logic or beliefs, the cognitive dissonance disrupts their receptiveness to the assumptions upon which the model was built. It is difficult to overcome, but the use of transformative explanations that acknowledge the audiences preexisting notions of a system, then provide an alternative explanation, can be useful. Effective transformative explanations do not dismiss or insult preexisting models, but rather they help provide the audience with alternative perspectives for interpreting familiar systems.

Iterative Nature of Systems Analysis

The five stages of systems analysis are highly interconnected. This systems approach is a heuristic process. Often components have been overlooked or misrepresented, requiring returning to an earlier step, often conceptualization or quantification.

Synthesizing analytical results illuminates system properties. Often this synthesis identifies where more analytical research is required. The new results will then be incorporated into the synthesis, which in turn will identify the further need for more analytical data. Analytical results are needed to provide components for synthesis, and synthesis identifies the priorities for analysis. Likewise, communicating with interested parties throughout the process can result in components be reconceptualized, which leads to a new synthesis of the information.

Summary

Ecological systems are open systems and exhibit organized complexity. They are complex because they are composed of many interacting components whose interactions are characterized by time lags, thresholds, feedback, and indirect effects. Ecological systems vary in size and scale, depending on the processes being studied or the questions being asked. Typical reductionistic methods do not illuminate system properties. In order to properly study ecological systems, methods that embrace the system as a unit are required. The systems approach is characterized by the conceptualization, quantification, evaluation, application, and communication of a model representing the ecological system of interest. This approach, including systems analysis and simulation, is necessary because the cause–effect relationships within complex ecological systems can only be identified by examining the system as a single, functionally integrated entity.

Systems Ecology: Ecological Network Analysis☆

Brian D Fath, Towson University, Towson, MD, United States; International Institute for Applied Systems Analysis, Laxenburg, Austria
Ursula M Scharler, University of KwaZulu-Natal, Durban, South Africa

Introduction

Ecological Network Analysis (ENA) uses network theory to study the interactions between organisms or populations within their environment. ENA follows along the synecology perspective introduced by EP Odum which is predominantly concerned with interrelations of material, energy, and information among system components. Bernard Patten was the originator of the environ analysis approach in the mid-to-late 1970s and along with colleagues expanded the analysis to reveal many insightful, holistic properties of ecosystem organization. During about the same time, Robert Ulanowicz developed several system's measures for networks motivated by information theory to analyze the system flows. This approach has been applied in ecological and socio-economic settings.

ENA starts with the assumption that a system can be represented as a network of nodes (compartments, vertices, components, storages, objects, etc.) and the connections between them (links, arcs, flows, etc.). In ecological systems, the connections are usually based on the flow of energy or matter (water, nutrients, etc.) between the system compartments, and in socioeconomic networks of money, trade, water, or social interactions. If such a flow exists, then there is a direct transaction between the two connected compartments. These direct transactions give rise to both direct and indirect relations between all the objects in the system. Network analysis provides a systems-oriented perspective because it is based on uncovering patterns and relations among all the objects in a system. Therefore, it gives a view on how system components are tied to a larger web of interactions.

Theoretical Developments of Ecological Network Analysis

The development of Environ Analysis was motivated by Patten to attempt to answer the question, "What is environment?". In order to study environment as a formal object, a system boundary is a necessary condition to avoid the issue of infinite indirectness, because in principle, one could trace the environment of each object back in history to the big bang origins. The realization of a boundary is, in fact, one of the three foundational principles in his seminal paper introducing the environ theory concept (Patten, 1978). The necessary boundary demarcates now two environments, the unbound external environment, which indeed includes all space–time objects in the universe, and the second internal, contained environment of interest. This quantifiable, internal environment for each system object is termed "environ," and is the study of Environ Analysis. An object's environ stops at the system boundary, but as ecosystems are open systems, they require exchanges across the boundary into and out of the system.

☆*Change History*: April 2018. Brian D. Fath and Ursula M. Scharler. The new article is a combination of two articles in the earlier edition. Previously there was one article Ecological Network Analysis, Ascendancy by Scharler and one titled Ecological Network Analysis, Environ Analysis by Fath.

Therefore, input and output boundary flows are necessary to maintain the system functioning at far from thermodynamic equilibrium. Objects and connections that reside wholly in the external environment are not germane to the analysis.

Another foundational principle of environ analysis theory is that each object in the system itself has two "environs" one on the receiving end and one on the generating end of interactions in the system. In other words, an object's input environ includes those flows from within the system boundary leading up to the object, and an output environ, those flows emanating from the object back to the other system objects before exiting the system boundary. This alters the perception from internal–external to receiving–generating. Thus, the object, while distinct in time and space, is more clearly embedded in and responsive to the couplings with other objects within the network. This shifts the focus from the objects themselves to the relations they maintain; or from parts to processes (or what Ilya Prigogine called from Being to Becoming).

The third foundational principle is that individual environs (and the flow carried within each one) are unique such that the system comprises the set union of all environs, which in turn partition the system level of organization. This partitioning allows one to classify environ flow into what have been called different modes: (1) boundary input; (2) first passage flow received by a compartment from other compartments in the system [i.e., not boundary flow, but also not cycled flow (in other words first time flow reaching a compartment)]; (3) cycled flow that returns to a compartment before leaving the system; (4) dissipative flow in that it has left the focal compartment not to return, but does not directly cross a system boundary (i.e., it flows to another within system compartment); and (5) boundary output. The modes have been used to understand better the general role of cycling and the flow contributions from each object to the other, which has had application in showing a complementarity of several of the holistic, thermodynamic-based ecological indicators (see Fath et al., 2001).

The link to thermodynamics has been incorporated into several other ecosystem measures and methodologies, used to calculate structural and functional systems indicators from the number and weight of links, or from the flows and associated biomass, or size, of nodes. Many of these have their roots in macroecological considerations, and were conceived by the desire to quantify the growth, succession and development of ecosystems (e.g., Ulanowicz, 1986), within the framework of "process ecology." Process ecology focuses less on the biomass (storage) of species, which often in conjunction with abundance is the main focus of ecologists. Rather, processes such as the biomass (or energy, nutrients, etc.) fluxes between species (nodes), recycling of material, decomposition, or production are the main focus. These lead to emerging properties on the ecosystem level, which links it to macro-ecology.

Data Requirements and Community Assembly Rules

On one level Ecological Network Analysis could be referred to as a holistic/reductionistic approach. It is holistic because it considers simultaneously the whole influence of all system objects, yet it is reductionistic in that the fine details of all transactions are entailed in the analysis. In other words, it is the opposite of a black box model. The network data requirements are considerable, which include the complete flow–storage quantities for each identified link and node (note flow and storage are interchangeable as determined by the turnover rate). Data can be acquired from empirical observations, literature estimates, model simulation results, or balancing procedures, when all but a few are unknown. While there is difficulty in obtaining complete network datasets, a number of ecosystem network models are available from various databases [see EcoPath (http://sirs.agrocampus-ouest.fr/EcoBase/), Ulanowicz (https://www.cbl.umces.edu/~ulan/ntwk/network.html), or Borrett (http://people.uncw.edu/borretts/research.html)].Due to this lack of requisite data for fully quantified food webs, researchers have developed community assembly rules that are heuristics to construct ecological food webs. Assembly rules are in general a set of rules that will generate a connectance matrix for a number of N species. Common assembly rules that have been developed are random or constant connectance, cascade, niche, modified niche, and cyber-ecosystem each with its own assumptions and limitations (see Halnes et al. (2007) for a review of these methods). In all but the last case, the assembly rules construct only the structural food web topology. The cyber-ecosystem methodology (Fath, 2004) also includes a procedure for quantifying the flows along each link. It uses a meta-structure of six functional groups: Producer (P), Herbivore (H), Carnivore (C), Omnivore (O), Detritus (D), and Detrital Feeders (F), within which random connections link species based on these definitional constraints.

Methods and Sample Network

To demonstrate a few network analysis methodologies it is best to proceed with an example. Consider the network in Fig. 1, which has five compartments or nodes (x_i, for $i = 1$ to 5). Compartments are connected by transaction of the energy–matter substance flowing between them. These pair-wise couplings are the basis for the internal network structure. A structural connectance matrix, or adjacency matrix, **A**, is a binary representation of the connections such that $a_{ij} = 1$ if there is a connection from j to i, and a zero otherwise (Eq. 1).

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 \end{bmatrix} \tag{1}$$

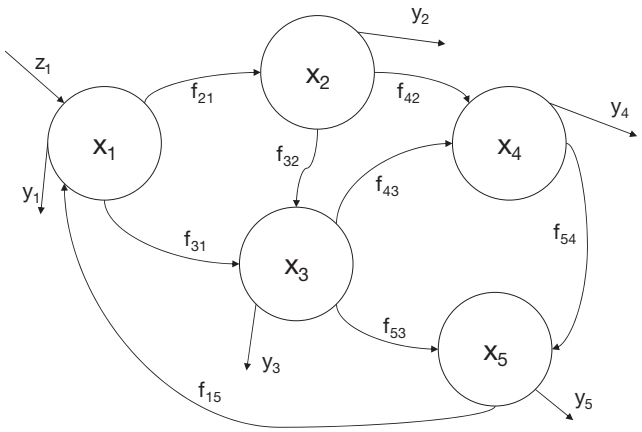

Fig. 1 Sample Network with five compartments use to demonstrate Environ Analysis notation and methodology.

Storage and flows must have consistent units (although it is possible to consider multi-unit networks). Typically, units for storages are given in amount of energy or biomass per given area or volume (e.g., g/m^2), and units for flows are the same but as a rate [e.g., g/(m^{2*}day)]. The intercompartmental flows for Fig. 1 are given in the following flow matrix, **F**:

$$\mathbf{F} = \begin{bmatrix} 0 & 0 & 0 & 0 & f_{15} \\ f_{21} & 0 & 0 & 0 & 0 \\ f_{31} & f_{32} & 0 & 0 & 0 \\ 0 & f_{42} & f_{43} & 0 & 0 \\ 0 & 0 & f_{53} & f_{54} & 0 \end{bmatrix} \tag{2}$$

Note that the orientation of flow from j to i is used in Environ Analysis because that makes the direction of ecological relation from i to j. For example, if i preys on j, the flow of energy is from j to i. To the contrary, other types of ecological network analyses direct the flow of energy from i to j when predator j feeds on i. It is therefore important to check the matrix setup before embarking on an analysis. All compartments experience dissipative flow losses (y_i, for $i = 1$ to 5), and here the first compartment receives external flow input, z_1 (arrows starting or ending not on another compartment represent boundary flows). For this example, these can be given as:

$$y = [y_1 \;\; y_2 \;\; y_3 \;\; y_4 \;\; y_5] \tag{3}$$

and

$$z = \begin{bmatrix} z_1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{4}$$

In this approach, there is no distinction between the types of outflow; whereas with other approach it is split into useable export and respiration loss. Total throughflow of each compartment is an important variable, which is the sum of flows into, $T_i^{in} = z_i + \sum_j^n f_{ij}$, or out of, $T_i^{out} = y_i + \sum_j^n f_{ji}$ the ith compartment. At steady state, compartmental inflows and outflows are equal such that $dx_i/dt = 0$, and therefore, incoming and outgoing throughflows are equal also: $T_i^{in} = T_i^{out} = T_i$. In vector notation, compartmental throughflows are given by:

$$T = \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix} \tag{5}$$

The sum of flows in a network can also be depicted as total system throughput, which is defined as the sum of flows in the system including ingoing and outgoing boundary flows, and all internal flows from i to j, TSTput $= \sum_{j=1}^n \sum_{i=1}^n f_{ij} + \sum_{i=1}^n E_i + \sum_{i=1}^n R_i + \sum_{j=1}^n z_j$ where E is the export of usable material, and R the respiration losses across the system boundary.

This basic information regarding the storages, flows, and boundary flows provides all the necessary information to conduct Ecological Network Analysis. Environ Analysis has been classified into a structural analysis—dealing only with the network topology, and three functional analyses—flow, storage, and utility—which require the numerical values for flow and storage in

the network (Table 1). Some of the analyses have been developed in tandem (e.g., utility analysis and mixed trophic impacts analysis) and their differences and similarities are pointed out below. In addition, an illustration of ascendency analysis follows.

The technical aspects of environ analysis are explained in detail elsewhere, so rather than repeat those here, the remainder of the entry highlights some of the important results from environ analysis. But first, one issue that must be covered is the way in which network analysis identifies and quantifies indirect pathways and flow contributions. Indirectness originates from transfers or interactions that occur nondirectly, and are mediated by other within system compartments. These transfers could travel two, three, four, or many links before reaching the target destination. For example, the flow analysis starts with the calculation of the nondimensional flow intensity matrix, **B**, where $b_{ij} = f_{ij}/T_j$. The generalized, **B** matrix corresponding to Fig. 1 would look as follows:

$$\mathbf{B} = \begin{bmatrix} 0 & 0 & 0 & 0 & b_{15} \\ b_{21} & 0 & 0 & 0 & 0 \\ b_{31} & b_{32} & 0 & 0 & 0 \\ 0 & b_{42} & b_{43} & 0 & 0 \\ 0 & 0 & b_{53} & b_{54} & 0 \end{bmatrix} \tag{6}$$

These values represent the fraction of flow along each link normalized by the total throughflow at the donating compartment. This elements give the direct, measurable flow intensities (or probabilities) between any two nodes j to i. To identify the flow intensities along indirect paths (e.g., $j \rightarrow k \rightarrow i$), one need only consider the matrix **B** raised to the power equal to the path length in question. For example, $\mathbf{B}^2$ gives the flow intensities along all paths of length 2, $\mathbf{B}^3$ along all paths of length 3, etc. This well-known matrix algebra result is the primary tool to uncover system indirectness. In fact, it turns out that due to the way in which the **B** matrix is constructed, all elements in $\mathbf{B}^m$ go to zero as $m \rightarrow \infty$. Therefore, it is possible to sum the terms of $\mathbf{B}^m$ to acquire an "integral" flow matrix (called **N**), which gives the flow contribution from all path lengths.

$$N = \mathbf{B}^0 + \mathbf{B}^1 + \mathbf{B}^2 + \mathbf{B}^3 + \ldots = \sum_{m=0}^{\infty} \mathbf{B}^m = (\mathrm{I} - \mathbf{B})^{-1} \tag{7}$$

where $\mathbf{B}^0 = \mathrm{I}$, the identity matrix, $\mathbf{B}^1$ the direct flows, and $\mathbf{B}^m$ for $m > 1$ are all the indirect flows intensities. Note, that the elements of **B** and **N** are nondimensional; to retrieve back the actual throughflows, one need only multiply the integral matrix by the input vector: $\mathrm{T} = \mathbf{N}z$. In other words, **N** redistributes the input, z, throughout each compartment to recover the total flow through that compartment. Similarly, one could acquire any of the direct or indirect flows by multiplying $\mathbf{B}^m z$ for any m.

A similar argument is made to develop integral storage and utility matrices.

$$\textit{Storage}: \quad Q = P^0 + P^1 + P^2 + P^3 + \cdots = \sum_{m=0}^{\infty} P^m = (I - P)^{-1} \tag{8}$$

$$\textit{Utility}: \quad U = D^0 + D^1 + D^2 + D^3 + \cdots = \sum_{m=0}^{\infty} D^m = (I - D)^{-1} \tag{9}$$

where $p_{ij} = (f_{ij}/x_j)\Delta t$, and $d_{ij} = (f_{ij} - f_{ji})/T_i$.

Network Properties

Patten has developed a series of "ecological network properties" which summarize the results of environ analysis. These have all been described in the literature (for an overview, see Patten, 2016; Jørgensen et al., 2007). The properties have been used to assess the current state of ecosystem networks and to compare the state of different networks. Furthermore, while interpreting some of the properties as ecological goal functions, it has been possible to identify the structural or parametric configurations that positively affect the network property values as a way to detect or anticipate network changes. For example, certain network alterations, such as increased cycling, lead to greater total system energy throughflow and energy storage, so one could expect that if possible ecological

Table 1 Basic methodologies for Network Environ Analysis

networks are evolving or adapting to such configurations. This leads to a new area of research on evolving networks. In this section, a brief overview is given for four of these properties: dominance of indirect effects (or nonlocality), network homogenization, network mutualism, and environs themselves.

Dominance of Indirect Effects

This property compares the contribution of flow along indirect pathways with those along direct ones. Indirect effects are any that require an intermediary node to mediate the transfer and can be of any length. The strength of indirectness has been measured in a ratio of the sum of the indirect flows intensities divided by the direct flow intensities:

$$\frac{\sum_{i,j=1}^{n}(n_{ij}-b_{ij}-\delta_{ij})}{\sum_{i,j=1}^{n}b_{ij}} \tag{10}$$

where δ_{ij}, the Kronecker delta, $=1$ if and only if $i=j$ and is 0 otherwise. When the ratio is greater than one, then dominance of indirect effects is said to occur. Analysis of many different models has shown that this ratio is often greater than one, revealing the nonintuitive result that indirect effects have greater contribution than direct effects. Thus, each compartment influences each other, often significantly, by many indirect, nonobvious pathways. The implications of this important result are clear in that each compartment is embedded in and dependent on the rest of the network for its situation, thus calling for a true systems approach to understand such things as feedback and distributed control in the network.

Network homogenization

The homogenization property yields a comparison of resource distribution between the direct and integral flow intensity matrices. Due to the contribution of indirect pathways, it was observed that flow in the integral matrix was more evenly distributed than that in the direct matrix. A statistical comparison of resources distribution can be made by calculating the coefficient of variation of each of the two matrices. For example, the coefficient of variation of the direct flow intensity matrix **B** is given by:

$$CV(G)=\frac{\sum_{j=1}^{n}\sum_{i=1}^{n}\left(\bar{g}_{ij}-g_{ij}\right)^2}{(n-1)\bar{g}} \tag{11}$$

$$CV(B)=\frac{\sum_{i,j=1}^{n}(\bar{b}_{ij}-b_{ij})^2}{(n-1)\bar{b}} \tag{12}$$

Network homogenization occurs when the coefficient of variation of **N** is less than the coefficient of variation of **B** because this says that the network flow is more evenly distributed in the integral matrix. The test statistic employed here looks at whether or not the ratio $CV(\mathbf{B})/CV(\mathbf{N})$ exceeds one. The interpretation again is clear that the view of flow in ecosystems is not as discrete as it appears because in fact the material is well-mixed (i.e., homogenized) and has traveled through and continues to travel through many, if not, most parts of the system.

Network mutualism

Turning now to the utility analysis, the net flow, utility matrix, **D**, can be used to determine quantitatively and qualitatively the relations between any two components in the network such as predation, mutualism, or competition. Entries in the direct utility matrix, **D**, or integral utility matrix, **U**, can be positive or negative ($-1 \le d_{ij}, u_{ij} < 1$). The elements of **D** represent the direct relation between that (i, j) pairing; for the example in Fig. 1, this produces the following:

$$\mathbf{D}=\begin{bmatrix} 0 & -\frac{f_{21}}{T_2} & -\frac{f_{31}}{T_3} & 0 & \frac{f_{15}}{T_5} \\ \frac{f_{21}}{T_2} & 0 & -\frac{f_{32}}{T_3} & -\frac{f_{42}}{T_4} & 0 \\ \frac{f_{31}}{T_3} & \frac{f_{32}}{T_3} & 0 & -\frac{f_{43}}{T_4} & -\frac{f_{53}}{T_5} \\ 0 & \frac{f_{42}}{T_4} & \frac{f_{43}}{T_4} & 0 & -\frac{f_{54}}{T_5} \\ -\frac{f_{15}}{T_5} & 0 & \frac{f_{53}}{T_5} & \frac{f_{54}}{T_5} & 0 \end{bmatrix} \tag{13}$$

The direct matrix **D**, being zero-sum, always has the same number of positive and negative signs.

$$\operatorname{sgn}(\mathbf{D}) = \begin{bmatrix} 0 & - & - & 0 & + \\ + & 0 & - & - & 0 \\ + & + & 0 & - & - \\ 0 & + & + & 0 & - \\ - & 0 & + & + & 0 \end{bmatrix} \tag{14}$$

The elements of **U** provide the integral, system-determined relations. Kazanci and Adams (2017) recently showed that convergence of the D matrix can always be achieved. Continuing the example, and now including flow values derived from 10% transfer efficiency along each link ($b_{ij} = 0.10$, if $a_{ij} = 1$, and $b_{ij} = 0$ otherwise), we get the following integral relations between compartments:

$$\operatorname{sgn}(\mathbf{U}) = \begin{bmatrix} + & - & - & + & + \\ + & + & - & - & + \\ + & - & + & - & - \\ + & + & + & + & - \\ + & + & + & + & + \end{bmatrix} \tag{15}$$

Unlike, the direct relations, this is not zero-sum. Instead, we see that there are 17 positive signs (including the diagonal) and 8 negatives signs. If there are a greater number of positive signs than negative signs in the integral utility matrix, then network mutualism is said to occur. Network mutualism reveals the preponderance of positive mutualistic relations in the system. Specifically, here, we can identify two cases of indirect mutualism, seven of exploitation, and one competition (Table 2).

Mixed Trophic Impacts Analysis (MTI)

Utility analysis (UA) and MTI have been developed in parallel. Essentially both analyses strive to elucidate the type of interactions between two nodes, both along direct and indirect pathways. Their similarities and differences have been defined in Scharler et al. (2009), and below is given a brief outline. At the start of the analyses, the orientation of fluxes between nodes differs in the **F** matrix between UA and MTI analysis, as pointed out above. Next, the imports across the system boundary are taken into account in the UA analysis (D^0) but not in the MTI analysis (Q^0 omitted), leading to more negative numbers along the diagonal in the M matrix of the MTI analysis. The signs of the relations over direct and indirect effects are used in both the MTI and UA analyses as qualitative descriptions of node relation. In UA, however, the fractions of the matrix are also re-dimensionalized by their total throughflow. All respiration flows are excluded in the calculation of impacts in the MTI analysis (Ulanowicz and Puccia, 1990). In UA they are included in the total system throughflow for each compartment. Lastly, the impacts to detritus are taken as zero in the MTI analysis, as the detritus nodes do not compete for these flows in contrast to living nodes, which actively impact their source nodes. In the UA analysis, on the other hand, a detritus node has a negative impact on the source node. This variation in weighting may give a reason for the different outcomes. Bearing these differences in mind, applying an MTI analysis to the example illustrated for the UA analysis above yields the following results.

In the MTI approach the positive effect of a prey on its predator is expressed as:

$$g_{ij} = f_{ij} / \sum_{k=1}^{n} f_{kj}, \tag{16}$$

where k represents all diets of j, and g_{ij} ranges from 0 to 1. The negative impact of the predator on its prey, is defined as:

Table 2 Direct and integral relations in sample network from Fig. 1

Direct	*Integral*
$(sd_{21}, sd_{12}) = (+, -)$ → exploitation	$(sd_{21}, sd_{12}) = (+, -)$ → exploitation
$(sd_{31}, sd_{13}) = (+, -)$ → exploitation	$(sd_{31}, sd_{13}) = (+, -)$ → exploitation
$(sd_{41}, sd_{14}) = (0, 0)$ → neutralism	$(sd_{41}, sd_{14}) = (+, +)$ → mutualism
$(sd_{51}, sd_{15}) = (-, +)$ → exploited	$(sd_{51}, sd_{15}) = (+, +)$ → mutualism
$(sd_{32}, sd_{23}) = (+, -)$ → exploitation	$(sd_{32}, sd_{23}) = (-, -)$ → competition
$(sd_{42}, sd_{24}) = (+, -)$ → exploitation	$(sd_{42}, sd_{24}) = (+, -)$ → exploitation
$(sd_{52}, sd_{25}) = (0, 0)$ → neutralism	$(sd_{52}, sd_{25}) = (+, -)$ → exploitation
$(sd_{43}, sd_{34}) = (+, -)$ → exploitation	$(sd_{43}, sd_{34}) = (+, -)$ → exploitation
$(sd_{53}, sd_{35}) = (+, -)$ → exploitation	$(sd_{53}, sd_{35}) = (+, -)$ → exploitation
$(sd_{54}, sd_{45}) = (+, -)$ → exploitation	$(sd_{54}, sd_{45}) = (+, -)$ → exploitation

$$h_{ij} = f_{ij} / \sum_{m=1}^{n} f_{im}, \tag{17}$$

where m represents all consumers of i (note, in the original MTI literature this matrix is called f_{ij}, but is renamed here h_{ij} to avoid confusion with the notation defined above).

The direct net impact (q_{ij}) of a network compartment on another is depicted as the difference of the positive impact the prey has on the predator (g_{ij}) minus the negative impact the predator has on its prey (h_{ij}):

$$q_{ij} = g_{ij} - h_{ji} \tag{18}$$

The indirect interactions (M) are calculated, similar to the Utility Analysis, by summing the powers of the matrices describing indirect steps over various path lengths. Note that imports across the system boundary are not part of the MTI analysis.

$$M = Q + Q^2 + Q^3 + Q^4 + \ldots \tag{19}$$

where Q, as defined in Eq. (18), is the matrix of the direct impacts of i upon j (path length of one), Q^2 the indirect impacts of i upon j over a path length of 2, Q^3 the indirect impacts of i upon j over a path length of 3, etc. Assuming the infinite power series converges, Eq. (19) can be written using the commonly known closed form solution as:

$$M = (I - Q)^{-1} - I \tag{20}$$

For the above example, the Q matrix of direct interactions, and M matrix for the integrated interactions are as follows:

Direct (Q)	*Integral (M)*
$(sd_{12}, sd_{21}) = (+, -)$ → exploitation	$(sd_{12}, sd_{21}) = (+, -)$ → exploitation
$(sd_{13}, sd_{31}) = (+, -)$ → exploitation	$(sd_{13}, sd_{31}) = (+, +)$ → mutualism
$(sd_{14}, sd_{41}) = (0, 0)$ → neutralism	$(sd_{14}, sd_{41}) = (+, +)$ → mutualism
$(sd_{15}, sd_{51}) = (-, +)$ → exploited	$(sd_{15}, sd_{51}) = (-, +)$ → exploited
$(sd_{23}, sd_{32}) = (+, -)$ → exploitation	$(sd_{23}, sd_{32}) = (-, -)$ → competition
$(sd_{24}, sd_{42}) = (+, -)$ → exploitation	$(sd_{24}, sd_{42}) = (+, -)$ → exploitation
$(sd_{25}, sd_{52}) = (0, 0)$ → neutralism	$(sd_{25}, sd_{52}) = (+, +)$ → mutualism
$(sd_{34}, sd_{43}) = (+, -)$ → exploitation	$(sd_{34}, sd_{43}) = (-, -)$ → competition
$(sd_{35}, sd_{53}) = (+, -)$ → exploitation	$(sd_{35}, sd_{53}) = (+, +)$ → mutualism
$(sd_{45}, sd_{54}) = (+, -)$ → exploitation	$(sd_{45}, sd_{54}) = (+, -)$ → exploitation

Environ analysis

This property mentioned here is the signature property, the quantitative environ, both in the input and output orientation. Since each compartment has two distinct environs there are in fact $2n$ environs in total. The output environ, **E**, for the ith node is calculated as:

$$E = (B - I)\hat{N}_i \tag{21}$$

where $\hat{N}_i$ is the diagonalized matrix of the ith column of **N**. When assembled, the result is the output oriented flow from each compartment to each other compartment in the system and across the system boundary. Input environs are calculated as:

$$E = \hat{N'}_i(B' - I) \tag{22}$$

where, $b'_{ij} = f_{ij}/T_i$, and $N' = (I - B')^{-1}$. These results comprise the foundation of Network Environ Analysis since they allow for the quantification of all within system interactions, both direct and indirect, on a compartment-by-compartment basis.

Ascendency analysis

The ascendency indicator was developed to quantify both the growth and development of ecosystems. Describing two attributes of ecosystems, ascendency consists of the total system throughput describing growth, and the average mutual information (AMI) describing how constrained fluxes are as they move from node to node (Fig. 2).

The total system throughput ($T..$) is described above, and a description of the AMI follows here. The degree of constraint of a flux between two nodes is described from its flow weight (T_{ij}), by the proportional weight of all flows entering the sink node in relation to total system flows ($T_j/T..$) and lastly by the proportion T_{ij} takes of all flows leaving i ($T_{ij}/T..$).

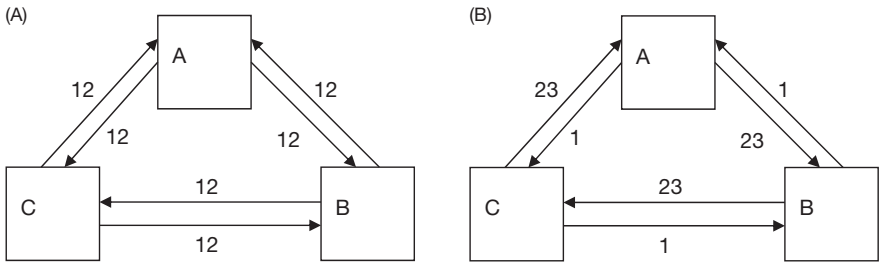

Fig. 2 (A) Hypothetical unconstrained network. Low AMI. (B) Hypothetical constrained network. Higher AMI.

Average Mutual Information

The probability that a quantum of material flows along the highly frequented routes is higher compared to a network where all routes transfer the same amount of material. Conversely, the probability that a quantum of material flows along the less frequented routes will be lower compared to a network where all routes transfer the same amount of material. Such a change in probability can be quantified with the help of information theory. Information is defined as the agent which causes a change in probability. Ulanowicz uses the term information to describe "the effects of that which imparts order and pattern to the system."

The most indeterminate, or least constrained, network is one where all compartments are connected with each other and where, in proportion to the compartmental throughput, equal amounts of material flow along the ingoing and outgoing pathways. Quantifying the information which is gained by transferring material along more and less frequented routes thus gives a clue about the unevenness of material flowing along pathways. The change in probability from a situation where a quantum of material flows along an equiprobable pathway (Fig. 2) and along a pathway which is not equiprobable (Fig. 2B) is calculated using conditional probabilities.

Since, from an ecological network point of view, joint and conditional probabilities refer to transfers of material from compartment i to compartment j, the above formula can be rewritten as

$$\mathrm{AMI} = K \sum_{i,j} \left(\frac{T_{ij}}{T_{..}} \right) \log \left(\frac{T_{ij} T_{..}}{T_{i.} T_{.j}} \right) \tag{23}$$

where the joint probability of a quantum of material $(p(a_i, b_j))$ flowing from species i to species j can be denoted as $T_{ij}/T_{..}$, remembering that the events in an events table are material flows in a system. $T_{..}$ is the total system throughput, or the sum over all combinations of T_{ij}.

Ascendency

The scalar constant, k, has been retained throughout all calculations. To be able to combine growth and development into one single index, k is substituted by the total system throughput or TST in order to scale the AMI to the size of the system in question. The resulting index is called Ascendency and is denoted by

$$A = TST \sum_{i,j} \left(\frac{T_{ij}}{T_{..}} \right) \log \left(\frac{T_{ij} T_{..}}{T_{i.} T_{.j}} \right) \tag{24a}$$

or

$$A = \sum_{i,j} T_{ij} \log \left(\frac{T_{ij} T_{..}}{T_{i.} T_{.j}} \right) \tag{24b}$$

Besides indirect mutualism there are a number of influences that can change the ascendency of a system. These influences are thought to not have a favored direction of change, whereas indirect mutualism is believed to drive development toward increased ascendency. Mutualism is furthermore not a result of events elsewhere in the system's hierarchy but can arise at any level. Previously, it was theorized that in the absence of overwhelming external disturbances, the ascendency of a system has a propensity to increase, that is, both activity (TST) and structure (AMI) increase. More recent research (e.g., Goerner et al., 2009; Ulanowicz et al., 2009) has shown that there are limits to the increase in ascendency (see section "Window of Vitality" below).

In theory, ascendency is higher when pathways are less in numbers (more specialization) and more articulated (few pathways transport most of the material). The highest theoretical value of ascendency is achieved when all players in the system have one input and one output only, and are thus joined in one big single loop. This configuration mirrors highest specialization, and in this case AMI = H. This situation cannot be achieved in real systems, due to reasons discussed below under the heading "Overhead" and "Window of Vitality."

Development Capacity

As mentioned above, the limit to development is set by Shannon's diversity index pertaining to the material transfers or flows. MacArthur applied Shannon's diversity index to the material flows in an ecosystem to arrive at a measure for the diversity of flows, H:

$$H = -k \sum_{i,j} \left(\frac{T_{ij}}{T_{..}}\right) \log \left(\frac{T_{ij}}{T_{..}}\right) \tag{25}$$

where k is a scalar constant, and $T_{..}$ is the total system throughput (TST), or the sum over all combinations of T_{ij}.

H can, like the AMI, be multiplied by TST to scale the diversity of flows to the system in question. TST $\times$ H is called the development capacity, or limit for development, C:

$$C = -TST \sum_{i,j} \left(\frac{T_{ij}}{T_{..}}\right) \log \left(\frac{T_{ij}}{T_{..}}\right) \tag{26a}$$

or

$$C = -\sum_{i,j} T_{ij} \log \left(\frac{T_{ij}}{T_{..}}\right) \tag{26b}$$

The initial complexity, H, consists of two elements. One is the AMI, describing the information gained by reducing the uncertainty in flow probability. It is an index of the organized part of the system. The other is the residual uncertainty, or H_c (also called conditional diversity). Thus, $H = \text{AMI} + H_c$.

H_c or Overhead

The overhead represents the unorganized, inefficient and indeterminate part of the flow structure and is considered an insurance for the system. Should the system become overly organized (high ascendency), it will also be prone to perturbations. The overhead is split into four components: overhead due to imports, exports, respiration and internal pathways.

The combined overhead is denoted by:

$$H_c = -k \sum_{i,j} \left(\frac{T_{ij}}{T_{..}}\right) \log \left(\frac{T_{ij}^2}{T_{i.} T_{.j}}\right) \tag{27}$$

Scaling H_c to the system by replacing k with by TSTput yields

$$\Phi = -\sum_{i,j} T_{ij} \log \left(\frac{T_{ij}^2}{T_{i.} T_{.j}}\right) \tag{28}$$

The relationship between C, A and Φ so becomes $C = A + \Phi$.

Similar terms can be derived for the flows that are imports, respiration, and exports.

The formula for the overhead on imports is as follows:

$$\Phi_I = -\sum_{j=1}^{n} T_{0j} \log \left(\frac{T_{0j}^2}{T_{0.} T_{.j}}\right) \tag{29}$$

where imports are assumed to originate from the environment labeled compartment 0.

The overhead on exports is denoted by:

$$\Phi_E = -\sum_{i=1}^{n} T_{i,\,n+1} \log \left(\frac{T_{i,\,n+1}^2}{T_{i.} T_{.,\,n+1}}\right) \tag{30}$$

where exports are assumed to flow into a fictitious compartment $n+1$.

The overhead on dissipation is:

$$\Phi_D = -\sum_{i=1}^{n} T_{i,\,n+2} \log \left(\frac{T_{i,\,n+2}^2}{T_{i.} T_{.,\,n+2}}\right) \tag{31}$$

where respiration is assumed to flow into a fictitious compartment $n+2$.

Redundancy

The fourth part of the overhead is that of internal transfers and represents the extent of pathway redundancy. There are disadvantages to the system in maintaining redundant, or parallel pathways. For once, there can be an increase in dissipations, if transfers occur not only along one most efficient route, but along more than one route. Also, the resource transferred along different parallel pathways might not always end up at the right time at the consumer.

An obvious advantage of parallel pathways is the insurance of having more than one route of transfer in case of disturbances of other routes. Redundancy is denoted by:

$$R = -\sum_{i=1}^{n}\sum_{j=1}^{n} T_{i,j}\log\left(\frac{T_{i,j}^2}{T_{i.}T_{.j}}\right) \tag{32}$$

Window of Vitality

The Window of Vitality describes a trade-off between organization and resilience in ecosystems through a new metric created from the measures of AMI and Overhead. As such it describes the trade-off in a system between its redundancy (high number of pathways with more uniform flow) and its degree of constraint (articulated pathways with more asymmetric flow). This new indicator has first been defined as "fitness for change" (Ulanowicz, 2009, Ulanowicz et al., 2009), consequently as sustainability (Goerner et al., 2009), and then called system robustness (e.g., Mukherjee et al., 2015; Kharrazi et al., 2013). It is derived by multiplying the ratio of A/C (or AMI/H) by the Boltzmann measure of disorder ($-k\log(a)$, Ulanowicz, 2009):

$$Robustness = -\alpha\log(\alpha)$$

where $\alpha = \text{AMI}/H$.

Work on empirical ecosystem networks revealed that the robustness of ecosystem peaks at intermediate values of AMI/H, which has been termed the "The Window of Vitality." This window describes an optimum balance between redundancy and efficiency in a network. On either side of the curve, where AMI (efficiency) is high or low relative to H (redundancy), the robustness values are comparatively low. Intermediate constrained networks are therefore thought to be of optimal robustness and sustainability (Ulanowicz, 2009; Ulanowicz et al., 2009; Goerner et al., 2009; Fig. 3).

Summary

A practical objective of ecological network analysis in general is to trace material and energy flow–storage through the complex network of system interactions, and has been a fruitful way of holistically investigating ecosystems. In particular, a series of "network properties" such as indirect effects ratio, homogenization, mutualism and ascendency have been observed using this analysis, which consider the role of each entity embedded in a larger system and so tie processes between nodes with their emerging properties describing ecosystem behavior.

Thermodynamics in Ecology

Jae S Choi, Bedford Institute of Oceanography, Dartmouth, NS, Canada

Glossary

Disorder/order In a thermodynamic context, the logarithm of the number of microstate configurations possible (n) in a *phase space* of some model-based representation of a system (also called "ensembles" in quantum mechanics). The greater this number, the greater the "*disorder*" and the lower this number the lower the "*disorder*." The logarithm of n is proportional to the *entropy* of the system in physical systems and is related to it by Boltzmann's constant, $k = 1.380 \times 10^{-23}\,\mathrm{J\,K^{-1}}$, such that *entropy* $= k\,\log(n)$. It has, therefore, a very specific meaning and definition and should not be conflated with more common usage of the term, such as for example the "order" in phylogenetic trees.

Dissipative structures Energy or mass transforming processes that have some identifiable or repeatable structure, pattern or organization. Common examples are convection cells (e.g., Rayleigh–Bénard convection), chemical oscillations such as the Belousov–Zhabotinsky and the Briggs–Rauscher reactions, predator–prey interactions (e.g., Lotka–Volterra model), eddies and vortices in turbulent energy cascades in the hydrodynamic flow of water, smoke and air, and metabolic cycles in living organisms (Kolmogorov, 1941; Glansdorff *et al.*, 1974). Their importance in the thermodynamic context is due to the causal relationship between dissipation of energy *and* the consequent local decrease in *entropy*. These processes are interpreted as being caused by symmetry-breaking instabilities attributed to linear and near-linear *nonequilibrium thermodynamics*. That is, "the flow of energy through a system organises it."

Emergy Energy embodied by some "product" or "service." The concept is attributed to Odum (1996) and is an attempt at a valuation of energy-systems using a common currency (solar energy equivalents in Joules, or sej) by accounting for the total amount of energy required to make an organism or product, including all intermediate steps, starting from solar energy. It is, therefore, an attempt to define a biologically relevant form of *exergy* (often *Life Cycle Analysis* in engineering applications) in a complex system setting where there is a multiplicity of energy and matter flows and cycles. It resembles in some ways the efforts of ecological economics to put a monetary value to "ecosystem services." Closely associated with the concept of emergy is *transformity*, the relative efficiency of emergy production attributable to a species or process. A key hypothesis associated with emergy is the "*maximum empower principle*" which is a variation of Lotka's (1922) "*maximum power principle*" (Odum and Pinkerton, 1955; Washida, 1995) but stated in terms of *emergy*.

Environ Attributed to Patten (1978), an algebraic representation of nested networks across levels of hierarchic (network) and holarchic (inward-outward) organization. It is used to describe the incoming and outgoing environments of *holons* circumscribed by the boundaries of open systems in which holons are component parts. Environ theory thus defines two system-bounded environments associated with each holon within the system, and is mathematically an ecological extension of economic input–output analysis.

Entropy The energy *irreversibly* lost from a system to some reference state due to inefficiencies in matter and energy transformations.

Exergy Energy available for a given process ("work") after boundary conditions are specified. The concept is generally used in simpler engineering problems, accounting for energy efficiency and quality (coal vs. electricity) where boundary conditions, including the reference state, can be clearly demarcated. The focus is, therefore, upon net boundary (aggregate) inputs–outputs of e(n/x)ergy. In ecological systems, as many different forms of energy exist which are transformed at wide ranges of space, time and organizational scales, the boundary conditions are difficult (impossible?) to specify objectively. The concept of *emergy* (below) tries to address this difficulty.

Laws of thermodynamics A coherent understanding of the empirically observed *thermodynamic* states of matter was developed by Carnot (1824), Thomson (1849), and Clausius (1850). It was a monumental feat in that only a few variables of state were shown to be sufficient to describe the behavior of matter even if they are composed of an enormous number of atoms and molecules. Shortly thereafter, Boltzmann (1884) and Gibbs (1902) developed a coherent and complementary *theoretical (mechanical, statistical)* description of the component parts that was connected to the *thermodynamic* variables of state through the medium of probabilistic inference. Thereafter, a nonstatistical, axiomatic and geometric formulation of these laws were made by Carathéodory (1909) and again as recently as Lieb and Yngvason (1999). Landsberg's (1972) representation of these laws are amongst the most concise and clear:

- 0th law: empirical temperature exists.
- 1st law: internal energy exists. It is also known as the principle of energy conservation: it is not created nor destroyed, only transformed.
- 2nd law: entropy and absolute temperature exists. It revolves about the principle of entropy increase, where every energy transformation results in some form of unrecoverable loss.
- 3rd law: systems cannot attain a temperature of 0 Kelvin.
- 4th law: extensive (global) and intensive (local) variables exists for equilibrium states and at least some subset of near-equilibrium/nonequilibrium states. [This law is attributable to Landsberg (1972). While not controversial, it is not universally acknowledged as a "law." Nonetheless, it is important in the Onsager/Prigogine/

Landsberg/Katchalsky tradition and merits emphasis as it is often not appreciated or understood.]

Nonequilibrium thermodynamics Thermodynamic principles as applied to systems that are not fully equilibrated, that is, a system with gradients of energy and matter flow. Usually these are observed in systems *open* to matter and energy exchange, however, *closed* systems can also exhibit internal gradients (e.g., due to transient phenomena).

Phase space A high-dimensional space in which each axis corresponds to one of the coordinates required to fully specify the state of a dynamical system. The canonical example is of m ideal particles. As mass and momentum in each of three dimensions are known to completely specify the knowledge of the system, the phase space representation would have a dimensionality of $6m$ and a point in this space corresponds to a full description of the state of the system at a given moment. The logarithm of the number of such points possible is proportional to the hypervolume and the statistical *disorder* and physical *entropy* of the system. In ecology, if one simplistically assumes the number of individuals in each species represents the fundamental variables describing an ecosystem and so fully specifying it, then the system at a given moment would be "completely" described by a point in this m-dimensional hypervolume. The logarithm of the number of possible such points for a given ecosystem would be proportional to the statistical *disorder* of the ecosystem. This "model" is simple in that the "species" category aggregates information about individuals and therefore ignores qualities such as age, sex, genetics, behavior, social structure, spatial interactions, ontogeny, phylogeny, etc.

Introduction

Thermodynamic principles are fundamental pillars of modern science. They permeate through all physical, chemical, and biological processes. Ecosystems, spanning these physical, chemical and biological processes, are thus equally subject to these universal energy and entropy principles. Though traces of this awareness are present as early as in the writings of Heraclitus ($\sim$500 BCE) where he describes life as being change and flux, a formal awareness of the connection between modern notions of life and thermodynamics might be best attributed to Spencer (1864) who suggested that "evolution is an integration of matter and concomitant dissipation of motion; during which the matter passes from an indefinite, incoherent homogeneity to a definite, coherent heterogeneity; and during which the retained motion undergoes a parallel transformation." Thus, shortly after Carnot (1824), Thomson (1849) and Clausius (1850) had developed the groundbreaking laws of thermodynamics and just before Boltzmann (1884), Planck (1901) and Gibbs (1902) had developed the *theoretical* models to provide a statistical and mechanistic basis to these laws, there was an appreciation for the connection between energy and matter transformation and life in ecological or at least natural history circles.

An overview of some of the main thermodynamic concepts in ecology can be found in Fath *et al.* (2001, 2004), Yen *et al.* (2014) and Chapman *et al.* (2016), while Schneider and Sagan (2005) and Jørgensen (2012) provide accessible historical overviews. What is immediately evident from the literature is that many of the landmark ecological studies such as those by Lotka (1922), Elton (1927), Hutchinson (1959), Lindeman (1942), von Bertalanffy (1950), Whittaker (1953), Odum and Pinkerton (1955), Margalef (1963), MacArthur and Pianka (1966), Odum (1969), Patten (1978), Ulanowicz and Hannon (1987), Kay (1991), Schneider and Kay (1994), Dewar and Porté (2008), Kleidon (2010) and many others have been trying to make refinements to this connection between ecology and thermodynamics. In fact, in some ways, they are almost unavoidable as even the most basic attempts at an empirical accounting or modeling of matter and energy flows or metabolic considerations necessarily begins by invoking conservation of energy and matter, and the implicit estimation of irreversible losses of energy from the study system.

While the empirical/phenomenological/macroscopic notion of energy is measurable and familiar, the notion of *entropy*, the irreversible loss of energy, is less so. This is because *entropy* requires an indirect accounting to measure what was lost and an explicit identification of where the loss went (i.e., the reference or ground state). Unfortunately, it is challenging to unambiguously specify where a system started and ended, and what the key energy and matter transformation processes may be. This is because in most ecological systems there is matter and energy cycling and leaving and entering a system at all sorts of space and time scales and with implied spacetime lag related nonlinearities. This difficulty has lead some such as Meixner (1973) to suggest entropy as being an ill-defined quantity in any system open to material and energy fluxes, that is, any system that is not fully at equilibrium. See Landsberg (1972) for a contrary perspective in fluid dynamics.

Order Principles

Order to Disorder: Entropy

A model-based, statistical–mechanical representation complementary to *entropy* was developed by Boltzmann (1884). The logarithm of the number of possible configurations or "microstates" in the high-dimensional *phase space* representation of a system was demonstrated to be proportional to the *entropy* of the system; the proportionality factor is Boltzmann's constant (Planck, 1901).

Boltzmann (1884) and Gibbs (1902) suggested that this increase in the number of microstates in phase space can be interpreted as the amount of randomness or variability in potential microstates, or more simply, "*disorder*."

For example, imagine an isolated container filled with n molecules of some gas, identical in all respects including, velocity and momentum. As it would take much energy and effort to force the molecules to stay in such an untenable state, the *entropy* associated with this configuration can be considered low. As it has only one microstate in the $6n$-dimensional phase space (two variables of state $\times$ 3 dimensions $\times$ n molecules), the *microstate randomness or disorder* of the system can also be considered low. Releasing the constraints that forced it to stay in this state, the *entropy* will increase to some larger value, as the potential energy is converted into kinetic energy and *entropy*. Simultaneously, the movements and collisions of the gas molecules will result in a spread of the velocity and momentum distributions with each collision until eventually this distribution no longer changes. The number of possible *microstate* representations in phase space would have increased to a maximal level of randomness or *disorder* corresponding to the increase in *macrostate entropy*.

Similarly, an internal combustion engine takes the chemical potential energy of dense long-chained hydrocarbons and in the process of using it, converts it into dispersed gases, heat and intermediately fractured molecules (*entropy* increase). Given the physical–chemical model of long-chained hydrocarbons and associated bond energies, the fuel goes from a structured to a disaggregated state; that is, the number of possible microstates in *phase space* has increased and so is more variable or *disordered*. Lasers are another example which follows along similar lines: filtering and reflection of light to create coherent wavelengths and amplitudes (*ordered*) which upon application to burn through an object causes heat (*entropy* increase) and decoherence of wavelengths and amplitudes (*disorder*). As a consequence of this relationship between *entropy* and *disorder*, the 2nd law entropy principle is also known as an "*order*→*disorder*" principle.

Note that herein, we reserve the word *entropy* to represent the thermodynamic (phenomenological) quantity and distinguish it from the words *disorder* and *order* for the information-theoretic (statistical) analog of entropy based upon the microstates of some theoretical statistical mechanical model representation of the system. In the literature, the word *entropy* has been used to mean both, often causing misinterpretations. Further, we reiterate that in this context, the words *disorder* and *order* have the above unique meanings (in phase space) and must not be conflated with the more common, lay usage of the terms.

Order to Order: Biology and Ecology

Schrödinger (1944) continued in this vein and used this more familiar concept of *order* to focus attention upon biological systems. He noted, in particular, that living systems were operating primarily with a principle that seemed quite distinct from the "*order*→*disorder*" principle associated with the 2nd law. For example, he described DNA as an "aperiodic crystal" of extremely high information content (all the information required to create and maintain life) which manages to replicate itself with extreme stability; DNA mutation rates are much lower than might be expected simply due to thermal effects in chemical reaction systems. We can simplistically represent the DNA of an individual in a phase space with dimensionality equal to the number of base pairs. (This implies a model that assumes each base pair acts independently, which is of course incorrect.) With each replication from parent to child the amount of order remains roughly constant and the range of variability at each base pair constrained to be within a range not too dissimilar from the previous generation. Thus the range of possible microstates are narrow, stable and robust.

Heuristically, biological and ecological systems seem to be operating upon an "*order*→*order*" principle, at least in the short-term. This stability is due to chemical activation energies and chemical bond stability; self-correcting enzyme systems and proteins; and of course Darwinian selection. Indeed, stable life cycles, developmental processes, canalization, phenotypic plasticity, ordered metabolic pathways such as the Krebs cycle, predator–prey interactions, host–parasite interactions, habitat-niche considerations, animal migration patterns, species distributions in space, all represent examples of intricately patterned stable or constrained processes of "*order*→*order*." They are the mainstay of biology and ecology: feedback cycles and their interrelationships (Yodzis, 1981).

The term, *dissipative structures* (Kolmogorov, 1941; Glansdorff *et al.*, 1974), is often used in thermodynamic studies to describe these stable, "*order*→*order*" systems that maintain their internal structure/order, at the cost of elevated energy degradation to their environment: literally pumping ordered energy in and entropy out. Other examples of this have been analyzed including: Rayleigh–Bénard convection cells, the Zhabotinsky reactions and Turing waves. Living systems, in the act of growth and maintenance, tap into these external matter and energy flows to maintain local order.

Disorder to Order: Ordered Complexity

When considering the steps that might be required to lead to the origin of life, from simple chemical compounds to more complex matter/energy cycles or "hypercycles" and eventually the evolution of replication mechanisms such as RNA, DNA, proteins and membrane based compartmentalization in the backdrop of strong energy gradients, they clearly suggest the operation of yet another principle, "*disorder*→*order*" (Lotka, 1922; Schrödinger, 1944; von Bertalanffy, 1950; Eigen and Schuster, 1979; Wicken, 1980; Wiley and Brooks, 1982; Schneider and Kay, 1994; Schneider and Sagan, 2005; England, 2013). They suggest that living systems seem to increase in complexity over evolutionary time: the sheer number, types and hierarchical organization of structures and metabolic pathways is high relative to our primordial ancestors that were presumably much

simpler and had shorter snippets of (D/R)NA, and in terms of the metabolic and organizational structures that they encoded. With this increase in complexity, there is seemingly a corresponding increase in *order* in the biota, due to the additional effort required to maintain this complex and often intricate biological structure. In other words, the action of Darwinian selection in the short-term seems to be to stabilize ("*order*→*order*") and in the long-term to increase order ("*disorder*→*order*"); where the latter occurs presumably through the accumulation of strategies for survival in the face of a relentlessly variable abiotic and biotic environment (van Valen, 1976; Bell, 1982).

This incongruence (some have used the word "antithetic") with the 2nd law has even been suggested by many of the above authors as being a means of defining or distinguishing between life and nonlife. Indeed, Lovelock (1972) used this logic to advantage and suggested the "Gaia hypothesis," that the presence of atmospheric homeostasis (i.e., a nonequilibrium stable state) can be used as an indicator of the presence of life on other planets and is now used as an organizing principle of planetary system models (Kleidon, 2010). Similar kinds of thermodynamic inference have been made for ecological succession, the stage-like patterns of colonization and abundance in various landscapes and increase in order over ecological time scales (Odum and Pinkerton, 1955; Odum, 1969; Margalef, 1963; Gladyshev, 1978; Johnson, 1981; Kay, 1991) and embryonic and developmental patterns (Zotin and Zotina, 1967; Lurié and Wagensberg, 1979; Briedis and Seagrave, 1984; Aoki, 1989; Holdaway *et al.*, 2010).

Synthesis of Order Hierarchies

The presence of the above three different *order* principles has precipitated a wide, sometimes confusing discussion of their relevance in living systems. What has been learned through these discussions is that it is absolutely necessary to specify the frames of reference by which we mean: (1) the focal energy and matter transformation processes; (2) the constraints such as boundary conditions, ground state; (3) the spacetime scale; and (4) whether it is a *thermodynamic* (*entropy*) or *information-theoretic* analysis (microstates of a model representation or *disorder*). To illustrate the above, we use the simple metaphor of water flowing downhill (**Fig. 1**).

In the frame of reference of the universe, *entropy* is always increasing and this is always true relative to the presumably low entropy state of the initial Big Bang. The downward flow of water can be seen as an analog of the universal constraint of the 2nd law, that is, the principle of "*order*→*disorder*." The "ordered" potential energy of water at elevation, "ordered" by solar and wind energy, is converted into kinetic energy, which is dissipated as heat, noise, erosion, and an admixture of molecular configurations until it eventually reaches the lowest elevation possible, where it is in the highest possible *entropy* state (the equilibrium "reference" state in this artificial example; **Fig. 1**A).

Under certain circumstances, however, the flow of water might seem to persist for a short period, such as for example, in eddies near rapids and falls. In the frame of these smaller windows (scales) of time and space, these cycling structures can seem stable and self-perpetuating: that is, "*order*→*order*" (**Fig. 1**B). Though of course, it is only a small volume that becomes part of the eddy and the bulk of the water continues to flow downhill. And so the question is: what are these special "certain circumstances"? As biologists and ecologists we endeavor to detail all these special "certain circumstances" and preconditions to stable material and energy flows, be they at subcellular, cellular, organismal, population, community, ecosystem or earth-system levels of organization.

In ecology, there is an *implicit* understanding that these matter and energy flows are only borrowed by biota, taking in a small fraction of energy and matter and so slowing down its eventual passage by redirecting them into organisms and ecosystems by

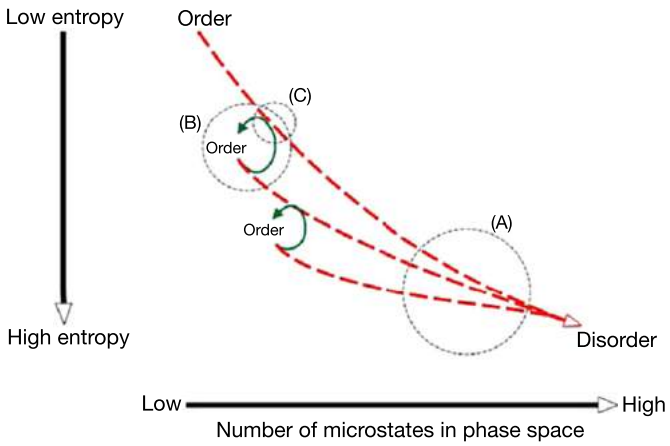

Fig. 1 Heuristic representation of the principles of (A) "*order*→*disorder*": the Second law principles such as in simple heat engines (*red-dashed lines*); (B) "*order*→*order*": homeostatic behavior in biochemical systems, stable ecological systems, genetic stability (*green self-loop*, or "dissipative structure"); and (C) "*disorder*→*order*": embryogenesis, succession, biodiversity increase over evolutionary time scales (transition from *red-dashed lines* to *green loops*). The *circles* show the focal processes for each order principle. Note the dissipation-cascade from top to bottom as each dissipative structure creates other dissipative structures, analogous to an energy-cascade of turbulent dynamics, or food-web dynamics.

growth and reproduction (biomass, chemical bonds), before their final release back into the entropic flow, "down the river" in the form heat, noise, breaking of molecular bonds, etc. Seldom are the latter entropic flows and constraints the explicit focus in biological and ecological studies. There is a matter-of-fact, a priori awareness that they are systems open to energy and matter flows. Instead, ecologists tend to focus preferentially upon the more "interesting" features of stable interactions and negative feedback dynamics.

Nonetheless, these more "interesting" eddy-like matter/energy interactions facilitate the overall boundary losses of energy and create *entropy* by "exporting" it, for example, as waste heat, via respiration, transpiration, mixing of degraded molecules, etc. As such, they act as (free) energy dissipating structures (or the eddies in the river metaphor) that borrow free energy and so helps to dissipate the energy more rapidly than if there had not been a dissipative structure. Lindeman (1942) was amongst the first to explicitly estimate such losses; his and subsequent estimates by Odum (1956), Odum (1969), Mann (1972) and others suggest ecological (trophic) efficiency to be generally quite low, ranging from 1% to 25% and about 10% on average. That is, entropic losses actually dominate most energy transformations in an ecological setting. Indeed from satellite-based radiation estimates, for many plants, >99% of incoming solar energy can be lost due to evapotranspiration and respiration (Schneider and Kay, 1994; Schneider and Sagan, 2005) though of course these processes are functional in that they are used to draw water and minerals from the soil. Only a very small fraction of inputs are aggregated and sequestered as biomass and with it, an associated local decrease in *entropy*. Yet even with such low efficiencies, biota continue to manifest and exert their global influence over geological time scales (Lovelock and Margulis, 1974).

Finally, if the frame shifts to ever smaller spacetime scales, we can focus upon the transition from downward flow to a nondownward flow of water, that is, to the initiation of an eddy (**Fig. 1**C). In this extreme close-up frame, a small fraction of the flow of water might actually seem to be reversing direction and moving uphill ("*disorder*→*order*"), though of course the bulk of the water does continue to flow downhill ("*order*→*disorder*"). The empirical observations in hydrodynamics suggest that stable laminar flow changes into nonlaminar flow once frictional (dissipative) forces increase in importance due to higher kinetic energy. These fluctuations selectively increase and if the higher kinetic energy conditions are sustained, alternate stability regimes can manifest via bifurcation and so in switching to an alternate stability regime, they seem to "self-organize." Empirically, such observations of switching behavior are also documented in ecology and evolution, often associated with feedback mechanisms altering due to major changes in external conditions and/or new biochemical, or species-interactions due to speciation or range expansions/contractions or trophic cascades causing new stable associations.

In the most general context of thermodynamics, Onsager (1931a, b) was one of the first to ask the question: How does this "reversal" begin? His answer was what are known as the Onsager reciprocal relations. The ramifications of his work are still being worked out in various quarters of science (Prigogine, 1955; Glansdorff *et al.*, 1974), including ecology. We will turn to this important development in section Extensive thermodynamics, as it serves as the bridge between the established principles of "*order*→*disorder*" and "*order*→*order*."

Thermodynamics and Ecology

To review, there are two complementary approaches to thermodynamics: (1) an empirical (phenomenological) analysis of *thermodynamic entropy* which is a physical description of a system's macrostate; and (2) an analysis of *information-theoretical order* that is contingent upon the *mechanical* model description of a system's possible microstates in phase space. The field of ecology, like most other scientific domains, looks toward thermodynamics as an ideal of how good science "should" be conducted and has tried to formulate both *empirical* principles with *theoretical* mechanistic/statistical processes. The yearning, of course, is to discover equally all encompassing *empirical* laws or at least some predictive rules of thumb which may serve as a scaffolding for further development of the *theoretical* underpinnings of component processes (Peters, 1991).

Information-Theory

The *information-theoretic* mode of analysis is extremely powerful as *order* is a concept that is readily understood in a mechanical context. However, this strength is dependent upon the completeness of the underlying model representation of the system. There is, therefore, a model-dependent subjectivity to the concept of *order* that is inherently sensitive to the structure and parameterizations of the model. In representing the well-understood molecular motion of physical systems, the underlying model representation has been demonstrated to be very close to reality. When minor divergences were found, further research demonstrated it was due to new physical processes that were previously not considered (e.g., quantum effects; Schrödinger, 1944, Jaynes, 1957).

Unfortunately, there is as yet, no mechanistic model that can be said to represent an ecosystem in any but the most simplistic of terms. The usual choices are some variations of a Lotka–Volterra formulation (e.g., Michaelian, 2005; Chakrabarti and Ghosh, 2009) or the even more aggregate models of first order input–output analysis (Patten, 1978). The utility of defining the microstate variables in the phase space of an incomplete model is not clear. As there exists subjectivity in what the categories are in a model and parameterization of these dynamics, the information content (i.e., *order*) also becomes a subjective concept.

Undeterred, information-theoretic measures of the topology of feeding networks were proposed by Ulanowicz and Hannon (1987) and Ulanowicz *et al.* (2006) as a first approximation to these microstate variables. Jørgensen *et al.* (1995) tried to define this *order* on the basis of the number of genes in various organisms with the assumption that this number would represent the

information content and, therefore, the *order* associated with an organism; but there was no mechanistic model representation of an organism's dynamics associated with gene number and confusingly called this information-theoretic measure, "exergy." Wicken (1980) and Wiley and Brooks (1982) focused upon similar approaches to describe information-theoretic components of phylogenetic complexity; again, a mechanistic model relating phylogenetic dynamics to a phase space representation was lacking.

Though direct application of the *information-theoretic* approach has been controversial, there have been a number of related developments that have impacted ecology. Jaynes (1957) was a strong proponent of using statistical mechanics and information-theory (Shannon, 1948; Wiener, 1949) to a number of different problems of inference that have been variously known as *maximum entropy production* (MEP), *maximum entropy* (MaxEnt) and *maximum relative entropy* (MaxREnt) depending upon the source literature (e.g., Yen *et al.*, 2014; Dewar, 2010). The approach has been used successfully in biodiversity–productivity modeling (Dewar and Porté, 2008); species distribution modeling (Elith *et al.*, 2011); climate modelling (Paltridge, 2001; Martyushev, 2010); as a methodological approach for choosing minimally biased priors for Bayesian inference; and as a foundation for "stochastic processes" and "random fields" approaches in problems of statistical inference (Besag, 1974; Pickens and Iliopoulos, 2005). Even the widely used AIC and related families of information-theoretic evaluation of models have a basis in information theory and MEP arguments. Dewar (2010) and Meysman and Bruers (2010) discuss the complexity of the connection between *information-theoretic* representation of *disorder* with the *extensive* thermodynamic concept of *entropy* (see below), using the stability properties of first order chemical reaction/chemostat-type models. While Nicolis and Nicolis (2010) warn of the naïve and problematic use of MEP.

Extensive Thermodynamics

The *extensive* thermodynamic approach is perhaps best exemplified by the engineering tradition which traces its origin directly to the founding work of Carnot (1824). (*Extensive* simply means an *aggregate*, such as aggregate entropy or aggregate free energy of a whole system.) The aggregate free energy available to do some form of work is the state variable of interest, so much so that it has even been given a name, "*exergy*." Engineering applications usually focus of upon systems whose bounds can be defined explicitly (e.g., some machine or production process) and revolve around a few well defined forms of energy and matter transformation, and an explicitly defined reference/ground state. These conditions permit repeated measurements of exergy and entropy, and transfer efficiencies can be calculated to permit cost-benefit or efficiency analysis of the whole system.

Following in this tradition, Kay (1991), Aoki (1993), Schneider and Kay (1994), Müller (1998), Schneider and Sagan (2005), Jørgensen (2012) and many others have focused upon an analysis of (*extensive*) *exergy* and in particular the role of *exergy* gradients. The core message in this tradition is that, "nature abhors an e(n/x)ergy gradient and that any and all mechanisms will be enabled to reduce their magnitude" (Schneider and Kay, 1994). In this *extensive* tradition, Aoki (1993, 1995) estimated whole system entropy dynamics from energy balance of lakes; while Schneider and Kay (1994) used satellite-based measurements of evapotranspiration as a proxy of entropy production and related this to vegetation cover. These *extensive* approaches, however, suffer a difficulty similar to those faced in defining *entropy* in a complex, open, nonequilibrium system with many mass–energy transformation processes (see section Introduction). There can be many exergy gradients involved (geothermal, tidal, solar radiation, geochemical, chemical, biological), operating at various spacetime scales, often in coupled and cyclic manners with ill-defined boundaries and reference states. That which is a resource for one organism can be not relevant for another or even a toxin. Complex relationships between entropy production and system stability have been shown that suggests a naive application of the *extensive* thermodynamic approach can be problematic (Meysman and Bruers, 2010).

To overcome or at least to acknowledge these challenges, Odum (1996) suggested the concept of "embodied energy" (*emergy*). Emergy attempts to trace and unroll all energy transformation steps starting from solar radiation to the component of interest and expresses it in terms of solar energy units. It is, therefore, a concept complementary to the exergy approach, with the exception of trying to refine the measurement of free energy in these more realistic and complex situations. Emergy is, however, *not* a thermodynamic variable of state and so one cannot connect it directly to thermodynamic theory although it may be amenable to analysis via the least action principle and the concept of path integrals (Vanriel and Johnson, 1995; Martyushev, 2010). Indeed, when Patten's (1978) algebraic approach of unraveling the energy transformation cycles as a first order linear expansion of input–output relations (*environ analysis*) was undertaken, these concepts were shown to be complementary, at least in the sense of dimensional analysis (Fath *et al.*, 2001, 2004).

Intensive Thermodynamics

In contrast to the above *extensive* (aggregate) thermodynamic properties, Onsager (1931a, b) and Prigogine (1955) focused upon *intensive* thermodynamic properties of systems of small spacetime elements. This is a subtle but significant distinction in that an assumption of linearizability of *local* forces and fluxes is reasonable for *intensive* variables but it is not necessarily a reasonable assumption for *extensive* variables. The reason for this is that an arbitrarily small spacetime element can be specified such that it is in approximate steady state with its immediate neighborhood (e.g., Oster *et al.*, 1971; Landsberg, 1972). Indeed, this is the basis for most spacetime discretization schemes; and even applicable in problems with hydrodynamic turbulence, where eddies form at many scales, with the energy cascading through these eddies to ever smaller scales until molecular dissipation occurs via diffusion (near Kolmogorov length scales; Kolmogorov, 1941). Landsberg (1972) called such quasi-steady state elements, "local semi-stable

equilibria with small fluctuations from reference states" and even elevated this distinction to the level of a 4th law of thermodynamics (see Glossary). Irrespective, this is an important distinction that seems to have been lost in the literature which tends to focus primarily upon the *extensive* (e.g., exergy) and *information-theoretic* (e.g., MEP) traditions.

Onsager focused upon the frame of reference of open, nonequilibrium thermodynamic systems that are said to be in the "linear range." Such systems are generalization of well-known phenomena such as Fick's law of diffusion, Fourier's law of thermal conduction and Ohm's law of electrical current. Beyond these wide-ranging connections, there were two substantive results that need to be emphasized. The first result being the presence of *reciprocal relationships*. That is, the gradient of one energy transformation process can affect the speed of another seemingly unconnected transformation process. A well-known, concrete physical example of this *reciprocity* of forces and fluxes is the *Seebeck effect* where electrons flow in the presence of a temperature gradient which serves as the basis of a thermocouple; and the inverse flow of heat with application of electricity, known as the *Peltier effect* which serves as the basis for a thermistor. For thermal–electromagnetic coupling, they are known as the *Nernst–Ettingshausen effects*. The same reciprocal coupling exists in chemical reactions and cell membrane dynamics (Oster *et al.*, 1971; Glansdorff *et al.*, 1974; Mikulecky, 1985).

In an ecological context, this is relevant in that feeding networks may be expected to demonstrate complex indirect effects between seemingly unconnected energy transformation processes such as respiration, photosynthesis, evapotranspiration, growth, or in relationships between organisms via competition, predation, consumption, mutualism, etc., in the presence of biochemical–physical gradients. And indeed, there are correlations between many of these metabolic processes (Kleiber, 1947; von Bertalanffy, 1950) and consumer dynamics. Another example can be seen in the complex benthic–pelagic coupling of lakes as a function of nutrient, oxygen and pH gradients (Regier and Kay, 1996) or the related concept of the marine biological carbon pump (i.e., production vs. carbon gradients; Eppley and Peterson, 1967) and even the relationship between evapotranspiration and sediment mineral profiles (gradients) in tropical versus temperate environments. A number of other potential couplings were also identified by Odum and Pinkerton (1955).

Onsager also demonstrated a second groundbreaking result: any variations (i.e., fluctuations) in these forces or fluxes will have a tendency to diminish and reach some steady state. This is a similar concept to the expectation of gradient reduction in the *extensive* thermodynamic schools, however, it is often misunderstood or ignored by the *extensive* thermodynamic schools. The significant difference being the explicit expectation of a local "steady state" or "homeostasis" in the *intensive* approach. At an organismal level, this expectation of homeostasis is not considered surprising by the literature as it is a necessary constraint for the continuity of life and so it not contested. However, at the population, ecological, evolutionary or even planetary levels of organization, arguments relating to homeostasis has usually been met with skepticism and ridicule, and pejoratively labeled as "vitalism," "Lamarckism," "Panglossianism" or "teleological" (e.g., Tansley, 1935; Gould and Lewontin, 1979; Dawkins, 1986; Mayr, 1991; Grimm and Wissel, 1997). The importance, in this context, is that this thermodynamic principle provides a general directionality of change that is clear without resorting to teleology, an expectation that is based upon the simple and universally accepted directionality of time.

This expectation for dynamical systems to evolve in a direction of *local intensive entropy* decrease was given a stronger basis by the formal demonstration that the second derivative in time of *local intensive entropy* can be considered a *local* Lyapunov function (Prigogine, 1955). This means that *local intensive entropy* acts as a *local* extremum principle; that is, there is a strong expectation for *local* homeostasis. Prigogine extended this analysis to chemical reactions and used the term, "dissipative structures," to denote the *locally* structured flows of matter and energy (reactions) that results in a low *local* entropy density by "exporting" the entropy to the external environment, and so respecting the overall expectations of the *global extrinsic* (aggregate) *entropy* to increase over time. The interpretation is that these hierarchical *cascades* of dissipative structures (**Fig. 1**C; Choi and Patten, 2001) represent *local* departures from equilibrium, that operate in a manner analogous to the cascade of energy in turbulent phenomena (Kolmogorov, 1941). (The Onsager relations represents an approximation of *Le Chatelier's principle* stated in terms of *entropy*. More correctly, the diagonals of Onsager's phenomenological coefficients represent the first order linear effects aligned with *Le Chatelier's principle and the off-diagonals the linearized indirect/cross effects*; von Bertalanffy, 1950.)

Attempts were made to extend this Lyapunov stability analysis into the nonlinear realm using variational principles by Nicolis and Prigogine (1989). But not surprisingly, there are no guarantees that universal stability criteria exist in nonlinear systems; they tend to have complex stability regimes or *attractors* (Byers and Hansell, 1996). Interestingly, Crooks (1999) and England (2013) suggest some statistical generalizations may still be possible in highly nonequilibrium conditions, as entropy production can be linked to the Markov transition probabilities in a statistical-fluctuation process representation of biochemical reactions (i.e., in an information-theoretic sense). But again, we would need a strong or at least believable probabilistic ecological model before this approach can be attempted.

There are, therefore, many deep connections between Onsager's relations to a variety of well-known physical and chemical processes. The question remains, how do they connect to biological and ecological processes. This has been the focus of von Bertalanffy (1950), Odum and Pinkerton (1955), Oster *et al.* (1971), Prigogine *et al.* (1972), Mikulecky (1985) and Choi *et al.* (1999). An ecologically relevant measure of this is heat production or the related processes that generates this heat: respiration (biochemical assays or allometrically estimated from size structure; Choi *et al.*, 1999). However, as Onsager's development is for *intensive* thermodynamic variables, this respiration needs to be normalized by the relevant biovolume or biomass. As such, it has been argued and demonstrated that *local intensive entropy* production is most readily approximated as the respiration/biomass ratio (also known as "Least specific dissipation"; Choi *et al.*, 1999). The word, "*specific*" dissipation was used to denote the *local intensive* nature of these thermodynamically related variables associated with Onsager's analysis. Indeed, the dimensional relationships

between these processes (biomass-storage and respiration-loss) and their underlying efficiency considerations (i.e., biological allometry; Kleiber, 1947, von Bertalanffy, 1950) provide the critical constraints that connect the *intensive* to the *extensive* thermodynamic variables (Choi *et al.*, 1999; Fath *et al.*, 2004). The study of these *intensive* thermodynamic processes in ecosystems shows much promise due to their strong connections with the ideas of stability and integrity in systems that are the product of numerous processes, spanning wider and wider ranges in spacetime and organizational scales such as environmental degradation, resource availability and rapid environmental change (Choi and Patten, 2001).

Finally, in a characteristically forward thinking manner, Odum and Pinkerton (1955) tried to generalize from the *intensive* to the *extensive* by examining thermodynamic efficiencies. Using linear nonequilibrium thermodynamics as a basis (i.e., Onsager, 1931a, b; Prigogine, 1955), they noted the quadratic form of power output as a function of efficiencies in Onsager's approximations. The presence of these power maxima were suggested to substantiate Lotka's (1922) heuristic arguments for the expectation of maximum power throughput in systems operating under Darwinian selection (and potentially the least action principle). (Odum's (1996) empower hypothesis represents a natural extension of these ideas in his attempt to deconstruct ecosystems in a path-integral type analysis.)

Summary

It is perhaps not surprising that there have been numerous misunderstandings about the relevance and utility of thermodynamics to ecological/biological systems, given the number of thermodynamic traditions and sheer range of phenomena to which thermodynamics is applicable: classical states of matter and molecular considerations; statistical (quantum) mechanics; chemical oscillations; electromagnetic phenomena; hydrodynamic phenomena including climate models; cell membranes; organismal growth and development; population, community, ecosystem and planetary systems analyses; engineering analyses of production systems, engines, agricultural production, etc. However, thermodynamics continues to have a critical role to play in the future evolution of the field of ecology. It provides a strong and systemic foundation. Irrespective of the thermodynamic tradition one follows, they converge upon very similar ideas. One must, however, explicitly define this tradition and the spacetime frame of observation and analysis. In the ecological context, we are now at a stage where Carnot began measuring efficiencies and Boltzmann tried to understand which microstates are relevant. There is much to do and a great richness to be expected as a deeper appreciation of thermodynamic constraints develops and guides us to construct more synthetic ecological concepts and models.

Agriculture Models☆

James C Ascough II†, Lajpat R Ahuja, Gregory S McMaster, Liwang Ma, and Allan A Andales, USDA-ARS, Fort Collins, CO, United States

Introduction

The inherent complexity of agroecosystems (Fig. 1) requires multidisciplinary analyses from a wide range of scientific disciplines to better understand agronomic production issues and solve complex, real-world problems in agriculture. For example, increased use of water, fertilizers, and pesticides necessary for expansion of global agricultural production has resulted in damage to agroecosystems including excessive runoff and leaching of agricultural chemicals, decline in soil organic matter, and increases in soil salinity and wind/water erosion. Other challenges threaten the viability and sustainability of agroecosystems, including issues related to global climate change and market-based global commercialization and competition. The solution or mitigation of these multifaceted and multidimensional problems requires continual improvement and changes in agricultural management, and selection of agronomic production systems using a whole-system approach. Whole-system approaches were developed specifically to support interdisciplinary studies (with the goal of solving significant agronomic, ecological, and environmental problems that require systemwide integration and quantification of knowledge), and their development and use have increased strongly in the past decade.

An important component for analyzing and assessing whole-system interactions in agronomic systems is the knowledge derived from agricultural model simulations. Simulation models of agroecosystems have evolved into highly useful tools for evaluating and quantifying the effects of management practices, crops, soils, water, and climate on sustainability of both agricultural production and the surrounding environment. Furthermore, agricultural models can serve as strategic and tactical guides for planning and assessment, and help transfer new technologies to various location-specific environments (e.g., climate, soils, production systems) within regions or countries. In this article, the current state of agricultural models and their applications for the above purposes are reviewed and current technologies in agricultural model use (related to modular model development, state of the art interfaces, scaling issues, integrated assessment (IA), and field research integration) are presented. In addition, research needs for agricultural system models are discussed, and conclusions offered as to what the future holds for agricultural system modeling.

Types of Agricultural Models

Several approaches are available for modeling dynamic agroecosystems. They vary from those using process-based or mechanistic-type models to those using statistically based or regression-type models. Mechanistic models may be defined by differential equations (ordinary or partial) or by a combination of differential equations and algebraic equations describing process interactions between the components and states of an agroecosystem (based on underpinning physical, chemical, and/or biological relationships). Regression models on the other hand are based on statistical analysis, that is, identifying a regression-type relationship correlating the inputs (i.e., soil, crop, management, environmental) to the outputs (quantifiable states of the system). Both statistical and mechanistic models use linear and nonlinear mathematical equations to describe the quantitative responses of various processes, and both types of models have advantages and disadvantages. The main advantage of the mechanistic-type models is that they relate to the description (physical, chemical, and/or biological) of the agricultural system, typically have wider generality of application, and can provide more insight into the response of different underlying processes to system management. Disadvantages of the mechanistic-type models are that they are often more complex than their counterpart empirical ones, and are more difficult to parametrize and evaluate. Empirical models provide a concise description about the observations on which they are based and do not need to rely on lower-level system attributes; however, they do not imply causality or even knowledge about underlying processes (although they may provide some insight into these). In addition, extrapolation beyond the data range from which the empirical model was derived involves caution. In this article, we focus on the larger and more complex mechanistic models that typically can simulate a wide range of soil–plant–atmosphere processes and thus have applicability to a diverse range of agroecosystems.

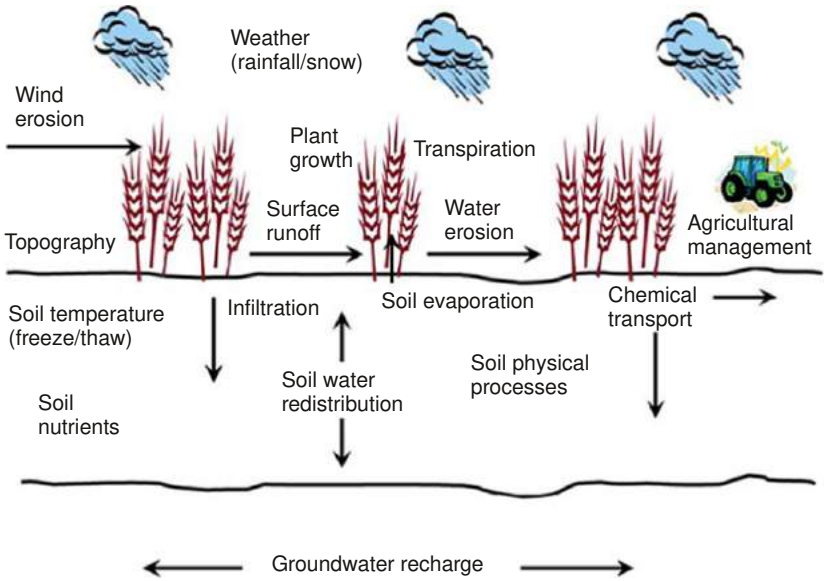

Fig. 1 Major processes in agricultural systems.

History of Agricultural Models

Agricultural modeling started in the early 20th century with the development of regression models exhibiting little attention to causative linkages and mechanistic understanding of the processes involved. This was largely due to limited knowledge concerning soil–plant–atmosphere processes and their response to the complex interactions between various factors in agroecosystems, and also to limited computing technologies available to integrate the processes. Since the early regression model phase, agricultural process modeling and system integration have undergone many years of development and evolution. Before the 1970s, considerable modeling work was undertaken for individual processes of agroecosystems and a foundation for system simulation was built. For example, in soil water movement, models and theories were developed in the areas of infiltration and water redistribution, soil hydraulic properties, tile drainage, and solute transport. In plant–soil interactions, models and theories were developed for evapotranspiration, photosynthesis, root growth, plant growth, and soil nutrients. In Europe, the development of mechanistic process-oriented models in plant biology began with the pioneering work of de Wit on quantitative relationships in the photosynthetic process, through development of a formula calculating photosynthesis of a closed crop surface. Further research modeling light interception and photosynthesis in plant canopies followed. These results, together with knowledge of the effect of soil moisture on uptake and transpiration rates, permitted a comprehensive approach to the study of the soil–plant–water–atmosphere system and its adequacy for plant growth. Lists of authors on early manuscripts suggest a great deal of interaction between crop simulation groups in Europe and the US.

There has been a rich history in the development of agricultural models since that time. The 1980s saw the beginning of the development of whole-system agricultural models. Much of this work began in The Netherlands, at Wageningen. The generic crop model SUCROS for potential production simulation was developed, which formed the basis for recent Wageningen crop models such as WOFOST, MACROS, and ORYZA. For water- and nitrogen-limited production situations, model components were added to SUCROS resulting in models such as ARID CROP, SAHEL, and PAPRAN. Several other important agricultural models developed in the 1980s were CREAMS (soil erosion by water), GOSSYM (cotton crop growth), EPIC (water quality with integrated economics), GLYCIM (soybean crop growth), PRZM (pesticide transport), NTRM (nutrient cycling), and GLEAMS (water quality). System models of even greater mechanistic complexity and level of detail continued to be developed in the 1990s and 2000s including WEPP (soil erosion by water), WEPS (soil erosion by wind), ALMANAC (multispecies crop growth), CropSyst (crop growth), APSIM (agricultural production), OPUS (water quality), SHOOTGRO (wheat growth), DAISY (nutrient cycling), RZWQM (water quality), SWAT (basin-scale water quality), and CSM (crop growth). Some agricultural models have also been linked to a decision support system (DSS) framework—these include GPFARM and DSSAT, which envelopes the CSM (formerly the CERES and CROPGRO model families). Agricultural system research and modeling are now being promoted by several international organizations, such as International Consortium for Agricultural Systems Applications (ICASA) and other professional societies.

In summary, agricultural modeling has evolved into detailed dynamic simulations of most physical, chemical, biological, biochemical, and biophysical processes in agroecosystems and their response to climate and crop management inputs. The advent of high-speed computers and other advances in computing technology are partly responsible for this rapid evolution. The enormous time and effort scientists have invested in simulating agroecosystems are reflected in the seemingly endless number of models cited in literature review articles. Cultivar selection, water and nutrient input optimization, planting date selection, and

water quality management are just a few of the areas of agricultural model application in agroecosystem management across multiple scales.

Agricultural Model Applications

In this section, we provide a brief sampling of applications of agricultural models in research and strategic management. This range of applications is by no means exhaustive as agricultural models are used for innumerable functions and purposes.

Managing Crop Production and Water Quality

A common application of cropping system models is to simulate various management options in different agroecosystems to predict effects on crop production. Crop growth models are also used in yield-gap analyses to quantify potential yield compared with actual yield; that is, the models are used to estimate potential yields at multiple locations to determine how genotype $\times$ environment $\times$ management interactions can be optimized. Simulating differences in yield among varieties is typically by using the appropriate genetic/phenotypic coefficients to characterize each crop variety. The cropping system models (CSM) within the DSSAT framework and the APSIM model have been extensively used for this purpose; for example, the DSSAT framework has been used to derive optimum combinations of management and planting dates for various crops. Another common application of crop models is simulating interactions between crop yield and levels of agricultural inputs such as irrigation water or nitrogen (N) fertilizer. Because agricultural models keep track of the water balance and N amounts in the system as well as the estimated uptake by crops, the models can help estimate the proper amounts and timing of irrigation or N fertilization.

Other major applications in crop production modeling are assessing the sustainability of existing cropping systems and potential for yield improvement through introduction of alternative crops in a rotation, especially in a dryland agriculture context. For example, models have been used in conjunction with experimental field data to show that cropping intensification more effectively utilized available soil moisture and increased overall system productivity compared to the prevalent rotation. In addition, an important requirement for the sustainability of current agricultural systems is the mitigation of adverse environmental effects. Intensive crop production has been recognized as a significant nonpoint source of water contaminants. A major concern is the movement of nitrate (NO_3-N), phosphorus, and agricultural chemicals (e.g., pesticides and herbicides) from agricultural fields into surface and groundwater bodies. Agricultural system models that have the capability to simulate transformations and movement of agricultural chemicals (e.g., GLEAMS, SWAT, and RZWQM) have been extensively used to assess the interactions between water quality and crop production management.

Evaluating Soil–Plant–Atmosphere Parameters and Processes

Agricultural management practices (e.g., tillage and reconsolidation; no-tillage and surface residues; plants and crop rotations; irrigation, manure, and fertilization practices; and grazing management) are major sources of temporal variability of soil properties and processes. Changes in soil properties and processes, in turn, impact soil water, mass transport, plant growth dynamics, and the environment. Weather-related factors such as freezing–thawing and wetting–drying may modify the management effects. Numerous field and agricultural modeling studies have shown evidence of the significant management effects on soil–water–nutrient–plant properties and processes. Important areas where agricultural models have been used to help investigate management effects on soil properties and processes include: (1) predicting effects of tillage and natural reconsolidation; (2) predicting surface roughness and detention storage effects; (3) quantifying the effects of wheel-track compaction; and (4) quantifying long-term no-tillage and crop residue effects, including the impacts of macropores and residue cover on infiltration.

Another extremely important area where agricultural models have been used to study changes in properties at the soil–plant–atmosphere continuum is the influence of roots on soil structure and macroporosity. The magnitude and distribution of root growth in a soil profile vary widely between and within plant species. The depth and temporal pattern of root growth also depends on soil properties such as soil bulk density, temperature, water content regime, salinity, and nutrient deficiencies, which change with depth in heterogeneous layered soils. The distribution of root growth with depth and time determines the distribution of water and nutrient uptake from the soil. This, in turn, influences water, chemical, and heat movement in the soil. Additional areas where agricultural models are being used at the soil–plant–atmosphere continuum include quantification of water and nutrient uptake by roots, and evaluation of transpiration and carbon dioxide fluxes at the canopy–atmosphere interface under water stress.

Assessing Climate Change Effects in Agroecosystems

In evaluating future agroecosystem sustainability, a main concern is the effect of climate change (e.g., increased atmospheric CO_2, elevated air temperature, increased/decreased water availability) on agronomic production. Many of the crop production models discussed previously have been used to investigate potential impacts of climate change on yield. Agricultural modeling is a practical approach to studying this global phenomenon as it is difficult to wholly quantify the interactions between climate change effects and crop production based on limited plot-scale experiments or controlled-environment studies. Another major

international issue with respect to global climate change is to improve our understanding of how agroecosystem soils and management contribute to climate change through emission of greenhouse gases such as CO_2, CH_4, N_2O, NO, and NH_3. Land-use changes are believed to account for about 8% and other agriculture sources about 15% of the anthropogenic greenhouse emissions. Several agricultural models (e.g., Century and DNDC) are being utilized to devise and evaluate management practices that will minimize greenhouse gas emissions and increase C sequestration, such as no-tillage and residue management, adding legumes into rotations, and optimal timing of manure applications. Changes in climate modify the soil environment, especially soil water and temperature and also a number of concurrent processes dependent on these including evapotranspiration, runoff, and erosion. Current global climate change models have predicted an increase in frequency of extreme events such as droughts and heavy rainfalls, but it is not known how these changes will affect agricultural production in different ecosystems around the world. Furthermore, it is unclear how extreme climate events will change worldwide soil resources—for example, changes in soil properties from accelerated soil erosion by wind and water. Agricultural models are increasingly needed to evaluate the magnitude of these influences in different agroecosystems and locations around the world, and to devise strategies for mitigating potential adverse effects. For example, agricultural models are just now being used to develop special management practices during drought conditions. Drought-mitigation strategies may include shift in production among regions and changes in crops, cultivars, and management practices, such as crop rotations and water conservation measures.

Tools for Technology Transfer and Decision Support

Agricultural models have been commonly used to extend the results of experimental research to other soil types, climates, and management conditions outside the experimental design. For example, they have been used for extrapolating limited duration experimental results to variability in climatic conditions across longer periods of time (e.g., 25–50 years), and to extreme climatic conditions (e.g., droughts or flooding) not encountered during the study period. Agricultural models have proven to be useful tools for in-depth analysis of problems in management, environmental quality, global climate change, and other ecological issues, and can thus be a basis for policy or regulatory use. Agricultural models also function as decision aids in choosing best management practices for long-term sustainable production, as well as helping to guide site-specific management on agricultural landscapes and within-season dynamic management in response to spatially variable soil moisture and weather conditions. Many natural resource DSSs have an agricultural model at their core, but are also supported by soil, climate, and management databases, environmental and economic analysis packages, user-friendly interfaces to check default data or enter site-specific data, and graphical visualization of simulation results. An example is the design of the USDA-ARS GPFARM DSS (Fig. 2). GPFARM is a whole-farm DSS for strategic planning and evaluation of cropping systems, range–livestock systems, and integrated crop–livestock farming options for production, economics, and environmental impacts.

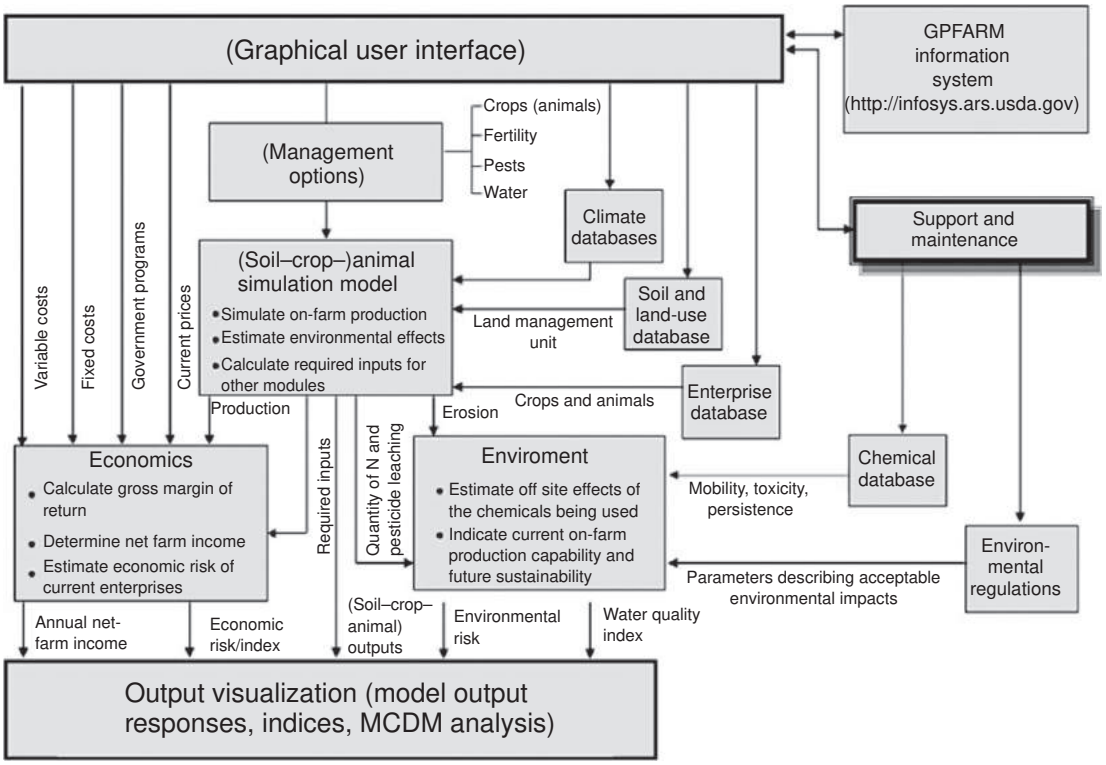

Fig. 2 Schematic of major GPFARM DSS components.

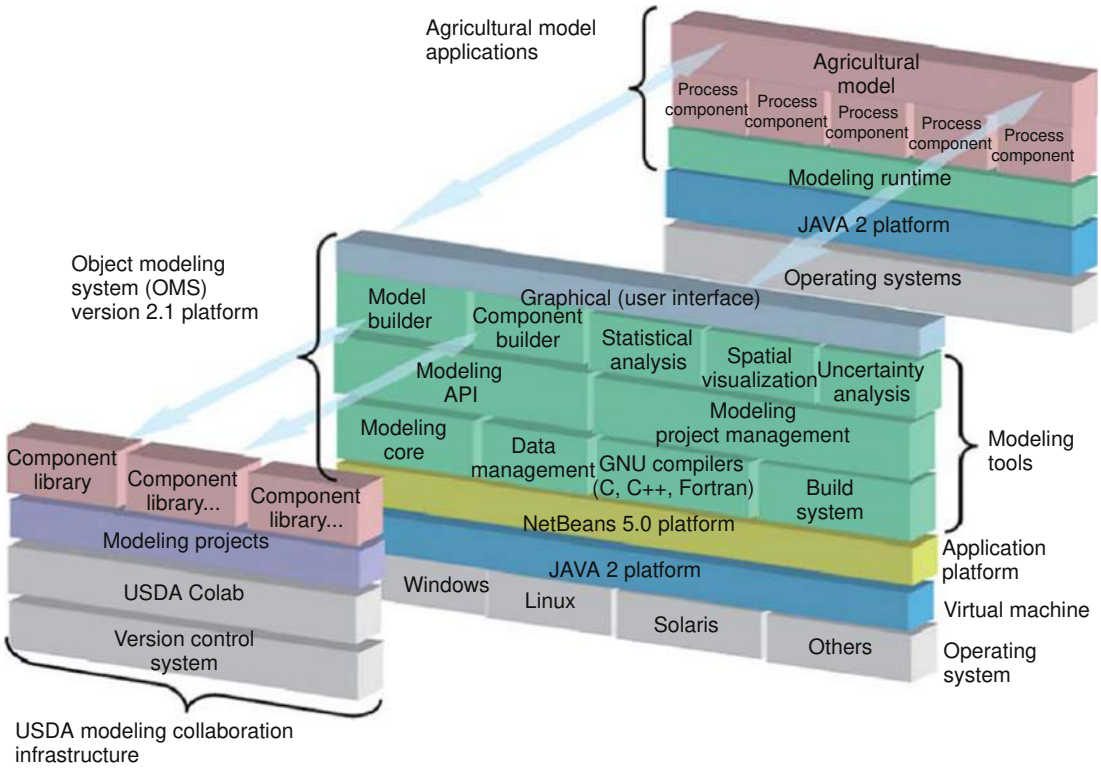

Fig. 3 Object Modeling System (OMS) 2.1 platform with linkages to a collaborative modeling infrastructure and agricultural modeling applications.

Complex and highly detailed process-level agricultural models are generally too difficult for consultants, producers, or policymakers to directly use. An alternative approach is to create an integrated research-information database as a DSS core in place of a simulation model. An agricultural system model, evaluated against available experimental data, is used to generate production and environmental impacts of different management practices for soil types, weather conditions, and cropping systems outside the experimental limits. The model-generated information is then combined with experimental data and long-term management experience of farmers and field professionals to create a database. These databases are often then combined with a socioeconomic analysis package or other tools (e.g., multiobjective decision analysis) in order to conduct a tradeoff analysis between conflicting objectives such as economic return and environmental quality. Overall, this type of approach is very flexible in generating site-specific management recommendations and avoids the problem of having to interpret complicated model output.

Current Technologies for Agricultural Model Development and Use

Modular Components and Frameworks

Agricultural model developers have recognized the value of a modular style of model development from the beginning; for example, the early mechanistic models from the "school of de Wit" were designed with a high degree of modularity in mind. Modular approaches to agricultural system model development are advantageous in that they: (1) facilitate substitution and reusability of different model components, (2) facilitate documentation and sharing of code, (3) allow linkage of components written in different programming languages, (4) allow greater flexibility in model updates and maintenance, (5) enhance collaboration opportunities between different model development groups, and perhaps most importantly, and (6) provide a cost reduction in model development and maintenance. In general, however, modular programming techniques have been slow to filter down to the agricultural modeling community where different approaches to model development in the various disciplines (e.g., crop growth, nutrient cycling, chemical transport, erosion, greenhouse gas emissions) have resulted in the proliferation of code and simulation models as described above. Most agricultural models are still monolithic, difficult to update as new knowledge becomes available, and are not extensible if new problems and modeling needs arise. Notable exceptions are the DSSAT 4.x CSM and the APSIM modeling platform. The basis for the DSSAT CSM design is a modular structure in which components are structured to allow for easy replacement or addition of modules and there are common components for soil water, soil nitrogen, weather, and competition for light and water among the soil, plants, and atmosphere. The APSIM modeling framework has the ability to integrate models derived in disparate research efforts via the implementation of a "plug-in-pull-out" approach; for example, the user can configure a model by choosing a set of submodels from a suite of crop, soil, and utility

modules. Thus, any logical combination of modules can be specified by the user "plugging-in" required modules and "pulling out" any modules no longer required.

Recently, as computer scientists trained in modern software engineering methods have entered the natural resource, environmental science, and ecology disciplines, the APSIM "plug-and-play" approach has been taken one step further with the development of formalized modular modeling frameworks. These frameworks bring together suites or libraries of modules, have architectures designed to fit well with the basic and natural structures of environmental problem situations, and can maintain reusability and compatibility of both science and auxiliary (e.g., parameter estimation, output visualization) components. A range of modeling frameworks with different capabilities currently exist, including the Interactive Component Modeling System (ICMS), Tarsier, the Spatial Modeling Environment (SME), The Invisible Modelling Environment (TIME), the European Open Modeling Interface and Environment (OpenMI) initiative (taking place under the Fifth European Framework Program project HarmonIT), and the Object Modeling System (OMS). The OMS framework development effort is interesting in that:

- a component or module can function as a whole model, a physical process, or a simple equation; that is, there is no assumption about component complexity level, whereas many other frameworks only support the connection of existing models in a loosely coupled fashion;
- spatial and temporal modeling entities are integrated parts of the OMS framework and not specific to an application domain; and
- OMS model development projects are tightly integrated with a web-based collaboration environment (i.e., the USDA Collaborative Software Development Laboratory) which makes it easier for model developers to efficiently collaborate on the design and development of application tools.

Major components within the OMS 2.1 platform are shown in Fig. 3. The goal of the majority of framework development efforts is to allow the agricultural, environmental, and ecological modeling community to focus more on the science module library and the system being modeled, thereby allowing core development, interpretation, and management requirements to be addressed more fully. Modularization is a key concept to simulation model development. The component-oriented and modular approach of the modeling frameworks and the modules/models implemented in them should provide a basis for more efficient and collaborative model development in the future.

Geographic Information System-Based and Visual Modeling Interfaces

With rapid improvements in computer technology and computational power, there are an increasing number of agricultural system models supported by Windows interfaces containing geographic information system (GIS) functionality to perform high-resolution simulation (e.g., multiple spatial land units within a field or watershed) of various biological, physical, and chemical processes in the soil–plant–atmosphere continuum. Most linkages between GIS and various models have been performed for models characteristically applied at larger scales (e.g., SWAT, WEPP-Watershed, and AGNPS), although field-scale models have been linked to GIS as well (e.g., GLEAMS and EPIC). Two important factors are commonly considered when developing high-resolution agricultural modeling tools: (1) agricultural system models require a large number of input data sets representing the initial conditions of the field or watershed; and (2) agricultural system models typically incorporate a large number of model parameters to quantify the underlying physical and biogeochemical processes. Thus, these tools should be capable of managing large and complex data sets while maintaining an acceptable level of user-friendliness. GIS technology has been used extensively for agricultural modeling including data preparation, model parameter extraction, and model results visualization. Research efforts have generally used one of the following approaches for linking GIS and simulation models: (1) embedding GIS functionalities into the model; (2) embedding

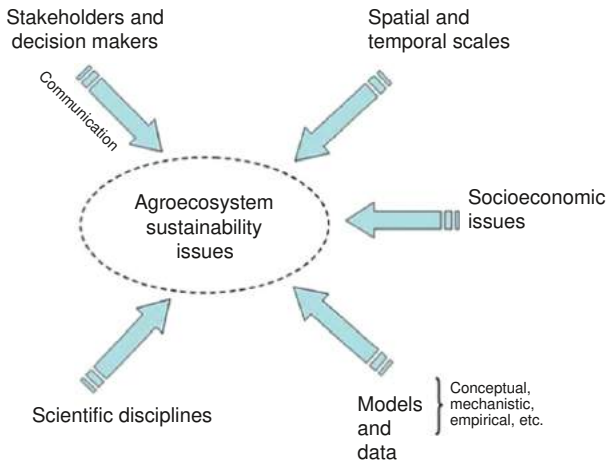

Fig. 4 Types of integration to address agroecosystem sustainability issues.

a model into a GIS; (3) loose coupling—that is, GIS is used to generate model input files and display model results; and (4) full coupling of GIS and a model. The most common approach for developing GIS-based agricultural modeling interfaces is loose coupling—examples of this include GIS linkages of the AGNPS, SWAT, and AGWA models. In general, the database (including multiple GIS layers) is used as a data-collection source, and GIS tools are used for extraction (in many cases automated) of necessary data from the GIS data layers including land-use areas, reach networks, soil information, and elevation. The extracted data are then passed to the model interface, read and processed, and model input files created for simulation. Many of the GIS-based interfaces for agricultural system models are based on the ESRI ArcView 3.x (Avenue) programming language. Ongoing research efforts for many agricultural system models are tied to new interface development under the ArcGIS 9.x (Visual Basic, VB · NET, Python, JavaScript) framework, and to system (software) updating to enhance Internet accessibility.

Traditionally, agricultural system models have been developed and implemented in a code-based modeling approach, that is, constructing a model as a sequence of lines of code in a common programming language such as Fortran, Visual Basic, C, C++, or Java. However, it is becoming increasingly more common to construct and link model components in a visual or 'icon-based' modeling environment. Proprietary visual modeling environments (e.g., Stella (isee systems, Inc.), Vensim (Ventana Systems, Inc.), POWERSIM (Powersim Software AS), and Model Builder (ESRI, Inc.)) are systems where models are constructed by assembling and linking icon-based model components using a sophisticated button- and menu-driven Graphical User Interface. There are three advantages in using these systems for agricultural model development: (1) they typically contain a large number of built-in functions (e.g., mathematical, logical, and statistical including risk and Monte Carlo analysis) that greatly simplify model development and evaluation; (2) they are easy to learn, intuitive to use, and familiar to users of Windows-based software; and (3) they can readily import and export data, generate graphs and tables, and work well together with other commercial applications through dynamic linking with spreadsheets and other software programs. In some respects, the icon-based modeling systems have many of the same capabilities of the more comprehensive modular frameworks described above; however, they are somewhat constrained in their flexibility and effectiveness in producing complex and multifaceted models. These limitations have been somewhat alleviated through a hybrid linkage of code- and icon-based modeling approaches. This concept has been successfully demonstrated by using Vensim to develop a new seed bank module and linking the module (through dynamic linked library support) to the APSIM farming systems model.

Scaling Issues

Scaling is an important issue for agricultural system models because results from fields or portions of a field often need to be extrapolated to another scale. A significant amount of new research in the refinement of agricultural system models is currently centered on determining scale-appropriate parameters for different model components. Generally, scaling-up involves both averaging spatial variability in parameters within a simulation unit, where the averaging process can be highly nonlinear, and incorporating process interactions beneath the simulation scale such that effects manifested at the scales of interest are captured by the upscaled parameters. For field and larger scales, uncertainty is most often due to unaccounted spatial variability of model parameters and processes within a simulation unit (typically assumed homogeneous) and errors in estimating so-called "effective parameters." For highly nonlinear soil-hydrologic processes, strictly speaking, there are no unique effective parameters; however, for practical purposes effective parameters may be calibrated to obtain a selected output variable.

For modeling and managing complex landscape and climate variability across multiple scales, ongoing research is helping to quantify the variability of soil parameters over space and time within a simulation unit using available spatial information about the causative factors, including physical soil properties and surrogate data such as terrain attributes. Management effects on soil hydraulic properties are being considered as well. For a given parent material, climate, biological factors, and time, topography is an important factor that has been shown to cause spatial variability of soil properties. Topographic data can now be rapidly and accurately measured at fine spatial intervals. An important question currently being researched is: can a set of topographic attributes in a given management system be related to spatial variability of soil properties, soil water content, and crop yield, and also used for upscaling?

New physically based methods of scaling up results from plots to field, farm, and watershed scales are also being developed. Historically, scaling of agricultural and landscape variables has been explored using a combination of empirical (data-based statistical) and theoretical (conceptual and numerical) methods. Both approaches have been used to explore scaling of soil properties and processes, field-scale relationships between grain yield, soil moisture, and topographic attributes, and theoretical scaling of infiltration using generated soils and rainfall patterns. Empirical methods provide evidence of real-world scaling behaviors that are useful for parameter estimation at different scales, while theoretical methods provide insights into process interactions in space and time that are currently infeasible to measure. Using measured spatial soil patterns in detailed spatial models allows one to simulate explicit interactions over space and time. Understanding and quantification of this information is being used to scale up responses over variable agricultural landscapes. In this way, the scale-dependence of agricultural management and conservation practices can be incorporated into larger scale (i.e., watershed and basin) models.

Integrated Assessment Approaches

As shown above, the historical motivation for understanding and modeling the dynamics and behavior of agricultural systems was primarily to assess and predict future food production and supply. More recently, however, it has become evident that in addition to functioning as entities for production, agricultural systems may also either damage or provide ecological goods and social

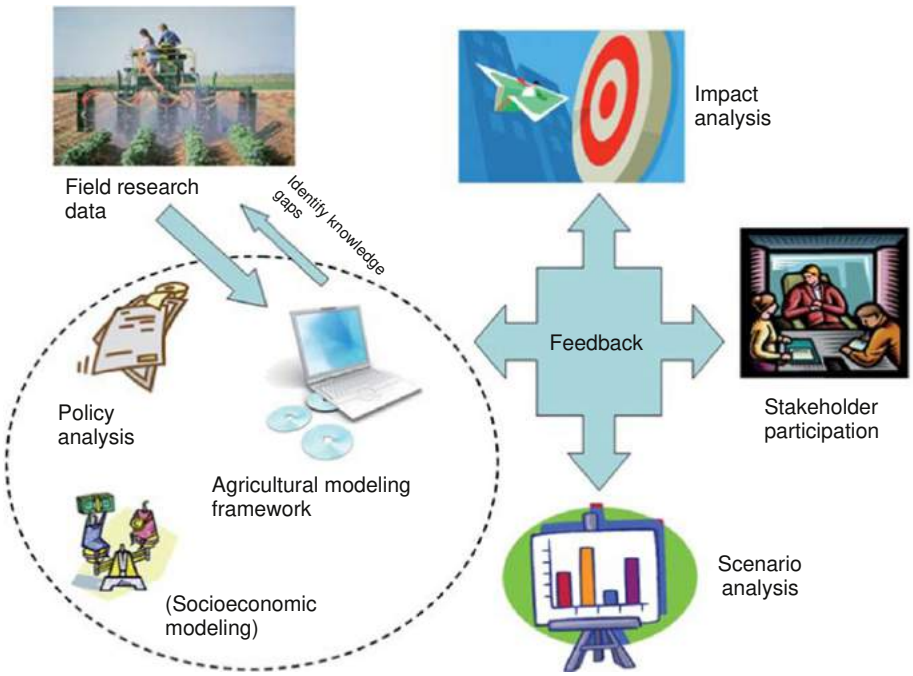

Fig. 5 Interactions among field research, modeling frameworks, and other components for integrated agroecosystem assessment.

welfare. Meeting sustainability challenges for agricultural system management requires approaches that assess socioeconomic concerns and environmental impacts integratively. IA is being increasingly used to integrate the numerous dimensions surrounding agroecosystem management including the consideration of multiple issues and stakeholders, the key disciplines within and between the human and natural sciences, multiple and cascading scales (both spatially and temporally) of agricultural system behavior, models of the different agricultural system components, and multiple databases (Fig. 4). Although there appears to be no universally agreed upon definition in the literature of what constitutes IA, there seems to be widespread agreement that IA:

- is a feedback-driven, interdisciplinary, and participatory (i.e., stakeholder involvement) process;
- is an iterative process of investigation and recommendation that stresses the importance of communication from scientist to decision-makers;
- explicitly accommodates linkages between the natural and human environment, and between research and policy; and
- uses the latest scientific tools including computer models, systems simulation, remotely sensed data, and other forms of information technology to assemble, integrate, and synthesize data from a wide range of sources and across a wide range of spatial and temporal scales.

Agricultural systems around the globe are continuously changing as a result of population demographics, climate fluctuations, and introduction of new agrotechnologies. There is consensus that modeling tools are needed to support sustainability within various agricultural sectors, and even more importantly to enhance the contribution of agricultural systems to sustainable development of societies at large. The integrated assessment modeling (IAM) process attempts to integrate various types of models (e.g., qualitative, quantitative, data, decision support) into an IA framework. More importantly, in current IAM approaches the earlier forms of systems modeling are being replaced with new integrated models that incorporate a three-pronged approach that considers ecological, social, and economic values when addressing sustainable usage of agricultural resources. Examples of this are recent IA analyses of climate change impacts on whole-farm systems. In these analyses, whole-system agricultural modeling frameworks were combined with a stakeholder-driven participatory process in order to assess potential effects of future climate change on agroecosystem land-use and management patterns. The System for Environmental and Agricultural Modelling; Linking European Science and Society Integrated Framework (SEAMLESS-IF) is an example of an IA tool that uses sustainability indicators (economic, environmental, and social) and agricultural systems evaluation (quantitative models, tools, and databases) to assess and compare alternative agricultural and environmental policy options. A review of the literature shows an increasing number of IAM exercises for solving agricultural problems; however, data availability, uncertainty characterization, and software platform development are key issues requiring additional research in the future.

Field Research and Modeling Integration

An important step toward improving model efficacy and usability is to further integrate system modeling with field research. An agricultural system involves complex interactions among several different components and factors (Fig. 1). These interactions need

interdisciplinary field research and quantification with the help of conceptual and process models. Integration of system models with field research has the potential to significantly enhance efficiency of agricultural research and raise agricultural science and technology to the next higher level. The integration will benefit both field research and models in the following ways:

- promote efficient and effective transfer of field research results to different soil conditions, climatic conditions, and alternative cropping and management systems outside the experimental design;
- encourage a whole-systems approach to field research that examines all major component interactions and facilitates better understanding of cause-and-effect relationships and quantification of experimental results; and
- assist field researchers to focus on identified fundamental knowledge gaps to make field research more efficient, and provide needed field evaluation and improvement of agricultural models before delivery to potential users.

A desirable vision for agricultural research and technology transfer is to have close integration between new field research, agroecosystem simulation models, and other components for integrated agroecosystem assessment (Fig. 5). After an agricultural system model has undergone thorough evaluation and both modelers and field scientists are satisfied with the results, it should be advanced to the application stage (with the goal of further model improvement through exposure to differing field conditions).

Future Research Needs for Agricultural System Models

As the development of agricultural models has progressed, controversy has not been lacking. Traditionalists felt that any attempt to simulate highly complex biological systems using mathematical algorithms in computers was bound to fail. Others argued that agricultural models should have a largely heuristic role in research rather than use as predictive tools. Further controversy regarding agricultural models stems from problems of complexity, testability, and parametrization. A commonly accepted truism is that agricultural models should be no more complex than the level of theory and measurements used to build them, and that components of models should also be balanced in terms of levels of complexity. Although this concept is extremely hard to quantify, it is important to note that this definition of model complexity is related to the kinds of questions the model is designed to answer rather than how much empiricism the model contains or the overall number of parameters.

What is incontrovertible is that the use of agricultural models to solve significant issues related to the economic and environmental sustainability of agroecosystems is on the rise rather than on the decline. Furthermore, the collective experiences of agricultural model developers and users show that, even though they are far from perfect, agricultural system models can be very useful in guiding field research, aiding technology transfer, and generating credible assessments of various impacts (e.g., sustainability, management, environmental impacts, climate change) on farming systems. However, a number of needs remain to be addressed that could improve agricultural system models and their application. Important issues include:

1. better quantification of how abiotic factors (e.g., water, temperature, light, nutrients) affect plant growth for both species and subspecies, and most importantly, genotype $\times$ environment interactions;
2. relationships among plant growth and other biotic factors (e.g., weeds, insects, diseases), including quantification of the competitive component to allow for better estimation of the effect of dynamic variations in plant population on growth and partitioning and the competitive aspects of crop–weed and crop–pest interactions;
3. development of comprehensive and common shared experimental databases based on existing standard experimental protocols, with measured values related to modeling variables so that conceptual model parameters can be experimentally verified;
4. improved collaboration between agricultural model developers and field scientists for appropriate experimental data collection, and for evaluation and application of models;
5. better methods of determining model parameters for different spatial and temporal scales, and for scaling and aggregating simulation results from plots to fields and larger scales;
6. continued development and improvement of environmental modeling frameworks to encourage replacement of monolithic agricultural models with modular component-based modeling tools where (a) each model component can be independently tested, improved, and easily substituted; (b) model components can vary with the scale of application; (c) hierarchical parameter estimation from varying degrees of input information is a component of the model; and (d) assembled agricultural systems models are kept compact and easy to use by customizing them to specific problems and regions; and.
7. better coordination of international efforts is needed in the future to improve agricultural system modeling and to encourage model developers and field scientists to work on identified knowledge gaps and research priorities.

Finally, while many important challenges and opportunities exist in model development, the greatest challenge facing the practitioners of agricultural system modeling in the future may center on demonstrating relevance to real-world decision-making rather than on building more accurate or comprehensive models.

Summary and Conclusions

This article describes the potential (and often realized) benefits of developing and implementing agricultural models for solving a broad range of agroecosystem research problems. It provides some examples of agricultural model applications in research and

management, presents various technologies surrounding current agricultural model development and use, and also identifies limitations and knowledge gaps in agricultural models where further improvements could be made. A remaining question to be answered is "what does the future hold?" Certainly there will be continuing (if not greater) attention to aspects of agricultural system models less related to agronomic production. The existing strong demand for agricultural models to address soil and water resource concerns (e.g., limited water issues, nutrient and organic matter cycling, soil salinity) and wider issues of sustainable agriculture in the face of global climate change (e.g., greenhouse gas emissions, wind and water erosion) will intensify. Environmental modeling frameworks will continue to mature, and development of large monolithic agricultural models will essentially disappear to be replaced by component-based models that link, as required, independent modules representing problem-specific processes of interest. The use of agricultural models in IA will continue to grow. Agricultural models provide objective tools to determine biophysical consequences of resource management options at various scales. To truly have a whole-systems approach, biophysical simulation and assessments need to be complimented by socioeconomic analyses (involving decision-makers and other stakeholders) before substantial benefits are realized. Finally, in order to further improve process representation in agricultural models (in whatever context they are used), model developers and field scientists in various scientific disciplines must continue to enhance their collaborative efforts.

Even with current shortcomings, agricultural models are very useful tools in synthesizing and quantifying scientific knowledge and experimental results across different climates, soils, and agricultural management systems at different locations across field, farm, and regional scales. The sustainability of agroecosystems depends on the maintenance of the ecological, social, economic, biological, and physical components that comprise the system. The high level of integration of these components implies that any evaluation of agroecosystem sustainability must consider the dynamics of these multiple factors. Agricultural models have become, and will remain in the future, important tools to facilitate assessment of agroecosystem sustainability.

Big Data for Ecological Models

Marin M Kress, US Army Corps of Engineers, Engineer Research and Development Center, Vicksburg, MS, United States

Glossary

Crowdsourcing The act of utilizing the general public to achieve a goal, through active or passive participation examples include raising money, solving puzzles, or calculating traffic speed from cell phone data.

Extensible Extensible is something designed to accommodate future changes, such as a computer programming language designed so that future capabilities can be added.

Machine readable Computer files that are formatted to be ingested and understood primarily by a machine but which may be further processed to be human-readable.

Metadata Information about the dataset, separate from the data itself. Metadata may include elements such as instrumentation or software used in data generation, study duration, spatial extent, file type, keywords, and point of contact.

Remote sensing An observation made without interacting with the subject being observed, such as a photograph of a landscape

Introduction

There is an increasing call for ecological models to be parameterized with long-term datasets, and for modelers to archive their model runs and code to facilitate scientific-defensibility, transparency, and repeatability. These data archives are often created ad-hoc, without standards for the metadata or storage format. In a world full of linked search results and an ever-expanding number of journals and publications trying to gather the right information for your research can seem like an endless rabbit hole of possibilities. Proper data archiving and sharing can improve search results by connecting existing ecological data with those searching for it. To facilitate such archiving, sharing, and discovery it is useful to understand basic technical terms and practices relevant to these efforts. This entry covers concepts relevant to ecological data archiving including metadata, big data, machine readable data and common formats, and major ecologically relevant archive sources, with specific focus on those sources commonly used in ecological modeling. Although ecologists may not envision themselves as computer scientists it will behoove any researcher to understand the basics of the technological standards which underpin so much of modern research sharing. Digital records are not as permanently accessible as they may seem, and the ongoing shift from hardcopy observations to computer-generated and stored results requires careful thinking about how future researchers will be able to access historical files. Technologies that were once seen as revolutionary options for long term information storage (e.g., microfiche, laserdisc) may be less accessible than paper records in future due to lack of playback devices. Ultimately, when it comes to proper archiving and sharing the best advice is to think about the end before you begin collecting data.

Quick Reference Recommendations

The following is a brief list of recommendations related to ecological data archiving and sharing. The remainder of this article provides further explanation behind these recommendations:

- Identify funding agency requirements for data management and archiving before writing a grant proposal.
- Look for an established archive to deposit your data where it will be discoverable and accessible to the public with no further assistance from you. There may be a fee to deposit data.
- Think about metadata and record it as data is generated, rather than trying to reconstruct it after the project is over.
- Complete all metadata fields provided by the archive, and take advantage of space for keywords or tags.
- When the data set is complete, save it in both human-readable and machine-readable file formats for future use.
- If timestamps are used in your data include the local time zone or describe the time zone used in the metadata.

Big Data and Data Science

Ecologists and modelers who do not consider themselves "interdisciplinary data scientists" may not be aware of the contributions that their findings can make to other fields of scholarship. The rapid increase in computing availability, internet connectivity, the number of electronic records, and the changing nature of available digital content has ushered in an era of "big data" (Kress 2016).

This article uses the term big data to refer to any single dataset containing over 10 million records, although this threshold may shift with time. Big data can be any kind of large database, for example, millions of health records, aggregated news articles, or financial transaction records. In ecological sciences, big data could include genetic records across phyla, or sensor records of animal movements, or physical conditions such as temperature. Large quantities of high resolution photographic files can also grow in size to quickly match the data processing needs associated with other big data databases.

Big data is often described in terms of four elements: volume, variety, velocity, and veracity (IBM 2015). Volume refers to the scale of data, which could come from internal or external sources, on a global scale some estimate that 2.5 quintillion bytes of data are created each day (IBM 2015). Variety of big data refers to the different forms and sources, such as transaction data, social media, sensors, and mobile devices—including new products such as wearable wireless health monitors aimed at the general public (IBM 2015). This expanded volume and variety of data may also be generated at a faster velocity than previously seen because of computing and connectivity advances. For example, the New York Stock Exchange captures 1 terabyte of trade information during each trading session, a data stream of interest to both regulators and market analysts. Finally, veracity, or uncertainty, is an important element of big data (IBM 2015). With any data generation there is the potential for errors to enter a data stream. For datasets that grow rapidly and are continuously analyzed there is the potential for undetected data distortion to become magnified and for errors to propagate through dependent systems. IBM asserts that veracity of data is a significant issue and that poor data quality costs the US economy around $3 trillion per year (IBM 2015).

Big data refers not just to datasets, but also requirements for handling data in ways that go beyond the capabilities of traditional statistical software packages (Lohr 2013) or even personal computers. For example, at the time of writing in 2016 a single file in the current widely used version of the Microsoft Excel® software program can contain slightly over 1 million records (Microsoft Corporation 2016). New computer programs have been developed in response to the computational demands of big data analysis such as Apache™ Hadoop® (The Apache Software Foundation 2015), other hardware and software processing tools will continue to develop in response to changing technology and user needs. The rise of big data and expansion of other new sources of data (including digitization of historical paper records) does more than simply provide more data points, this availability can spur new questions about the world and the development of research subdisciplines. Finding, accessing, and organizing data across multiple disciplines is facilitated through best practices in data archiving and sharing. The next section describes important technical standards used in online data sharing.

Machine Readable Data

In scientific research there is no substitute for well-planned and carefully collected observational data. Such observations may be recorded with pen and paper, but increasingly, observations of the world around us are coming from digital instruments. Digital instruments may be associated with proprietary software packages, however many proprietary software packages offer output capabilities into standard open file formats. It is these standard open digital file formats, especially formats for data designed to be shared with a wide audience via the internet, that are the focus of this article.

Standard, nonproprietary, files formats are key to open data and data sharing. Readers are likely to be familiar with widely used electronic file formats such as Portable Document Format (PDF) or the graphics standard from the Joint Photographic Experts Group (JPEG or JPG). These types of files can be opened by many computer programs, and many programs can create files into these formats. However, files that are widely digitally accessible and designed for human readability may not be machine readable. Archiving and sharing required both human readability and machine readability, both terms are defined below.

Human readable: file formats that a human can read and interpret (but often a machine cannot), such as hand written notes, photographs, or PDF files.

Machine readable: file formats intended to be processed by another machine, organized in a specific structured format.

Machine readable data is critical to web services, which are the backbone of any sort of interactive website. Everything from online shopping to location-enabled restaurant recommendations through an app on your phone uses web services. Web services also run background processes you might not be aware of such as speed tracking that contributes to traffic forecasting. Web services matter to ecologists because anyone wanting to share real-time monitoring data will have to establish some type of web service to do so. A brief list of terms relevant to web services and data sharing is included in the **Table 1**. Creating or querying large databases on the internet will likely involve the use of these tools (either directly or behind the scenes).

How would an ecologist interface with these technological elements? In one case an ecologist might transfer field notes and data into a spreadsheet, save the file in a CSV format, and then post it to a website with an existing API that sends alerts when new files are available. In another setting, a researcher might sequence DNA, then create a file from a standard template with the DNA sequence and metadata, then submit the file to an archival institution which has established processes for querying their archive based on keywords and metadata.

Nontraditional Data Sources: Social Media and Crowdsourcing

Rooted in observations of the natural world by scientists, ecological research has expanded to take advantage of social media platforms and the power of crowdsourcing to promote broad participation in observations of natural phenomenon. One

Table 1 Commonly used abbreviations in online data sharing

Abbreviation	*Full name*	*Uses*
RDF	Resource Description Framework	An open standard data language to represent information as a web resource that can be linked to other web resources.
XML	eXtensible Markup Language	A language used to improve metadata accessibility. Proper XML use results in tags that can extracted by a computer, aiding information discovery.
JSON	JavaScript Object Notation	Machine readable data format, used to represent simple data structures and associative arrays. Used for data shared by 'syndication' in regularly updated feeds.
RSS	Really Simple Syndication	A programming language that contains both content and metadata, used in online "syndication" processes. Based on XML or RDF.
CSV	Comma Separated Value	An open file format for storing numerical and text data in a plain-text format.
API	Application Programming Interface	The way that machine readable information is made directly available to other machines. Used for programs that request information over an internet connection.

dictionary defines "crowdsourcing" as the "practice of obtaining needed services, ideas, or content by soliciting contributions from a large group of people and especially from the online community rather than from traditional employees or suppliers." (Merriam-Webster Incorporated 2015) With the spread of the Internet, and Internet-connected smartphones, the ability for spatially distant groups to share information in near-real time is enormous. In addition to Internet connectivity, many mobile communication devices include the ability to share georeferenced information (i.e., latitude and longitude) along with an observation record (e.g., photo or social media posting) directly from the device itself. In some cases mobile phones are able to act as sensors without conscious action by their owner, a functionality already utilized by some companies to generate location-specific crowdsourced observations (Kress 2016). For example, any mobile phone with the Google Maps application and GPS-location services enabled will report movement speeds back to Google, which continuously combines data from millions of users and projects it through the Google Maps application in the form of color-coded street overlays (Barth and Google Inc. 2009). Examples of crowdsourced ecology research projects are listed below.

1. *Encyclopedia of Life*: This project began with the idea to provide a webpage for every species on earth, and seeks to bring together information from trusted resources such as museum, professional societies, and expert scientists into a massive database (Encyclopedia of Life Contributors 2015).
2. *Wildbook for Whale Sharks*: This photo-identification library allows anyone to upload photographs of whale sharks and associated location information for processing and photo matching by a trained researcher. The information provided by contributors is used to identify individual animals and help track the movements and distribution of the world's largest fish (Holmberg 2016).
3. *iNaturalist*: This free mobile phone application allows users to take observations and photographs of any animal or plant in the wild, then upload and share that information to a central website. The organization compiles and shares information with scientific repositories and makes data, and open source code, available to anyone (iNaturalist 2016).

Due to the potentially enormous numbers of individually-generated records from social media postings or georeferenced Internet search queries, there is interest in using these sources to monitor near real-time events, including predicting or tracking disease outbreaks or other ecologically relevant phenomenon.

Crowdsourced Data, Big Data Hubris, and Algorithm Dynamics

Researchers who rely on crowdsourced data or datasets of opportunity should be aware of fundamental limitations in the explanatory power of such data and the risk of "big data hubris." Big data hubris is the "assumption that big data are a substitute for, rather than a supplement to, traditional data collection and analysis" because "quantity of data does not mean that one can ignore foundational issues of measurement and construct validity and reliability and dependencies among data" (Lazer et al. 2014). The caution has even greater relevance when large data sets are generated through opaque processes that a researcher may not be able to account for within their analysis. For crowdsourced data from private sources, such as online search engines, it is also possible that algorithm dynamics may play a role in influencing any records generated. "Algorithm dynamics" refers to the changes made by software engineers to improve the commercial service being used and changes in behavior of consumers using the service (Lazer et al. 2014). The act of suggesting additional search terms, or using an "autocomplete" function in a text field, can influence user behavior. Lazer et al. (2014) note that "search behavior is not just exogenously determined, it is also endogenously cultivated by the service provider". For example, the act of presenting results in a certain order means that they have the potential to be seen by more people and receive more exposure, creating a positive feedback loop (Kress 2016).

Crowdsourced data from social media might be an accurate reflection of posted content within a single social media site, but such data should not be confused with a being an accurate representative sample of anything beyond a narrowly defined universe of subjects. For example, users of an insect-photo observation website might be more attracted to larger colorful species such as

butterflies, generating fewer records for smaller or more camouflaged species. Active participation rates for various online social media platforms may vary between demographic groups. However, other types of crowdsourced data do not require active participation or content generation, but instead only the use of a certain level of technology (i.e., smartphones) and so may draw from a larger population (Kress 2016).

Section Summary

Crowdsourced and social media data, including big data derived from these sources, can be seen as both rich and dangerous. Data culled from social media offers the potential of highly detailed temporal and spatial topical records that could provide fascinating social insights at low cost, but also of meaningless correlation on a grand scale. The difference between reported data (subject to human discretion) and recorded data (generated through established processes by sensors) will continue to be an important distinction. Ecological researchers who draw upon these sources for their research should document known limitations of such data within the metadata.

Interdisciplinary Health Research Using Ecological Data

Archived ecological data may contribute, and has contributed, to other fields of study such as medicine. Types of data that were not specifically designed for health-related research are regularly being used to investigate environmental health questions. To illustrate this point three examples of environmental health research that drew upon ecological data are summarized below.

Rift Valley Fever Predictions Based on Climate Anomalies

Anyamba et al. (2009) investigated the historical relationship between climate anomalies and Rift Valley fever (RVF) outbreaks in the Horn of Africa to develop a predictive model. Remotely-sensed ecological data relating to mosquito habitat was combined with epidemiological information on previous RVF outbreaks in the regional to develop early warning risk maps (Anyamba et al. 2009). Their results demonstrate the feasibility of combining remote-sensing data and historical epidemiology data to make near-term predictions about disease risk for a virus whose spread is closely coupled with regional environmental conditions (Kress 2016).

Linking Cholera Dynamics in Bangladesh to Environmental Influences

To examine the links between cholera risk and environmental forcing in Bangladesh, Koelle et al. (2005) tied together ecological data related to rainfall and river discharge, spatial data on flood extent, and epidemiological data on previous cholera cases to model the influence of climate anomalies on local cholera dynamics (Koelle et al. 2005). The question of climate anomalies and cholera disease ecology is an example of untangling the interaction between aquatic environmental conditions, disease vector biology, seasonal factors that affect large scale human behavior, and human population-level immunity using both traditional and non-traditional data (Kress 2016).

Predicting Kawasaki Disease in Japan from Regional Air Parcel Movements

Rodó et al. (2014) investigated possible airborne causative agents of Kawasaki Disease (KD) in Japan. They combined epidemiological data, regional wind pattern data, regional ecological land cover data, and microbial profiling of tropospheric and ground aerosol samples collected at times when air was coming from region identified as the possible source of the KD trigger (Rodó et al. 2014). The researchers found that air parcels associated with higher incidence of KD in Japan had previously moved over intensively cultivated croplands for corn, rice, and wheat in northeastern China during a time when the ground was frozen. By combining remote sensing records, field measurements of the airborne, and spatially-based epidemiological data, this research has suggested new avenues of investigation to understand and predict changes in KD risk (Kress 2016).

Section Summary

Revealing linkages between large-scale physical environmental phenomenon (such as sea-surface temperature anomalies, wind patterns, or rainfall levels) and local conditions is increasingly important in solving complex problems involving multiple states or countries (Kress 2016). The examples cited above illustrate the value of archived ecological data when applying a synthesis approach to complex research questions.

Ecology Data in the Public Domain but not Discoverable Online

The potential audience for ecological data is wide, spanning basic science, commercial operators with business interests, and the public health and governance community (Kress 2016). In addition to academic or private research efforts, public government entities engage in a variety of ecology-related research. However, not all data that falls within the public domain is automatically available online. In the United States data is generally considered to be in the public domain if it is the product of official government work, or work paid for with public funds. In 2013 the Presidential Executive Order 13642 "Making Open and Machine Readable the New Default for Government Information" directed US federal government agencies to release data to the public in ways that "make the data easy to find, accessible, and usable" (Obama 2013). This generally means publishing the data online. Data discovery is facilitated through the Data.Gov website, which provides an every-expanding catalogue of federal datasets data available to the public. At the time of writing there were over 190,000 datasets with searchable descriptions and web links available to the public through Data.Gov (US General Services Administration 2016).

For local and state-level offices with limited resources it may not be standard practice to post all public data online. In these cases it may be necessary for researchers to contact public agencies directly to request that they share data files directly. One example of such public domain ecological data is the state-sponsored water sampling of Boston Harbor and Massachusetts Bay. The Massachusetts Water Resources Authority (MWRA) has made certain water quality monitoring data (e.g., bacteria counts, nutrient observations) from Boston Harbor available for select observations starting in 1989 (Massachusetts Water Resources Authority 2015b). However, at the time of writing, similar water quality monitoring results for the larger Massachusetts Bay area are not posted online. Instead, researchers may contact the MWRA to initiate a discussion with staff members who can assist them in their research and provide files extracted from the main database held by the MWRA. Although this is just one example, similar situations likely exist at other state and local government agency offices which may hold ecologically-relevant data.

Notable Public Data Archives

The results from purpose-designed experiments generating direct observations still constitute the highest tier of scientific data, complementing such experimental data are environmental monitoring data which may reveal changes over long time periods (Kress 2016). Magnifying the value of the cumulative efforts of individual scientists, laboratories, and institutions are national and international repositories for data or publications. These data repositories may be managed or funded by nonprofit organizations, academic institutions, government agencies, or some combination thereof. Major examples of such databases are described below, these examples were chosen because of their stability and public accessibility. Some of the example archives are focused on providing public access to government-funded research products, while others allow submissions from the broader research community. Scientists who might wish to deposit their findings in such public archives should consult the associated format requirements early on in their research to make the final archiving process easier.

Ecology and Environment Databases

These databases examples span multiple environment types and may include both biotic and abiotic environmental data.

1. *Ecological Society of America Data Registry*: This registry describes data sets on ecology and environmental topics from articles published in the journals of the Ecological Society of America (Ecological Society of America 2015).
2. *Integrated Ocean Observing System (IOOS®)*: A regional-national partnership for sharing ocean, coastal, and Great Lakes data on topics including wave heights, sea level, wind, temperature, salinity, and dissolved oxygen levels. IOOS is a member of the Global Ocean Observing System (GOOS) coordinated through the United Nations (National Oceanic and Atmospheric Administration 2014). Within the United States there are multiple regional contributors to ocean and weather monitoring data streams ranging from the Northeastern Regional Association of Coastal and Ocean Observing Systems (NERACOOS) to the Pacific Islands Ocean observing System (PacIOOS) (Northeastern Regional Association of Coastal and Ocean Observing Systems 2014).
3. *TRY Plant Trait Database*: The Max Planck Institute for Biogeochemistry in Germany hosts this international database developed by scientists of morphological, anatomical, biochemical, physiological, or phenological features of plants, with many geo-referenced records (Boenisch and Kattge 2014).
4. *National Centers for Environmental Information*: A project of the US National Oceanic and Atmospheric Administration, this website provides public access to climate and historical weather data, along with geophysical, oceanographic, and coastal data (National Oceanic and Atmospheric Administration, 2016). This source publishes data that spans "from the depths of the ocean to the surface of the sun and from million-year-old sediment records to near real-time satellite images." (National Oceanic and Atmospheric Administration, 2016).
5. *Water Information System for Europe*: A joint product of the European Commission and the European Environment Agency, this website connects users with water-related information including water statistics, forecasting models, and policy information across Europe (European Commission and European Environment Agency 2016).

6. *National Water Information System*: Produced by the US Geological Survey, this archive is the principal repository of water resources data for the United States. Through the public website users can access data on streamflow, floods, drought, groundwater, and aquatic habitats (US Geological Survey 2016).
7. *Australian Soil Resource Information System*: This government-run website provides information on soil resources in Australia in a consistent format. Records include information on soil depth, water storage, permeability, fertility, carbon and soil erodibility (Commonwealth Scientific and Industrial Research Organisation 2013).
8. *Long Term Ecological Research Network*: The Long Term Ecological Research Network was established with support from the National Science Foundation with the goal of understanding "a diverse array of ecosystems at multiple spatial and temporal scales." Observational and experimental data from over 25 sites across North America, Tahiti, and Antarctica are available through an online data portal (Long Term Ecological Research Network 2013).

Multi-topic Databases

These multi-topic databases may be useful to researchers in a wide variety of fields, from ecology and biology to computer science to history.

1. *US Census Bureau*: This website provides historical demographic, economic, health, housing, and other official statistical data for the United States. Products may combine categorical data with spatial detail at the level of census block groups (ranging from 600 to 3000 people) (US Census Bureau and US Department of Commerce, 2015; US Census Bureau 2012). The level of detail published by the US Census allows for nuanced spatial analysis over time.
2. *Google Trends*: This website from Google displays stories that are "trending" based on user-entered search terms in the free Google search engine. Topics can be filtered by categories such as "Business" or "Sci/Tech" and by country. Within the United States, Google Trends displays a map of interest by region (state level) for an individual story (Google Inc. 2015).
3. *Dryad Digital Repository*: Dryad is a nonprofit long-term repository for data used in international scientific and medical literature, including data in the form of text, spreadsheets, video, photographs, and software code (Dryad 2015a). Datasets deposited in Dryad are free to use and citable in new publications (Dryad 2015b). Each Dryad data package received a unique Digital Object Identifier that can be used when citing or locating data. Datasets are free to use but there is a small charge for depositing data packages with Dryad (Dryad 2015a).

Health and Medicine Databases

These databases are relevant to health and medicine researchers, topics range from basic biology to clinical specialties. There are numerous websites and databases that serve specific molecular biology topics.

1. *PubMed*: PubMed is a database of over 24 million citations from biomedical literature, it is managed by the US National Institutes of Health (NIH, a government entity) (US National Library of Medicine 2015).
2. *GenBank®*: An annotated genetic sequence database of all publicly available DNA sequences maintained by the NIH since 1982. GenBank releases a public update every 2 months and, as part of the International Nucleotide Sequence Database Collaboration, exchanges data with the DNA DataBank of Japan and the European Molecular Biology Laboratory. Each nucleotide sequence uploaded to GenBank receives a unique Accession Number, as of mid-2015 GenBank has archived over 100 million sequence records representing over 100 billion nucleotide bases (National Center for Biotechnology Information 2014).
3. *Foodborne Outbreak Surveillance System (FOSS) Online Database*: This database is run by the US Centers for Disease Control and Prevention (CDC). FOSS receives reports from state, local, and territorial public health agencies about recorded foodborne illnesses (Centers for Disease Control and Prevention 2013).
4. *HealthData.Gov*: This website is run by the US Department of Health & Human Services (HHS) and aims to make data from the HHS agencies (including the CDC, FDA, and NIH) easily available and accessible to the public. This evolving website aims to make all the data it serves up to be machine-readable, downloadable, and accessible via application programming interfaces (US Department of Health and Human Services 2015).
5. *ClinicalTrials.Gov*: This website is maintained by the National Library of Medicine in the United States. The archive contains information about publicly and privately supported medical studies in human volunteers in the United States. Both interventional studies (aka clinical trials) and observational studies are included in the records (National Library of Medicine 2016).

Environmental Health Databases

These databases contain information relevant to environmental topics with a close relationship to human health.

1. *Enhanced Infectious Diseases (EID2) database*: This database, funded by the European Union and hosted at the University of Liverpool, contains data on pathogenic organisms and the country in which they may occur, lists of carrier organisms, genetic sequences, and publication links (University of Liverpool 2015).

2. *Center for Coastal Monitoring and Assessment National Status & Trends Database (NS&T)*: Run by the US National Oceanic and Atmospheric Administration (NOAA), the NS&T is comprised of three nationwide programs, Benthic Surveillance (discontinued in 1993), Mussel Watch and Bioeffects that are designed to describe the current status of, and detect changes in, the environmental quality of US estuarine and coastal waters through environmental monitoring, assessment and related research. Starting in 1986, the Mussel Watch program is the longest running continuous contaminant monitoring program in US coastal and Great Lakes waters (National Oceanic and Atmospheric Administration 2012).
3. *National Pollutant Discharge Elimination System Permit (NPDES) Database*: A product of the US Environmental Protection Agency this database provides spatial information about facilities holding NPDES permits, including the associated latitude and longitude data (US Environmental Protection Agency 2015).

Remote Sensing Data Sources

Some national space agencies are public sources of satellite remote sensing data and model output products derived from that data. Other remote-sensing data is available from private entities.

1. *US National Aeronautics and Space Administration (NASA)*: NASA provides satellite remote sensing data from multiple spacecraft and instruments sources with varying temporal scales, spatial scales, and image resolution. Topic areas include global precipitation, thermal anomalies, ocean color, land cover and vegetation, and snow and sea ice cover (National Aeronautics and Space Administration 2014).
2. *European Space Agency*: The European Space Agency provides public data related to radar imagery, radar altimetry, optical/multispectral radiometry, atmospheric data, and gravimetric data from multiple missions (European Space Agency 2015).
3. *Japan Aerospace Exploration Agency*: The Japan Aerospace Exploration Agency provides data to the public from satellites and probes. Observation data from multiple satellites provide remotely sensed records on topics such as greenhouse gases, typhoons, and precipitation (Japan Aerospace Exploration Agency, 2016).

The expanding use of small unmanned aerial vehicles (UAVs) (e.g., drones, quad-copters, low orbit weather balloons) with the capacity to carry photographic and sensory equipment is rapidly changing the amount of remotely sensed data available to researchers (Botanical Society of America 2016). As this field develops new repositories may emerge with their own sets of metadata standards.

The data archived in each source listed above requires specialized knowledge to interpret. For example, foodborne illness outbreaks are a different type of data than land cover type images, but when combined they might provide scientific new insights. Proper metadata documentation may help with the data discovery and hypothesis generation process. The need for individuals or specialized data science teams that can combine and utilize diverse data types may grow as society poses research questions related to multiple disciplines (Kress 2016).

Database of Researchers

This article focuses on data archiving and sharing, but researchers should also be aware of ORCiD (2016), an organization which will provide them with a unique number to associate with their name on publications. The purpose of a unique identifying number is for scientists to keep track of their intellectual contributions over time even as their name, affiliation, or field of research changes. Some academic journal publishers and funding agencies are requiring ORCiD identification codes from researchers as part of their normal administrative process (ORCiD 2016). While the practice of tying a unique number to an individual's publication record is clearly beneficial to people with commonly used names or names translated from other languages, it will also serve to keep a consistent record across publications with varying author name formats.

The Variety of Data Sources Consulted for a Single Project

Well documented, and discoverable, ecological data sources can contribute to multiple interdisciplinary or cross-disciplinary studies. For example, the **Table 2** from a doctoral dissertation in the field of ocean and human health shows the wide variety of sources consulted in a single research effort. Ecology data (water samples for microorganisms, nutrient data, physical observations) was combined with human demographic data, geological data (river flow), and public health data (beach water quality testing) to investigate relationships between human inputs to coastal waters and their influence on potential marine-sourced risks to human health from those same coastal waters (Kress 2016).

Chapter Summary

This article discussed the changes in the type and amount of data available to ecological modelers, and the technological standards that are important to web-based data sharing processes. Data accessibility changes include increasing numbers of observations

Table 2 Example of sources used in a single environmental health research project

Source name	*Source type*	*Data types*	*Sampling frequency*	*Source*
US Census, Decennial Census	Federal government	Population, age, sex, housing units, household income, other demographic data	Every 10 years, entire United States	US Census Bureau and US Department of Commerce (2015)
US Census, American Community Survey	Federal government	Housing stock, wastewater treatment, other demographic data	Every year, approximately 1 in 38 US households receive the survey	US Census Bureau (2014)
Dog population in coastal cities bordering, Massachusetts Bay	Compiled by author via phone and email survey in 2012	Number of dogs registered to town, some estimates of unregistered dogs	One time survey	Unpublished data
US Geological Survey, River discharge data	Federal government	Average daily discharge rate at 8 stations along waterways, no data on Cape Cod	Continuous, June–August records 2007–14	US Geological Survey (2015a), and US Geological Survey (2015b)
Northeastern Regional Association of Coastal and Ocean Observing Systems	Nonprofit organization, partnership	Ocean and weather conditions from buoys in the northeast. Air temperature, water temperature at multiple depths, salinity, chlorophyll, turbidity, wind direction, current direction	Minute by minute, but reports of daily averages are available. Annual data acquired for of 2000–14.	Northeastern Regional Association of Coastal and Ocean Observing Systems (2014)
NOAA Buoy Station BHBM3, Boston Harbor	Federal government, data also served via NERACOOS	Air temperature, water temperature	6-min intervals	National Oceanic and Atmospheric Administration (2015)
NOAA National Climatic Data Center	Federal government	Precipitation, air temperature to tenth of degree, average daily wind speed	Daily average	National Oceanic and Atmospheric Administration and National Centers for Environmental Information, 2015)
Massachusetts Department of Public Health, Beach Water Quality Testing	State government	*Enterococcus* sampling results	Weekly, monthly, or daily during summer bathing season depending on location and previous test results	Massachusetts Department of Public Health (2012)
Massachusetts Water Resources Authority	State government	Boston Harbor bacteria counts	Varies, weekly or monthly	Massachusetts Water Resources Authority (2015b)
Massachusetts Water Resources Authority	State government	Boston Harbor nutrient data: Ammonium, Nitrate + nitrite, Total Kjeldahl Nitrogen, Phosphate, Total phosphorus, Chlorophyll *a*, Phaeophytin	Varies, weekly or monthly, Acquired data spanning 1992–2014	Massachusetts Water Resources Authority (2015b)
Massachusetts Water Resources Authority	State government	Ammonium, Nitrate + nitrite, Phosphate, Total P/N, Particulate P/N/C, Chlorophyll *a*, Silicate, Salinity, zooplankton	Varies, weekly or monthly, Acquired data spanning 1995–2014	Massachusetts Water Resources Authority (2015a)
Massachusetts Water Resources Authority	State government	Beach water quality, bacteria counts and precipitation in the form of rainfall	Spring to fall. Daily during summer bathing season	Massachusetts Water Resources Authority (2015b)
Massachusetts Water Resources Authority	State government	*Pseudo-nitzschia* species count data	Approximately monthly from 1992 to 2014 (date range varies by station)	Massachusetts Water Resources Authority (2015c)
US Environmental Protection Agency	Federal government	Location and information for facilities within a National Pollutant Discharge Elimination System (NPDES) permit	Monthly	US Environmental Protection Agency (2015)
Massachusetts Department of Public Health	State government	Enteric diseases diagnosed in the Commonwealth of Massachusetts	Annually, with 1 + year lag for public release	Massachusetts Department of Public Health (2013)

from multiple sources, and the increasing speed of data generation from traditional sources as well as new sources like social media platforms or mobile phone-based applications. For ecological data and models to have the greatest impact, they should be properly documented, archived, and shared through an online platform. Dataset discoverability and usability, scientific defensibility, and transparency are all improved using clearly documented metadata and open file formats that facilitate file sharing across software programs.

Biogeochemical Models☆

Joyita Mukherjee, Krishna Chandra College, Hetampur, West Bengal, India
Santanu Ray, Visva – Bharati University, Santiniketan, India

Introduction

The field of biogeochemistry deals with the effect of biological organisms on the chemistry of the Earth. Since there are numerous living organisms, all of which affect the chemistry of their environment in multiple ways, biogeochemistry is a large subject area covering many processes. One process that receives a lot of attention is the emission of CO_2 by humans and the associated global increase in atmospheric CO_2. However, biogeochemistry also deals with the effect of other organisms on the global carbon cycle, like the conversion of CO_2 to organic carbon by marine phytoplankton. Biogeochemical processes can also be of subglobal scale, like the respiration of O_2 by bacteria at the bottom of a lake. Biogeochemistry encompasses all types of chemicals. Nitrification, the conversion of ammonia to nitrate, by bacteria in soils is a biogeochemical process. So is the reduction of sulfate to sulfide by bacteria in groundwater. Also, the chemistry of minor elements is included, like the methylation of mercury by bacteria in sediments. Further, although the field of biogeochemistry traditionally focuses on naturally occurring elements and compounds, it also includes the effect of organisms on the chemistry of manmade chemicals, like the biodegradation of polychlorinated biphenyls (PCBs) by bacteria.

Biogeochemical models are abstract and simplified representations of biogeochemical processes. This includes qualitative models in the form of narratives or diagrams that describe how a process works and convey mechanistic information. It also includes quantitative models in the form of mathematical equations that predict chemical concentrations and fluxes. Quantitative biogeochemical models are used as research tools to test hypotheses, and as management tools to evaluate "what if" scenarios (e.g., nutrient load reduction to prevent eutrophication of lakes). In application, biogeochemical models are typically smaller components of larger models that describe the biogeochemical cycling of elements at various scales ranging from a small volume of soil to the globe. As such, biogeochemical models have to be compatible with other models, including physical models that describe the transport of chemicals in the environment (advection, diffusion, and dispersion) and ecological models that describe population dynamics.

The purpose of this article is to present an overview of biogeochemical modeling. A thorough review of this article would necessitate covering the effect of every biological organism on the chemistry of all affected compounds, which is beyond the scope of this article. Therefore, this article focuses on how the transformation of chemicals by organisms is modeled in general, with applicable references to actual processes. Microorganisms constitute the bulk of the biomass and they have a higher turnover rate than organisms at higher trophic levels. They are therefore generally considered to be the main drivers of biogeochemistry and this article will focus on them. Also, consistent with the scope of this encyclopedia, the article focuses on naturally occurring substances, rather than manmade ones (e.g., PCB). Often, the effect of organisms on chemistry is indirect (e.g., via the redox potential), but that is, strictly speaking, a chemical problem, and this article therefore focuses on the direct effect of organisms on the chemistry. First, basic modeling approaches are reviewed, including conceptual and descriptive models, mechanistic chemistry- and biology-type models, and empirical models. Then the integration of ecology and biogeochemistry models is discussed, including their role, methods of integrating them, examples of integrated aquatic and terrestrial models, and the past, present, and future of those models. Following that, is a description of one of the grand challenges of biogeochemical modeling, the scaling problem. Then, the transformation of arsenic by phytoplankton is presented as a case study.

Modeling Approaches

Conceptual and Descriptive Models

The simplest type of model, and therefore often a starting point in a biogeochemical modeling study, is a qualitative, conceptual or descriptive model. This type of model can be effectively communicated using diagrams, like that shown for mercury methylation in Fig. 1. The purpose of this model is to describe the requirements for mercury methylation, and the model is simplified for that purpose. Water, for example, is also part of the overall reaction, but it is omitted from the model because it typically does not affect the process. Also, no information on what occurs inside of the bacteria, the biochemical reaction(s), is included in the model. Despite (and maybe because of) the simplifications, the model conveys important aspects of the process for this particular

☆*Change History*: March 2018. J Mukherjee and S Ray updated (1) A section on Ecology and Biogeochemistry models has been added, (2) Two biogeochemical models on carbon and nitrogen cycle following process based dynamic modeling have been added as examples, (3) A paragraph on application of biogeochemical cycles added and (4). Relevant references has been added.

This is an update of F.L. Hellweger, Biogeochemical Models, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 386–396.

Fig. 1 Conceptual model of mercury methylation by sulfate-reducing bacteria.

Box 1 Narrative presentation of a model for dissimilatory Fe(III) reduction

The oxidation of detritus to CO_2 by dissimilatory Fe(III) reduction is a multistep process. First, the complex organic compound is hydrolyzed to smaller soluble compounds (e.g., amino acids, fatty acids). Then, those compounds are metabolized to acetate by fermentative microorganisms. Finally, the acetate is oxidized to CO_2 and the Fe(III) is reduced to Fe(II) by iron-reducing bacteria.

purpose. Another way to communicate a qualitative model is in the form of a narrative, as shown for dissimilatory iron reduction in Box 1.

Chemistry-Type Models

Qualitative models are useful, but often quantitative predictions are needed. One common approach to quantitative biogeochemical modeling is to apply the concepts of chemistry. That is, organisms are quantified as concentrations and their effect on chemistry is considered a reaction. There are a number of ways organisms can be incorporated into chemical models, as described in this section.

Organism Is Ignored

The simplest way to model the effect of organisms on chemistry is to simply ignore them, or to not explicitly recognize them or their action in the model. Nitrification, for example, is a two-step process carried out by nitrifying bacteria. First, *Nitrosomonas* converts ammonia (NH_3) to nitrite (NO_2^-) and then *Nitrobacter* converts nitrite to nitrate (NO_3^-):

$$2NH_3 + 4O_2 \rightarrow^{Nitrosomonas} 2NO_2^- + 2H^+ + 2H_2O$$
$$+O_2 \rightarrow^{Nitrobacter} 2NO_3^- + 2H^+ + 2H_2O$$

As shown in the equation, the reaction is mediated by and requires the two organisms. However, in the natural environment, nitrifying bacteria are often present in sufficient quantities, and therefore they are typically not included in rate expressions:

$$\frac{d[NH_3]}{dt} = -k[NH_3]$$

where k (day^{-1}) is the first-order reaction rate constant for the nitrification process. Sometimes the effect of O_2 is included in the rate expression by modifying the rate constant k as a function of $[O_2]$.

Organism Is Included as Reactant or Product

Another way to model the effect of biological organisms on chemistry is to consider them a chemical molecule that participates in a reaction as a reactant or product. Photosynthesis, for example, is often represented using the following reaction:

$$106CO_2 + 122H_2O + 16HNO_3 + H_3PO_4 \rightarrow \underbrace{(CH_2O)_{106}(NH_3)_{16}(H_3PO_4)}_{A} + 138O_2$$

where the molecule A is a simplified chemical-type representation of algae, also called Redfield molecule. This type of representation is useful for composition analysis. It says, for example, that the N:P ratio of phytoplankton is 16:1, which can be used to determine which one of these nutrients will run out first and end up limiting primary production.

Such organism molecules can also be included in kinetic rate expressions. For growth on a substrate or nutrient, it is often observed that the specific growth rate is proportional to the substrate concentration at low substrate concentrations, meaning the substrate is rate limiting. However, at higher substrate concentrations the growth rate is limited by other factors, like the rate of processing the substrate. This type of behavior can be simulated using the well-known Monod model:

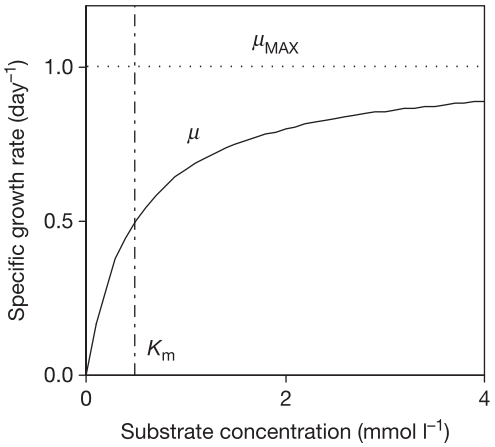

Fig. 2 Monod growth model. $\mu_{MAX} = 1.0\ \text{day}^{-1}$, $K_m = 0.5\ \text{mmol L}^{-1}$.

$$\frac{d[A]}{dt} = \mu_{MAX}\frac{[HNO_3]}{K_m + [HNO_3]}[A]$$

where $[A]$ (mmol L^{-1}) is the phytoplankton concentration, $\mu_{MAX}(day^{-1})$ is the maximum specific growth rate (when $[HNO_3] \gg K_m$), and K_m (mmol L^{-1}) is the half-saturation constant. The Monod model has a hyperbolic shape as illustrated in Fig. 2. The amount of nutrient consumed per biomass synthesized can be calculated using a yield coefficient

$$\frac{d[HNO_3]}{dt} = \frac{-1}{Y}\frac{d[A]}{dt}$$

where Y (1 mol A/16 mol HNO_3) is the yield coefficient.

Organism Is Included as Catalyst

Another method is to consider organisms as a mediator in a chemical reaction without being a reactant or product, which is called catalyst in chemistry and enzyme or biological catalyst in biology. The nitrifying bacteria discussed above can be considered catalysts for the nitrification reaction, although the rate expression does not explicitly recognize that. The general sequence of an enzyme-mediated reaction is

$$S + E \leftrightarrow SE \rightarrow P + E$$

First the substrate S combines with the enzyme E in a reversible reaction to form the complex SE. Then, the SE reacts to form one or more products P and E in an irreversible reaction. The mechanistic rate expression for enzyme kinetics is the Michaelis–Menten equation:

$$\frac{d[S]}{dt} = V_{MAX}\frac{[S]}{K_M + [S]}$$

where V_{MAX} (mmol L^{-1} day^{-1}) is the maximum reaction velocity, and K_M (mmol L^{-1}) is half-saturation constant. The parameters V_{MAX} and K_M are related to the enzyme concentration and the rate constants of the individual reactions. The Michaelis–Menten equation has the same hyperbolic shape as the Monod equation illustrated in Fig. 2.

Biology-Type Models

In some cases treating organisms as chemical molecules is overly simplistic and introduces excessive error into the model. Then, a more explicit representation of their effect on chemistry is needed. Organisms only directly affect the chemistry of their environment by removing (uptake) or adding (excretion) chemicals from or to their environment. These processes can be passive or active, as discussed in this section.

Passive Uptake and Excretion

Substances continuously diffuse in and out of organisms across the cell membrane, with a net transport in the direction of decreasing concentration. Movement through cell membranes can be complicated by multiple layers and binding sites, and therefore models often assume simple diffusion across one layer. For that case, the transport rate is proportional to the concentration gradient across the cell membrane:

$$V = P_m A(S_{IN} - S_{OUT})$$

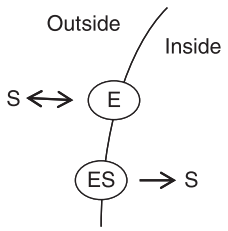

Fig. 3 Enzyme-mediated uptake.

where V (fmol cell^{-1} day^{-1}) is the transport rate, P_m (m day^{-1}) is the membrane permeability coefficient, A (m^2 cell^{-1}) is the cell surface area, and S_{IN} and S_{OUT} (fmol m^{-3}) are the chemical concentrations inside and outside of the cell, respectively. The intracellular concentration can be related to the cell quota (fmol cell^{-1}) using the cell volume (m^3 cell^{-1}). For chemicals that speciate, the model applies to the same species, and care should be taken when the speciation chemistry is significantly different inside and outside of the cell.

Active Uptake and Excretion

Organisms can also actively take up and excrete substances using transport sites (enzymes) on the cell membrane. This process can move chemicals against a concentration gradient, in which case it requires an external input of energy. The nutrient phosphate, for example, is taken up by an active uptake process. Cadmium is an example of a toxic chemical that is excreted from cells using an active excretion process. The sequence of events is similar to that of enzyme kinetics described above, and consists of a two-step process, illustrated in Fig. 3 for uptake. First, the chemical binds reversibly to the transport site. Then, it is transported into the cell in an irreversible reaction. This is typically modeled using the Michaelis–Menten equation:

$$V = V_{\mathrm{MAX}} \frac{S}{K_M + S}$$

where V (fmol cell^{-1} day^{-1}) is the transport rate, V_{MAX} (fmol cell^{-1} day^{-1}) is the maximum transport rate, S (mmol L^{-1}) is the chemical concentration, and K_M (mmol L^{-1}) is half-saturation constant. Active uptake systems are typically designed for and specific to a chemical. However, under certain circumstances other chemicals can be transported by the uptake system by mistake. The equation can be modified for the case where different substances (e.g., phosphate and arsenate) are taken up by the same transport system (competitive inhibition), and for the case where an internal compound slows the reaction (noncompetitive inhibition), using methods from enzymology. In addition, kinetic data sometimes reveal multiple uptake systems for one compound, and the ability of organisms to switch systems on/off.

Empirical Models

The chemistry- and biology-type models discussed above are based on theoretical or known relationships, like molecular diffusion in the case of passive excretion, and those models are therefore classified as mechanistic. Empirical modeling is an alternative approach, based entirely on data. That is, the model is constructed with the objective of reproducing an observed pattern, and little or no attention is paid to the mechanistic correctness of the model equation(s). If a mechanistic understanding of every detail of a process is known, there is really no reason to adopt the empirical approach. However, when a process is too complex and unknown, the empirical approach may be the only viable alternative. Unfortunately, this is the rule rather than the exception in biogeochemistry and many operational models therefore contain at least some empirical components. Consider, for example, the temperature dependence of the endogenous respiration rate of akinetes (resting stage cells) of the cyanobacterium *Anabaena circinalis* shown in Fig. 4. If we do not know the mechanism(s) responsible for the observed pattern, we may simply accept that fact and construct an equation that fits the data. The line in Fig. 4 corresponds to a simple two-part equation with a slope of 0.0055 below 30°C and -0.0035 above that. Although this modeling exercise did not further our mechanistic understanding of the endogenous respiration process, it did provide us with a simple means of predicting the rate, which may be useful and needed as a component of a larger mechanistic ecological model or for management purposes.

Since we have already admitted that our model has no mechanistic basis, the form of the equation (e.g., linear, exponential) is not important, and other empirical approaches are available (e.g., neural networks) that are not based on equations at all. However, it is generally accepted that models should be as simple and with as few parameters as possible. Also, since empirical modeling is based entirely on data, it is generally considered to be less transferable to conditions outside of those used to develop the model. So we should not apply our empirical model for akinete respiration to temperatures higher than 45°C, other experimental conditions (e.g., higher/lower nutrient concentration), or other species (e.g., *Anabaena flos-aquae*).

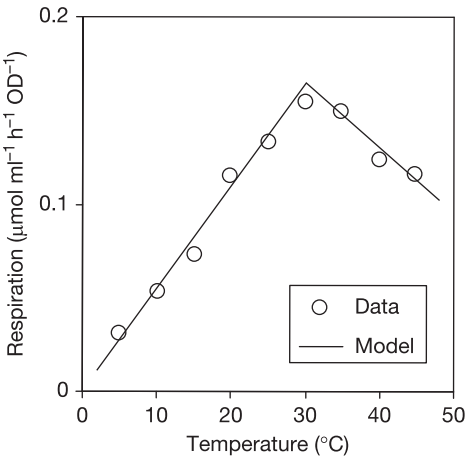

Fig. 4 Temperature dependence of the endogenous respiration rate of *Anabaena circinalis* akinetes. Data from Fay, P. (1988). Viability of akinetes of the planktonic cyanobacterium *Anabaena circinalis*. *Proceedings of the Royal Society of London B* **234**, 283–301.

Integrated Ecology and Biogeochemistry Models

Biogeochemical models are most useful when integrated into larger biogeochemical cycling models, which requires integration with physical and ecological models. Here, the integration with ecological models is discussed in some detail.

Interactions of benthic pelagic coupling are another facet of biogeochemical modeling. Processes and interactions between water column and sediment have long been neglected in the study of biogeochemical modeling. In last few decades, general models included the relationship of fluxes among particulate deposition and bottom-water composition to sediment–water exchange of oxygen and nutrients (e.g., Jahnke *et al.*, 1982; Rabouille and Gaillard, 1991; Ruardij and Van Raaphorst, 1995; Soetaert *et al.*, 1996a), alkalinity and total inorganic carbon (e.g., Boudreau, 1987; Archer, 1991; Hales *et al.*, 1994; Jahnke *et al.*, 1994, 1997; Cai *et al.*, 1995) and silica (e.g., Vanderborght *et al.*, 1977; Schink and Guinasso, 1980; Boudreau, 1990).

Generally, there should be no constraint to combine these models to water column biogeochemical models. However, research on deep sea sediment has got much attention and studies are restricted to steady state condition. A number of non-steady-state models have also become accessible. These models are capable to represent the dynamics of fluxes of sediment–water exchange and coupling to water column models (e.g., Rabouille and Gaillard, 1990; Sayles *et al.*, 1994; Boudreau, 1996; Soetaert *et al.*, 1996b; Jahnke, 1998; Wijsman *et al.*, 2002).

Role of Ecological Models in Biogeochemical Research

Ecological models play an important role in biogeochemical research, as illustrated in **Fig. 5**. Often, the starting point of biogeochemical research projects are field studies where certain spatial or temporal patterns are noticed. Those studies prompt controlled laboratory experiments that often more clearly demonstrate functional relationships and provide kinetic data on processes. Based on those studies, biogeochemical process models are developed. In this sequence of events, the laboratory experiments and process model development were motivated by the desire to understand the field data, and they do provide a qualitative understanding of the field data. However, a more quantitative understanding of the field data is often desired, which can be achieved by integrating the biogeochemical process model into a full ecological model and used it to simulate the field data. This, in turn, will identify further knowledge gaps and the cycle continues. Therefore, ecological models, and their integration with biogeochemical process models, are essential for biogeochemical research.

For example, the study of carbon and nitrogen cycle in the mangrove estuarine system (Mukherjee *et al.*, 2013; Mandal *et al.*, 2009) are illustrated here.

Both the studies follow the process-based numerical simulation modeling approach to understand the dynamics of the state variables and calibration and validation to the models have been applied using data collected from the field.

The transport of organic matter (OM) from terrestrial to aquatic system is a key link in the global biogeochemical cycle (Smith and Hollibaugh, 1993). One of the major transferable organic carbon reservoirs on the planet is dissolved organic carbon (DOC) pool in the oceans. Coastal waters and the wetlands can serve as source and sink of carbon, as well; thus, act as crucial link in the cyclic pathway. The rate and direction carbon flux among the carbon pools are also important (Mitsch and Gosselink, 2000). Particulate and dissolved organic matter (POM and DOM) from mangroves can provide energy and nutrients to the heterotrophic communities of adjoining estuarine and marine ecosystems (Odum and Heald, 1975). Through the process of photosynthesis carbon is trapped into the ecosystem. Eventually, following various biological and physical processes this carbon is transferred to the soil all the way through litter fall, root turnover or death of plants and hence, make up for the substrate for the formation of soil organic carbon (Kirschbaum, 2000).

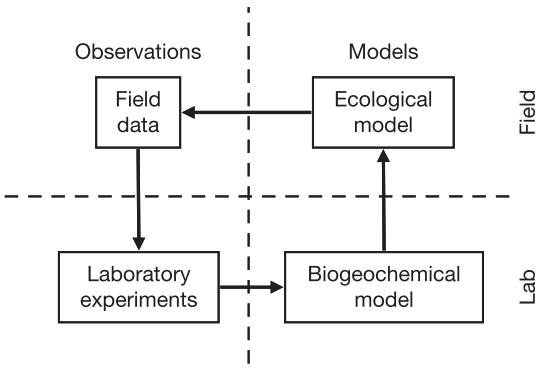

Fig. 5 Role of ecological models in biogeochemical research.

Ionized dissolved inorganic carbon (*DIC*) includes dissolved carbon dioxide (DCO_2), dissolved bicarbonte (*DBC)*. The organic pools take in dissolved organic carbon (*DOC*) and particulate organic carbon (*POC*) (Wetzel, 2001).

These models are the endeavors to assess the role of input of nitrogen and carbon from Sundarban mangrove litter to adjacent Hooghly estuary. For this purpose, two models were constructed to understand the dynamics of nitrogen and carbon up to the formation of dissolved inorganic carbon *(DIC)* and dissolved inorganic nitrogen (*DIN*) respectively from mangrove litterfall via the formation of detritus. The studies looked after following objectives:

(i) Experimentally determining different forms of nitrogen and carbon present in litter, soil and estuarine water.
(ii) Finding out the transformation rates from one form to another for nitrogen and carbon, mineralization rate of detritus and input rate of *DIN* and *DIC* to the adjacent estuary.
(iii) To construct the conceptual and quantitative models of nitrogen and carbon dynamics, that is, from litter nitrogen and litter carbon to dissolved inorganic nitrogen and dissolved organic carob in estuary via formation of detritus and its contribution to grazing food chain.
(iv) Assessment of important environmental factors presiding over litter nitrogen and carbon dynamics.
(v) Determination of sensitive parameters for nutrient dynamics.

Experiments have shown that the contribution of dissolved inorganic nutrients (nitrogen and carbon) to the Hooghly–Matla estuary from adjacent Sundarban mangrove forest is reliant on high litter production and breakdown of detritus. Litter degradation and subsequent uptake of nutrients by the autotrophs are the source of energy in this system. Benthic macrofauna, mainly gastropods, anaemons, bivalves, crabs, polychaetes, nemerteans, plays a noteworthy role by taking first step in degradation of dead organisms and also consumes about 61% and 39% of primary and secondary production respectively (Ghosh, 2001). Litter decomposition leads to the formation detritus which supports detritus food chain. Complete degradation and decomposition of mangrove litter contribute to the inorganic nutrient pool. This is vital to augment the growth of phytoplankton and other higher plants which in turn, enhance the production of zooplankton and other aquatic fauna of higher trophic levels in the estuary.

Decomposed dead, decaying parts of plants and animals enrich the *SOC* and *SON* pool. Increased temperature in premonsoon accelerates microbial activity which in turn results higher values of SIC and *SIN* in premonsoon and the opposite condition is seen in postmonsoon.

Extent of DCO_2 flux is chiefly regulated by two processes—photosynthetic uptake and respiratory release which are in turn, reliant upon various factors like allochthonous input of labile organic matter, water residence time, sunlight availability, rates of community metabolism, temperature and nutrient load (Ahad *et al.*, 2008; Smith and Hollibaugh, 1993). The pathways of the carbon and nitrogen cycle are shown in **Figs. 6** and **7**.

Flux, distribution and fate of dissolved organic and inorganic nutrients are pivotal because these nutrients take part in primary production and global geochemical cycling (Mukherjee *et al.*, 2013). Dissolved organic nutrients are significant machinery to provide nutrients for both bacterial and phytoplankton productions (Seitzinger and Sanders, 1999). It is found from this study that exudation, a portion of primary production of phytoplankton has a recognized role in *DOC* dynamics. Some studies have revealed a positive correlation between river discharge and *DOC* concentration and an increase in *DOC* due to leaching from soil and plant litter during periods of high discharge (Goni and Gardner, 2003). The study also shows that leaching rate of *SOC* is a sensitive parameter in this estuarine region. *DOC* derived from allochthonous input accounts for more than 90% of organic carbon in the water column and is a key substrate for metabolism in the system (Cole *et al.*, 2002). Biological activities thoroughly link *DOC* and *POC* pools. According to the present model, benthic detritivorous animals have important influence upon the composition and dynamics of *POC* pool. Benthic invertebrates residing in forest beds and estuary nourish upon the decaying leaves and facilitate in degradation process. Microorganisms colonize on the incompletely decomposing leaves and dead bodies of the soil and aquatic animals. Invertebrates and detritivores mostly regulate the *POC* pool by their activities. Recalcitrant portion of POC is assumed to export during tidal flush.

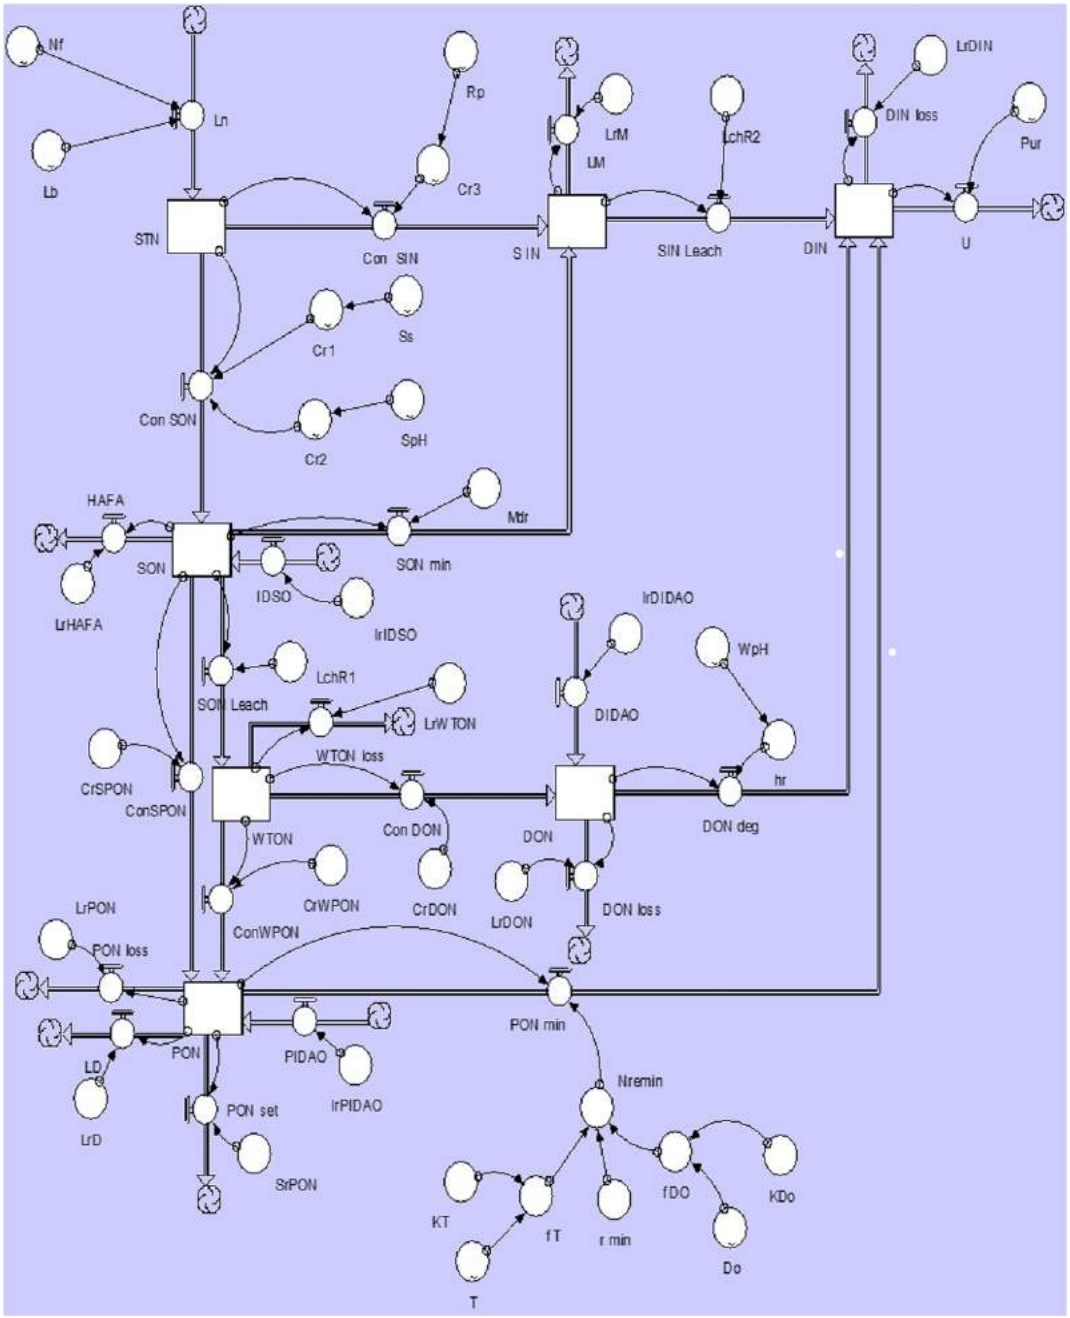

Fig. 7 Conceptual model of the contribution of dissolved inorganic nitrogen (*DIN*) from the litterfall of adjacent mangrove forest using STELLA 6.0 software.

In this estuarine system, the existence of *SIN* mainly depends upon temperature, redox potential of soil and microbial activity. *DON* undergoes degradation and forms *DIN* through pH dependent hydrolysis and the process is dependent upon water temperature and dissolved oxygen. Organic load from the *SON* pool enriches *DON* pool which is been utilized by bacteria. *DIN* is higher in monsoon and lower in premonsoon. In general, mineralization process is governed by dissolved oxygen and water temperature.

A huge data collected through the JGOFS and NASA ocean- color satellites programs are useful for testing and validating hypothesis integrated in model on ocean biogeochemistry. A coupled model of global ocean describing the general circulation, biogeochemistry and radiation of oceans were validated using the satellite data sets. In the model biogeochemical processes were determined through the dynamics of circulation and turbulence, availability of solar irradiance and the exchanges among multiple phytoplankton functional groups (diatoms, chlorophytes, cyanobacteria, and coccolithophores) and four nutrients (nitrate, ammonium, silica, and dissolved iron) in order to analyze its efficiency. In this way, shortcomings in our knowledge and assumptions could be identified, by taking into consideration the global ocean biogeochemical models in a holistic approach (Gregg *et al.*, 2003).

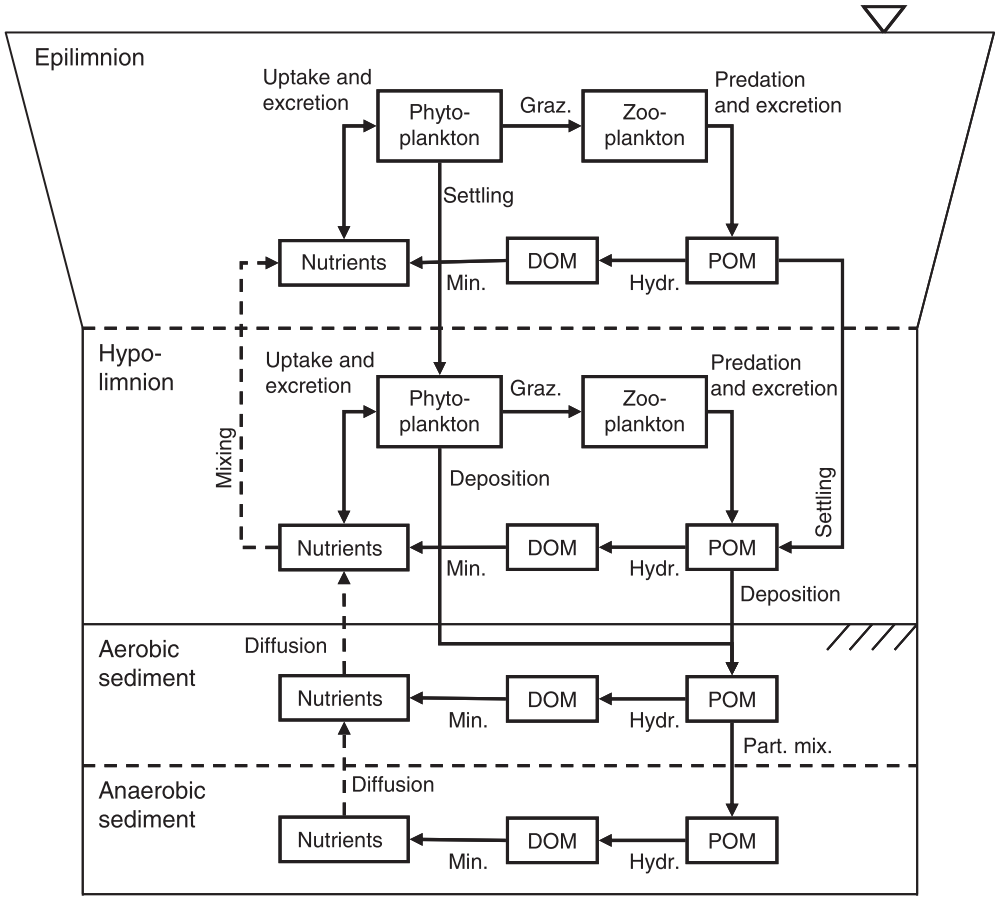

Fig. 8 Schematic of a typical integrated ecological and biogeochemical model. Some components (e.g., herbivorous and carnivorous zooplankton), reactions (e.g., DOM excretion), and transport pathways (e.g., phytoplankton mixing) are omitted from this illustration for simplicity. Integrating Ecological and Biogeochemical Models

The degree of complexity to be incorporated into the ecosystem model serves as equilibrium between superfluous detail and unjustified simplification (Flynn, 2001). Now, there lies serious need to recognize ecosystem model structures and formulations that are geographically transferable, that is, are pertinent over a number of varied ecosystems. There remain a trade-off between the complexity and realism of a model and to the extent to which it can be controlled with the given data (Friedrichs *et al.*, 2007).

The integration of ecological and biogeochemical models can be challenging, because they typically use different modeling approaches. Although ecological models have traditionally used a population-level approach, individual-based approaches are becoming more common. In individual-based models (IBMs) (also called agent-based models, ABMs), the individual members of the population are simulated separately. Each wolf or moose is an independent entity, that moves, eats, reproduces, dies, etc., and a population-level behavior emerges as a result of the action of individuals. This is in contrast to population-level models that modify population-level properties, like the total number of wolfs and moose, directly. Chemical and biogeochemical models typically use a population-level modeling approach, although there is now a movement of individual-based modeling for microorganisms, like algae and bacteria.

Example 1: Aquatic Environment

An important practical management problem that has led modelers to construct linked ecological–biogeochemical models is cultural eutrophication, the excessive growth of algae due to anthropogenic input of nutrients. The cause of eutrophication is typically increased levels of nutrients (phosphorus, nitrogen), which are chemical quantities—a chemical modeling problem. However, the problem manifests itself by increased number of algae, the dynamics of which are often controlled by zooplankton—an ecological modeling problem. Models that address this problem have traditionally been constructed by extending the chemistry concepts to phytoplankton and zooplankton. That is, the algae are quantified as concentration and their growth is conceptualized as a chemical reaction between them and the nutrients. A typical flow diagram for a lake eutrophication model is presented in Fig. 8, which shows

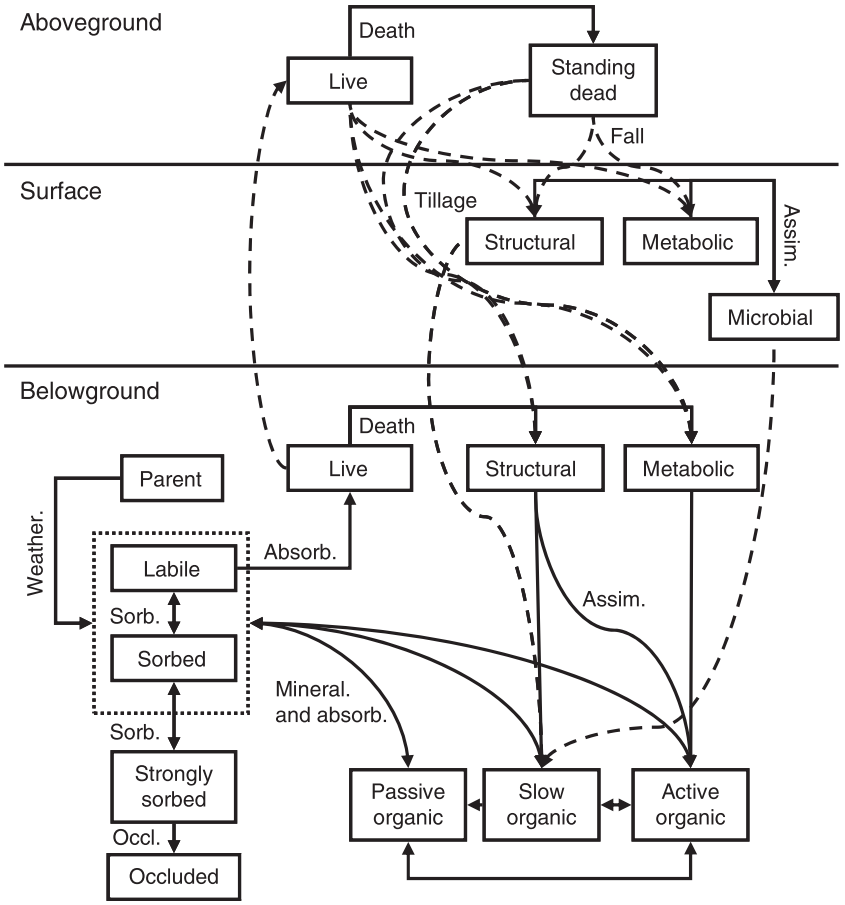

Fig. 9 Schematic of the CENTURY integrated ecological and biogeochemical model for the terrestrial environment. Some transport pathways (e.g., leaching, harvesting) are omitted for clarity.

the state variables (boxes) and processes (arrows) in the various spatial compartments. The spatial segmentation consists of two layers in the water column and two layers in the sediment bed. In the water column, the surface layer (epilimnion) is separated from the bottom layer (hypolimnion) by the seasonal thermocline. In the sediment bed the aerobic layer is separated from the anaerobic layer by the depth of oxygen penetration. The model accounts for nutrients, phytoplankton, zooplankton, particulate organic matter (POM), and dissolved organic matter (DOM). The number of state variables is typically larger than the number of boxes shown in Fig. 8. That is because the models typically track various elements (C, N, P, and Si) individually in each of the components. For P, for example, the state variables can be the concentrations of PO_4 (nutrient), phytoplankton P, zooplankton P, particulate organic P (POM), and dissolved organic P (DOM). Dissolved oxygen and sulfide are also often simulated. Important transport pathways include phytoplankton and POM settling from the epilimnion to the hypolimnion where they decay to DOM and then nutrients. The nutrients are mixed back into the epilimnion when the lake overturns. Phytoplankton and POM also deposit to the sediment bed, where they decay to DOM and nutrients, which diffuse out of the sediment. Important reactions include phytoplankton uptake and excretion of nutrients. The phytoplankton are grazed by zooplankton, which results in the phytoplankton biomass being assimilated by the zooplankton or excreted as detritus (POM). Zooplankton die by predation from higher organisms, which also produces POM. POM hydrolyzes to DOM, which mineralizes to nutrients.

Note that this model includes a zooplankton state variable, which is unusual. Most operational eutrophication models do not explicitly consider zooplankton, but rather implicitly include their effect on the algae by assigning a seasonally varying grazing rate. This is due to the functional complexity of zooplankton, which can, for example, enter stages of diapause or dormancy at various stages of their life cycle that can last from a month to over a decade.

Example 2: Terrestrial/Soil Environment

Linked biogeochemical and ecological models also exist for the terrestrial environment. The development and application of those models is motivated by the desire to understand how terrestrial ecosystems respond to changes in management (e.g., crop rotation, fertilization) and/or climate (e.g., increased CO_2, temperature). A typical P flow diagram for a terrestrial model is presented in Fig. 9. Live plant P is divided into above and below (i.e., roots) ground pools. Upon death above ground, P is moved to a standing dead pool, which can fall to become surface litter in structural or metabolic pools (different decay rates). A surface microbial pool

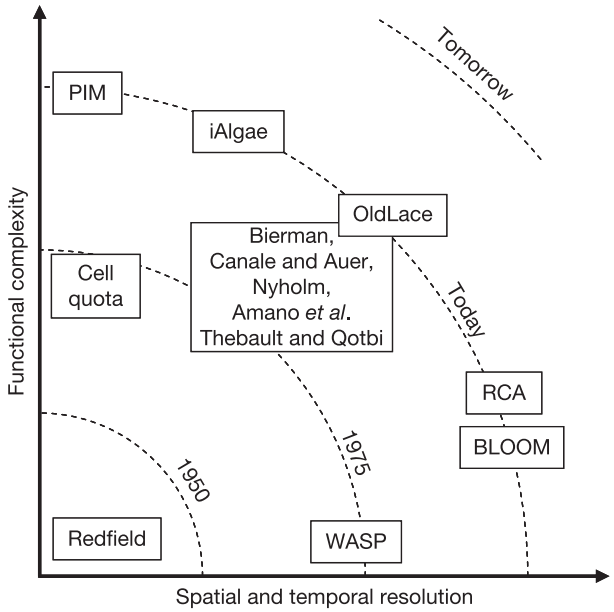

Fig. 10 Resolution and complexity of integrated ecological and biogeochemical models. For simplicity only selected models are included. More detailed information on the specific models is included in the references listed in the References and Further reading section.

is associated with the surface litter. Upon death below ground, P is moved to belowground, structural or metabolic pools. Other soil organic matter is divided into active, slow, and passive pools with different decomposition rates.

Various inorganic forms of P are simulated. Labile P is in equilibrium with sorbed P, and sorbed P is in equilibrium with strongly sorbed P, which in turn is lost to occluded P. Weathering of parent material P (e.g., apatite) results in labile and sorbed P.

Consider, for example, a potential history of a P molecule leached from the parent material. It enters the labile/sorbed pool, where it may become absorbed by the roots of a tree, transported above ground and incorporated into a branch. When the tree dies, it may stand for some time (standing dead), but eventually it will fall and the P molecule may become part of the surface structural pool. If it is not decomposed by surface microbes, it will become part of the belowground, slow organic pool. Below ground it may be absorbed by microbes and enter the active organic pool, which may die and release the molecule back to the labile/sorbed pool.

Past, Present, and Future of Integrated Ecological and Biogeochemical Modeling

This section reviews the past, present, and future of integrated ecological and biogeochemical models. The Redfield relation introduced above can be considered to be the simplest integrated ecological/biogeochemical model. Following the work of Redfield, significant improvements were made to this model in basically two dimensions: (1) spatial and temporal resolution and (2) functional complexity, as illustrated in **Fig. 10**. A similar perspective on the advancement of ecological modeling in Saginaw Bay is shared by V. Bierman:

> Model development is proceeding along two parallel pathways. The first of these involves the development of research-oriented process models, which include biological and chemical detail but which, for simplicity, do not include any spatial detail. The second pathway involves the development of an engineering-oriented water quality model that mimics, as closely as practicable, the actual physical system, including spatial detail. At any given point in time, the water quality model will contain those chemical and biological processes that have previously been investigated and developed using the spatially-simplified model. There is constant feedback between these two pathways and constant interaction between the entire modeling effort and an ongoing sampling effort on Saginaw Bay.

Application of biogeochemical models has a reasonably wide range to solve various problems (Jørgensen and Bendoricchio, 2001); such as, optimization of biological treatment plant (Snape *et al.*, 1995), to recover ground water contamination (covered in National Research Council, 1990), to sort out acidification problem (Alcamo *et al.*, 1990), Forest growth and yield (Vanclay, 1994), air pollution (Gryning and Batchvarova, 2000; Baldasano *et al.*, 1994), to optimize agriculture (France and Thornley, 1984).

It is useful to mention a number of models in **Fig. 10**, because they constitute significant milestones. The introduction of the WASP (Water Quality Analysis and Simulation Program) model represented a significant improvement in model resolution. Further advances in resolution, and the state of the science of today, are represented by the RCA (Row-Column Aesop) and BLOOM models. These models are typically set up with a high spatial and temporal resolution (thousands of

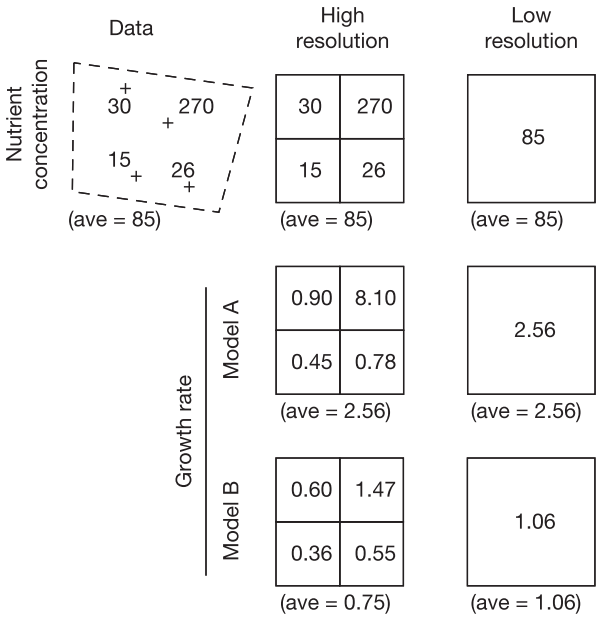

Fig. 11 Illustration of scaling problem. Nutrient concentration, S (nmol L^{-1}); specific growth rate, μ (day^{-1}); model A: $\mu = \mu_{MAX}S/K_m$; model B: $\mu = \mu_{MAX}S/(K_m + S)$; maximum specific growth rate, $\mu_{MAX} = 1.8\ day^{-1}$; half-saturation constant, $K_m = 60$ nmol L^{-1}.

mass balance compartments). Functional model complexity varies mainly in the way nutrient uptake and cell composition are simulated. At the lowest level, there is net uptake (uptake–excretion) of nutrients and a fixed "Redfield" cell composition. Departures from this model were motivated by the realization that phytoplankton composition is variable, and as a result various "variable stoichiometry" or "variable composition" models were developed. At an intermediate level of complexity one variable (e.g., total algal P) is used to describe the composition of the algae. Those models are commonly called "cell quota" models, where the cell quota is the mass of nutrient per cell. At a high level of complexity, models explicitly account for uptake and excretion and various species of the nutrients (e.g., PO_4, polyphosphates, etc.) and reactions in the algal cells. The phosphate interaction model (PIM), for example, has three state variables for intracellular P (soluble inorganic P, polyphosphate, structural and soluble organic P). Variable phytoplankton composition models have been integrated with spatially and temporally explicit models, as exemplified by the Bierman and other similar models. Increasing the spatial and temporal resolution and functional complexity of models can be problematic and for that reason, IBMs, like iAlgae, are being constructed as a potential alternative to the traditional population-level models. Individual-based modeling of algae and bacteria is a current research topic and will likely be a significant factor in future modeling in the area of integrated ecological and biogeochemical modeling.

Grand Challenge: Saling Problem

An important problem in ecological and biogeochemical modeling is related to scale. To illustrate this "scaling problem," consider the illustrative case of nutrient-limited grass growth on a field. The soil nutrient concentration was measured at four locations, roughly equally spaced and representative of an equally large portion of the field, as shown in **Fig. 11** (top left). Two different models are used to estimate the growth rate. Model A is linear and has the form $\mu = \mu_{MAX}S/K_m$, and model B is the nonlinear Monod equation introduced above. Both models are applied at two different scales or resolutions. The high-resolution application (middle column) has four segments each corresponding to one measurement, and the low-resolution application (right column) has one segment with a nutrient concentration equal to the average of the four measurements. When model A is applied, the growth rates are different, but average out to the same value, regardless of the resolution of the model (middle row). This is an important point: linear models are scale insensitive and the resolution can be chosen freely to suit other needs, like the availability of input data, desired resolution of output data, computing resources, etc. The output from model B for the low- and high-resolution applications does not average out to the same value (bottom row). That is because nonlinear models are scale sensitive. Applying them to the same data at different resolutions will produce different results, and the model resolution can not be chosen freely. The underlying mathematical theory is known as "Jensen's inequality."

In future, the scaling problem will become increasingly important as (1) the spatial and temporal resolution of data increases as a result of advances in in situ and remote-sensing technology, and (2) process models are becoming increasingly functionally complex and nonlinear. The heterogeneity of terrestrial and soil environments is well known, but increasingly recognized as

Box 2 Descriptive model of arsenic transformation by phytoplankton

The transformation of arsenic by phytoplankton is linked to the uptake of phosphate. Algae actively take up As(V) ($AsO(OH)_3$) because they cannot differentiate it from phosphate ($PO(OH)_3$). However, because As(V) is toxic, the algae has to detoxify it, which is done by reduction to As(III), methylation to MMA and DMA, and excretion. The end product of the overall transformation reaction is a function of the phosphorus nutrient status of the algae. Under P-limited conditions the algae take up As(V), reduce it to As(III), methylate it to MMA and DMA, and then excrete it as DMA. Under P-replete conditions the algae upregulate their phosphate transport system (luxury uptake), and since As(V) is taken up by the phosphate transport system, it is also taken up at higher rates. The reduction to As(III) is fast, but the methylation is slower, causing As(III) to build up in the cell and be excreted into the medium.

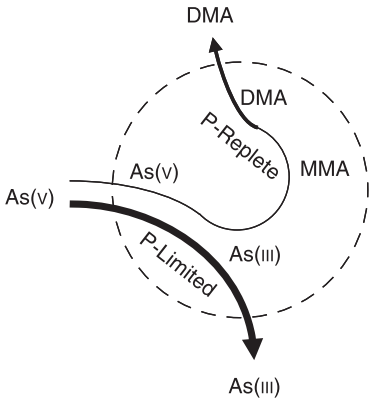

Fig. 12 Conceptual model of arsenic transformation by phytoplankton.

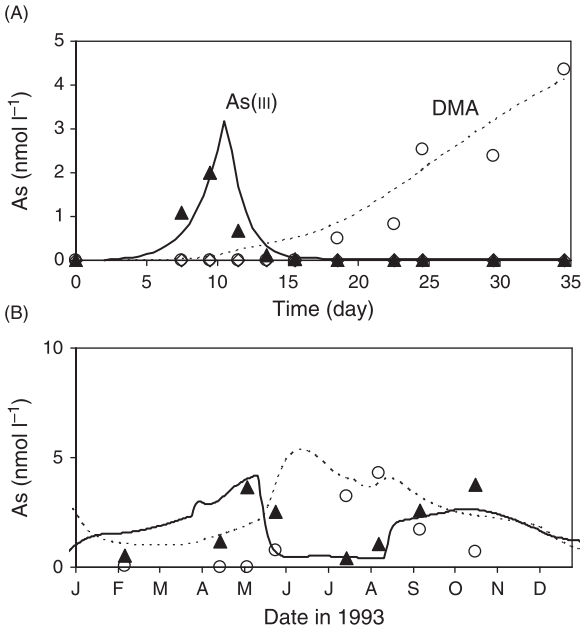

Fig. 13 Simulated and observed transformation of arsenic by phytoplankton in (A) a laboratory batch experiment and (B) Lake Biwa, Japan.

important in the aquatic environment. Two-dimensional imaging fluorometers capture spatial phytoplankton variability of almost an order of magnitude at subcentimeter scale. Moored sensors record fluctuations in phosphate concentration of over an order of magnitude within the course of a day. Phytoplankton models simulate intracellular speciation and transformation among multiple nitrogen species. Models consider luxury uptake of nutrients and trace elements, their intracellular transformation and

excretion. These two trends in spatial and temporal resolution and functional complexity are on a direct "collision course" with the scaling problem. This is one of the grand challenges of integrated ecological and biogeochemical modeling.

Case Study: Arsenic Transformation by Phytoplankton

Recent models (Aumont and Bopp, 2006; Le Quéré *et al.*, 2005; Moore *et al.*, 2004) make out between different plankton functional types (silicifiers, N-fixing plankton, calcifiers, zooplankton of different size-classes) and nutrient-limited conditions (Fe).

Transformation of arsenic by phytoplankton constitutes an interesting case study of coupled ecological and biogeochemical modeling. Arsenic can exist in a number of species, including arsenate (As(V)), arsenite (As(III)), methylarsonate (MMA) and dimethylarsinate (DMA). Under oxygenated conditions As(V) is the only thermodynamically stable form, and the other species spontaneously demethylate and oxidize to As(V). However, early field observations in the Pacific Ocean revealed that, although As (V) is the predominant form, other species are present at relatively high concentrations, meaning that there has to be a process continuously producing them. Algae were identified as being responsible for the transformation. In addition, field and laboratory data revealed that the end product of the transformation reaction varies and is a function of the growth rate and/or nutrient status of the algae. A model was proposed for the transformation of arsenic by phytoplankton, which is presented in Box 2 and **Fig. 12**.

A quantitative biogeochemical model has been developed for transformation of arsenic by phytoplankton using the concepts presented above. The model simulates uptake using the Michaelis–Menten equation modified for competitive inhibition and upregulation (luxury uptake). The model was calibrated to laboratory data. The results, presented in **Fig. 13**A, illustrate that the model captures the major temporal patterns in the data, including the production of As(III) early and DMA later in the experiment. Then, the model was integrated with an ecological model and used to simulate arsenic speciation in a lake. The results, presented in **Fig. 13**B, illustrate that the model captures much of the major temporal patterns in the field data, including spring and fall increases of As(III) and higher DMA in the summer.

Carbon Biogeochemical Cycle and Consequences of Climate Changes☆

Vladimir N Bashkin, Institute of Physico-Chemical and Biological Problems of Soil Science RAS, Moscow, Russia; Institute of Natural Gases and Gas Technologies—Gazprom-VNIIGAZ, Moscow, Russia

Introduction

Cyclic processes of exchange of carbon mass are of particular importance for the global biosphere, both in terrestrial and oceanic ecosystems especially owing to the close connections to the global climate changes.

This element is distributed in the atmosphere, water and land as follows. According to existing data there are 6160×10^9 tons or 1.4×10^{16} mol of CO_2 in the atmosphere (1680×10^9 tons of C). A major source of atmospheric carbon dioxide is respiration, combustion, and decay, compared with oxygen, whose main source is photosynthesis. In its turn, an important sink of CO_2 is photosynthesis (about 66×10^9 tons/year or 1.5×10^{15} mol/year). Since carbon dioxide is somewhat soluble in water ($K_H = 3.4 \times 10^{-2}$ mol/L/atm), exchange with the global ocean must also be considered. The approximate global balance of atmosphere–ocean water exchange is 7×10^{15} mol/year (308×10^9 tons/year) being taken up and 6×10^{15} mol/year (264×10^9 tons/year) being released in different parts of the oceanic ecosystem. The residence time of CO_2 in atmosphere is about 2 years, which makes the atmospheric air quite well mixed with respect to this gas. However, a more recent analysis shows that the terrestrial ecosystems have much stronger sinks of carbon dioxide uptake.

In the global ocean, along with occurrence in living organisms, carbon is present in two major forms: as a constituent of organic matter (in solution and partly in suspension) and as a constituent of exchangeable inorganic ions HCO_3^-, CO_3^{2-}, and CO_2.

$$CO_2(g) \leftrightarrow H_2CO_3(aq) \leftrightarrow -H^+/+H^+ \leftrightarrow HCO_3^-(aq) \leftrightarrow -H^+/+H^+ \leftrightarrow CO_3^{2-} \leftrightarrow +Ca^{2+} \leftrightarrow CaCO_3(s)$$

The amount of CO_2(aq) in the oceans is sixty times that of CO_2(g) in the Earth's air, suggesting that the oceans might absorb most of the additional carbon dioxide being injected at present into the atmosphere. However, there are some drawbacks restricting this process. First of all, CO_2 uptake into surface oceanic waters (0–100 m) is relatively slow ($t_{1/2} = 1.3$ years). Secondly, these surface waters mix with deeper waters very slowly ($t_{1/2} = 35$ years). Consequently the surface oceanic waters have the capacity to remove only a fraction of any increase in the anthropogenic CO_2 loading (Fig. 1).

The known analytical monitoring data obtained over many years at the Mauna Loa Observatory in Hawaii, a location far from any anthropogenic sources of carbon dioxide pollution, show a pronounced 1 year cycle of CO_2 content (Fig. 2).

One can see the peak about April and then through around October each year. These data indicate that the content of carbon dioxide in the Earth's atmosphere is not perfectly homogeneous. Some explanations would be of interest to understand this figure.

Hawaii is in the Northern Hemisphere where the photosynthetic activity of vegetation is maximal in summer time (May–September). In this period CO_2 is removed from the air a little bit faster than it is added. The reverse situation occurs during the winter. This is a reasonable explanation and accordingly the monitoring stations in the South Hemisphere show the highest concentration of CO_2 in October, and the lowest in April (see http://mlo.hawaii.gov).

A gradual increase in the partial pressure of carbon dioxide over the last decades is clearly pointed out from Fig. 2. The value of $p(CO_2)$ was ca. 315 ppmv in 1958, it had reached 350 ppmv in 1988, ab. 370 in the beginning of 21th century and ab. 400 at present. Accordingly, this trend can give a doubling of carbon dioxide content in the Earth's atmosphere sometime during the end of the 21st century and this seems reasonable prediction.

Here we should refer to the opinion of some other authors who have argued that increased CO_2 levels in the atmosphere may be a consequence of atmospheric warming, rather than the cause. The statistical analysis of various authors (see "Further Reading" section) led to the conclusion that, although there is a correlation between $p(CO_2)$ and global temperatures, the changes in $p(CO_2)$ appear to lag behind the temperature change by ca. 5 months. A possible explanation, if this trend is proved correct, would be that natural climatic variability like the solar activity alters the temperature of the global Ocean, which contains about 90% of total CO_2

☆*Change History:* February 2018. V. Bashkin made edits throughout the text. Figures 2 and 3 have been replaced with a more up to date versions.

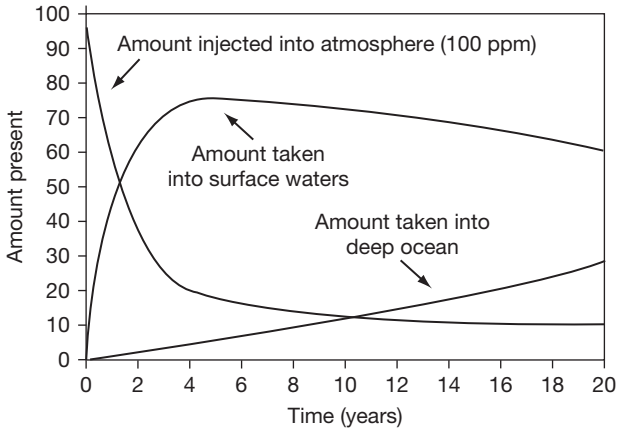

Fig. 1 Calculated uptake of CO_2 from atmosphere to the surface and deep oceanic waters. From Holsten, K. (1992). The global carbon cycle. In: Butcher, S. S., Charlson, R. J., Orians, G. H. & Wolfe, G. V. (eds.) *Global biogeochemical cycles*, pp 239–316. London: Academic Press.

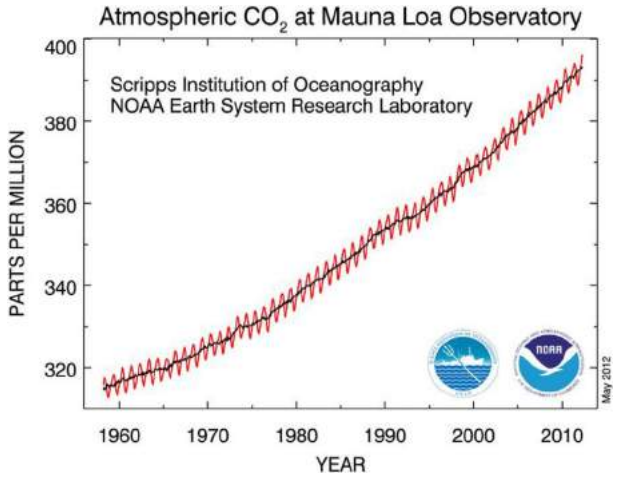

Fig. 2 Observations of CO_2 concentration at the Mauna Loa Observatory for the period of 1958–2012.

mass. In turn, this leads to increase of CO_2 flux from the warmer oceanic water to atmosphere in accordance with the Henry law. Moreover, now the solar activity is decreasing and accordingly the increase $p(CO_2)$ might be changed to the opposite process.

Turnover of Carbon in the Biosphere

As it has been pointed out earlier, the terrestrial ecosystems are the main sink of carbon dioxide due to the photosynthesis process. The present bulk of living organisms is confined to land, and their mass (on dry basis) amounts to 1880×10^9 tons. The average carbon concentration in the dry mater of terrestrial vegetation is 46% and, consequently, the carbon mass in the land vegetation is about 865×10^9 tons.

In accordance with various estimates, the oceanic biomass of photosynthetic organisms contains 1.7×10^9 tons of organic carbon, C_o. In addition, we have to include a large number of consumers. This gives 2.3×10^9 tons of C_o. Totally, the oceanic organic carbon is equal 4.0×10^9 tons or about 0.5% from that in land biomass.

Moreover, a substantial amount of dead organic matter as humus, litter fall and peat is also present in the terrestrial soil cover. The mass of forest litter is close to 200×10^9 tons, mass of peat is around 500×10^9 tons and that of humus, 2400×10^9 tons. Recalculation of this value for organic carbon amounts to 1550×10^9 tons.

However, the greatest amount of carbon in the form of hydrocarbonate, HCO_3^-, ($38{,}600 \times 10^9$ tons) is contained in the ocean, 10 times higher than the total carbon in living matter, atmosphere, and soils.

Thus, in the terrestrial ecosystems the least amount of carbon is monitored in living biomass, followed by dead biomass and atmosphere.

Table 1 Mass distribution of carbon in the Earth's crust

Earth's compartments	*Mass, 10^{18} tons*	*Average concentration, %*			*Mass, 10^{15} tons*				
		CO_2	*C_c*	*C_o*	*CO_2*	*C_c*	*C_o*	*$C_c + C_o$*	*Ratio of C_c/C_o*
Total Earth's crust	28.5	1.44	0.38	0.07	409	108	20	128	5.4
Continental type	18.1	1.48	0.40	0.08	267	72	14	86	5.1

Table 2 The major global carbon reservoirs

Reservoirs	*C, 10^9 tons*
Atmosphere, CO_2	1680
Global land	
Vegetable biomass prior to human activity (estimates)	1150
Present natural vegetable biomass	900
Soil cover	
Forest litterfall	100
Peat	250
Humus	1200
Total	1550
Ocean	
Photosynthetic organisms	1.7
Consumers	2.3
Soluble and dispersed organic matter	2100
Hydrocarbonate ions in solution	38,539
Total	40,643
Earth's crust	
Sedimentary shell, C_o	15,000,000
Sedimentary shell, C_c	81,000,000
Continental granite layer, C_o	4,000,000
Continental granite layer, C_c	18,000,000
Total	118,000,000
Total present global C mass	118,044,773

The mass distribution of carbon in the Earth's crust is of interest for understanding of the global biogeochemistry of this element. These values are shown in Table 1. One can see that carbon from carbonates (C_c) is the major form. The C_c/C_o ratio is about 5 for the whole Earth's crust as well as for its main layers (sedimentary, granite, and basalt) and crustal types: continental, sub-continental and oceanic. However, for the latter this ratio is higher.

The sedimentary layer of the Earth's crust is the main carbon reservoir. The C_c and C_o concentrations in the sedimentary layer are by an order of magnitude higher than in granite and basalt layers of lithosphere. The volume of sedimentary shell is about 0.10 from the crust volume, however, this shell accounts for 75% of both carbonate and organic carbon. Dispersed organic matter contains most of the C_o mass. Localized accumulation of C_o in oil, gas, and coal deposits are of secondary importance. It has been estimated that the oil/gas fields amount of 200×10^9 tons of carbon, and the coal deposits contains 600×10^9 tons, totally 800×10^9 tons. This is by three orders of magnitude less than the carbon mass of dispersed organic matter in the sedimentary shell. The general carbon distribution between reservoirs is shown in Table 2.

Thus, there are two major reservoirs of carbon in the Earth: carbonate and organic compounds. It should be stressed that both are of biotic origin. Non-biotic carbonates, for instance, from volcanoes, are the rare exception of the rule. A connecting link between the carbonate and organic species is CO_2, which serves as an essential starting material for both the photosynthesis of organic matter and the microbial formation of carbonates.

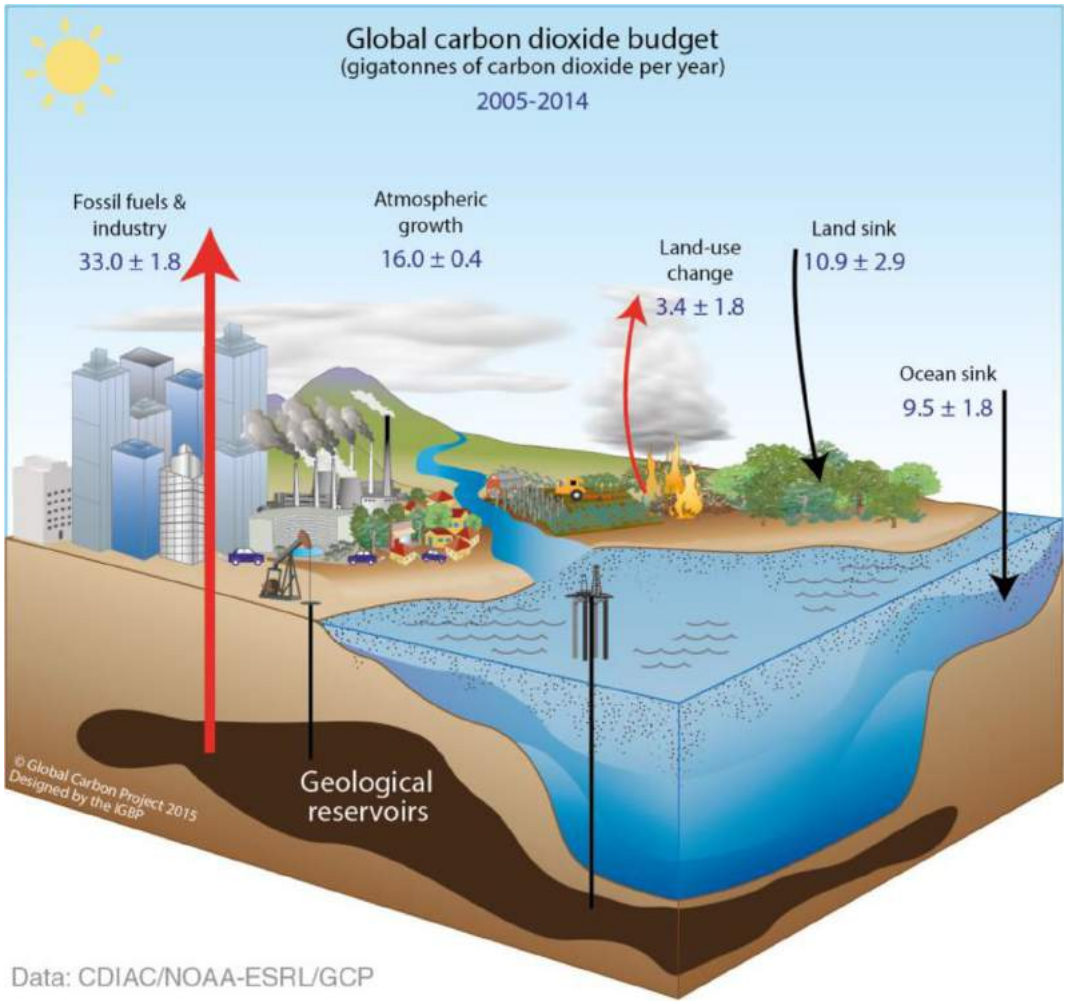

Fig. 3 The global carbon cycle, showing the reservoirs (in 10^9 tons per year) relevant to the anthropogenic perturbation as annual averages over the period 2005–14.

Atmospheric CO_2 provides a link between biological, physical, and anthropogenic processes. Carbon is exchanged between atmosphere, the ocean, the terrestrial biosphere, and, more slowly, with sediments and sedimentary rocks. The faster components of the cycle are shown in Fig. 3.

The component cycles (Fig. 3) are simplified and subject to considerable uncertainty (compare with Table 2, for example). In addition, this figure presents average values. The riverine flux, particularly the anthropogenic portion, is currently very poorly qualified and is not shown here. While the surface sediment storage is approximately 150×10^9 tons, the amount of sediment in the bioturbated and potentially active layer is of order 400×10^9 tons. Evidence is accumulating that many of the key fluxes can fluctuate significantly from year to year (e.g., in the terrestrial sink and storage). In contrast to the static view conveyed by figures such as this one, the carbon system is clearly dynamic and coupled to the climate system on seasonal, inter-annual and decadal time scale.

The carbonate formation and photosynthesis have to be considered as two general processes in the global activity of living matter over geological history of the Earth. The C_c-to-C_o mass ratio may specify the "growth limit" of living matter at sequential stages of Earth's geological history over the period of 3.5–3.8 billion years. This ratio tends to decrease regularly with the last 1.6 billion years. The C_c/C_o ratio was 18 in the sedimentary layers of the Upper Proterozoic period (1600–750 million years); that of the Paleozoic (570–400 million years), 11; of the Mesozoic (235–66 million years), 5.2, and of the Cainozoic (66 million years to the present), 2.9. The never interrupted increase in the relative content of organic matter in the ancient stream loss provides evidence for a progressively increasing productivity of terrestrial photosynthetic organisms. This provides also the proof for growing importance of global terrestrial ecosystems in fixation of CO_2. Apparently, the increasing productivity of land vegetation would be the major sink of CO_2 under the increasing content of this green-house gas in the atmosphere, however, the role of increasing input of nitrogen, for instance, with atmospheric deposition, has to be considered. Moreover, both carbonate formation and the photosynthesis of organic matter share in the common tendency for removal from the atmosphere of CO_2 continually supplied from the mantle.

Table 3 Net primary production of the Earth's major ecosystems

Global ecosystem zone	*Area, 10^6 km^2*	*Plant mass, 10^9 tons*	*C-NPP, 10^9 tons*
Polar	8.1	13.8	1.3
Coniferous forests	23.2	439.1	15.2
Temperate	22.5	278.7	18.0
Subtropical	24.3	323.9	34.6
Tropical	55.9	1347.1	102.5
Total land	133.9	2402.1	171.6
Lakes and rivers	2.0	0.04	1.0
Glaciers	13.9	0	0
Total continents	149.3	2402.5	172.6
Oceans	361.0	0.2	60.0
Earth total	510.3	2402.7	232.6

Consequently these processes take part in the global mechanisms for maintaining the present low concentration of carbon dioxide in the Earth's gas shield, which is an essential parameter in the greenhouse effect.

Carbon Fluxes in Terrestrial Ecosystems

All three CO_2-controlling processes (ocean soaking, photosynthesis and carbonate formation) play an important role in maintaining equilibrium in the biosphere–atmosphere–hydrosphere system. The photosynthetic process is of great importance for living plants and microorganisms. The difference between total photosynthesis and respiration processes is defined as "net primary production," NPP. The global NPP distribution in the Earth's major ecological zones is shown in Table 3.

Oceans, despite their much larger surface area, contribute much less than half of the global NPP. The reason is related to highly nutrient deficiency in surface waters, which limits the photosynthesis process. Oceanic production is mainly concentrated in coastal zones, especially where upwelling of deep water brings the nutrients (P and N, of major interest) into the surface layer, 0–100 m. On land the photosynthetic process is also often limited by nutrient deficit, however, the influence of water storage and low temperature plays more important role. That is why subtropical and tropical ecosystems contribute much more to global NPP than their proportional share.

The amount of annually decaying organic matter is the subject of speculation. However, some estimates might be done. For instance, in terrestrial ecosystems only, the humus accumulation of carbon in soils is about 70% of the total accumulation of CO_2 in the atmosphere. We may presume therefore that the stable long-lived humic compounds acquire some 30% of carbon annually from the dead organs of plants, and the complete renewal of humus in soils extends over period of $0.3–1.0 \times 10^3$ years. The variance depends on the moisture and temperature conditions in the region of question.

Terrestrial biomass is divided into a number of sub-reservoirs with different turnover times. Forest ecosystems contain 90% of all carbon in living matter on land but their NPP is only 60% of the total. About half of the primary production in Forest ecosystems is in the form of twigs, leaves, shrubs, and herbs that only make up 10% of the biomass. Carbon in wood has a turnover time of the order of 50 years, whereas these times for carbon in leaves, flowers, fruits, and rootlets are less than a few years. When plant material becomes detached from the living plant, carbon is moved from phytomass reservoir to litter. "Litter or litterfall" can refer to a layer of dead plant material on the soil surface. A litter layer can be a continuous zone without sharp boundaries between the obvious plant structures and a soil layer containing amorphous organic carbon. Decomposing roots are a kind of litter that seldom receives a separate treatment due to difficulties in distinguishing between living and dead roots. Total litter is estimated as 60×10^9 C and total litterfall as 40×10^9 tons C/year. The average turnover time for carbon in litter is thus about 1.5 years, although for tropical ecosystems with mean temperature above 30°C, the litter decomposition rate is greater than the supply rate and so storage is impossible. For colder climates, NPP exceeds the rate of decomposition in the soil and organic matter in the form of peat is accumulated. The total global amount of peat might be estimated at 165×10^9 tons C. Average temperature at which there is a balance between production and decomposition is about 25°C.

Humus is a type of organic matter in terrestrial ecosystems that is not readily decomposed and therefore makes up the carbon reservoir with a long turnover time (300–1000 years). An assessment of the various carbon pools for a temperate grassland soil is presented in Fig. 4.

The undecomposed litter (4% of the soil carbon) has a turnover time measured in tens of years, and the 22% of the soil carbon in the form of fulvic acids is intermediate with turnover times of hundreds of years. The largest part (74%) of the soil organic carbon (humic acids and humins) also has the longest turnover time (in thousands of years).

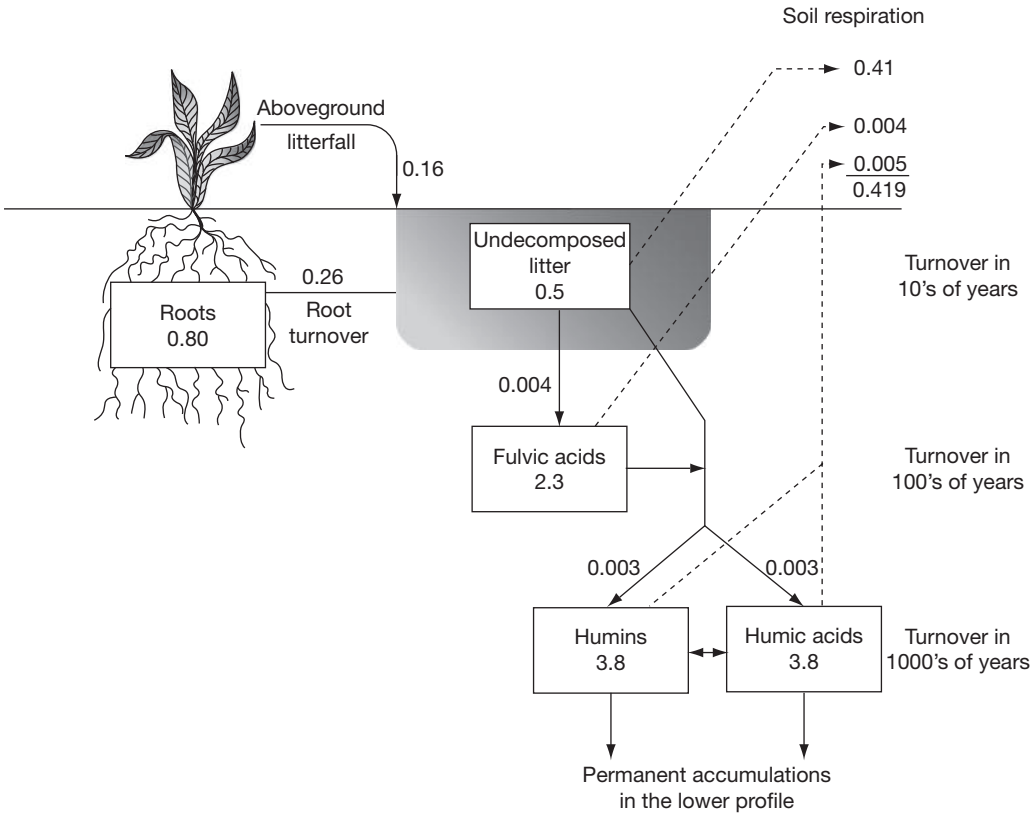

Fig. 4 Detrital carbon dynamics for the 0–20 cm layer of chernozem grassland soil. Carbon pool (kgC/m^2) and annual transfers (kgC/m^2/year) are shown. Total profile content down to 20 cm is 10.4 kgC/m^2.

Comparison of Carbon Biogeochemical Processes in Terrestrial and Aquatic Ecosystems

The synthesis and degradation of organic matter in the ocean are significantly distinct from those in terrestrial ecosystems. The phytoplankton provides for a larger part of photosynthetic organic matter. The dry mass of phytoplankton is three orders of magnitude less than global terrestrial mass, whereas the annual production is only about three times smaller. This can be related to the much faster life cycles of plankton organisms in comparison with the terrestrial vegetation.

Let us consider the renewal of terrestrial and oceanic organic matter. The terrestrial biomass might be assessed as 2400–2500 $\times$ 10^9 tons of dry organic matter and annual production as 170–175 $\times$ 10^9 tons. These values present a period of 13–15 years for complete renewal of organic matter. In the oceans, the problem is much more complicated. The various authors give 8–10-fold discrepancy in the existing estimates of phytoplankton productivity and biomass. It is estimated also that phytoplankton mass cycle takes 1–2 days to be completed. Taking this into account, we can reasonably consider that the renewal of the total biomass in the global ocean takes about 1 month. Based on modern assessments, the annual production of photosynthesis varies from 20–30 $\times$ 10^9 to 100 $\times$ 10^9 tons of organic carbon and the average values are 50–60 $\times$ 10^9 tons C_o. Furthermore, we can hypothesize that the plankton-synthesized organic matter is almost completely assimilated in subsequent upper food webs. Thus, the organic precipitation would not exceed 0.1 $\times$ 10^9 tons. These calculations present the annual uptake of terrestrial and oceanic living organisms of about 440 $\times$ 10^9 tons CO_2 or 120 $\times$ 10^9 tons C_o. Most of this amount recycles into the ocean and atmosphere.

Carbon Dioxide Interactions in Air-Sea Water System

The interaction between carbon dioxide in the atmosphere and the hydrosphere is the principal factor for understanding large carbon biogeochemical cycles. As it has been mentioned above, the gases of the troposphere and the surface layer of the ocean persist in a state of kinetic equilibrium.

Compared with the atmosphere, where most carbon is presented by CO_2, oceanic carbon is mainly present in four forms: dissolved inorganic carbon (DIC), dissolved organic carbon (DOC), particulate organic carbon (POC), and the marine biota itself.

DIC concentrations have been monitored extensively since the appearance of precise analytical techniques. When CO_2 dissolves in water it may hydrate to form H_2CO_3(aq), which, in turn, dissociates to HCO_3^- and CO_3^{2-}. This process depends on pH and specification is shown in Fig. 5.

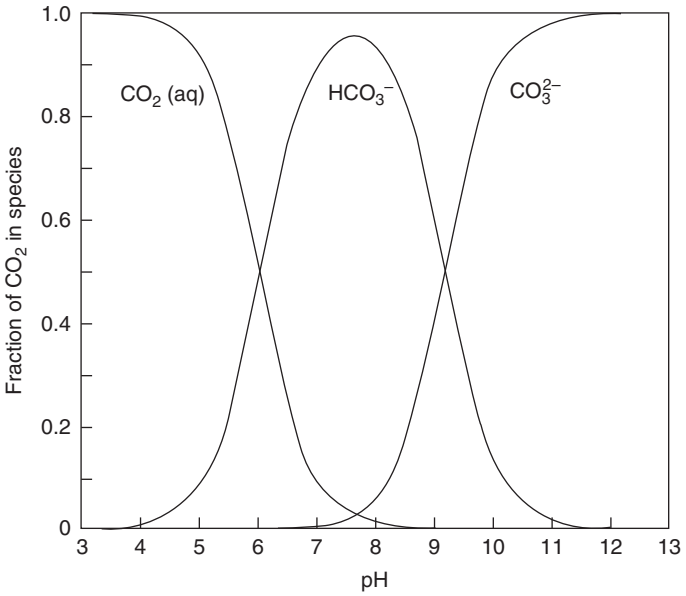

Fig. 5 Distribution of dissolved carbon species in seawater as a function of pH at 15°C and a salinity of 35‰. Average oceanic pH is about 8.2.

The conjugate pairs responsible for most of the pH buffer capacity in marine water are HCO_3^-/CO_3^{2-} and $B(OH)_3/B(OH)_4^-$. Although the predominance of HCO_3^- at the oceanic pH of 8.2 actually places the carbonate system close to a pH buffer minimum, its importance is maintained by the high DIC concentration (~2 mm). Ocean water in contact with the atmosphere will, if the air-sea gas exchange rate is short compared to the mixing time with deeper water, reach equilibrium according to Henry's Law. At the pH of oceanic water around 8.2, most of the DIC is in the form of HCO_3^- and CO_3^{2-} with a very small proportion of H_2CO_3. Although H_2CO_3 changes in proportion to CO_2 (g), the ionic form changes little as a result of various acid–base equilibrium.

From chemical aqueous carbon specification, the alkalinity, Alk, representing the acid-neutralizing capacity of the solution, is given by the following equation:

$$Alk = [OH^-] - [H^+] + [B(OH)_4^-] + [B(OH)_3] + 2[CO_3^{2-}]$$

Average DIC and Alk concentrations for the World's Ocean are shown in Fig. 6.

With an average DIC of 2.35 mmol/kg seawater and the world oceanic volume of 1370×10^6 km^3, the DIC carbon reservoir is estimated to be $37{,}900 \times 10^9$ tons C. The surface waters of the World's ocean contain a minor part of DIC, $\sim 700 \times 10^9$ tons C. However, these waters play an important role in air-deep water exchange (see above).

Oceanic surface water is everywhere supersaturated with respect to the two solid calcium carbonate species calcite and aragonite. Nevertheless, calcium precipitation is exclusively controlled by biological processes, specifically the formation of hard parts (shells, skeletal parts, etc.). The very few existing amounts of spontaneous inorganic precipitation of $CaCO_3$(s) come from the Bahamas region of the Caribbean.

The detrital rain of carbon-containing particles can be divided into two groups: the hard parts comprised of calcite and aragonite and the soft tissue containing organic carbon. The composition of the soft tissue shows the average ratio of biophils as P:N:C:Ca:S = 1:15:131:26:50, with C_c:C_o ratio as 1:4.

The estimation of C_c and C_o mass annually eliminated from the biogeochemical cycles in ocean is a very uncertain task. The carbonate–hydrocarbonate system includes the precipitation of calcium carbonate as a deposit:

$$\begin{array}{lc} \text{Atmosphere} & CO_2 \\ & \uparrow\downarrow \\ \text{Surface ocean layer} & H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \leftrightarrow H^+ + CO_3^{2-} + Ca^{2+} \\ & \uparrow\downarrow \\ \text{Deep ocean water} & CaCO_3 \end{array}$$

The binding of carbon into carbonates is related to the activity of living organisms. However, the surface runoff of Ca^{2+} ions from the land determines the formation of carbonate deposits to a significant degree. The Ca^{2+} ion stream is roughly 0.53×10^9 tons/year, which can provide for a $CaCO_3$ precipitation rate of 1.33×10^9 tons/year. This would correspond to the loss of 0.57×10^9 tons CO_2, or 0.16×10^9 tons C from the carbonate–hydrocarbonate system.

The surface runoff from the World's land plays an important role in the global carbon mass exchange. The continental runoff supply of HCO_3^- is 2.4×10^9 tons/year, that is, 0.47×10^9 tons/year for carbon. Besides, the stream water contains dissolved organic matter at 6.9 mg/L, which makes up to an annual loss of 0.28×10^9 tons/year. The average carbon concentration of suspended insoluble organic matter in the stream discharge is 5 mg/L, which gives the loss of about 0.2×10^9 tons/year. Most of

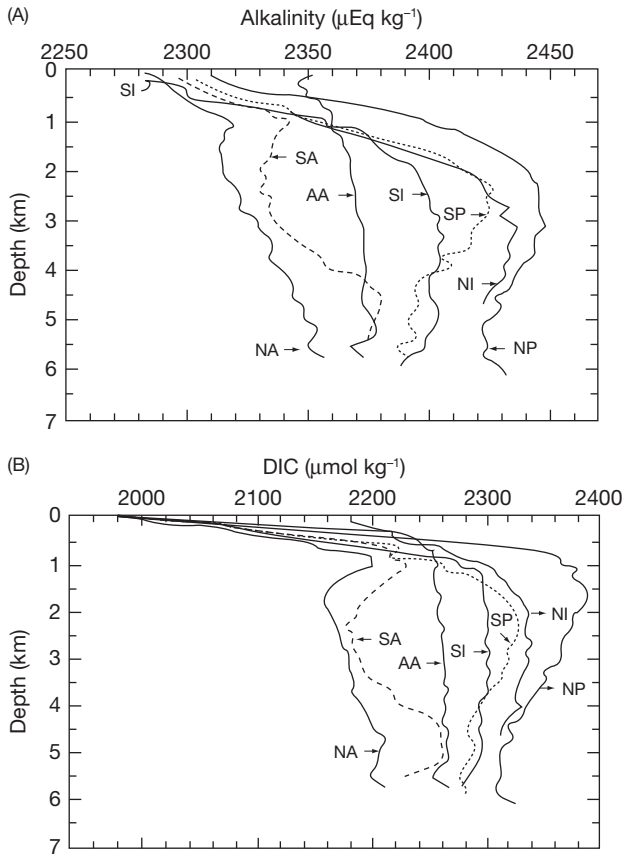

Fig. 6 The vertical distribution of alkalinity (A) and dissolved inorganic carbon in the World's Ocean. Ocean region are shown as NA (North Atlantic), SA (South Atlantic), AA (Antarctic), SI (South Indian), NI (North Indian), SP (South Pacific), and NP (North Pacific).

this mass fails to reach the open ocean and becomes deposited in the shelf and the estuarine delta of rivers. We can see that equal amounts of C_c and C_o (0.5×10^9 tons for each) are annually lost from the World's land surface.

The formation of carbonates and the accumulation of organic matter are not confined solely to ocean; these processes occur also on the land. The mass of carbonates annually produced in the soils of arid landscapes appears to be high enough.

Global Carbon Fluxes

Two large cycles determine global dynamics of carbon mass transport in the biosphere. The first of these is provided for by the assimilation of CO_2 and decomposition of H_2O through photosynthesis of organic matter followed by its degradation to yield CO_2. The second cycle involves the uptake—release of carbon dioxide by natural waters via chemical reactions of CO_2 and H_2O leading to build-up of a carbonate–hydrocarbonate system. The cycles are intimately related to the activity of living matter. The living matter of the biosphere, the global water cycle, and carbonate–hydrocarbonate system regulate the cyclic mass exchange of carbon between atmosphere, land, and ocean. These global carbon fluxes are shown in Table 4.

A specific feature of these two major biogeochemical cycles of carbon is their openness, which is related to the permanent removal of some carbon from the turnover as a dead organic matter and carbonates. The carbon burial in the sea deposits is of great importance for biosphere development.

There is a suggestion that the alteration of glacial and interglacial periods in the Pleistocene was mainly due to fluctuations of CO_2 in the atmosphere. It may be hypothesized that the spread of land ice and the drastic reduction of forest areas with their typically high biomass were favorable to an elevated content of carbon dioxide in the atmosphere and the subsequent climatic warming up. In its turn, the resulting contraction of glacial areas and reforestation was attended by an increased CO_2 uptake from the atmosphere and by its binding to the biomass and soil organic matter. The resulting effect was a gradual cooling and the onset of a new glaciation followed by reduction of forest areas and repetition of the whole cycle.

The role of carbon dioxide in the Earth's historical radiation budget merits modern interest in arising atmospheric CO_2. There are, however, other changes of importance. The atmospheric methane concentration is increasing, probably as a result of increasing

Table 4 Fluxes of carbon in the biosphere

Fluxes	*C, 10^9 tons/year*
World's ocean	
Turnover of planktonic photosynthesis organisms	50
CO_2 uptake by ocean	30
CO_2 release by ocean	30

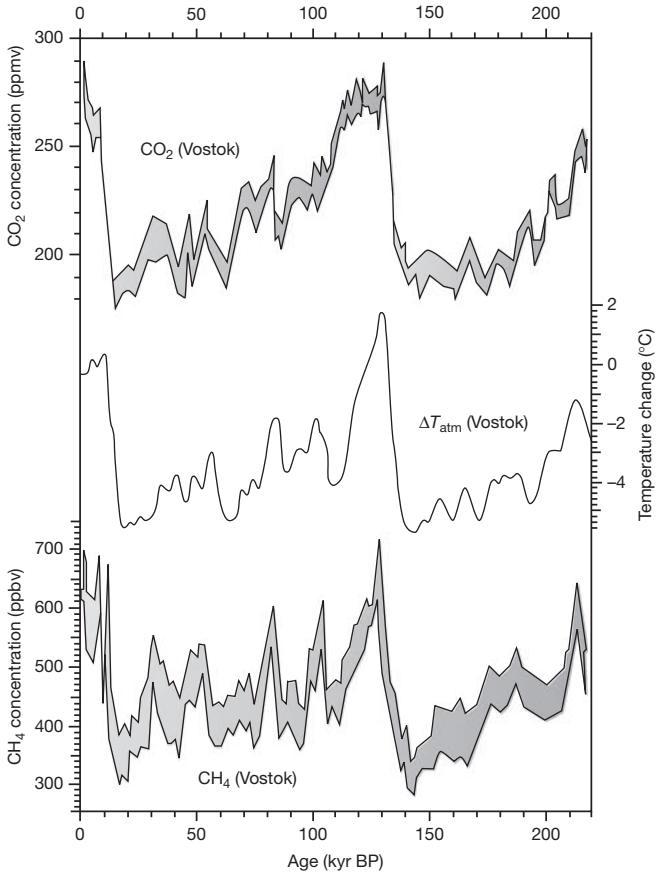

Fig. 7 Temperature anomalies and methane and carbon dioxide concentrations over the past 220,000 years as derived from the ice core records at Vostok, Antarctica.

cattle population, rice production, and biomass burning. Increasing methane concentrations are important because of the role they play in stratospheric and tropospheric chemistry. Methane is also important to the radiation budget of our planet.

Analyses of ice cores from Vostok, Antarctica, have provided new data on natural variations of CO_2 and CH_4 levels over the last 220,000 years. The records show a marked correlation between Antarctic temperature, as deduced from isotopic composition of the ice and the CO_2/CH_4 profiles (Fig. 7).

Clear correlations between CO_2 and global mean temperature are evident in much of the glacial-interglacial palaeo-record. This relationship of CO_2 concentration and temperature may carry forward into the future, possibly causing significant positive climatic feedback on CO_2 fluxes.

Global Climate Changes and Critical Loads of Sulfur and Nitrogen at the European Ecosystems

Global biogeochemical cycle of carbon and its alterations seemly attracted the great attention in the mass media due to CO_2 increase in the atmosphere is closely related to the various changes in the Earth biosphere. These changes include both climate changes and environmental pollution. Here we should mention a project on the integrated assessment of regional air pollution and climate change in Europe, AIR-CLIM project, which inter alia examined whether climate change will alter the effectiveness of agreed-upon or future policies to reduce regional air pollution in Europe. Climate changes and emission abatement strategy can be estimated using the calculations of pollutants critical loads and their exceedances (see "Further Reading" section).

A critical load has been defined as the maximum input of pollutants (sulfur, nitrogen, heavy metals, POPs, etc.), which will not introduce harmful alterations in biogeochemical structure and function of ecosystems in the long-term, that is, 50–100 years according to present knowledge. Starting from this general definition, methodologies have been developed during the 1990s by the working group on effects (WGE) under the Long-Range Transboundary Air Pollution (LRTAP) convention for calculating and mapping critical loads in Europe. This has been used by European countries to calculate critical loads of pollutants for various ecosystems (forests, surface waters, semi-natural vegetation).

Transboundary air pollution by sulfur, nitrogen, heavy metals and persistent organic species is not the only environmental problem calling for internationally agreed abatement policies. In developed countries, it is the issue of climate change, which currently attracts most attention and resources, and negotiations under the framework convention on climate change (FCCC) trying to come up with equitable mitigation policies. To date, climate change policies are mostly discussed in isolation. However, any measures taken (or not taken) to slow down global climate changes are likely to have an impact on other environmental problems.

Eight scenarios for different combinations of future green house gas (GHG), sulfur and nitrogen emissions, covering the years 1990–2100, were developed during the AIR-CLIM project (Table 5).

To assess the risk of ecosystem damage due to a given scenario, critical loads have to be compared with the resulting deposition patterns. Within the integrated assessment framework of AIR-CLIM, deposition fields due to emission scenarios are computed with the source-receptor matrices (SRMs) derived from the EMEP long-range atmospheric transport model. The SRMs derived for the meteorological years 1985–1996 were averaged to minimize the effects of inter-annual variability. With the aid of these SRMs, the sulfur and nitrogen ($NO_x + NH_3$) emissions of the European countries the respective depositions in every grid cell are computed. If the depositions are greater than critical loads, we say the critical loads are exceeded. While in the case of a single pollutant the exceedance can be defined in an obvious manner, for example, $Ex(Ndep) = Ndep - CLnut(N)$, there is no unique exceedance (i.e., amount of deposition to be reduced to reach non-exceedance) in the case of acidifying N and S.

Fig. 8 depicts the temporal development of the percentage of forest area for which critical loads of acidity and nutrient nitrogen are exceeded under the eight AIR-CLIM scenarios. The area for which critical loads are exceeded declines under all scenarios, starting from 41% for acidity critical loads and 75% for nutrient N in 1990. The speed decrease after 2010, however, differs between the two sets of scenarios, with larger decreases in the B1-set. In all the cases, the A1-P and the B1-450-A scenarios are the least and most stringent one, respectively, with the other scenarios giving intermediate results. The most striking conclusion is that acidification (almost) ceases to be a problem, with exceedance percentages in 2100 between 4.7% (A1-P) and 0.7% (B1-450-A). In drawing this conclusion it has to be borne in mind that considering the in-grid variability of deposition (e.g., by reducing the grid size) would certainly lead to higher exceedances. Furthermore, areas that cease to be exceeded at some point in time are not at once without the risk of adverse effects. The recovery of the chemical, and especially the biological, status of the soil is delayed due to finite buffers, which have to equilibrate with the lower deposition. Only dynamic models can provide estimates of the times needed for a full recovery.

Table 5 Overview of AIR-CLIM scenarios

Scenario	*Green house gas policies*	*SO_2/NO_x policies*
A1-P	None	Present policies
A1-A	None	Advanced policies
A1-550-P	To achieve 550 ppm CO2 stabilization	Present policies
A1-550-A	To achieve 550 ppm CO2 stabilization	Advanced policies
B1-P	None	Present policies
B1-A	None	Advanced policies
B1-450-P	To achieve 450 ppm CO2 stabilization	Present policies
B1-450-A	To achieve 450 ppm CO2 stabilization	Advanced policies

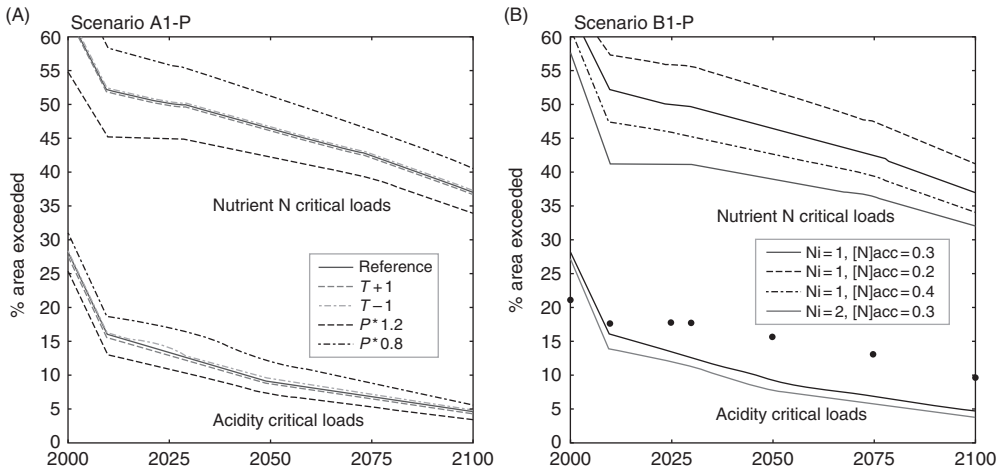

Fig. 8 Temporal development of the percentage of forest area for which the critical loads of acidity and nutrient nitrogen are exceeded for the four scenarios in the A1-set (*left*) and for corresponding four scenarios in the B1-set (*right*).

Eutrophication, on the other hand, continues to be a widespread problem, even under the most stringent scenario, which brings the exceedance hardly down to 15% of the forest area. This confirms the conclusion that nitrogen will be the main pollutant in need of future mitigation.

Summary

The changes in the global biogeochemical carbon cycle become more and more obvious however the relative contributions of natural and anthropogenic activities are still uncertain. However, the role of carbon dioxide in the Earth's historical radiation budget merits modern interest in arising atmospheric CO_2. The relative changes include both climate changes and environmental pollution.

Critical loads have been widely used to formulate European emission reduction policies for sulfur and nitrogen. The critical load values depend on the ecosystem characteristics that might be altered due to climate changes. An investigation of the impact of different scenarios of climate change on critical loads and their exceedances is of both scientific and political interests.

The recent estimates have shown that the acidity critical loads will be exceeded only in small parts of Europe under all scenarios. It should be borne in mind, however, that: (a) non-exceedance does not mean immediate recovery, and (b) higher resolution deposition fields, capturing some of their small-scale variability, would certainly lead to more widespread exceedances.

Eutrophication, on the other hand, will continue to be a problem even under the most stringent scenario. This confirms the important and increasing role nitrogen plays in environmental problems, both in its oxidized and reduced forms. Thus, research should focus on the effects of nitrogen in the environment, especially under conditions of climate change, whereas, policies should concentrate on further reductions of nitrogen emissions. This not only reduces acidification and eutrophication, but also helps curbing the formation of tropospheric ozone.

Climate Change Models[☆]

Andrey Ganopolski, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Introduction

This article presents an overview of the climate change, climate modeling, and future climate predictions. Of the subsequent sections, the first section discusses the concept of natural and anthropogenic climate change and the mechanisms causing climate variability. The second section, based on the results of paleoclimatological studies and observational data, presents an overview of past climate changes. The third section presents the scientific basis and the existing types of climate models. The fourth section discusses the prediction of future climate change based on the simulations performed with climate models and potential impact of global warming on natural ecosystem and human life.

Climate and Climate Change

Definition of Climate and Climate Change

Traditionally, the term "climate" referred to the averaged weather conditions, such as the mean July temperature or annual precipitation. For many applications it is important to know not only the averaged characteristics, such as monthly averaged temperature, but also different measures of variability (statistics), like the interannual variability of the precipitation or a number of extreme weather events. Thereby, more precisely the term climate is characterized as "the statistical description (of the climate system) in terms of the mean and variability of relevant quantities." Temporal evolution of the climate characteristics beyond the timescale of individual weather events is named "climate variability" while statistically significant trend of climate state on longer timescales (decades and more) is referred to as "climate change." For example, North Atlantic Oscillation (NAO) or El Niño/Southern Oscillation (ENSO) represents climate variability, while dramatic climate variations over past several million years associated with waning and waxing of the Northern Hemisphere ice sheets are the example of climate change. Pronounced trends of many climate characteristics recorded during the 20th century are primarily attributed to human influence on climate and hence represent anthropogenic climate change.

Natural Climate Variability and Anthropogenic Climate Change

It is known that climate has changed in the past and will change in the future under the influence of numerous natural factors such as changes of solar luminosity and orbital parameters of the Earth, volcano eruptions, changes in the atmospheric composition and Earth's geography. Apart from the response to change of external and internal factors, the climate experiences natural fluctuations,

[☆]*Change History*: March 2018. Todd T. M. Swannack updated references.

the so-called internal climate variability. It arises from the fact that the climate system is a strongly nonlinear system and even under constant external conditions posses permanent secular variations of the state variables. The most well known example is the instability of large-scale atmospheric circulation which gives rise to permanent generations of cyclonic and anticyclonic eddies which affect the weather over the globe. Interaction between several components of the climate system can also lead to development of more or less periodic self-sustained climate oscillations. The most known example is ENSO which originates from the interaction between the atmosphere and the ocean in the Tropics and affects a large part of the globe.

Natural climate factors, such as changes in the Earth's orbital parameters or volcanic eruptions, cause additional variations of climate state. Together with internal climate variability, they produce natural climate variability. The term "anthropogenic climate change" refers to the part of climate change attributed to all aspects of human activity, such as emission of greenhouse gases and aerosols, and land-cover changes. Anthropogenic climate change is added on the top of natural climate variability and separation of anthropogenic and natural climate variability still represents a formidable challenge since the magnitude of both types of climate variability are comparable.

Climate Forcings

There are many processes inside and outside of the Earth system which affect climate. On the timescales from billion years to decades, the climate is affected by changes in solar luminosity, composition of the atmosphere, volcanic activity, changes in the position of the continents, and variations of the Earth's orbital parameters. Changes in the internal and external (for the Earth system) factors which directly affect climate are often referred to as "climate forcing." Climate forcing can be quantified in term of "radiative forcing," defined as an energy imbalance imposed on the climate system by changes of given factor. For example, a doubling of CO_2 concentration causes globally averaged imbalance at the top of the troposphere of about 4 W m^{-2}. Radiative forcing is a convenient measure to compare climate impact of different factors, such as changes in concentration of greenhouse gases and aerosols but not all climate forcings can be easily expressed in term of radiative forcing. For example, variations of the Earth orbital parameters cause large changes in seasonal distribution of incoming solar radiation but their globally averaged direct effect on energy balance of the planet is rather small. However, due to a number of strongly nonlinear climate feedbacks associated with the ice sheets and greenhouse gases, the variations in the Earth's orbital parameters caused significant climate changes over the past several millions of years.

While some of climate forcings, such as the Earth orbital parameters or solar luminosity, are external for the Earth system, changes in atmospheric composition on the timescales of thousand years are internal ones and represent internal climate feedbacks to external forcing. For example, the growth of large ice sheets under varying Earth orbital parameters caused widespread cooling, which, in turn, leads to an enhanced carbon uptake by the ocean and a lowering of atmospheric CO_2 concentration. This, in turn, cools climate additionally and facilitates further growth of the ice sheets.

Since the last century human activity became an important factor of climate change. The most important anthropogenic climate forcing is the change in atmospheric composition of the so-called greenhouse gases: CO_2, CH_4, N_2O, and others. Apart from that, burning of fossil fuel and forest leads to an increase of atmospheric concentration of several types of aerosols. It is believed that the net effect of anthropogenic aerosols is cooling and hence aerosols partly compensate the warming effect of greenhouse gases. Changes in land cover (land use), primarily via deforestation of the large part of the continents, also affect climate. The direst effect of deforestation is a cooling, but since deforestation also contributes to an increase of CO_2 concentration, the sign of temperature changes related to deforestation depends on the regions. Atmospheric pollution by several chemicals also affects tropospheric and stratospheric concentration of ozone. The former is increasing under the influence of anthropogenic factors while the latter is decreasing which contributes to the development of the so-called "ozone hole" that represents the direct danger for human health.

Past Climate Changes

Climate Change on Geological Timescale

Paleoclimate records provide rich information about temporal evolution of climate on different timescales. Reconstructions of past climate changes are now extensively used as a test bed for the climate models to assess their performance for the climate conditions different from the present one. Past climate changes have also been used to assess climate sensitivity to change in the atmospheric CO_2 concentration. At last, past climate changes clearly demonstrate a strongly nonlinear response of the climate system to gradual changes in external forcing and hence indicate a possibility of the existence of some thresholds, crossing of which could lead to irreversible climate change.

On the geologic timescales (tens and hundreds of million years), paleoclimate records provide a strong support to the dominant control of the atmospheric CO_2 concentrations on the Earth's climate, although other factors, such as changes in Earth's geography, also played an important role. Over the past tens of million years climate progressively cooled, and some 3 million years ago a periodic widespread glaciation of the Northern Hemisphere began. The cycles of waning and waxing of the Northern Hemisphere ice sheets became progressively stronger and longer with time (Fig. 1A). The last million years were dominated by 100,000-years cyclicity, the nature of which is still not fully understood. However, a strong coupling between ice volume and CO_2 concentrations (Fig. 1B) suggests that the latter represent an important feedback in the climate system amplifying and shaping the glacial cycles.

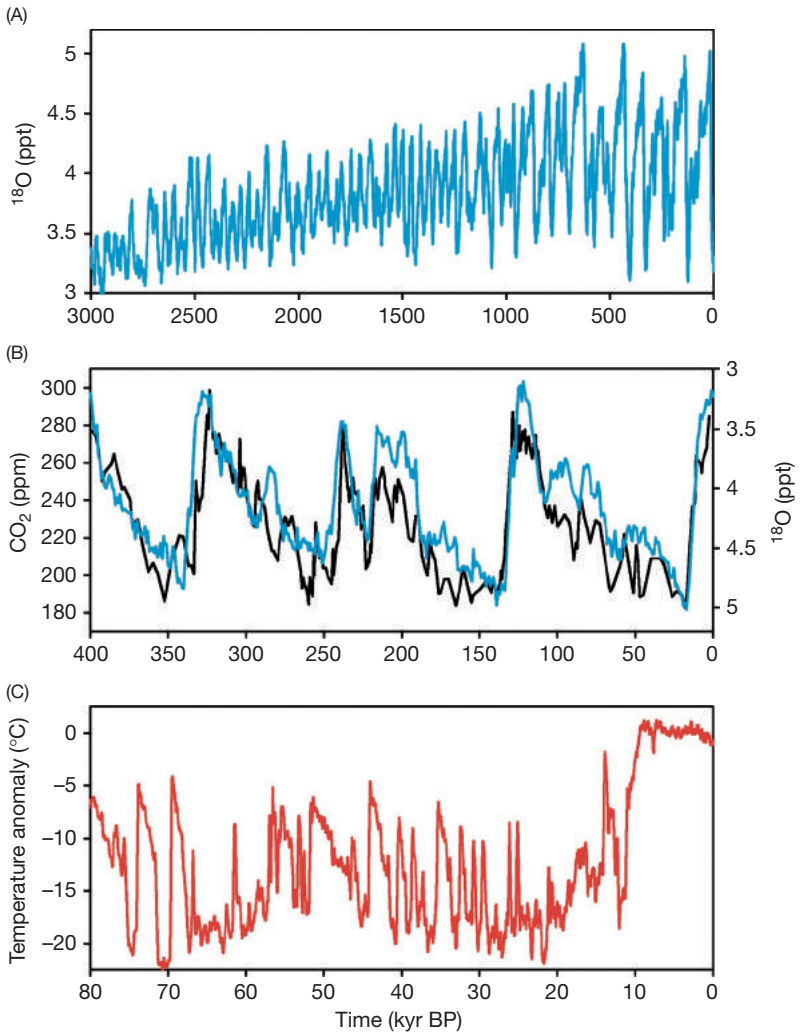

Fig. 1 Past climate changes on different timescales. (A) Temporal variations of ^{18}O isotope concentration in marine sediments over the past 3 million years. This isotope represents a proxy for the global ice volume. (B) Variations of CO_2 concentration in ppm (*black line*) versus variations of global ice volume (*blue line*) over the past 400,000 years. (C) Greenland temperatures from the GRIP ice core during the last 80,000 years. Ice volume data are from Lisiecki, L.E. and Raymo, M.E. (2005). A Pliocene–Pleistocene stack of 57 globally distributed benthic $\delta^{18}O$ records. *Paleoceanography* **20**, https://doi.org/10.1029/2004PA001071; concentration of CO_2 is from Petit, J.R., Jouzel, J., Raynaud, D., et al. (1999). Climate and atmospheric history of the past 420,000 years from the Vostok ice core, Antarctica. *Nature* **399**, 429–436; and Greenland temperature record is based on Daansgard, W., Claussen, H.B., Gundestrup, N., et al. (1982). A new Greenland deep ice core. *Science* **218**, 1273–1277.

During the peak of the last glacial cycle, about 21,000 years BP, the globally averaged temperature was about 5°C below present, with a large portion of this cooling explained by a lowering of the concentration of the major greenhouse gases. In particular, atmospheric CO_2 concentration at that time was only two-thirds of its preindustrial value and almost one-half of the current CO_2 concentration.

Abrupt Climate Changes

Analysis of the Greenland ice cores and the North Atlantic marine sediment cores performed in the early 1990s revealed that climate changes in this region were everything but gradual. Reconstruction of Greenland temperature during the last glacial cycle shown in Fig. 1C reveals pronounced instability of the climate system on millennial timescale. Most of this temperature record with a notable exception for the last 10,000 years is punctuated by numerous rapid warming events known as Dansgaard–Oeschger events. These events are characterized by extremely rapid warming with the magnitude exceeding 10°C, that is, more than a half of the glacial–interglacial temperature variations observed in Greenland. Although the strongest climate signal associated with Dansgaard–Oeschger events were recorded in Greenland and in the Northern Atlantic, synchronous climate variations have been found in many other places around the world. Analysis of paleoclimate data and model simulations suggests that these abrupt

climate changes are related to the rapid reorganizations of the Atlantic thermohaline circulation and events of massive iceberg discharge into the Atlantic Ocean from surrounding ice sheets.

Due to very different climate conditions of the glacial age as compared to the present ones, abrupt climate changes which occurred in the past cannot be considered as a direct analog for the future "greenhouse" world but they represent an important evidence for the potential instability of two components of the climate system—the thermohaline ocean circulation and the ice sheets. These two components of the climate system are considered by many experts as the prime suspects for dangerous and irreversible future climate changes.

Climate Change During 20th Century

Historical data based on meteorological observations over the last hundred years clearly show a warming trend on the global and hemispheric scales as well as over most regions and for all seasons. In accordance with observational data, the globally averaged surface temperature has increased by *c*. 0.6°C during the 20th century (Fig. 2). In some regions, especially over the continents in the middle and high latitudes of the Northern Hemisphere, the temperature has risen much faster than the globally averaged.

Although observed temperature rise represents the most direct manifestation of climate change during the last century, other climate characteristics related to the hydrological cycle, cryosphere, and extreme weather events also have experienced detectable trends. These changes are not only important as additional indicators of global warming, but also because they affect natural and

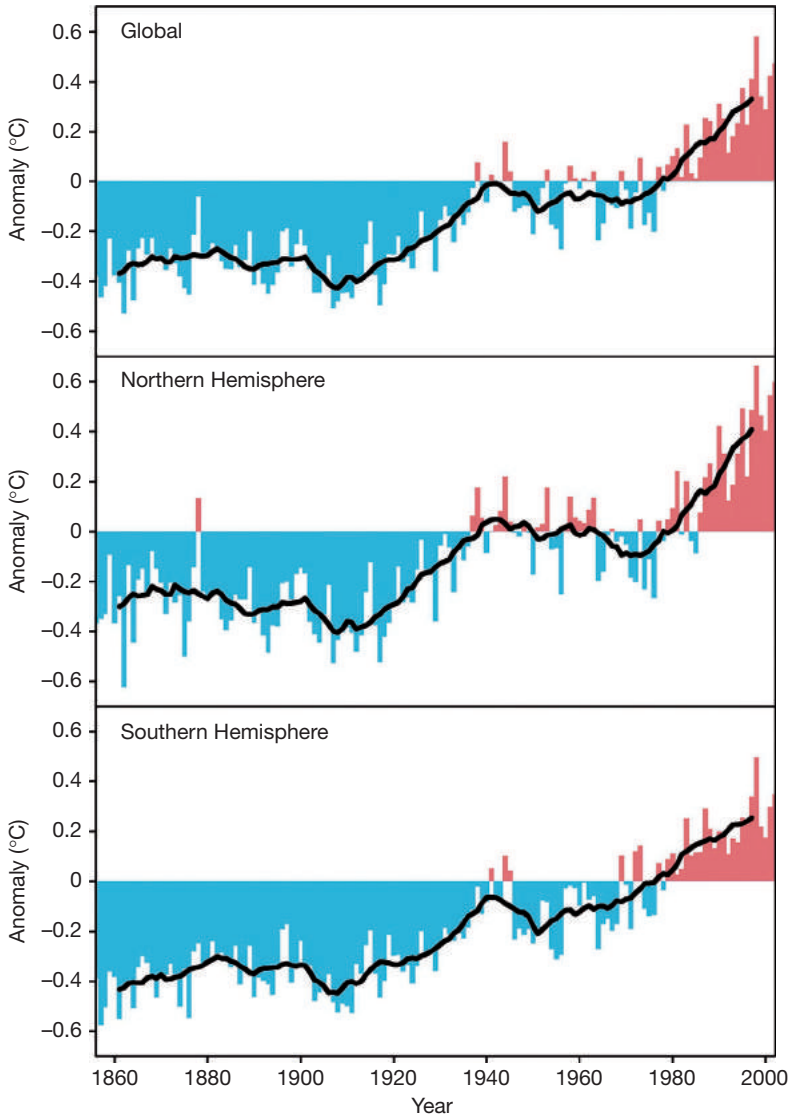

Fig. 2 Global Northern and Southern Hemisphere surface air temperature anomalies over the last 140 years. Color bars represent annual data, while solid line shows 10-year running mean. Temperature anomalies are calculated relative to the averaged period 1950–1979. The data are from the HadCRUT2 database (http://www.cru.uea.ac.uk/cru).

anthropogenic components of the Earth system. In particular, the observations show that the total precipitation over the land area has increased by about 2% during the 20th century, and at high latitudes in the Northern Hemisphere this increase was as large as 5%–10%. However, the increase of precipitation was not uniform during the past several decades. For example, Northern Africa suffered long and devastating droughts.

Global warming leads to a gradual "shrinking" of the cryosphere, that is, a reduction of snow and sea-ice cover. The data show a decrease in snow and sea-ice areas in the Northern Hemisphere during the 20th century. Not only is sea-ice area decreasing, but the ice layer is becoming considerably thinner. These trends are statistically significant and consistent with the results of model simulations. Mountain glaciers are probably the most sensitive to climate changes. It is known that glaciers worldwide have been retreating since the beginning of the 20th century. Because the mass balance of glaciers is affected both by temperature and precipitation, in some areas, where increase of precipitation dominated, some glaciers advanced in recent decades, but the overall number of retreating glaciers is much higher than the advancing glaciers.

Climate Models

The Scientific Basis of Climate Modeling

The most advanced climate models describe the main physical processes in the climate system (atmosphere, ocean, and land surface) and are based on a set of equations for energy, momentum, and mass conservation. Even after being considerably simplified, the governing equations of climate models can only be solved numerically and thereby the development and broad applications of climate models began after the advent of sufficiently powerful computers. Climate models simulate a large set of physical characteristics of the climate system, such as atmospheric and ocean circulation, radiative fluxes, temperature, cloudiness, precipitation, snow and sea-ice cover. Although fundamental physical processes in the atmosphere, the ocean, and on land surface can be described by well-known laws of physics, the enormous complexity of the climate system and limitations of modern computers do not allow to design climate models solely based on the first principles. For example, microphysics of individual water droplets in clouds is well understood but not only individual water droplets, also individual clouds, cannot be resolved in climate models since their spatial resolution is about 100 km at best. Thereby, the description of many important processes in the climate system is based not on the physical laws but on the so-called parametrizations, that is, rather simple, often semiempirical, submodels of individual processes. With the progress in geosciences and growing computer power, these parametrizations become more sophisticated and realistic but the use of different parametrizations in climate models still remains the major source of uncertainties in climate predictions.

Types of Climate Models

There are several types of models used at present for climate research (see also Table 1). The most complex and realistic climate models are the so-called coupled general circulation models (GCMs) of the atmosphere and the ocean. These models are based on the most comprehensive set of dynamical and thermodynamical equations and they describe a large set of relevant processes in the ocean and the atmosphere. The name "general circulation" reflects the fact that these models, unlike more simple models, simulate three-dimensional circulation of the atmosphere (wind speed) and the ocean (current velocity). Climate GCMs originated from the weather prediction models and some models can be used both for weather and climate predictions. The main difference is how the models are used. The weather prediction is aimed on simulations of temporal development of individual weather systems, such as cyclones and anticyclones. Due to chaotic nature of weathers, an accurate prediction of meteorological conditions is only possible on the timescale order of 1 week. On a longer timescale, even small differences in the initial conditions result in large differences in simulated fields. The aim of climate modeling is to simulate climate, that is, the averaged weather conditions. To obtain a sufficiently accurate climate state (i.e., statistics of weather), an averaging of simulated meteorological conditions over at least several decades is required. Current generation of coupled GCMs employs spatial discretization with the resolution of about several hundred kilometers and both the atmosphere and the ocean are divided in vertical direction by several dozens of unevenly spaced

Table 1 Comparison of different types of climate models

Types of climate or Earth system models	*Spatial aggregation and resolution*	*Resolved timescales*	*Number of variables*	*Examples*
Simple models	Box type, 1-D[a] or 2-D	1–10^9 year	1–10	Budyko–Sellers energy balance model, Stommel ocean box model
EMICs	2.5-D or 3-D spatial resolution: 500–1000 km	1 day–10^6 year	10–50	CLIMBER-2, LOVECLIM, UVic
GCMs	3-D spatial resolution: 100–300 km	1 min–10^3 year	>100	CCM3, ECHAM-5 HadCM3

[a]*n*-D: *n*-dimensional model.

levels. Since atmosphere and the ocean are characterized by a number of fast processes, a relatively short time step of numerical integrations—from minutes to hours—is required to guarantee numerical stability and accuracy. This makes coupled GCMs extremely computationally expensive tools which require the use of the most powerful computers.

Another extreme in the spectrum of climate models is represented by simple climate models. Such models describe only a very limited subset of the processes in the climate system and, usually, they employ a very coarse spatial resolution. A prominent example of simple climate models is an energy balance model developed in the mid-1960s. This model is based on one equation for the energy balance of the climate system and it simulates only atmospheric temperature. Atmospheric circulation in this model is parametrized as a large-scale horizontal diffusion. In spite of their simplicity, this class of climate models still remains a useful tool for the analysis and better understanding of some important aspects of climate dynamics, especially related to its nonlinear aspects.

At last, a new type of climate models, the so-called models of intermediate complexity, emerged in the recent decade. These models are aiming on closing a wide gap between simple climate models and GCMs. Design of the models of intermediate complexity represents a compromise between a high degree of complexity required to realistically simulate climate and the necessity to reduce computational cost to perform long-term simulations. Unlike simple climate models, models of intermediate complexity are able to simulate a much large set of climate characteristics, often comparable with GCMs, but due to considerable simplifications of the governing equations and, usually, a much coarse spatial resolution, models of intermediate complexity are suitable for much longer simulations than GCMs. This makes models of intermediate complexity very useful for the study of past climate changes and for long-term (thousand years and longer) future climate predictions.

From Climate Models to Earth System Models

Initially, climate models described only physical processes in the atmosphere, the ocean, and on land surface (Fig. 3A). However, future climate predictions also require modeling of geochemical, biochemical, and biological processes. Indeed, future changes in the chemical composition of the atmosphere, which is the primary cause of anthropogenic climate change, is not known and due to a number of important feedbacks between physical and biogeochemical processes in the climate system, they have to be modeled in consistent matter. For example, at present only one-third of anthropogenic carbon dioxide remains in the atmosphere while the rest is partitioned between oceanic and terrestrial carbon uptakes. This implies that both terrestrial and marine carbon cycles have to be properly modeled. Moreover, terrestrial vegetation not only plays an important role in the carbon cycle but also provides an additional positive climate feedback by alternating surface albedo and other surface characteristics. At the same time, simulation of other important components of anthropogenic changes, such as methane, ozone, and aerosols, requires a detailed description of the atmospheric chemistry. When the simulations on the timescales longer than hundred years are concerned, especially during the glacial age, the dynamics of the ice sheets (both terrestrial and shelf ice) also have to be simulated. Incorporating of all these components into climate models (Fig. 3B) represents an important step from climate models to the comprehensive Earth system models. Currently, a number of the Earth system models based both on GCMs and models of intermediate complexity are used for variety of climate change studies.

Validation and Application of Climate Models

Before application to future climate predictions, it is important to test model ability to simulate observed climate state and past climate variability. Current generation of climate models demonstrates a considerable skill in simulation of different atmospheric and oceanic characteristics as well as their interannual and interdecadal variability, such as tropical climate variability associated with ENSO. This is, however, only the first step in validation of the climate models. Another important step in climate models validation is testing of their ability to simulate different climates and climate change known from observations. For example, a pronounced global warming trend during the 20th century is successfully simulated by climate models when changes in all major climate forcings, both natural and anthropogenic, are prescribed. Paleoclimate reconstructions of past climates present another

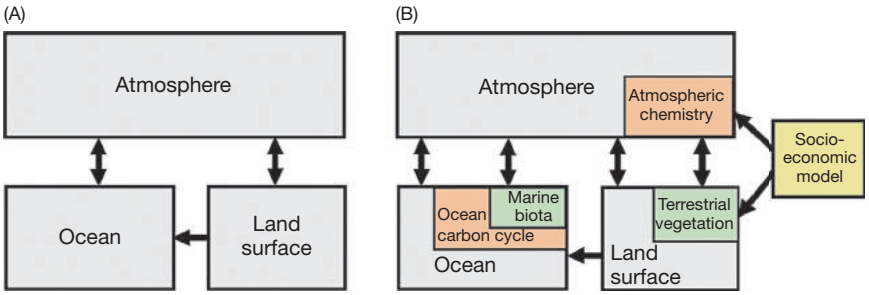

Fig. 3 The principal structure of the coupled climate models (A) and Earth system models (B). *Gray* shading represents physical components; brown, geochemical components; and green, ecological components of the model.

important opportunity to test models under climate conditions different from the present one. For example, climate of the last glacial maximum about 21,000 years ago is relatively well studied and all necessary boundary conditions and atmospheric composition are known for this time with sufficient accuracy. Comparison of model simulations of the last glacial maximum with numerous available paleoclimate reconstructions shows that climate models are able to reproduce major aspects of the glacial climate reasonably well, although some discrepancies between data and model simulations remain and still have to be explained.

Future Climate Change Predictions

Climate Change Prediction and Related Uncertainties

Prediction of future climate change is solely based on the results of computer climate models simulations. In spite of considerable progress in climate modeling achieved in recent decades, large uncertainties remain in predictions of future climate change. These uncertainties stem from several sources. First, to simulate future climate changes, climate models require scenarios for future concentration of atmospheric greenhouse gases, aerosols, and land-cover changes. The latter, in turn, are based on predictions of economic, demographic, and technological development which are rather uncertain. This is why a set of plausible scenarios for anthropogenic climate forcing is produced based on very different assumptions about future socio-economical development. As an example, the upper and lowest projected CO_2 emission at the end of 21st century differs by factor of 6 for the latest set of emission scenarios produced by Intergovernmental Panel on Climate Change (Fig. 4A). These uncertainties in emission scenarios result in a considerable range of uncertainties in the future rise of atmospheric CO_2 and global temperature (Fig. 4B and C).

Another important source of uncertainties in future climate predictions is due to a poor understanding of the radiative properties of atmospheric aerosols. Concentration of several types of aerosol is strongly affected by anthropogenic activity. Among them are sulfate, organic carbon, black carbon (soot), and mineral dust. Some of these aerosols cause cooling, while others cause warming of the Earth's surface. In addition, aerosols affect the optical properties of clouds and hydrological processes in the atmosphere (so-called indirect effect of aerosols). Uncertainties in the direct and indirect effects of aerosols remain very large. Furthermore, unlike the well-mixed greenhouse gases, spatial and temporal aerosol distribution is extremely heterogeneous.

Additional source of uncertainties in future climate predictions arises from the interaction between climate and biosphere. It is still not well understood how natural ecosystems will respond to the combination of climate changes and rise of CO_2 concentration. Some modeling results suggest that terrestrial biosphere under global warming conditions can turn from a sink of carbon, as it is the case at present, to a considerable additional source of CO_2, hence amplifying global warming. Additional methane release from the northern wetlands could also contribute to the amplification of climate change.

At last, different climate models simulate substantially different responses to the same anthropogenic forcing. The globally averaged equilibrium surface temperature response to the doubling of CO_2 concentration is used as a benchmark for the climate model sensitivity to changes of the greenhouse gases concentration. This characteristic, called "climate sensitivity," falls into the broad range between 1.5°C and 4.5°C for different climate models. The reason for such large differences in the climate sensitivity is primarily attributed to the uncertainties related to climate feedbacks, such as water vapor, cloud, and surface albedo feedbacks. Since it is not known which of the climate models is the most accurate for future climate prediction, the whole range of model results has to be used to assess the possible range of uncertainties. Moreover, a possibility remains that the actual climate change may go above the envelope of current climate model simulations.

Predicted Climate Change in the 21st Century

Results of climate model simulations performed for a whole spectrum of possible greenhouse gases and aerosols emission scenarios indicate that globally averaged surface air temperature will rise till the end of the 21st century by additional 1–6°C compared to the present one (Fig. 4). This temperature rise, however, will not be uniform and the warming trend over the continents and high latitudes is expected to be much stronger than the averaged one (Fig. 5A). In the Southern Hemisphere, where the ocean area is much larger than in the Northern Hemisphere, warming will occur at a lower rate.

Another important aspect of global warming is change in the hydrological cycle. All climate models predict an increase in the globally averaged precipitation due to global warming; however, simulated regional patterns of precipitation changes are much less robust and show a low correlation between different models. This is related to a strong spatial variability of precipitation and the large number of factors affecting precipitation changes. Still, some common features can be derived from model simulations (Fig. 5B). In particular, most of the climate models predict the largest increase in precipitation in the equatorial region and middle latitudes, while in the subtropics they predict the precipitation to remain unchanged or even to decrease. Due to the increased contrasts between the land and ocean temperatures, climate models predict considerable intensification of the Asian and African monsoons.

Results of model simulations and analysis of paleoclimatological data suggest that the climate system represents a strongly nonlinear object and its response to gradual changes in external and internal forcing may not necessarily be smooth and reversible. There are several components of the Earth system which are suspected for such strongly nonlinear behavior. One of them is the Atlantic thermohaline circulation which is known to be sensitive to variations in the freshwater flux and did experience major reorganizations during the glacial age. Some model simulations indicate that global warming and associated changes in the hydrological cycles and melting of the Greenland ice sheet can cause a complete shutdown of the Atlantic thermohaline circulations

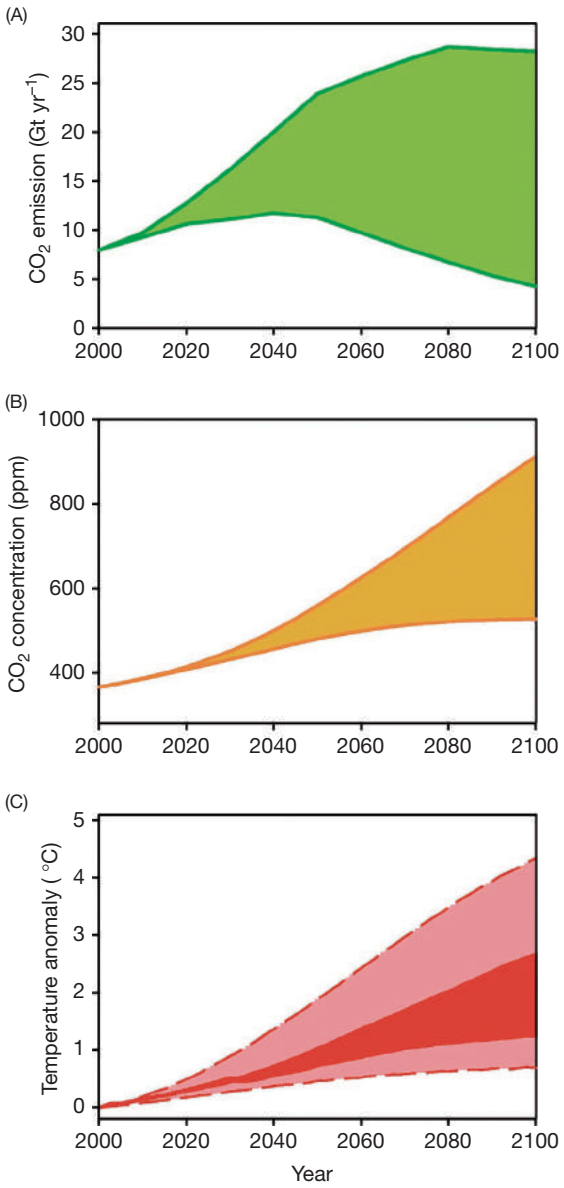

Fig. 4 The range of SRES emission scenarios and corresponding CO_2 concentration and globally averaged temperature changes simulated with the earth system model of intermediate complexity CLIMBER-2. (A) Envelope of the SRES CO_2 emission scenarios for the next 100 years in Gt C $year^{-1}$. (B) Simulated CO_2 concentration scenarios corresponding to SRES emission scenarios in ppm. (C) Simulated range of global temperature changes. *Dark red* area corresponds to the range of emission scenarios with the same climate model parameters. Light red area represents the combined range of uncertainties related to emission scenarios and different climate models. SRES emission scenarios are from http://sres.ciesin.org.

and, as a result, severe and abrupt changes in the regional climate and sea level. The shutdown of the Atlantic thermohaline circulation would also have a pronounced effect on marine ecosystems.

Another component of the climate system which can respond strongly to the future climate change is the West Antarctic ice sheets. There is a possibility that global warming can destabilize the West Antarctic ice shelf, which in turn may trigger abrupt destabilization of the grounded ice sheet. The latter will led to an additional sea-level rise of up to 5 m within several centuries. Due to very complex and still not well understood dynamics of the West Antarctic ice sheet, it is impossible so far to quantify a probability of such collapse, but recent disintegrations of smaller ice shelves and associated accelerations of adjacent ice streams add to the concern about potential instability of the West Antarctic ice sheet.

Although it is still impossible to predict all important consequences of anthropogenic climate change, there is a growing consensus that global warming above several degrees represents a "dangerous climate change," which could pose a danger of severe and irreversible consequences for the human civilization.

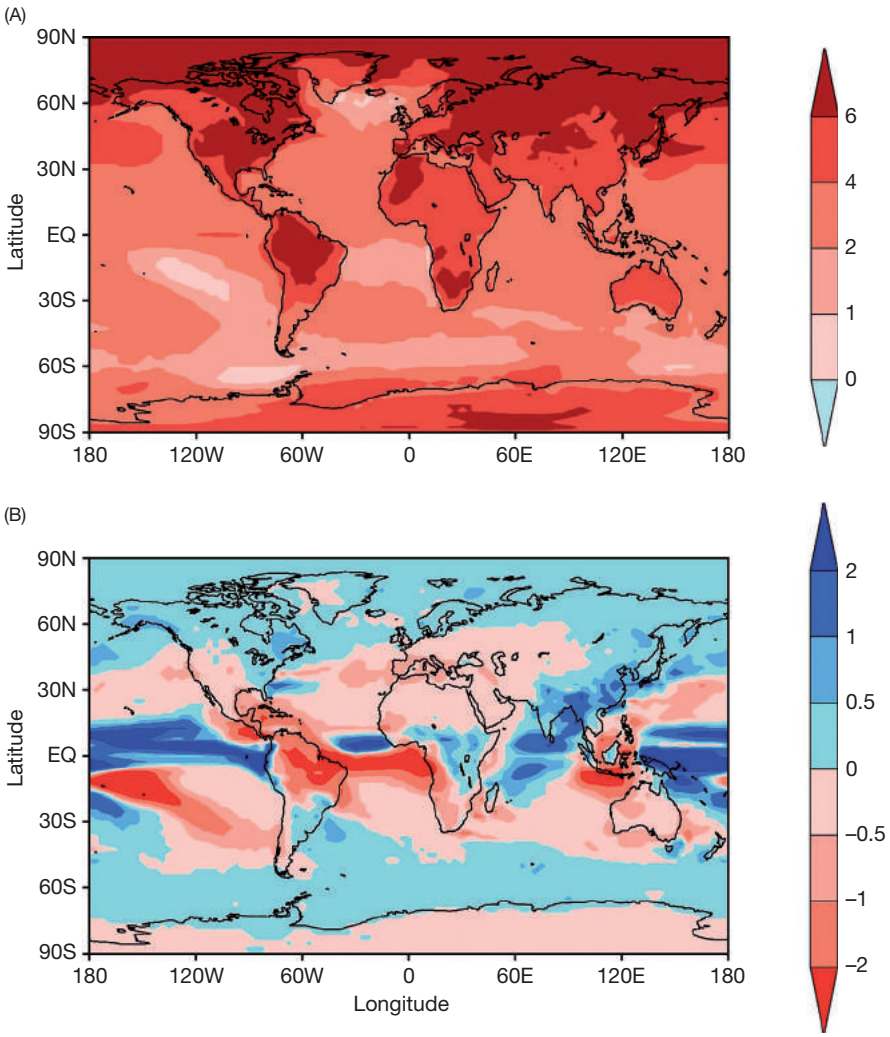

Fig. 5 Mean annual temperature (A) and precipitation (B) changes around the year 2080 compared to the year 1990, simulated with the HadCM3 coupled climate model for SRES A1FI scenario. Temperature changes are in °C. Precipitation changes are in mm per day. The data are from the IPCC data distribution center (http://www.ipcc-data.org).

Climate Impact on Natural Ecosystems and Human Society

Global warming and associated changes in the hydrological cycle and sea-level rise are expected to cause serious negative impact on natural ecosystems, human health, and economy. It is predicted that climate change will disrupt ecosystems and will result in loss of species diversity, as many species will be not be able to adapt to rapidly changing environmental conditions. Some ecosystems, such as tropical montane, mangrove forest, and Arctic ecosystems, are likely to disappear because warmer climate or sea-level rise will not support them. In the high latitudes, warming will cause degradation of permafrost and an increase of methane release from wetlands. Because methane is the next important greenhouse gas after CO_2, this will also amplify global warming.

Simulations with coupled climate model indicate that during 21st century soil moisture in summer will decrease considerably over the large portion of Europe and United States. This could have potentially serious negative impact on natural vegetation and agriculture, and lead to an increase of forest fire frequency. Combination of warming and changes in hydrological cycle will have serious impact on water resources in many regions. Already now one-third of global population is living in water-stressed countries. Unmitigated global warming will considerably increase the number of people exposed to water stress. At the same time, increased probability of extreme weather events, such as catastrophic floods, heat waves, and more devastating hurricanes, are expected to increase the death rate associated with natural disasters.

Sea-level rise will have a profound negative socio-economic impact by increasing the risk of coastal flooding and causing the loss in coastal wetlands. In particular, the estimates show that unmitigated global warming could increase annual number of people in coastal storm surges by factor 10 already in the year 2080. Another potential health impact of global warming is related to the increase of the area where climate is suitable to malaria transmission. Currently, distribution of malaria is limited to the Tropics but global warming could considerably extend this area, which will lead to an increase in the number of people exposed to malaria.

Among recently recognized aspects of rising of atmospheric CO_2 concentration is the acidification of the ocean. The observation and modeling results indicate that carbon dioxide emission from human activity has already led to a reduction of the averaged pH of surface seawater of 0.1 units and pH will fall additionally by 0.5 units by the year 2100. This could lead to mass extinction of coral and some plankton species causing disruption of the entire marine food chain.

Summary

It is established that climate has changed considerably in the past under the influence of natural internal and external factors. However, the recent climate trend revealed by direct instrumental measurements cannot be explained by natural factors alone and a considerable portion of recent climate changes with a very high degree of confidence has to be attributed to the human activity, primarily the emission of greenhouse gases. Growing concern about future climate change stimulated development of climate models, the only tool available for future climate predictions. Current generation of climate models demonstrates a considerable skill in simulation of modern climate and past climate changes. This substantially enhances the confidence in the models ability to provide a reliable picture of the future greenhouse world. Predictions of future climate changes made with numerical climate models clearly demonstrate that unmitigated fossil fuel combustion will lead to an accelerated global warming which represents a serious threat for the well-being of the future generations.

Glossary

Conceptual model Presentation of reality in a form of concepts (entities) and interactions (influences) between them.
Mental model These are cognitive representations of external reality. Creating mental models is our only way to explore the world around us. Note that our mental representations of reality are always simplifications, since they do not, cannot and should not take into account all the possible details.
Rich pictures One of the popular graphic ways of presenting a mental model. In addition to concepts and influences it uses icons, images, graphics, text and lines to explain how we think the system works.
System dynamics A modeling approach based on ordinary differential equations used to present how systems change in time. It assumes that reality can be described in terms of stocks (certain amounts of material, energy, money, biomass, individuals, etc.) and flows between them.

Introduction

In most cases he modeling process starts with a conceptual model. A conceptual model is a qualitative description of the system. A good conceptual model is half the modeling effort. To create a conceptual model we need to study the system and collect as much information as possible about the system itself, and about similar systems studied elsewhere. When creating a conceptual model we start with the goal of the study and then try to explain the system that we study in terms that would match the goal. In designing the conceptual model we decide what temporal, spatial and structural resolutions are needed for our study to reach the goal. Reciprocally, the conceptual model becomes important in part to define the goal. In many cases the goal of the study is quite vague, and it is only after the conceptual model is created that the goals of modeling can become clear. Modeling is an essentially iterative process. We cannot prescribe a sequence of steps that takes us to the goal. It is an adaptive process when many times the target is adjusted and moved as we go, depending both on our modeling progress and on the external conditions that may be changing the scope of the study. Building a good conceptual model is an important step on this path.

Temporal Domain

In the temporal domain we first figure out the specific rates of the main processes that we are to model and decide for how long we want to observe the system. If there is little change registered over the study period, the model may not need to be dynamic. It may be static and focus on other aspects of the system. If temporal change is important, we need to identify how this change occurs. In reality, time is continuous. However in some cases it may be useful to think of time as discrete and describe the system using the event-based formalism.

We should start thinking about the appropriate resolution of our temporal model. This resolution is dictated by the goal, which tells us how often we need to update the model to match the expected temporal detail of the study: is once a year is enough as when we model forests, or we need to track the dynamics every 1/100th of a second as when we model the movement of a fly wing. An example of a conceptual diagram depicting the sequence of events in a landscape model is presented in Fig. 1.

☆*Change History*: March 2018. Alexey Voinov introduced small edits in the text of the article including citations.

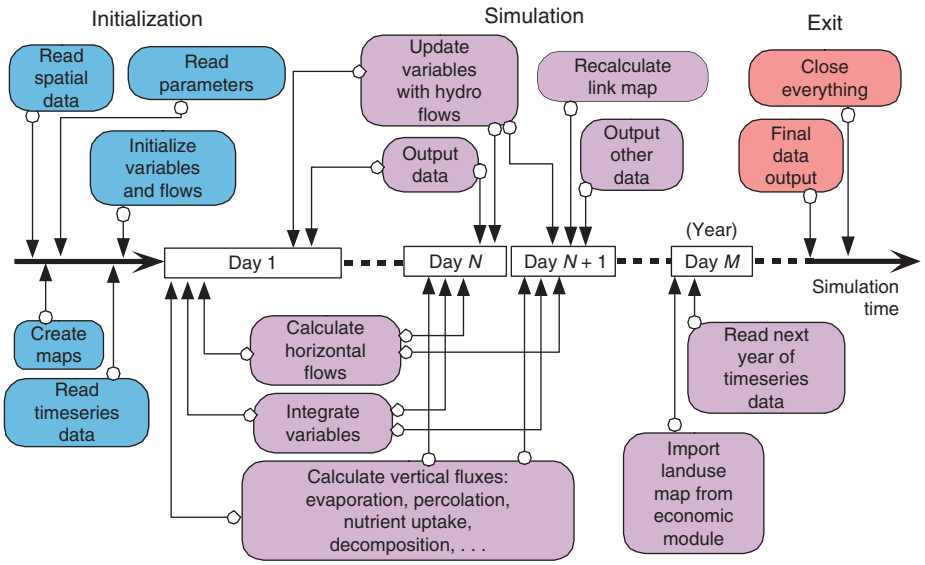

Fig. 1 A conceptual diagram for time in a landscape model. Note that while many processes actually occur at the same time, we need to sequence them when putting in a model. Sequencing of processes is important and may produce quite different results depending upon which processes are executed in the model first, and which ones—next.

Spatial Domain

In the spatial domain we are to make similar decisions about representation of space in the model. Is there much spatial heterogeneity in the system to justify a spatially explicit description? Or the system can be considered spatially homogeneous? Or there are large segments in which the system parts are uniform and the whole system can be described as a collection of these spatially homogeneous compartments. How big are these compartments? Can we describe the system spatially with a map of a 1:1,000,000 scale or should it be 1:100?

In all these decisions diagrams can be helpful to understand the system and to communicate our understanding to others. The picture in Fig. 2 describes how a lake ecosystem is to be modeled in space. It shows that there are large parts of the system that may be considered homogeneous and presented by some average values. The geometry of the lake is described; the central deeper part is considered as a separate compartment and is subdivided in depth. The shallow litoral segments are assumed to be entirely mixed to the bottom and are therefore described by one layer.

Structural Domain

In the structural domain we decide how to represent the structure of the system. In an empirical "black box" model, we are not concerned with what happens inside the system and how. The internal structure in this case is not analyzed, and we describe the system by finding an appropriate function that translates inputs into outputs. This is usually done by statistical methods. In contrast, in a process-based model we describe the structure of a system, which is best done by a diagram, representing the major components of the system: variables, forcing functions, control functions. When deciding about the model structure it is important to match the structural complexity with the goals of the study, the available data and the appropriate temporal and spatial resolution. For example if we are modeling fish populations (Fig. 3), that grow over several years, there would be little use in considering the

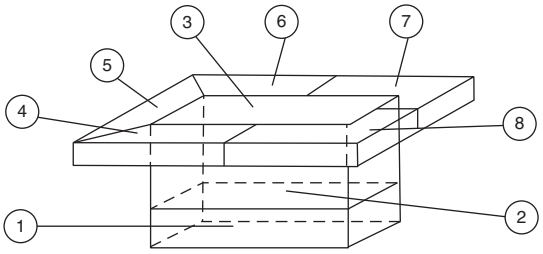

Fig. 2 Spatial representation of a lake described as a diagram. Segment (1)—deep hypolimnion zone, (2)—metalimnion, (3)—epilimnion, (4–8)—shallow litoral zone.

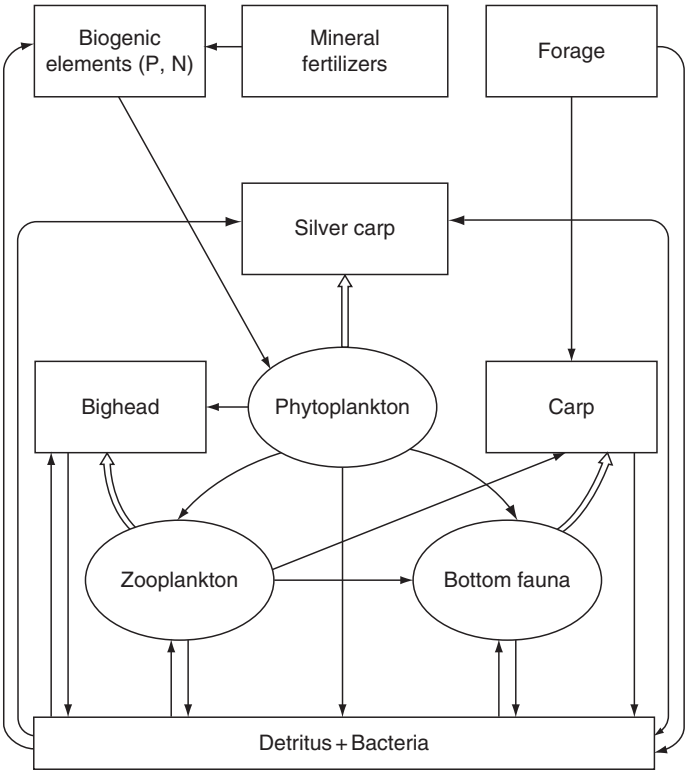

Fig. 3 Structural representation of a fishpond ecosystem.

dynamics of bacterial processes, that have a specific rate of hours. In this case we may probably think of the bacterial population as already at equilibrium, quickly adapting to any changes occurring in the system in the "fish time," which is weeks, or months. We may still want to consider the bacterial biomass for mass balance purposes, but in this case it makes perfect sense to aggregate it with the detrital biomass.

However certain fast processes may have a detrimental effect upon the system. For example, it is well known that fish kills may occur during nighttime in the early morning hours, when there is still no photosynthesis, but only respiration. As a result oxygen content may fall below certain threshold levels. The oxygen concentrations in this case vary from hour to hour, whereas fish biomass changes much slower. We might want to consider oxygen as part of the system to make sure that we do not miss such critical regimes.

In a lake ecosystem model in Fig. 4 in addition to trophic relations certain spatial properties are depicted. The diagram shows how the model structure is presented in the three vertical segments that describe the pelagic part of the lake. In the upper part three phytoplankton groups (A1, A2, and A3) are present, they are food for zooplankton (Z) and fish (R). Various forms of nutrients (organic and inorganic nitrogen and phosphorus) are supplied by decomposition of detritus. In the bottom segments, there is no biota, only nutrients and detritus.

When making all these decisions about the model structure, its spatial and temporal resolution, we should always keep in mind that the goal of any modeling exercise is to simplify the system, to seek the most important drivers and processes. If the model becomes too complex to grasp and to study, its utility drops. There is little advantage in substituting one complex system that we do not understand by another complex system, which we also do not understand. Even if the model is simpler than the original system, it is useless if it is still too complex to shed new light and to add to the understanding of the system.

Forrester put some formalism into the diagrams using a series of simple symbols or icons associated with various processes. The two main ones were level and rate (Fig. 5). Levels were used to identify storages of material or energy, while rates were controlling the flows between them. Using this formalism Forrester created complex models for such systems as cities, industries and even the whole world. Similar formalism was later used in several modeling software packages.

Odum created another set of symbols to model systems based on the energy flows through them. He called them energy diagrams, and used six main icons shown in Fig. 6. All systems were described in terms of energy, assuming that for all variables and processes we can calculate the "embodied" energy. In this case energy works as a general currency to measure all processes and "things."

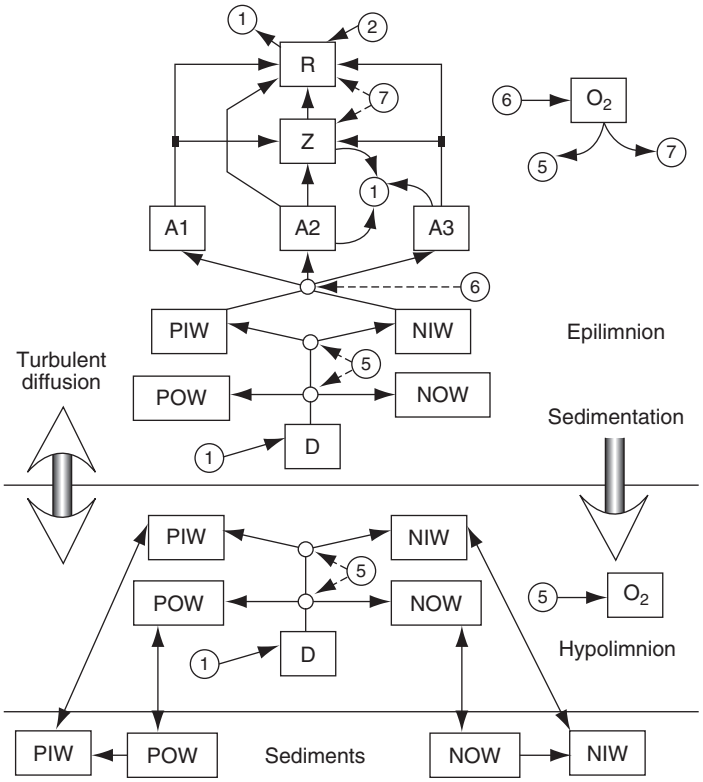

Fig. 4 A conceptual model of a lake ecosystem, which includes elements of spatial and structural description.

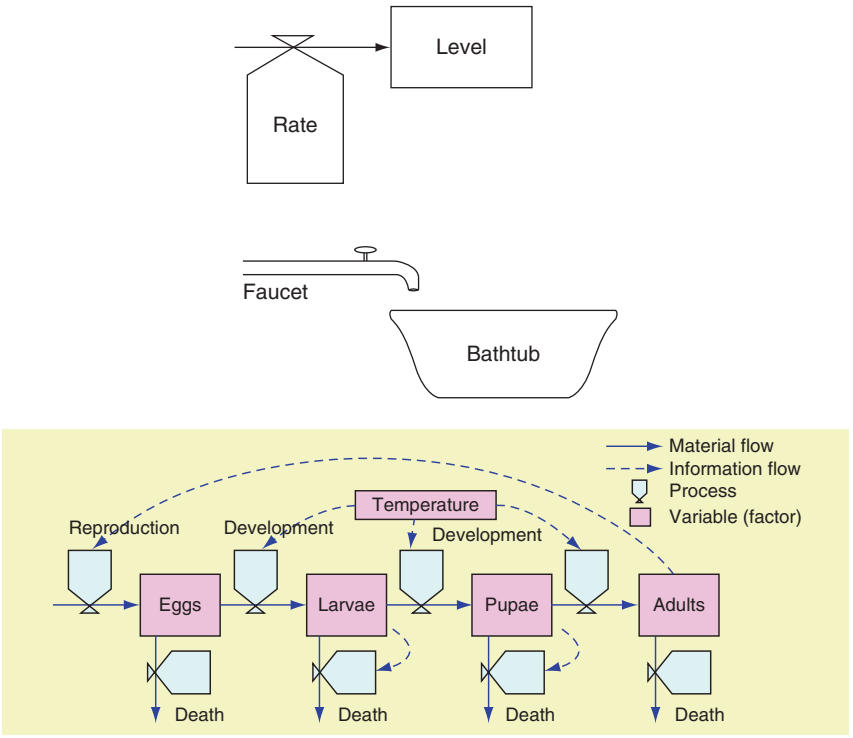

Fig. 5 Forrester's formalism for conceptual diagrams. The rate and the level are two main icons that can be used to put together more complex diagrams such as the one for the insect population. From: http://www.ento.vt.edu/~sharov/PopEcol/lec1/struct.html.

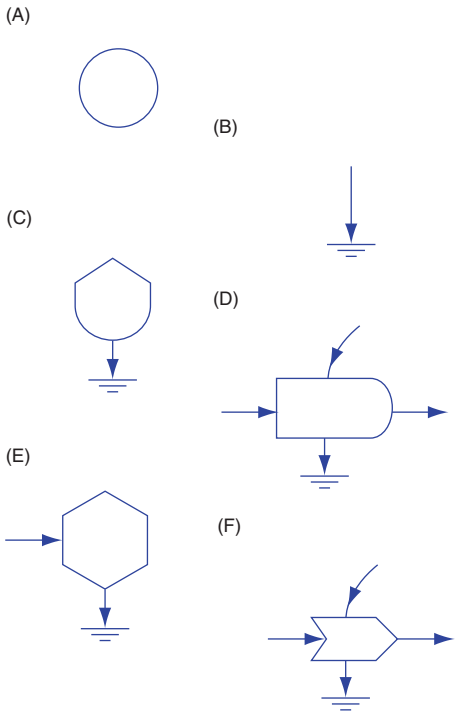

Fig. 6 Odum's formalism for energy-based conceptual diagrams. (A) Source of energy, (B) sink (loss of energy from system), (C) storage tank, (D) production unit (takes in energy and information to create other quality of energy), (E) consumption unit, and (F) energy mixer of work gate.

Modeling Software

In many software packages conceptual diagrams are used as the interface to input the model. For example, one of the reasons that systems dynamics software, such as Stella, became so popular in modeling is because they are also handy tools to put together conceptual diagrams, and, moreover, these diagrams can be then converted into numeric computer models. Fig. 7 presents a sample conceptual model for a river system put together in the Stella interface. It describes the river network as a combination of subwatersheds, river reaches and reservoirs. The Stella interface can be used as a drawing board to put together various conceptual diagrams and discuss them with other people in a process known as participatory modeling. In this case the major value of the interface is that one can easily add or delete variables and processes and immediately see what impact this may have on the model performance. The model itself becomes a tool for deliberations and consensus building.

Very similar diagrams can be put together using other systems dynamics software such as Madonna, Vensim, Powersim or Simile. In these software packages the "stock-and-flow" formalism is used to describe the system. The diagrams are also known as flow diagrams because they represent how material flows through the system.

A somewhat different formalism is used in such packages as GoldSim, Simulink, and Extend. Here we have more flexibility in describing what we wish to do in the model and the model does not need to be presenting only the stocks and flows. Groups of processes can be defined as submodels and encapsulated into special icons that become part of the icon set used to put together the diagrams. As usually we get more functionality and versatility at the expense of a steeper learning curve and higher complexity of design.

Yet another option in building conceptual diagrams is given by the Universal Modeling Language (UML), which is a standardized specification language for object modeling. It is designed as a diagrammatic tool that can be used to build models as diagrams, which can be then automatically converted into a number of object-oriented languages, such as Java, C++, Python, etc. In this case you are actually almost writing computer code, when developing the conceptual model. Once again, even more universality and almost infinite flexibility is achieved at a price of yet more efforts you will need to spend mastering the tool. Fig. 8 presents a sample conceptual diagram created in UML to formulate an agent-based model of a landscape used by sheep farmers, foresters, and National Park rangers that are interacting on very different temporal and spatial scales with different development objectives (sheep production, timber production, nature conservation).

There are several types of diagrams that you can create using UML. One of them is the activity diagram, which describes the temporal dimension of your model. The class diagram presented in Fig. 8 in a way corresponds to the structural dimension, but may also have elements of the spatial representation, like in the Lake model in Fig. 5. Most of software tools designed to create UML diagrams, such as Visual Paradigm would also provide code generators that would convert your UML diagram into computer code in a language of your choice.

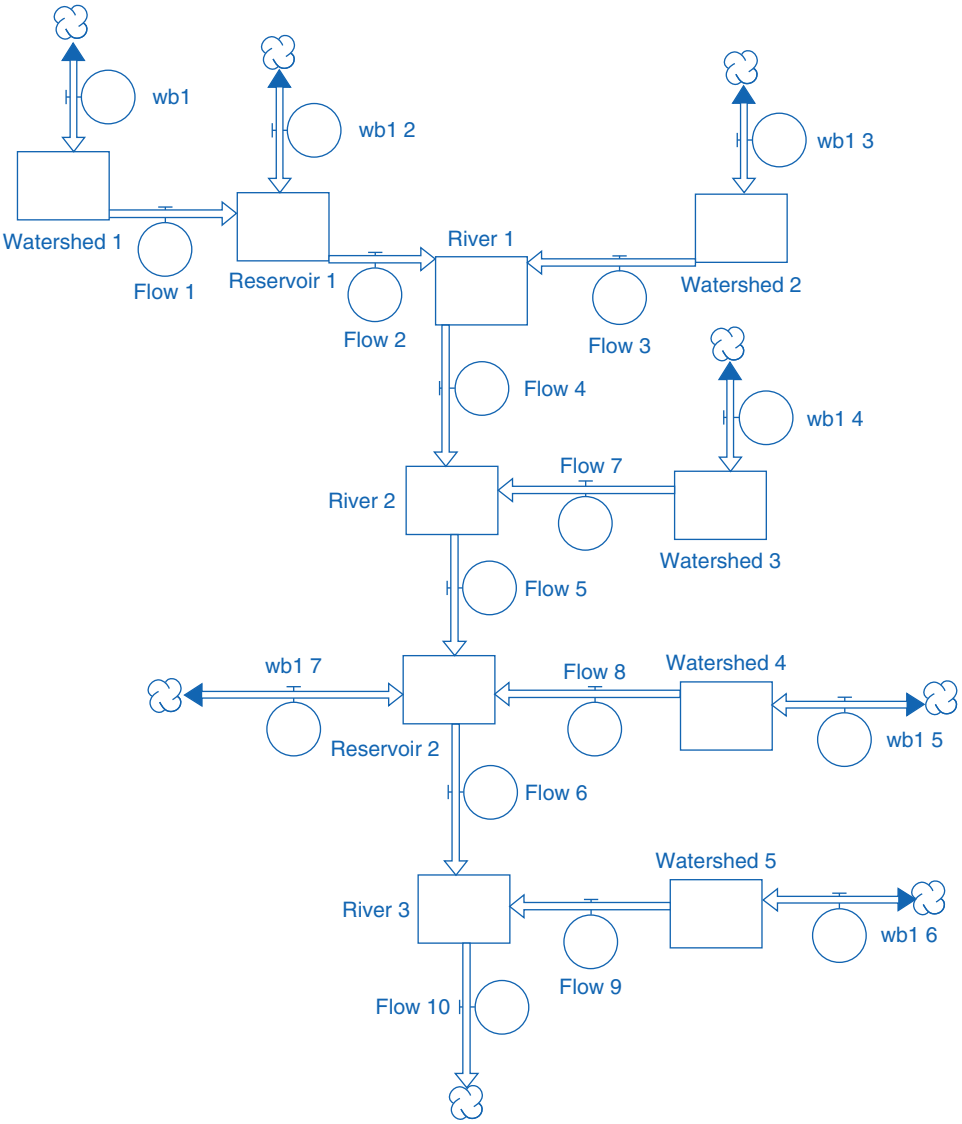

Fig. 7 Using Stella to create conceptual diagrams as stock-and-flow representations of processes in systems.

More recently there have been attempts to standardize the conceptual, diagrammatic representation of system using domain ontologies. A domain ontology represents a certain domain, ecosystem, or part of an ecosystem by defining the meaning of various terms, or names as they apply to those ecosystems. The idea was to define all the various components of ecosystems and present their interactions in a hierarchical way, so that once you need to model some part of the world you could pull out the appropriate set of definitions and connections and have your conceptual model. Several formal languages have been proposed to describe such ontologies. Among them OWL is probably best known, and designed to work over the World Wide Web. So far it is yet to be seen how these ontological approaches will be accepted by the modeling community. Like with other attempts to streamline and automate the modeling process, we may be compromising its most essential part, that is, the exploration and research of the system, its elements and processes, at the level of detail needed for a particular study goal. Any attempt to automate this part of the modeling process may forfeit the exploratory part of modeling and may diminish the new understanding about the system that the modeling process usually offers.

Conclusions

Conceptual diagrams are powerful modeling tools that help design models and communicate them to stakeholders in case of a collaborative, participatory modeling effort. In most cases building a conceptual diagram is the first and very important step in the modeling process.

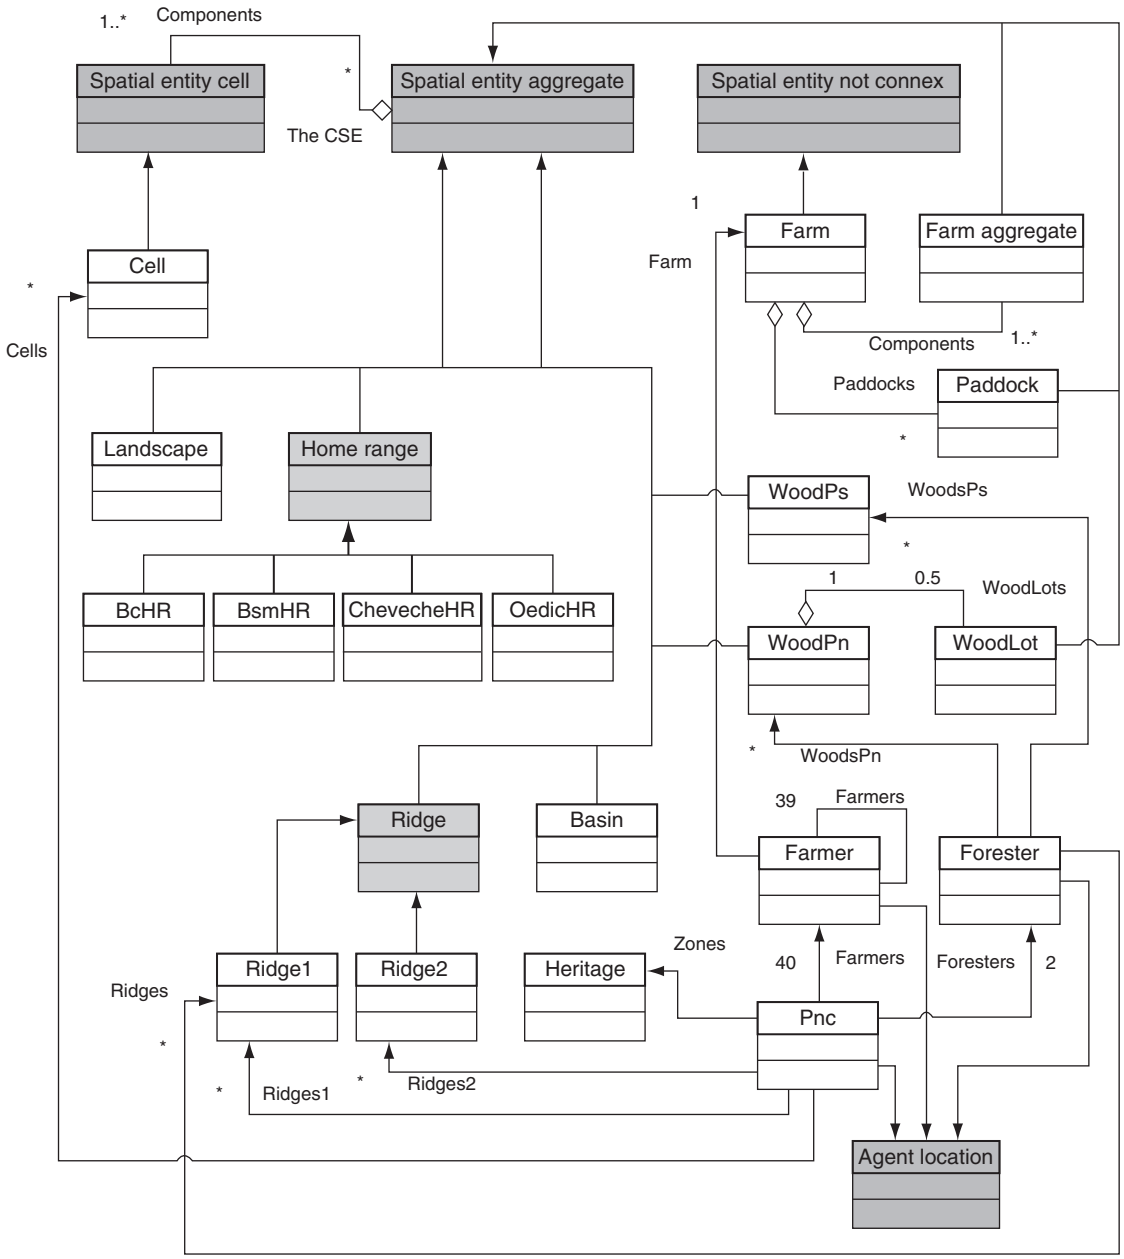

Fig. 8 A UML class diagram of a system can be used both as a conceptual diagram and as a way to program the model. From: http://jasss.soc.surrey.ac.uk/6/2/2.html.

Ecological Models: Individual-Based Models☆

Volker Grimm, Helmholtz Centre for Environmental Research—UFZ, Leipzig, Germany

Introduction

Individual-based models (IBMs) describe individual organisms as autonomous, unique entities. Some IBMs deal with quite simple individuals, which are characterized by just their position. Other IBMs include the individual's adaptive decisions of what to do next, which are based on features of the individuals, for example, age, sex, size, social rank, energy reserves, memory, and of their biotic and abiotic environment. But why should ecological models be based on the representation of individuals in the first place? Models always have to simplify, so why do not we ignore individuals, their variability, and their behavior, and rather consider average individuals as in classical theoretical population ecology?

There are three main reasons why it can be necessary to represent individuals in ecological models: (i) Individual variability. Individuals usually are different, even if they are of the same age. If resources like food or space are scarce, individuals that larger, stronger, or have more experience than others may have a competitive advantage. Moreover, during their life cycle individuals not only change in size but often also in food requirements, behavior, trophic interaction etc. (ii) Local interactions. Most mathematical population models assume global interactions, that is, all individuals interact with all other individuals, but real interactions are local, which can be important. For example, the global density of individuals may be low enough to provide, on average, enough food or space for each individual, but local density may in some places be much higher than global density. (iii) Adaptive behavior. Individuals seek to maximize fitness, that is, survive and produce as many offspring as possible that reproduce themselves. To achieve this aim, they adapt their behavior to the current state of themselves and their biotic and abiotic environment (Fig. 1). Behavior not only includes movement, foraging, mating, etc., but also physiology, growth, development, and life history. Adaptive behavior is very likely to affect or even determine system-level properties of populations, communities, and ecosystems. For example, herbivores like elks change their foraging behavior in the presence of predators, for example, wolves, by selecting other types of habitat. This in turn affects the structure and dynamics of the vegetation and of entire herbivore community, etc.

These three aspects of individual-based ecology are hard to deal with mathematically, for example, using calculus. Therefore IBMs have to be formulated as simulation models that are run on computers. Computers with enough power for running IBMs are generally available since the end of the 1980s, which is the time when individual-based modeling became a declared branch of ecological modeling. Nowadays the IBM approach is widely used in ecology but the term individual-based is used in a very broad sense. Some IBMs include only one individual-based aspect, for example the discreteness of individuals, or local interactions, but otherwise are very similar to classical mathematical models, whereas other IBMs include detailed descriptions of the individuals' fitness-seeking behavior.

In the following we first describe the elements of IBMs, which have to be specified by the modeler. Then we explain a general modeling strategy that can be used to optimize the complexity of IBMs and to deal with uncertainty in model structure and parameters (pattern-oriented modeling). Then we describe how IBMs are analyzed, and finally we briefly present three example models and give an outlook on the future of individual-based modeling. The emphasis of the following is thus more on what IBMs are and how they are developed and analyzed then on what so far has been achieved with the individual-based approach.

☆*Change History:* March 2018. V Grimm updated Synopsis, keywords, Introduction, "Elements of individual-based models," "Implementing individual-based models," Examples, "The future of individual-based modelling," references. No changes to figures and tables.

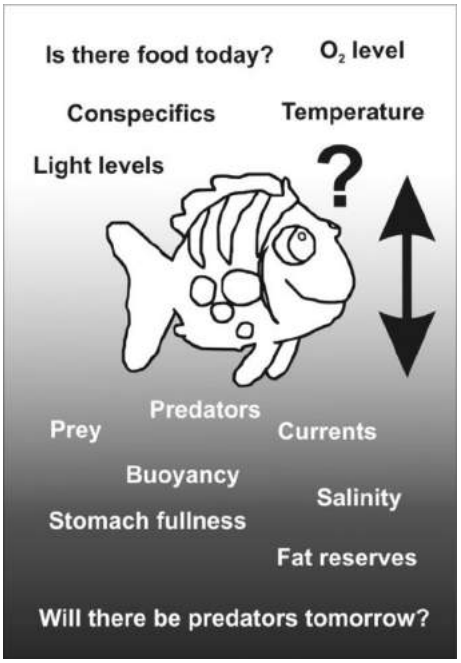

Fig. 1 Real individuals have to make adaptive decisions all the time, i.e., decisions that minimize their risk of starving or being eaten, and maximizing the chance to reproduce. For example, for many fish species vertical migration is a key behavior. Moving up usually means better conditions for feeding, but also higher risk of predation. The very decision made by an individual depends on many internal and external variables, i.e., we assume the fish knows, or at least has estimates, of these variables Modified after Strand, E. (2003). *Adaptive models of vertical migration in fish*. Doctoral Thesis. University of Bergen. Bergen, Norway.

Note that IBMs are referred to as "agent-based models" (ABMs) in disciplines that deal with human agents, for example, economics, social sciences, and demography. In these disciplines emphasis of ABMs always was on the agent's adaptive decisions, whereas most IBMs in ecology so far focus on individual variability and local interactions. But behavioral decisions are increasingly considered also in ecology, so no distinction between "individual-based" and "agent-based" should be made in the future. Likewise, "multiagent systems" are agent-based models which have their roots in computer science and artificial intelligence, but if they are used to tackle ecological problems, they are not fundamentally different from IBMs or ABMs.

Elements of Individual-Based Models

A mathematical model consists of a set of equations, which are formulated in the general language of mathematics. For IBMs, equations and the language of mathematics are only applicable to submodels that describe certain processes, but the entire model consists of further elements, which are listed in the following. This list describes the decisions a modeler has to make while developing and formulating an IBM, and the details of each of these decisions can significantly influence the behavior of the IBM. In 2006, a general format for describing IBMs was proposed, which is now widely used in ecology and increasingly also in other disciplines, the ODD (=overview, design concepts, details) protocol. ODD cannot only be used to describe an existing model, but also as a hierarchical checklist for compiling and designing IBMs. It consists of seven numbered elements, with the first three providing an overview, the fourth being a list of relevant design concepts, and remaining ones providing details of model initialization, data input, and submodels.

1. Purpose

   What is the specific purpose of the model, and what patterns and criteria are used to decide that a model is realistic enough for this purpose?
2. Entities, State Variables, and Scales

   IBMs contain at least two types of entities: individuals and their environment. In the simplest case, there is only one type of individuals, for example one plant species, and a homogeneous environment in which the individuals are located. More complex IBMs consider more than one type of individual, for example a plant species, a herbivore, and a predator, and a more complex environment, for example a heterogeneous landscape consisting of different types of habitat.

   The entities of the IBM are characterized by a set of state variables or behavioral attributes. Individuals might have one or more state variables, for example, numbers representing position, age, sex, size, stage, rank, condition, energy reserves, memory of suitable habitat, etc., or being risk prone, highly mobile, or aggressive. It dependson the question addressed with the model

which state variables are included, but the general guideline is to keep the representation of the individual as simple as possible. The environment often is represented as a grid of square grid cells, which represent spatial units of the landscape and may be characterized by the state variables habitat/nonhabitat, cover, biomass, moisture, temperature, soil type, exposure to wind or predators, etc.

A further important design decision of an IBM is its spatial and temporal resolution and extent. The spatial resolution is determined by the size of the grid cells, which in ecology can range from cm^2 to km^2, and spatial extent is set by the number of grid cells, for example, 100×100 cells. The temporal resolution is given by the length of a time step, which often is a year, a week, a day, or even less than an hour. Different parts of a year may also be represented with different resolution. The temporal extent is set by the time horizon considered, for example, 100 years.

3. Process Overview and Scheduling

   Processes cause changes of the state variables and, in case of individuals, also of the number of entities. Examples of processes in IBMs include energy budgets, growth, dispersal, foraging, habitat selection, mating, habitat dynamics, disturbance events, phenology, mortality, reproduction, etc. The modeler has to decide which process to represent explicitly, and in which detail. This decision is linked to the decisions on state variables and scales. If, for example, temporal resolution is 1 year, the process of foraging may not need to be represented explicitly. If, on the other hand, habitat selection in response to short-term environmental changes is considered important for the problem addressed with the model, a temporal resolution of 1 day or even less might be required, and in turn an explicit representation of the individual's decision where to move in the next time step.

   If processes are not considered important enough to be included explicitly, they usually are represented by constant parameters. Mortality, for example, can explicitly depend on foraging and interaction with predators; or, mortality is represented by a constant parameter, which in the model is implemented as the probability of dying in a certain time step.

   The submodels implementing the model processes are often formulated as a combination of mathematical expressions and IF-THEN conditions. Growth, for example, can be represented by a growth equation, whereas habitat choice will require probabilistic IF-THEN rules: "IF the best habitat within my perception range has higher quality then my current habitat AND IF predation risk is low THEN with a certain probability I will move to the new habitat."

   All design decisions of the modeler regarding entities, processes, scheduling etc. are experimental, that is, they have to be tested and analyzed and, as a result, usually be modified.

   A further important design decision of the modeler is the scheduling of the processes: who does what at what time in what order? IBMs are implemented as computer simulations, so processes cannot, as in reality, run in parallel, but only one after the other. The sequence in which processes are executed can be decisive for the resulting dynamics. An IBMs schedule describes the actions of the IBMs and how they are executed. An action is a list of model entities, the processes performed by these entities, and the order in which the entities are processed. For example, the action "feeding" may be defined as the list of all individuals which feed, one after the other in a fixed order, in their habitat cell. Or, feeding might be an action where all individuals first move to the neighbor habitat which has most food and then feed and where the individuals are processed in a random order.

   Fixed schedules, which are used in most IBMs, define a single order in which events always occur, that is, a cycle which is repeated every time step. Dynamic schedules as in discrete-event simulation allow the order to be changed while the model executes. For example, an individual that has just had an interaction with a predator and survived may put itself on a higher rank in the model's schedule, which would mimic its fleeing behavior. Flow charts, which are often used to illustrate how a model works, usually refer to model processes itself, for example dispersal, but not necessarily to the models schedule and actions. Table 1 shows a typical schedule of an IBM.

4. Design Concepts

   Many IBMs are designed ad hoc, without reference to any general theoretical or conceptual framework. Therefore, general concepts for the design for IBMs have been formulated, which are mainly taken from the research on Complex Adaptive Systems. These design concepts do not require that models necessarily have a certain structure, but their purpose is to make design decisions consciously. The most important design concepts are related to adaptive behavior: emergence versus imposed properties, adaptation (does the model explicitly include behavior decisions), fitness (if adaptation is included, what fitness measures are used by the individuals), what do individuals know, and how do they predict the consequences of their decision alternatives? Further design concepts include: basic concepts, interaction, stochasticity, and collectives.

   Particularly important for model testing and analysis is the design concept "observation." To test whether an IBM's implementation is correct and to understand how system-level dynamics emerge from the individuals' interactions, specific observation tools are needed. These tools include graphical displays of patterns over space and time and the option to execute the model step by step and watch how state variables change. Some software platforms for IBMs like Swarm, Repast or NetLogo provide so-called monitors: on a graphical interface single individuals can be selected and their state variables displayed and manipulated (Fig. 2). Further observation tools are graphical and file output of summary statistics, for example average abundance, point-pattern characteristics of the individual's spatial distribution, or time series characteristics. Observation tools are not part of the model itself, but their appropriate choice determines what we can learn from an IBM.

5. Initialization

   The outcome of an IBM simulation can critically depend on the initial number and state of the model entities. It is therefore important to test different initializations and to carefully document those which were used for the results presented in a publication. Sometimes, dependence on initial conditions is part of the question, for example if we want to understand whether a small, re-introduced population will establish. More often, however, we are interested in results which do not depend on initial

Table 1 Scheduling of the coyote model of Pitt and coworkers as an example of how the schedule of IBMs is organized into actions and IF-THEN rules

Pack actions (executed by all packs):
- Check whether both an alpha male and an alpha female are present
- If both alphas exist, and it is April, produce offspring: create pups, the number of which is stochastic but also depends on pack size, and add them to the pack
- Check whether either alpha is replaced
- If it is December, and there is a contender (another adult of the same sex in the pack), both the male and female alpha coyotes are at risk of being replaced
- Replacement is a stochastic function with the probability of being replaced increasing with the alpha's age
- If replacement occurs, the alpha becomes a transient and the contender becomes the new alpha
- Update the dispersal probability of each member according to its age and pack size
- Force death of pups less than 2 months old if the pack has no adults

Pack member actions (executed by all individual coyotes that belong to a pack):
- If the age of 2 months is attained, leave the den
- If the age of 2 months is attained, change from pup to beta adult
- Update the age-dependent mortality probability and determine whether death occurs
- If individual is a beta less than 2 years old, determine whether it leaves the pack, according to its dispersal probability

Transient coyote actions (executed by all individuals not belonging to packs):
- Update individual's mortality probability, depending on the total number of transients
- Determine whether death occurs

Pack alpha replacement actions (executed by packs that lack a alpha individual):
- If there are beta individuals of the appropriate sex in the pack, promote the oldest beta to alpha
- Otherwise, select a transient of the appropriate sex and promote it to alpha
- If there are no available transients, select a beta from another pack

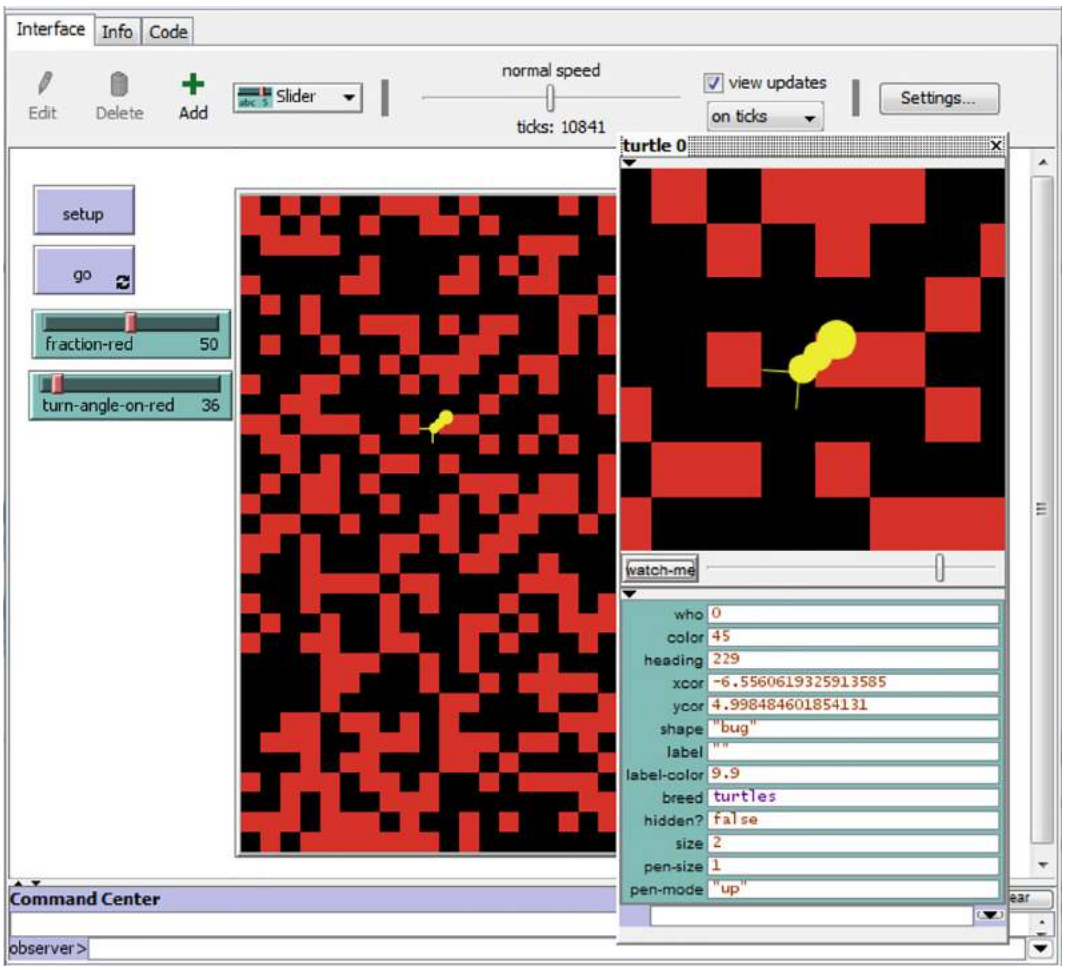

Fig. 2 Screenshot of the interface of a typical NetLogo implementation of an IBM. The interface consists of the grid representing the space, which consists of grid cells (patches), buttons to setup and run the model, sliders to change parameters. Further elements that are added by drag and drop are plots, output windows for text, etc. Individual patches and agents (=individuals) can be inspected (see window labeled ‚turtle 0′), i.e., all their built-in and user-defined state variables displayed while the model is executed. State variables can also be modified interactively. Besides of the Interface tab, the Info tab contains a verbal description of the model, and the Code tab the program, which is using a programming language, NetLogo, that contains numerous commands for dealing with patches and agents (see NetLogo web pages). Note that typical NetLogo applications include more than two types of patches and many agents that interact with each other and the environment, i.e., the patches.

conditions. To achieve this, we can prerun the model until the distribution of the state variables becomes quasi-stationary and evaluate the model only from this time on.

6. Input Data

   IBMs may also be driven by environmental variables, which are not generated by the model itself, but read as an input to the model from external files. Annual rainfall, for example, may be calculated by a rainfall submodel, or, if long-term rainfall data are available, they are taken from an input file. All inputs to an IBM must be carefully documented and, if possible, made available.

7. Submodels

   The processes listed in the ODD element 3, process overview and scheduling, are implemented in submodels which are described here in all detail, using the same submodel names as in the overview and the program implementing the model. "In all detail" means that all information should be provided to allow for a complete re-implementation of the model, so that replication, the cornerstone of the scientific method, is also guaranteed for IBMs. This implies that here also all parameter values used should be listed in a table.

   For complex models, the Submodels section often gets too long to be included in a journal article or book chapter, so that the full ODD has to be provided in an electronic supplement, while the main text only includes a summary description of the Overview part and the most important submodels.

Optimizing Model Complexity and Dealing With Uncertainty

IBMs are more complex than most mathematical population models, because they consider local interactions of individuals that are different and autonomous. This fact has led to the stereotype that IBMs are so complex that they are as hard to understand as nature itself, but this certainly is not true because even the most complex IBMs still are simplified representations of reality. Nevertheless, complexity is a challenge. Many IBMs seem to be more complex than really needed; specific techniques to test and analyze complex IBMs are not routinely used, which severely limits the potential for general insights. However, the general strategy of pattern-oriented modeling (POM) has been formulated which allows to optimize model complexity. POM is also useful for dealing with another important challenge of individual-based modeling: uncertainty of model structure and parameters. How can we know which process to include in a model and how to represent this process, for example dispersal? And how can we determine uncertain parameters?

POM is based on the notion that patterns observed in real systems are indicators of the system's internal organization. If we are able to understand how these patterns emerge then we learned about key processes that determine the systems structure and drive its dynamics. A pattern is defined as anything beyond random variation, or any signal beyond noise. Some patterns are striking, like cycles in the abundance of small mammals, outbreaks of forest insects, or patchy and wave-like spatial patterns. Other patterns are less obvious but nevertheless contain information about the system's key processes: patterns in age and size structure, typical recovery dynamics after disturbance events, the fact that certain system-level state variables like biomass or number of species remain within certain limits, etc.

Patterns are the key to decode the internal organization of any system: atomic spectra helped decoding the structure of atoms, the red shift in the light of galaxies helped formulating the big bang theory, etc. With complex systems, however, that consist of many interacting building blocks, single patterns are not sufficient to narrow down our theories about the system to one single model. For example, there are at least eight models that explain the cycles of small mammals in the boreal zone, and more than 20 theories that explain why ecosystems near the equator have much more species than in other zones.

Thus, for complex systems we need multiple patterns observed at different scales and hierarchical levels. For example, Chargaff's rule of DNA base pairing was not sufficient to decode the structure of DNA. Two additional patterns helped to narrow down the model of the structure to the double helix: patterns from x-ray diffraction of DNA and tautomeric properties of the purine and pyrimidine bases.

Patterns for Model Structure

The most important guide for designing a model is the question addressed. This question, or problem, allows us to decide, in an experimental way, which element of the real system to represent in the model and at which resolution. With POM, in addition we are asking: what patterns can we observe? If we agree that a certain pattern is typical, or even essential for describing the system's identity, we should chose a model structure that in principle allows the same pattern to emerge in the model. This means in particular that we have to include the state variables of the pattern. If, for example, the pattern is spatial, we need to include spatial variables in the model; if the pattern is in size distributions, we need to include size as an individual's state variable; if the pattern is a response to a disturbance event, for example, a drought, we need to include soil moisture as an environmental state variable, etc. Patterns thus make the choice of the model structure and complexity less arbitrary and more directly linked to the internal organization of the real system. The task of the modeler then is to check whether the model is able to reproduce the observed patterns. If not, key processes might be still be missing in the model.

Patterns for Testing Alternative Theories

The first milestone in developing an IBM is a first version of the model that, without too much fine-tuning of parameters, largely behaves like the real system. For example a population which largely has the right size and spatial distribution. The question then is, how can we find the best representation of a certain process, for example habitat selection, mate choice, or life history? The answer is to follow the scientific method of strong inference and formulate alternative models, or theories, of the process and then to check how good the entire IBM, including one of the alternative theories, is capable of reproducing a set of observed patterns. In this way model development becomes less ad hoc, more rigorous, and it becomes easier to communicate why a certain model formulation has been chosen.

Patterns for Reducing Parameter Uncertainty

With IBMs, easily too many parameters are too uncertain, or even completely unknown, to use the model for any practical purpose. It has also been argued that the complexity of IBMs leads to error propagation: even moderate uncertainties of individual parameters would multiply to such a large uncertainty at the system level that the model becomes useless. If, however, the IBM was designed according to POM, it should be structurally realistic, that is, reflect the key structures of the real systems and allow for independent predictions for model validation. This structural realism makes it possible to determine entire sets of unknown parameters by inverse modeling: the model is fitted to the entire set of observed patterns. Technically, this is straightforward: for each unknown parameter, a range and a number of values within this range is specified. Then the set of all possible parameter combinations is constructed, which can be very large. Specific techniques, like Latin Hypercube Sampling, exist for reducing the number of parameter sets, but typically thousands of parameter sets need to be analyzed. The model is run for each parameter set and checked if it is able to reproduce a certain pattern, otherwise the parameter set is discarded. This is repeated for two or more patterns. Eventually, typically less than 50 parameter sets remain that are able to reproduce all patterns simultaneously (Table 2). It has been shown in several examples that uncertainty in model output of this remaining parameter set is largely reduced, so that the model can even be used to support management decisions.

Analyzing Individual-Based Models

IBMs have to be constructed in an iterative way. The first model version should be very simple, for example by making the environment constant, or consider identical individuals, or by representing a certain process by a constant parameter only, etc. This first, or Null, version of the model is deliberately oversimplified. It serves the purpose to start the iterative process of model development as soon as possible. This is done by providing a first set of tools for analyzing the model, for example graphical output, summary statistics, etc. Once we have these observation tools implemented, we can start refining the model, testing its implementation, and comparing it to observed patterns. Analyzing and developing the model then is a time consuming and complex task, but it can be performed as rigorous as real experiments and allows us to understand the relative importance of different processes and how individual behavior is related to system-level properties, and vice versa. In the following, three main elements of analyzing IBMs are explained in more detail.

Currencies

IBMs contain much more information about the state of all the individuals and their environment than we can process. We thus need to aggregate this information into one or more aggregated system-level state variables. We need to define currencies (often also referred to as "indices") that allow us to characterize a single run of the model over a certain time horizon by, ideally, one single number. This number is then used as a currency to compare different parameterizations or formulations of the model. For example, in models addressing extinction risk of small populations, the risk of extinction over a certain time horizon is such a currency; or, if we want to compare model output to an observed time series, we can use root mean square deviation as a currency. In general, any quantitative measure of how good a certain observed pattern is reproduced is a good currency. Often, it is not clear from the outset which currency allows for deepest insights, so currencies are experimental and have to be tested and we usually we will need to consider a set of currencies simultaneously.

Simulation Experiments

Once we have a first version of the model that runs over the time horizon of interest and have both first observation tools and currencies implemented, we can start doing science with the model by performing controlled simulation experiments. As in real experiments, we try to create situations where all but one parameter is kept constant; we try to design experiments whose results are easy to predict just by reasoning. If our predictions fail, we either design even simpler experiments, or we modify our predictions, etc. It is thus useful to consider an IBM as a virtual laboratory. As in real laboratories, we build up understanding step by step. We might, however, not necessarily end up with a full comprehensive understanding of how the model system works. We should, however, be able to say under which conditions the model produces certain types of outputs.

Table 2 Pattern-oriented parameterization of an IBM describing brown bears spreading from Slovenia into the Alps

Pattern description	*Patterns*	*Number of model parameterizations in agreement with observed pattern*
No filter	0	557
Density of females in transition area	1	506
Bear observation in central Austria	2	138
Bear observation in the Carnic Alps	3	154
Bear observation in the Karawanken	4	180
Census time series of females with cubs	5	12
	2 + 3 + 4	13
	5 + 1	10
	2 + 3 + 4 + 1	11

Five different observed patterns are used as filters to reduce the number of possible parameter sets. Note that pattern 5 is as good a filter as patterns 2, 3, and 4 in combination.

Modified after Wiegand, T., Revilla, E., and Knauer, F. (2004). Dealing with uncertainty in spatially explicit population models. *Biodiversity and Conservation* **13**, 53–78.

Robustness Analysis

With many IBMs, we are interested in understanding one fundamental property of real systems, for example persistence of a population, diversity of a community, or coexistence of different life forms, for example trees and grass in savannas. The first task of model development and analysis is to reproduce the desired property with the model. But a model might produce a certain phenomenon only for a very restricted range of parameter combinations, which would make it unlikely that the real system has that property for the same reasons as the model. What we want to achieve are robust explanations that do not depend too much on details of the IBMs formulation and parameters (the same holds for any type of simulation model). For example, IBMs reproducing schooling behavior of fish turned out to be quite robust, even in a quantitative way, to details of how the interactions of neighbor fish is described, as long as the principle mechanism was included that the influence of neighbor fish is averaged in some way. Similarly, complex IBMs of tropical and temperate forests turned out to be quite robust to changes in many model parameters. This robustness reflects internal feedbacks, for example between mortality, recruitment, and dynamics of gaps in the canopy. Such feedbacks are likely to play a similar role in real forests.

Robustness analyses thus means to test the robustness of key model results to changes in model structure and parameters, and also to identify thresholds, for example critical parameter values, or key mechanisms that have to be in the model in order to get the desired model output. Robustness analyses thus helps to check how much of the model's complexity really is needed for explaining the real system's internal organization.

Implementing Individual-Based Models

Implementing an IBM as a computer program, including tools for observation and analyses of a large number of parameterizations and formulations, can be quite challenging. Many tools exist in computer science that support the development and maintenance of complex software, but ecologists usually have no training in computer science. Most developers of IBMs thus are writing their software from scratch, without using concepts and tools of, for example, object-oriented programming. This makes the resulting software prone to errors and its development very inefficient.

There are mainly two alternatives to programming from scratch: (i) Software libraries. The modeler still has to use a certain all-purpose programming language but can utilize many predefined elements that support the implementation of IBMs. Examples of such libraries include Swarm (based on Objective C), Repast (Java), and Mason (Java). These libraries are supported by active user communities and their developers, but often are lacking a comprehensive documentation and tutorials. The learning curve for beginners is quite steep, but for the experienced they provide a very powerful framework for implementing IBMs. (ii) Modeling environments. They consist of menus or simplified programming languages that are easy to use and learn and allow to very quickly developing prototype IBMs. Examples include CORMAS, and NetLogo. NetLogo is freely available on the internet, is well-documented, comes with a good tutorial and many example models, and is actively maintained by its developers. Comparisons with Swarm and Repast showed that NetLogo is much less limited in performance and scope than one might expect due to NetLogo's history as a teaching environment. Being first designed for education and later being recommended for beginners in modeling, NetLogo is now increasingly used for entire modeling projects, sometimes of high complexity. In social simulation NetLogo has become the dominant software platform, while in ecology its use is increasing, a trend that is fostered by textbooks that were published since 2012.

Modern personal computers usually have enough memory and power for developing and running IBMs, but vast analyses of parameter space, for example for parameterization, may need the combined power of PC clusters. For analyzing the output of IBMs, many modelers are using other software packages, for example R, Matlab, Mathematica, Excel, SPSS, etc. For NetLogo, also direkt links to R exist.

Examples

Three example IBMs are briefly described. The coyote model is an example of an IBM that does not explicitly include adaptive behavior. Rather, individuals behave according to empirically determined rates or probabilities. The shorebird model, in contrast, explicitly represents adaptive behavior: each bird is, on a time scale of several hours, making decisions where to move and feed in the habitat. Gap models, finally, have a very long and successful history in ecological modeling of forests.

Coyote Model

The coyote model of W. C. Pitt and coworkers is a good example of an IBM that describes a species with a quite complex social behavior but nevertheless is quite simple. The purpose of the model is to support management decisions. Individuals have the state variables sex, age, social status (alpha, beta, pup), and the group (pack) they belong to. The model considers packs but not territories, and is thus not spatially explicit.

The most important rules of the coyote model are for individuals leaving the group and density-dependent mortality and reproduction. Coyotes between 1.5 and 2 years old have a probability of leaving their pack that is proportional to the square of pack size. Coyotes that leave their pack enter a pool of transients. Mortality of transients increases with the total number of transients and thus tends to be higher than that of pack members. The number of offspring produced is assumed to be density-dependent, that is, to decrease with pack size.

The coyote model was implemented using the Swarm software library. This had the advantage that Swarm's framework for implementing an IBM's schedule could also be used for communicating this schedule (Table 1). This makes is easier to understand and re-implement the model. The schedule also shows that the coyote model consists of actions that are very simple. The complexity of IBMs is more in its implementation and analysis, not necessarily in its formulation.

The model was verified by using five currencies: mean pack size, proportion of transients, average offspring survival rate, average litter size, and proportion of females breeding. Model prediction matched observations surprisingly good, even without fine-tuning of parameters that were taken from the literature. An important insight gained from the coyote model was that the transients are buffering population dynamics. On the one hand they limit, due to their density-dependent mortality, population growth. On the other hand they buffer the loss of alpha individuals.

Shorebird Models

The shorebird models of J. D. Goss-Custard, R. A. Stillman, and coworkers are good examples of IBMs that needed to include adaptive behavior because empirical model rules would not have been sufficient. The IBMs were developed to predict the impact of land reclamation, resource harvesting, and recreation on the winter mortality of species of shorebirds and waterfowl, for example the oystercatcher (*Haematopus ostralegus*) in the Exe estuary in England. The IBMs had to predict the effect of new environmental conditions, for which no empirical rules or data were available. The models had thus to operate on basic principles, that is, physiology and fitness-seeking feeding behavior that is based on adaptive decisions.

The tidal-flat habitat is divided into discrete patches, which vary in their exposure and their quantity and type of food. During each time step birds choose where and on what to feed, or whether to roost. Times steps typically represent 1–6 h. The bird's state variables include foraging efficiency, dominance, location, diet, assimilation rate, metabolic rate, and amount of body reserves. Key environmental inputs to the models are the timings of ebb and flow and temperature, which both affect feeding and the amount of food needed to survive.

A main behavioral process of the model is interference competition (e.g., food stealing), which is related to the individual's dominance status and to local bird density on the patches. The submodels describing the bird's decision where to move, what to eat, and how much time to spend feeding, are based on first principles from optimal foraging theory and game theory. The individuals are assumed to always try and maximize their own chance of survival.

Model predictions were compared with many observed patterns, and after several iterations of the modeling cycle, patch selection, prey choice, and the proportion of time spent feeding were accurately predicted for many species and sites. In one case, the increase in winter mortality due to land reclamation was known from observations. The model was parameterized for the preimpact situation, then run for the situation with reduced feeding area and the increase in winter mortality determined. The match of observed and predicted increase in winter mortality was almost perfect. It could also be shown that the model if it had existed at the time the land reclamation took place, could have been used to recommend a certain mitigation measure that was under discussion but not realized because it was unclear whether it could really compensate the loss of original feeding areas.

The first shore-bird model of the group of Goss-Custard and Stillman needed several years for implementation, parameterization, and testing, but subsequently simpler and more flexible models were developed, that could be used for management support within one to 2 years. Since then, the model has been used for a suite of species of shorebirds, waterfowl, and other bird species at more than 20 different sites all over Europe.

Gap Models of Forests

Gap models describe the change of species composition on a gap in the forest that was created by death of a canopy tree. Typical gap size in early gap models is 0.01 ha. The entire forest is assumed to be an ensemble of gaps with temporally and spatially

independent dynamics. The purpose of gap models is to understand long-term species composition and succession and how they depend on environmental variables. Gap models were thus developed by ecologists, not forest managers.

The representation of the individuals, the trees, is extremely simple: they have only one state variable, trunk diameter at breast height (dbh), which is a standard measure of size in forestry. Tree height is calculated from dbh using an empirical relationship. The structure of gap models is extremely simple: each tree grows according to a sigmoidal potential growth curve. Potential annual growth is then reduced by multipliers which reflect the influence of competition and environmental factors. Competition is only considered vertically and calculated from the vertical distribution of light that is determined by the trees existing in the gap.

Thus, each time step of the model, which usually represents a year, first the vertical light profile is calculated, and then the growth increment. Different species are characterized by different parameters of the growth equation and the relationship between dbh and height. Mortality depends on the growth rate: trees that do not grow for a certain time span, that is, are suppressed by larger trees, will die sooner or later.

Starting from the pioneering model JABOWA, more than 30 gap models have been developed for a wide range of forest types and questions. More recent gap models try to be more realistic in some way, for example by including spatial interactions between neighboring gaps. The great success of gap models has three main reasons: they are conceptually very simple, their growth equations are relatively easy to parameterize, and they make important testable predictions regarding species composition and dynamics of real forests. Modern gap models, which are more complex but also more flexibe, include representations of photosynthesis and thereby link forest models to the global carbon cycle. Using information from satellite images it is nowadays possible to model, for example, the entire Amazon rain forest, taking into account each individual tree.

The Future of Individual-Based Modeling

IBMs are a flexible and powerful tool and very likely to lead to important insights into how system-level properties of ecological systems, for example stability properties (e.g., resilience), emerge from the interactions of the individuals among each other and with their environment. The approach poses also new challenges, in particular optimization of model complexity, coping with uncertainty in model structure and parameters, formulating the models according to a unifying framework, and implementing, testing, and communicating IBMs according to general standards.

IBMs will continue to be used both in a more pragmatic and a more paradigmatic way. Pragmatic IBMs usually do not refer to adaptive behavior and often are designed to be as compatible with more simple mathematical models as possible. There are certainly many questions where this type of IBM is sufficient, because, as we have seen in the coyote model and gap models described above, for many questions we do not need to refer to adaptive behavior explicitly.

Paradigmatic IBMs, however, are based on the assumption that adaptive behavior, that is, the simple fact that individuals adapt their behavior to their current situation and that they are seeking to maximize fitness, is key to understanding most, if not all phenomena at the system level. Paradigmatic IBMs are seen as the nucleus of an Individual-based Ecology which links individual behavior, including life history and phenotypic plasticity, to system-level structures and dynamics. Next-generation IBMs are based on first principles, use information on trait distributions and remotely-sensed data, and are tested and parameterized with multiple patterns, observed at different scales and levels of observation. They make testable predictions about functional relationships, and they are designed to link theory and application via high levels of structural realism.

Introduction

A model is a simplified and imperfect representation of a system, describing only the features essential for the model's purpose. It is crucial for model acceptance and credibility that the modeling process is transparent and follows best practice. The development of a model requires clear agreement on the model purpose and context, involving not only the modelers but also the stakeholders in its use. The process of achieving agreement is iterative, with continual refinement of the purpose and objectives as the modelers and stakeholders learn more about the system to be modeled and the scope for using the model. From that point conceptual models can be developed to guide the choice of model features and families and to help determine how model structure and parameter values are to be found. Performance criteria can then be developed, geared to the model purpose and context, the model structure and the available data. Once the model has been constructed, it must be subjected to calibration, quantification of uncertainty, testing and evaluation of its effectiveness. At any point in the model development it may be necessary to revisit and revise earlier steps as new information unfolds.

This article discusses a 10-step modeling approach (see "Further Reading") in the context of two ecological models developed for a wetland. Modeling should be viewed as a process, and its effectiveness for learning and supporting decision making hinges on how the model is developed, analyzed and reported.

Case Study: Gwydir Wetlands

The Gwydir wetlands comprise a large terminal floodplain wetland complex covering 3000 km^2 in the Murray-Darling Basin in New South Wales, Australia (Fig. 1). The development and regulation of the Gwydir River system, including large headwater storage, diversions, and extractions for irrigated agriculture, has reduced the extent and duration of flooding of the wetlands. Rainfall varies from over 800 mm/year in the upper parts of the catchment to less than 450 mm/year over the wetlands, while potential evapotranspiration can exceed 1400 mm/year. The Gwydir wetlands support a diverse flora and fauna community, including rare, vulnerable and endangered species and migratory bird populations. Part of the wetlands is listed as a Ramsar site of international importance.

Models that represent the ecological response to flows and flooding improve water management by providing a tool to assess management scenarios and facilitate an informed compromise between environmental and human water needs. Here we discuss two ecological models developed in parallel for the Gwydir wetlands. One model represented bird, fish, and vegetation response to flow at a species level; this will be referred to herein as the species model. The other model represented broader landscape unit vegetation productivity response to flooding; this model will be referred to as the vegetation productivity model. Although both were coupled to a water balance model, the two ecological response models were built using different modeling approaches. The models will be described to illustrate the 10-step good-practice framework for model development (see Further Reading).

Step 1: Define the Model Purpose

Modeling involves the systematic organization of data, knowledge and assumptions to fulfill a specific purpose. Models can be used to:

- improve understanding of the system;
- elicit, review and represent knowledge and reveal system properties;
- reveal weaknesses in our knowledge and set research priorities;
- generate and test scientific hypotheses;
- provide a focus for discussion of a problem or simulate further questions about system behavior; and
- forecast or predict outcomes under a range of management or environmental scenarios.

The crucial question in the wetlands case study is "What flow regimes are required to support known ecological assets and maintain the ecological values of the wetland system?" From a water management perspective, this is akin to asking how

☆*Change History*: March 2016. S Hamilton updated all sections including the reference section, deleted Figures 3 and 6 (original version) and added Figure 4 (revised version).

This is an update of S. Powell, J.P. Norton and A.J. Jakeman, Model Development and Analysis, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2402–2410.

 doi:10.1016/B978-0-12-409548-9.11118-2

environmental water can be delivered for greatest ecological benefit. The vegetation productivity model was developed to improve understanding of the flood dynamics of the wetlands and assess possible impacts of inflow and climate change scenarios on vegetation. The species model was developed as part of a decision support system (DSS) for managers of environmental flows into wetlands. The ecological component of the DSS, that is, the species model, was developed to predict the response of various wetland attributes (bird, fish, and vegetation) to environmental flows.

For both models, stakeholders were identified early in the process to ensure relevancy of the model. Stakeholders included representatives of a range of government departments, local landowners, independent scientists, and other interest groups. Funding organizations, technical experts and data suppliers may also be considered as stakeholders. Model end users, in particular, need to be involved in the modeling process from the beginning to make sure they share a common understanding with modelers with regards to the purpose and design of the model.

Ultimately stakeholders may want the model to forecast outcomes (e.g., flood extent and duration, vegetation response) for a range of environmental flow scenarios. The spatial and temporal resolutions must be decided relative to that purpose. Water for the environment is in limited supply and delivery can be both technically and politically difficult. The ability to model a range of water-delivery scenarios provides greater assurance of beneficial outcomes while observing practical constraints.

There are other outcomes of the modeling exercise benefiting all stakeholders, such as better understanding of the system. Partial answers, at least, are obtained for broad questions such as

- How do floods behave and how does flooding affect the vegetation and other ecological communities?
- What are the interactions between flooding, vegetation response and fauna, and which of these processes are of interest to water managers?

For both wetland models, model development also provided a focus for discussion of problems associated with the wetland ecosystem. It enabled a range of stakeholders to define the system and its problems, incorporate prior knowledge and concentrate on the problems rather than being distracted by matters outside their boundaries.

The modeling steps should be revisited if necessary. For example, the first version of the vegetation productivity model revealed gaps in knowledge of flood patterns, vegetation response to flooding and triggers for waterbird breeding, and highlighted the need for further research. The results of that research should allow better definition of the model type, structure, and complexity. This is a cycle of iteration: tentative choices of model scope, type, structure, and resolution determine data needs, which when filled allow refinement of those choices (which may then reveal further needs). The process also includes revision of stakeholder expectations as what is practicable becomes clearer.

Step 2: Model Context

The scope of both models were defined in consultation with stakeholders. For the species model, this was done through a workshop with natural resource managers, scientists, and local landholders. The model process for the vegetation productivity model was

introduced to stakeholders through meetings, position papers, and one-to-one discussion to gain acceptance and elicit advice on specific questions and model boundaries. Questions to which the stakeholders expected answers from the model included

- How much water is required to inundate specific areas (ecological "assets" including Ramsar sites, bird breeding areas, specific vegetation communities and water holes) for a specified length of time?
- What was the flooding pattern and vegetation response in each "asset" prior to and after river regulation?
- Is it just a matter of water volume entering the system, or does timing (for example the daily flow pattern) influence the flood pattern and vegetation response?

Model development included the opportunity for stakeholders to continue to refine their objectives through meetings, focus-group discussions and individual responses.

Spatial and temporal boundaries and scales were also considered at this stage. Selection of appropriate scale depends on factors including the processes of interest and the variability of attributes across time and space. Vegetation response to inundation can be measured in days to weeks, while ecological community structure is a product of longer-term flow and flood patterns (frequency and depth). Spatially the smallest vegetation community covers an area of approximately three square kilometers, but other ecological assets can be smaller. There is also the question of whether to start small (spatially) and build up the model or start larger and refine the model.

Resources in people, time and effort available for the modeling must be identified. The vegetation productivity model project had a timeframe of 3 years, with one researcher. The financial resources available for that project precluded additional staff, expensive or extensive monitoring programs or expansion of the project significantly beyond the identified scope. The species model was developed under a larger project, however the ecological model for Gwydir wetlands was just one of several components in the project. Therefore resources for developing the ecological model were also constrained. Given these constraints, the species model was based on existing models and also designed to be adaptable so that new data and knowledge can be readily incorporated into the model when made available. The species models were based on the likely habitat condition for select species of management interest.

Step 3: Conceptualize System, Data and Prior Knowledge

A conceptual model is an important step in model development, and may be a useful tool on its own. It is used as an abstraction of reality in ecosystems to delineate the level of organization that best meets the objectives of the model. It is not only a list of state variables and forcing functions of importance to the ecosystem and the problem at hand; it also shows how these components are connected by processes. A range of conceptual tools is helpful in this process as summarized in **Table 1**.

With the model objectives and context in mind, the concept for the vegetation productivity model was initially based on a semi-lumped water balance approach as shown in **Fig. 2**. This concept defines the most important drivers of the flood patterns and identifies spatially distributed components that represent different flood dynamics and ecological responses. This water balance component was then linked to vegetation response.

A number of possible concepts were considered for representing vegetation response. Important vegetation species may be modeled in detail if there is sufficient information about their requirements. The flood dependence of each life stage (e.g., germination, establishment, growth, reproduction, death) could be represented and some measure of success devised, based on successful recruitment to the seed-bank or sufficient storage in rhizomes, for example. This approach requires two temporal scales to be considered: the "within-event" scale where day-to-week inundation patterns and vegetation response are important, and multiple "events" which influence the functional groups that respond to many events, ultimately influencing the community structure of the system. The information can be incorporated into a response model as a surrogate for whole-community response, or in conjunction with the functional-group approach. A simpler approach was adopted in the study, based on a surrogate of primary productivity—the normalized difference vegetation index (NDVI). This approach quantified the vegetation (community) response through green-up, maturity, senescence and dormancy. Applying this concept to the study area, multitemporal remote sensing analysis of a flood event clearly demonstrated the vegetation response pattern; not only detecting the green-up, maturity

Table 1 Conceptualization methods

Method	*Description*
1. Word models	A purely verbal description
2. Picture models	A pictorial representation of the system
3. Box models	Boxes represent components; arrow represent processes
4. Input/output models	Same as box models except values for input to and output from the boxes are added
5. Matrix conceptualization	Using matrices to assess possible interactions between components
6. Forrester diagrams	Symbolic language representing variable, parameters, sources/sinks, flows and rate equations
7. Computer flow chart	Flow chart to show the sequence of events in a process
8. Signed digraph models	Plus and minus signs used to represent positive and negative reactions between system components in a matrix
9. Energy circuit diagrams	Designed to give information on thermodynamic constraints, feedback mechanisms and energy flows

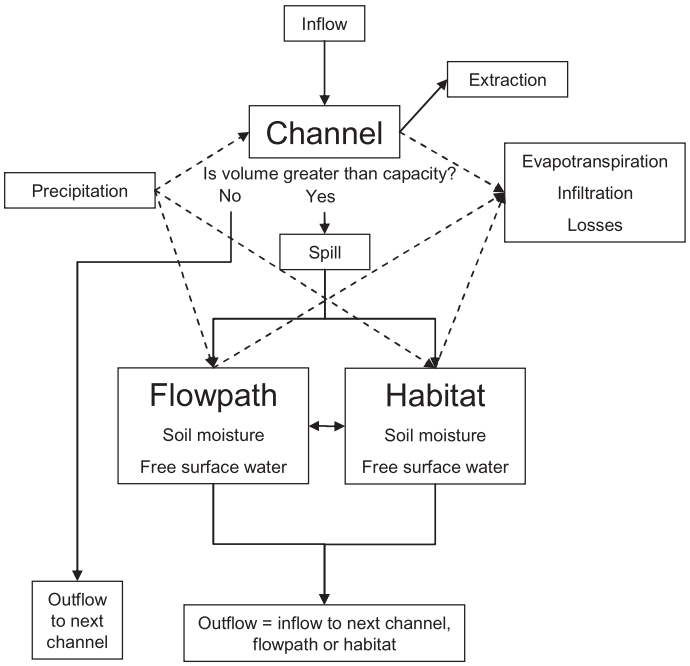

Fig. 2 Conceptual flowchart of channels, flow paths and habitats that can be used to create a semi-distributed model of flooding, soils moisture and vegetation response across a floodplain system.

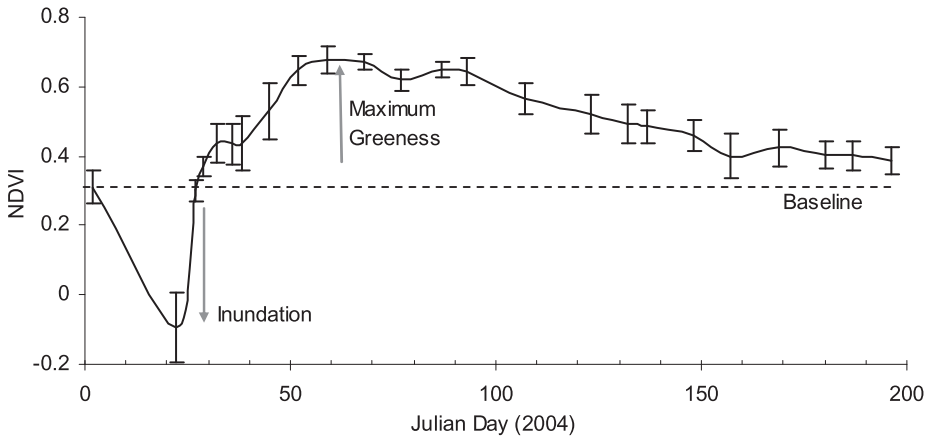

Fig. 3 Vegetation response curve (mean, $\pm$ standard deviation) for a Ramsar site. The initial flooding is shown as normalized difference vegetation index (NDVI) values of less than 0 on day 22. Response to maximum greenness is rapid.

and senescence stages, but also the initial flooding of the area (Fig. 3). Linking the phenology over a range of floods to vegetation functional groups provided the basis for better understanding vegetation community response.

For the species model, the conceptualization step was divided in two stages. Firstly, conceptual models capturing the ecological assets, interactions and drivers of the system were developed by the key stakeholders and DSS end users through workshops. These workshops also identified potential scenarios to be modeled and existing data sets. Secondly, the conceptual models were reviewed by the modelers and updated as appropriate for the DSS. The final conceptual framework (Fig. 4) contained two major components: the hydrological component and the ecological component. More detailed conceptual models were developed for waterbirds, fish, and vegetation. The conceptual models were a useful basis for focusing the scope of the model.

Step 4: Select Model Features and Families

The selection of model features and families depends on the items of interest and the form of model output. Model families and features include:

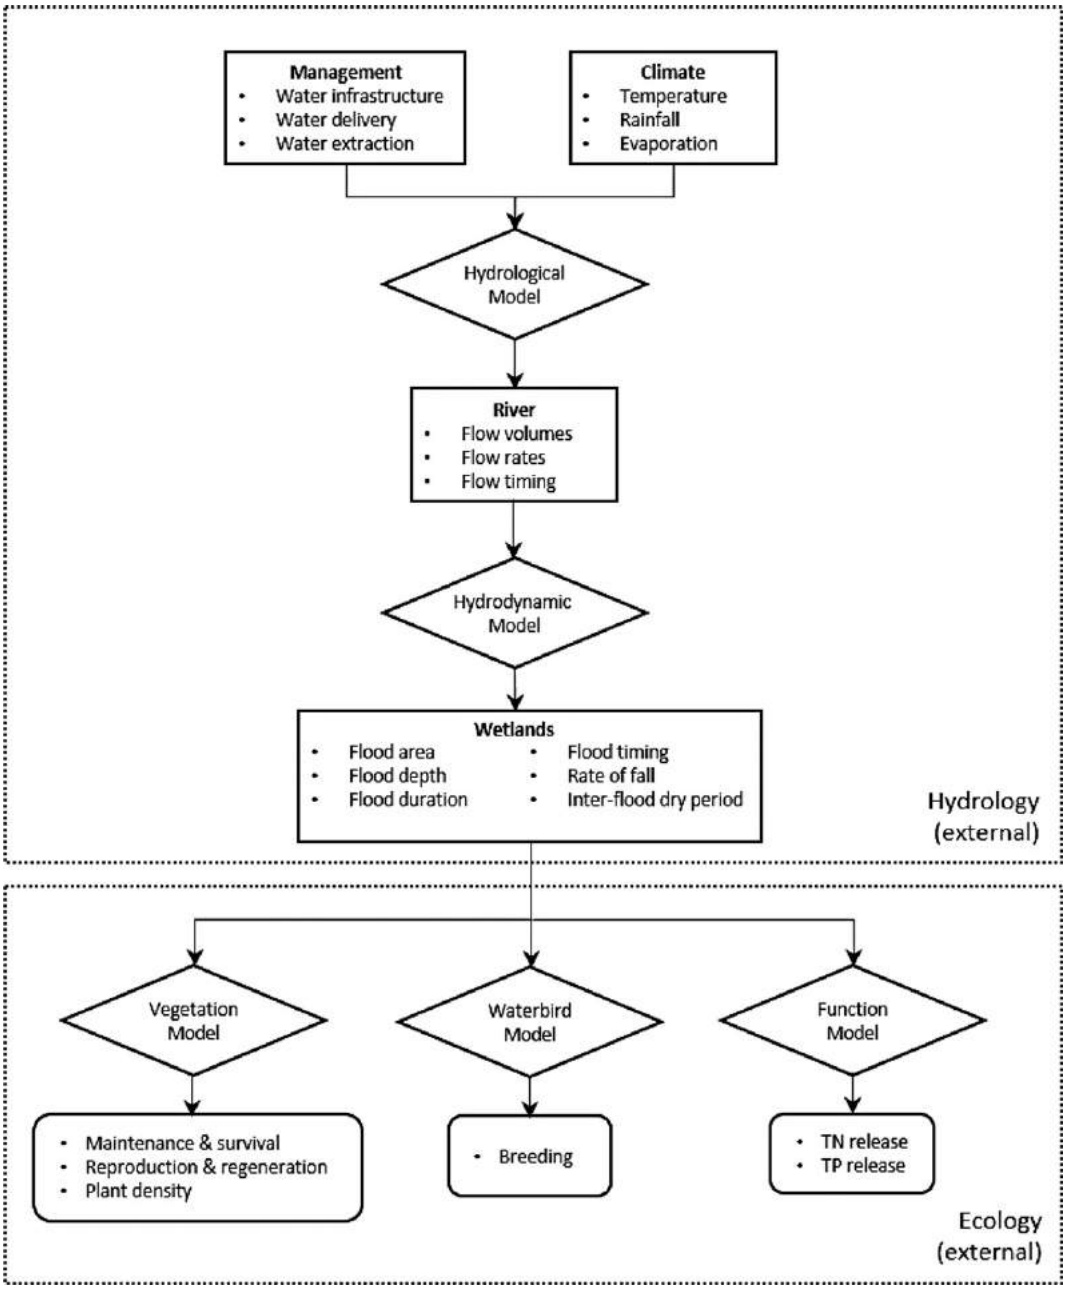

Fig. 4 Conceptual framework of the Gwydir wetlands Decision Support System (DSS). (Adapted from Fu, B., Merritt, W., Pollino, C.A. and Jakeman, A.J. (2010). Decision support system for the Gwydir wetlands—Phase 2. Final report for NSW Department of Environment, Climate Change and Water.)

- *empirical, data-based, statistical models* such as parametric or nonparametric time-series models, regressions and their generalizations such as autoregressive moving-average exogenous models, power laws and neural networks. Such models have detailed structure and parameter values determined exclusively by observational data, rather than selected in advance on the basis of prior scientific knowledge, expert judgment, or custom;
- *stochastic, general-form but highly structured models* which can incorporate prior knowledge, for example, state-space models and hidden Markov models;
- specific *theory-based or process-based models* (usually deterministic, that is, not probabilistic and thus not directly allowing for uncertainty), as often used in environmental physics and economics, for example, specific types of partial or ordinary differential or difference equations;
- *conceptual models* based on assumed structural similarities to the system, for example, Bayesian networks, compartmental models, cellular automata;

- *agent-based models* allowing locally structured emergent behavior, as distinct from models representing regular behavior that is averaged or summed over large parts of the system;
- *rule-based models*, for example, expert systems, decision trees;
- a spectrum of models which represent dynamics, that is, time-spread responses to the inputs at any given instant. This spectrum spans instantaneous (static, nondynamical, algebraic) models, discrete-event and discrete-state models, lumped but continuous-valued dynamical models, and distributed and delay-differential models with infinite state dimension; and
- a corresponding spectrum of spatial treatments, comprising nonspatial, "region-based" or "polygon-based" spatial, and more finely (in principle continuously) spatially distributed models.

For the vegetation productivity model example, the relationships between flow and flood dynamics and flooding and vegetation response to flooding were based on regression analysis. A regression-based model was deemed sufficient, given the good fit found between observed variables. Spatially the model was semilumped into landscape units of similar behavior. The model was to provide a daily time series estimate of productivity as its output.

Bayesian networks were selected as the modeling approach for the species model. In Bayesian networks, linked variables are used to describe cause and effect, and relationships are described probabilistically. This type of model was deemed suitable due to their flexibility in representing components of varying detail, their representation of uncertainty and their capacity to use a broad range of data to populate the model, including expert elicitation. One major limitation of Bayesian networks is their poor representation of spatial and temporal dynamics; this was overcome by linking the networks to a spatially distributed, dynamic hydrological model and dividing the wetland area into "storages," the unit at which outputs were reported.

Step 5: Choose How the Model Structure and Parameter Values Are to Be Found

In finding the structure, prior science-based theoretical knowledge might be enough to suggest the form of the relations between the variables in the model. In the flood dynamics component of the vegetation productivity model, there was insufficient data to allow empirical modeling from scratch, so existing water-balance principles were used. Other parameters in the model were estimated by optimizing the fit of model outputs to observations such as measured water depth at a location, and remote sensing that provided NDVI response as a surrogate for productivity. This approach was used with caution, as experience showed that the river system had been manipulated during past floods, with channel structures altered during the course of a flood or vegetation cleared, grazed, or burnt.

If theoretical understanding is one of the model objectives, and some prior knowledge of system processes exists, then an approach that does not determine model structure solely according to fit to observed data should be favored. Such an approach is very likely to produce a model structure which is an uneconomical summary of the behavior observed in the data, as the structure is partly or wholly dictated by prior knowledge (an empirical modeler would say "prejudice"). Such prior fixing of model structure can impose realistic constraints on possible behavior and may make interpretation of the model parameters much easier, but there is often a conflict between making the structure reflect what is known in advance and making it identifiable (through testable parameter values) from observations. In the vegetation productivity modeling project several parameters were estimated using expert opinion. Experts in the wetland vegetation and ecology were called upon to check vegetation response parameters and model structures. There is little safeguard against misjudgment on their part, however.

Degree of spatial aggregation in the vegetation productivity model was determined by a mapping approach based on identified ecological "assets," major vegetation communities and remote-sensing analysis to identify major flow paths and flood areas. Landscape units that were relatively homogeneous (in their flood regime and vegetation response), but as large (lumped) as practicable to match the objectives of the research and the resolution of the input data were identified and used in the model.

For the species model, the model structures for the waterbird, fish, and vegetation submodels were based on multiple sources of knowledge and data. The fish model structure was developed in collaboration with domain experts, and estimates of the relationship between flow, spawning and recruitment were derived from monitoring data, literature values and expert judgment. The vegetation and waterbird response models were primarily based on an existing database containing the water and habitat requirements of biota in the Murray-Darling Basin. Model structure and parameters can be drawn from various sources including expert opinion where data do not exist.

Step 6: Choose the Performance Criteria and Parameter Estimation Techniques

The criteria by which the model performance is judged should reflect the desired properties of the estimates. This is particularly important in this case study, which must gain the acceptance of a group of nonmodeler stakeholders. Demonstrated lack of bias is important, as there will be significant input from stakeholders who may be perceived to have particular viewpoints or desired outcomes. Stakeholder confidence in the model is best achieved through acceptable prediction performance. This may be a challenge in view of the dynamics of the system; a solution might be to discuss the results with the stakeholders, employing collective memory of past events as well as hard data.

To test for over-parameterization, analysis of the sensitivity of the model outputs to the parameters is useful. It can be performed on the individual components (e.g., the flood dynamics and the vegetation response), but ideally should be performed

on the integrated model. Sensitivity assessment will also help to identify critical parameters whose values may need refining, scope for further lumping, nonlinearities which affect the nature of the responses, and behavior inconsistent with expert knowledge.

Step 7: Identify the Model Structure and Parameter Values

The final model structure should balance sensitivity with complexity and represent the dominant responses of the system at the time and spatial scales of concern. The structure should also ensure that system descriptors such as numbers of variables and processes are aggregated where this makes the representation more efficient. As discussed in step 5, aggregation may be spatial or temporal, or it may be in the way in which ecological response is modeled, focusing on landscape units (or other functional groups) or total productivity rather than individual species. Alternatively, a few specific species may be modeled as indictors of wetland health. Finally, the structure should not be over-flexible as that may result in unrealistic behavior, ill-conditioning and poor identifiability (inability to find well defined parameter values). This should be tested in step 8 if performance criteria are well chosen and verification properly carried out.

Step 8: Verification

Verification of the model structure and parameterization ensures that the model adequately reproduces the observed behavior with regard to the original purpose and context. Common metrics used to measure model performance include root mean square error and coefficient of determination (r^2), however such criteria on their own may be insufficient. Fig. 5 illustrates a simple comparison of outputs from the vegetation productivity model (the inundation depth) against the observed depth at one of the wetland sites. Here measures of model fit such as the root mean square error would indicate a poor fit, but the errors are largely due to mistiming. To address this, model outputs were generated for both daily and 16-day time steps, with the latter producing better model fit. Nonetheless matching of extent, rates and pattern of response may be considered acceptable for the purpose. Testing should also examine the robustness of the model outputs to insignificant changes to data and assumptions.

Assumed physical properties should be plausible, defensible and consistent with prior knowledge (if we are clear about what prior knowledge is genuinely known and what is assumed). In the water-balance component of the vegetation productivity model, for example, assumptions about the behavior of soil moisture were made according to plausible physical processes, but need to be tested and modified as required. Soil moisture and inundation over a floodplain can be modeled but there was no observed dataset to verify. Instead, stakeholders examined the results in the light of personal experience and judged the results to be plausible and consistent with their expectations.

It is also important that the model is tested against statistical knowledge and assumptions, for example, that residuals do not disagree significantly with statistical assumptions, such as absence of systematic structure or significant correlation with the inputs. It is desirable to confirm that parameter estimates have converged, although with short or sparse data sets this may not be possible as was the case in the species model. Excessive variation of parameters with time or location may expose shortcomings of the model structure or the observations. As discussed previously, the entire modeling process must conform with the purpose and context of the model; the verification step is no exception. At this stage, the assumptions and boundaries within which the model seems valid must be clearly established. In the absence of sufficient data for testing, qualitative assessment including peer review can be a useful form of verifying model behavior.

Step 9: Quantify the Uncertainty

Primary sources of uncertainty in a model include errors and finite sample size in the observations, experimental or subjective error in supplied parameter values, and approximation error in the model algorithms and structure. This last source includes both error deliberately incurred in exchange for model simplicity or reduced data needs and, importantly, intrinsic variability in the processes

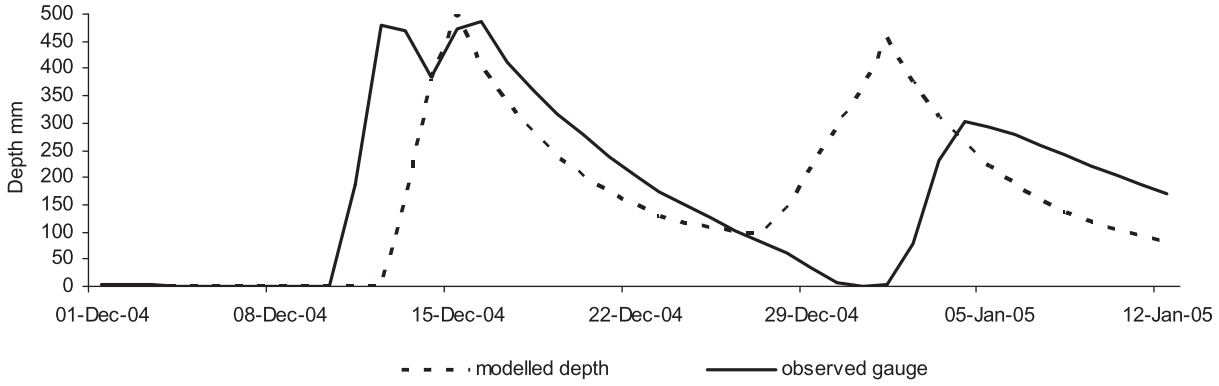

Fig. 5 Modeled and observed depth of inundation for two vegetation communities.

modeled, due to finer-grained processes for which there is no realistic prospect of modeling. In the present examples, this source is prominent and ineradicable.

Bayesian networks explicitly express uncertainties through the use of probabilities, although no distinctions are made between the different uncertainty types and sources. Uncertainties, represented as distributions of probabilities across the states of nodes (variables) in the model, are propagated through the network to the final output. For example, an output of the waterbird model can include the likelihood (%) that good habitat conditions are provided for breeding for a specific species, under specified climate and environmental flow scenarios. These uncertainty values can be valuable for managers, who can use the probability values to weigh up risks of undesirable outcomes associated with management alternatives.

For other model structures such as stochastic models, it is possible to incorporate quantification of uncertainty within the model structure itself. However for model structures such as that used for the vegetation productivity study, uncertainty testing is a separate item. To establish which variables and what types of uncertainty are significant for the model purpose, the results of sensitivity assessment have to be examined, together with estimates of the parameter uncertainties and unmodeled inputs. Some parameter-estimation algorithms (e.g., least squares and its recursive generalizations) provide estimates of parameter uncertainty in the form of error covariances, and can account for observation errors and responses to unknown inputs as "noise" with assumed or estimated statistical properties. Alternatively, fitted parameters can be estimated from different sections of the records and the variation in the parameter values and the output residuals assessed (or approximate probability densities found by resampling, as in bootstrapping). Cross-validation by comparing residuals across various subsamples of the records (see below) is an instance of this process.

Structural uncertainty is often overlooked in modeling, and is potentially large in ecological models partly due to the need to drastically simplify reality. Structural uncertainty is one type of uncertainty not accounted for in the probability values of Bayesian networks. Ideally for any ecological model, one would consider a number of model structures (e.g., based on different hypotheses) to assess the uncertainty associated with the model structure.

Step 10: Evaluate and Test the Model

Finally the model can be evaluated on an independent data set with different input series to test the predictive performance (or cross-validated using a range of subsamples of the original data, in which case steps 9 and 10 are intimately linked). The practical difficulties mentioned in steps 5 and 6, arising from channel or vegetation manipulation in past floods altering the behavior modeled, are typical. Changes in the system (as distinct from its inputs) are common in environmental modeling yet hard to represent, being often episodic and not unambiguously identifiable from the primary records. Auxiliary sources of information, for example, aerial photographs at long intervals, vegetation monitoring and the memories of stakeholders, may be critical in identifying and understanding the changes.

In the context of these case study models, some uncertainties are not readily characterized, especially those stemming from omission or over-aggregation of significant behavior, or incomplete observation records. Moreover, the main performance criteria of the model include its effectiveness as a guide to what water flow regimes will achieve the required ecological values and its value in improving understanding of the effects of floods and regulated flows. Neither is adequately measured by exclusively statistical or other formal means. Consequently, an important approach to model testing (although not the only one) is to look for, explain and if possible rectify anomalies in the outputs produced for realistic input datasets. For example, dummy input flow and climate series may be constructed to test the flood dynamics. The opinions of expert stakeholders can be sought on the plausibility of the responses at selected locations (e.g., flood plains), in crucial periods and overall. Where the results are implausible, the model must be reexamined. Conversely, results accepted as plausible may raise confidence in the fitness of the model for evaluating environmental flow delivery scenarios.

Conclusions

The case studies demonstrate how a best-practice modeling framework helps ensure that modeling is well considered, well documented and transparent. The approach increases the evidence on which the model development may be accepted by the stakeholders. Regardless of a model's final success in relation to its predictive purposes, the 10-step process should ensure benefits to all involved, in the form of better insight into the system, the data and the scope and limitations of modeling.

Requirements for transparency may be summarized as:

- clear statement of the model objectives and end user requirements;
- documentation of the nature, scope and quality of the data;
- a strong rationale for the choice of model families and features;
- justification of the methods and criteria used in calibration and parameter estimation, including readiness to acknowledge, critically, informal or unorthodox methods and criteria where circumstances require them;
- thorough analysis of the performance relative to the resources and application;
- documentation of the model's utility, assumptions, accuracy, limitations, and need and potential for improvement; and
- adequate reporting of the above to inform criticism and review of the model.

Forest Models☆

Guy R Larocque, Canadian Forest Service, Quebec, QC, Canada

Introduction

Many models that simulate the dynamics of forest ecosystems have been developed during the last few decades. The term dynamics is meant to represent the attributes of forest ecosystems that describe the changes occurring over time, including growth, productivity, yield, net primary productivity, biomass turnover, or succession. Forest ecosystem models are used as research tools to better understand the mechanisms that govern tree growth and ecosystem dynamics and as decision-making tools to predict the growth of unmanaged and managed forest ecosystems, plan forest management activities, and predict the effects of disturbances. The majority of forest ecosystem models have a relatively complex structure to describe the complexity of the processes that govern the dynamics of forest ecosystems. Forests are characterized by the presence of complex interactions among processes and environmental factors that are regulated by many nonlinear feedback mechanisms.

Forest ecosystem models can be classified into three broad categories. The first category consists of growth and yield models, also known as empirical growth models, and they are used to predict tree and stand productivity. The second category includes process-based models, also known as mechanistic models, and they focus on the modeling of ecophysiological processes that govern the behavior of forest ecosystems. The third category consists of gap models, also known as forest succession models. In this article, the main characteristics of these three categories of forest models are discussed.

Growth and Yield Models

Forests have been managed more or less intensively for the last few centuries to ensure a sustainable supply of stemwood for the production of different goods, including lumber, pulp and paper, or fuelwood. The development of forest management plans requires estimates of forest productivity. Stand tables have been developed for many decades to provide estimates of forest productivity over the life of forest stands, mostly in terms of stem volume. They provide relatively accurate estimates of stand productivity, but only if the growing conditions of forest stands do not change appreciably. As soon as growing conditions change or silvicultural treatments are performed, stand tables become less accurate or reliable. The advent of computers has made it possible to develop sophisticated models to simulate tree and stand growth. One of the reasons that justified the development of such models was to provide forest managers with quantitative tools flexible enough to predict the outcomes of silvicultural treatments. Growth and yield models are developed using stand inventory data collected by forest agencies (e.g., government forestry departments or forest companies), usually through monitored long-term sample plot networks. Predicted state variables include tree or stand attributes, such as stemwood volume or mean diameter at breast height (dbh) at different time cycles (e.g., years) along the development pathways of forest ecosystems. Statistical methods, such as ordinary least squares or maximum likelihood, are used to estimate the parameters of the relationships. Usually, the accuracy and precision of model parameters increase with the availability of historical measurements (tree and stand data collected at different ages). In the literature, the term empirical model is also used to design a growth and yield model. A common definition of an empirical model is a model derived from empirical knowledge obtained from experience or experimentation. Empirical models do not focus on explaining the underlying mechanisms, even though they may have a theoretical foundation or predict biologically consistent patterns of tree and stand growth. Growth and yield models can be classified into two large subcategories: whole-stand models and single-tree models.

Whole-Stand Models

Whole-stand models predict the growth of stand attributes of forest ecosystems, such as basal area, stand volume, or stand density. Basal area is the summation of the cross-sectional area at breast height (usually 1.3 m aboveground) of individual tree stems appropriately weighted to reflect a particular unit area (e.g., 1 ha). Stand volume (e.g., $m^3\ ha^{-1}$) is the summation of the volume of individual tree stems within a forest ecosystem and stand density is the number of trees per unit area (e.g., hectare). An example of a model form to predict basal area over age is

$$\Delta B = \alpha_1 + \alpha_2 T + \alpha_3 B_T + \alpha_1 S + \varepsilon \quad (1)$$

$$B_{T+1} = B_T + \Delta B \quad (2)$$

where ΔB is basal area increment rate (e.g., $m^2\ ha^{-1}\ year^{-1}$), T stand age (year), B_T basal area ($m^2\ ha^{-1}$) at age T, S site index, and

This is an update of G.R. Larocque, Forest Models, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1663–1673.

ϵ the error. Site index, a measure that estimates the potential productivity of a forest ecosystem, consists of the average tree height at a reference age. For instance, in North America the most common reference age is 50 years and average tree height is based on the average height of the hundred largest trees in dbh per hectare. In this example, basal area at age $T + 1$ is computed by adding ΔB to basal area at age T.

The derivation of whole-stand models to predict the changes in stand attributes over time has been an active field of research for the last few decades. Thus, many models with different forms of mathematical relationships were derived, including linear as well as nonlinear relationships. For instance, the nonlinear Chapman–Richards model has been frequently used in the development of whole-stand models. Different variants were also developed, such as the integration of dbh distribution classes, the derivation of distribution functions to represent the dbh distribution, or the use of transition matrices.

A particular type of whole-stand model that has received much attention is the self-thinning model. The self-thinning model was derived for different types of plant communities, including herbaceous plants and tree species. Self-thinning can be defined as the mortality that occurs in even-aged monospecific ecosystems due to competition among plants. As stand density increases within a forest ecosystem, tree mortality is more likely to occur due to the increase in competitive stress. Indeed, as plant size increases, the intensity of competitive stress accentuates, resulting in mortality. The foundation of the self-thinning model is based on a relationship proposed by Yoda and colleagues in the early 1960s in which the logarithm of mean plant biomass is inversely related to plant population density:

$$\log(\overline{w}) = \log\ (\alpha) + \sigma\ \log\ (N) \tag{3}$$

where $\overline{w}$ is average plant mass, N stand density, α a species-specific parameter, and σ the slope. The work by Yoda and collaborators is largely cited in the literature where the origin of the self-thinning model is discussed. However, similar relationships were also derived by different authors. For instance, Reineke derived in 1933 a stand-density index based on a relationship between stand density and average diameter. Several studies conducted for different types of plant communities, including forest ecosystems, concluded that the slope of the self-thinning model was $-3/2$. The self-thinning model assumes that the species-specific constant and the slope define a maximum limit of plant yield in terms of biomass or size for a given density. This limit is in fact an upper boundary of density-dependent mortality that occurs under competitive conditions in even-aged forest ecosystems. For forest stands, the self-thinning model was widely applied and average plant mass was replaced in many instances by average stem volume. Further research resulted in the development of models of stand-density management diagrams to identify different species-specific development phases related to the intensity of competition. For instance, zones were defined to indicate the initiation of competition, which could be associated with the onset of crown closure, or the lower limit of competition-induced mortality, or to better highlight the asymptotic limit of mean biomass or size as a function of density.

Individual-Tree Models

The dbh, height, basal area, biomass, or volume growth rate of individual trees is predicted by deriving models that represent inter- or intraspecific competitive interactions that occur among a subject tree and its neighbors within a forest ecosystem. The majority of individual-tree models are based on the derivation of competition indices, which are generally classified into spatial and nonspatial indices. This long-used classification distinguishes competition indices that require tree growth data and information about the physical location of individual trees from those that only require tree growth data. Different terms have been used in the literature to define both types of models based on the use of competition indices. For models based on competition indices requiring spatial information, the following terms have been frequently used: single- or individual-tree distance-dependent models, single-tree spatial models, space-dependent models, or spatially explicit models. The terms single- or individual-tree distance-independent models, single-tree nonspatial models, or space-independent models have been used for models based on competition indices that do not use spatial information.

Space-Dependent Models

The derivation of space-dependent models is based on the use of competition indices that integrate spatial information on stand structure to describe the intensity of competition that a subject tree experiences from neighboring trees. The level of detail in the description of competitive interactions varies among competition indices. A common classification of spatial competition indices includes four major groups: (1) amount of overlap between the zone of influence of a subject tree and the zones of influence of competitors, (2) absolute or relative size of competitors adjusted by distance or a distance-based factor, (3) crown interference effect, and (4) potential available area. For the first type of competition index, the zone of influence represents the area within which trees compete for site resources and is a function of the crown width of an open-grown tree of the same dbh to represent the maximum zone of influence of a subject tree and each competitor. Examples of the first three types of competition indices are presented in **Table 1**.

The majority of space-dependent models that were developed using spatial competition indices were derived using multiple linear regression with the following general form:

$$\Delta G_i = \beta_1 + \beta_2 G_i + \beta_3 \mathrm{CI}_{ic} + \beta_4 X + \varepsilon \tag{4}$$

where ΔG_i is the growth rate in dbh, height, tree basal area, volume or biomass of the subject tree; G_i the initial size of the subject tree in terms of dbh, height, tree basal area, volume, or biomass; CI_{ic} the competition index that describes the intensity of competition

Table 1 Examples of three types of spatial competition indices to model competitive interactions among individual trees within a forest ecosystem

Competition index[a]	*Type*	*References*
$\sum_{c=1}^{N_i}\left[\left(\frac{ZO_{ic}}{ZA_i}\right)\left\{\left(\frac{D_c}{D_i}\right)^T\right\}\right]$	Zone of influence	Bella (1971)

$\sum_{c=1}^{N_i}\left(\frac{CSA_{ic}}{H_i}\right)\left(\frac{BA_i}{BA_c}\right)$	Crown interference	Hatch *et al.* (1975)

[a] a and b, constants; CSA_{ic}, exposed surface of the crown of the subject tree that is not shaded by the presence of competitors; D_c, diameter at breast height (dbh) of a competitor tree; D_i, dbh of a subject tree; d_{ic}, distance between a subject tree and a competitor; N_i, number of competitors for a subject tree; h_c, height of a competitor; h_i, height of a subject tree; h_d, dominant height of a forest stand; H_i, distance between breast height and the base of the crown of a subject tree; T, constant that accounts for species-specific tolerance; ZA_i, area of the zone of influence of a subject tree; ZO_{ic}, area of overlap between the zone of influence of a competitor and a subject tree.

between a subject tree i and the neighboring competitor c, β_n the parameters, and ε the error. X represents any other stand or tree variable that may be included alone or in combination with other variables. For instance, these variables may consist of site index to represent the effect of site quality, age, or basal area or number of trees per unit area to account for the effect of stand density.

Space-Independent Models

Many single-tree space-independent models (i.e., without reference to spatial information on individual trees) were developed using the multiple linear model form listed above (see Eq. 4) to predict individual-tree growth rate in terms of dbh, basal area, height, or volume. Predictor variables consist of tree and stand attributes that may include initial tree size, age, a nonspatial competition index, or other variables representing the effect of stand density or site quality. The derivation of nonlinear models has also been quite common in the last three decades, probably because advances in computer power have facilitated the use of complex algorithms for the derivation of the parameters of nonlinear models. A typical form of an individual-tree nonlinear model is

$$\Delta G_i = \left(\gamma_1 X^{\gamma_2}\left(1 - e^{\gamma_3+\gamma_4 CI_{ic}+\gamma_n Z}\right)\right) + \varepsilon \tag{5}$$

where ΔG_i is the growth rate in dbh, height, basal area, volume, or biomass of the subject tree; CI_{ic} the nonspatial competition index that describes the intensity of competition between a subject tree i and the neighboring competitor c, γ_n the parameters; and ϵ the error. X and Z represent tree or stand variables that influence tree growth.

The effect of competition is commonly modeled by computing nonspatial competition indices that represent the effect of the presence of competitors on the growth of individual trees. Simple competition indices based on the sum of the size of competitors in terms of diameter or basal area have been used quite extensively. Relatively complex competition indices have also been derived (**Table 2**). The effect of the presence of competitors on the growth of the subject tree was also modeled by computing indices or functions that considered in more detail the social status of individual trees within stands, such as the sum of the basal area, the crown surface or volume of the trees within the stand that are greater than the subject tree, percentile in dbh, or tree basal area distribution.

One of the space-independent models that has received much recognition in North America over the last few decades is the Forest Vegetation Simulator (FVS) model. It has a long history of development and calibration for different tree species, forest types, and regions in the United States and Canada. Several variants were developed for specific geographic areas. An important feature of FVS is the development of various model components to simulate different types of silvicultural treatments. FVS has its foundation in the Prognosis model, which was originally developed by Albert R. Stage at the USDA Forest Service in the early 1970s. Several modifications have been made or new components have been implemented over the last few decades to expand its capabilities, including the integration of components from other models, such as TWIGS. The model components of FVS were designed such that simulations could be conducted by using forest inventory or basic stand data to characterize the initial conditions of the forest stands for which growth predictions are desired. For instance, the basic form of the model to predict diameter growth rate of individual trees may include the following independent variables, in addition to a competition index: current tree dbh, stand basal area, site index, or crown ratio (the ratio of crown length to stem height). For some variants, the representation of the effects of site fertility on tree growth was performed by integrating variables describing ecological characteristics, such as elevation or habitat type. Other FVS components include a mortality model to predict individual-tree death, an establishment model to predict regeneration, and other submodels to predict the impacts of disturbances on tree and stand growth, such as insect infestations, diseases, or fire.

Process-Based Models

Process-based models, also known as mechanistic models, are structurally designed to describe and simulate the ecophysiological mechanisms in forest ecosystems that govern their growth, productivity, or development. The ecophysiological mechanisms include the processes that regulate carbohydrate production (such as photosynthesis), drive water movement (such as evapotranspiration), or control the synthesis of hormones or the cycle of nutrients (such as nitrogen mineralization). Typical process-based models include descriptions of the effects of environmental factors and their interactions on the processes, including photosynthetic active radiation (PAR) conditions, soil nutrient levels, and climatic conditions. Process-based models are developed by assuming that forest productivity, which can be defined as the allocation of carbohydrates in the different ecosystem compartments (stems, branches, foliage, roots, understory vegetation), and transfer of carbon compounds and nutrients among compartments (e.g., transfer from litter to soil organic matter (SOM)) can be defined and divided into specific interdependent pools and that their properties and behavior can be characterized independently of their functional environment.

Compared with growth and yield models, process-based models are generally considered as powerful tools that contribute to better understanding the processes that regulate the behavior of forest ecosystems, as they are based on the description of cause–effect relationships. Hence, it is largely believed that they have more potential than growth and yield models to predict forest behavior when environmental conditions change significantly, such as the effects of climate change or particulate pollution. For instance, the models that describe the mechanisms involved in the carbon cycle can be used to simulate the changes in the different carbon pools of forest ecosystems under changing conditions of atmospheric carbon and climate. Thus, if the descriptions of the mechanisms are based on realistic mathematical representations, it may be possible to simulate different scenarios of climate change to predict if the CO_2 uptaken by the vegetation may be transferred into pools that may sequester carbon for more or less long periods (e.g., carbon compounds in the SOM) or release it in CO_2 through respiration. Given the amount of details usually included and the number of parameters that must be calibrated, their predictions may be realistic, but not necessarily accurate. On the other hand, the developers of growth and yield models aim at deriving as accurately as possible predictive models using statistical methods on historical data sets, not at explaining causal relationships. Growth and yield models are generally considered "statistically accurate" when environmental conditions do not change appreciably.

Process-based models confer important advantages, in addition to the prediction of the effects of disturbances. Their development, validation, and application may significantly reduce the number of experimental studies and analytical efforts in forest ecosystems. If time and resources were available to undertake experiments under all possible environmental conditions for both unmanaged and managed forest ecosystems, it would be possible to derive the necessary empirical knowledge that would contribute to developing statistical models using historical data sets. However, this approach can be cost-prohibitive for the study of forest ecosystems. For instance, the evaluation of the response of a tree species under all possible combinations of climatic conditions, soil characteristics (e.g., texture, drainage, nutrients), and management scenarios is theoretically possible, but practically and economically unfeasible. The problem becomes cumbersome for the study of mixed forest ecosystems because the interactions that must be considered become more complex and their number increases exponentially. Process-based models may also contribute to predicting the effects of different scenarios of disturbances for which experimentation may be difficult, if not impossible, to achieve using traditional field experimental studies. A good example is the study of the effect of global change on the dynamics of forest ecosystems. Even though experimental sites can be established, such as the Free Air CO_2 Enrichment (FACE) facilities, they can only be implemented under a small range of environmental conditions because of limited resources. In addition, it is not evident that this type of experimental approach appropriately captures the "longevity factor" of forest ecosystems. (FACE facilities consist of experimental sites established in terrestrial plant ecosytems that contain the technology to simulate realistic growing conditions of elevated atmospheric CO_2 concentration for the vegetation.)

Several process-based models have been developed in the last few decades by different groups of modelers (Table 3). They differ in the type and number of simulated processes and level of details, as indicated by the differences in the characteristics of the models provided as examples in Table 3. Among the numerous models, FOREST-BGC, developed by Steven Running and collaborators at the University of Montana, drew much attention. In a way, FOREST-BGC established a benchmark for process-based models of forest ecosystems because several processes were modeled, including several feedback mechanisms, and remote-sensing data were used as input to simulate ecosystem dynamics over large forest regions. FOREST-BGC simulates the main processes in the carbon, nitrogen, and water cycles in forest ecosystems (Fig. 1). For the carbon cycle, model components are included to describe photosynthesis, maintenance and growth respiration, litterfall, litter decomposition, root turnover, and above- and belowground carbon allocation. The nitrogen cycle is tightly coupled with the carbon cycle. Foliage nitrogen retranslocation, soil nitrogen mineralization, and the effect of nitrogen on photosynthesis and leaf growth are represented. Evaporation and evapotranspiration are simulated. Input climatic variables include daily air temperature, solar radiation, precipitation (water or snow), and humidity. FOREST-BGC includes both a daily and yearly time cycle. While the main physiological processes, including photosynthesis, maintenance respiration, evaporation, evapotranspiration, and litter mineralization, are predicted daily, the partitioning of above- and belowground carbon and nitrogen is predicted yearly. Carbon and nitrogen pools are defined for the foliage, stems, roots, and soil. A model like FOREST-BGC can simulate the amounts of carbon sequestered by forest ecosystems. The development of FOREST-BGC was continued and subsequently evolved into descendants, BIOME-BGC and BGC++.

CENTURY is another process-based model that has been widely used for different types of ecosystems. Even though there are model components to simulate vegetation development, CENTURY focuses on the soil carbon, nitrogen, phosphorus, and sulfur cycles. In fact, the physiological processes that occur in the vegetation are not represented in detail in CENTURY. On the other hand, the model components that simulate the processes occurring in the soil are rich in details. SOM is divided into active, slow,

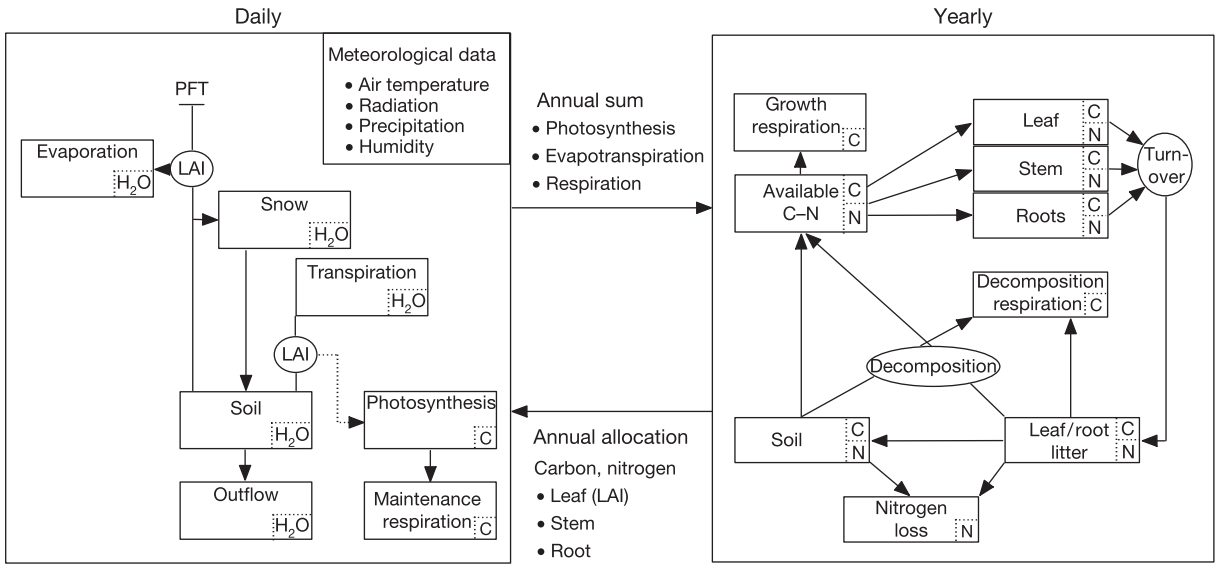

Fig. 1 Schematic diagram that illustrates the compartments and daily and yearly components of FOREST-BGC. C, carbon; N, nitrogen; LAI, leaf area index. Adapted from Running, S.W. and Coughlan, J.C. (1988). A general model of forest ecosystem processes for regional applications. Part I: Hydrologic balance, canopy gas exchange and primary production processes. *Ecological Modeling* **42**, 125–154, with permission from Elsevier.

and passive pools. These three SOM pools differ in the type of carbon compounds they contain and mineralization rate. For instance, the mineralization rate of the active pool may vary from a few months to a few years, while the mineralization rate of the passive pool may be as long as 1000 years, if not greater. The mineralization rates of the SOM pools may be affected by temperature and soil texture and humidity. CENTURY is one of the detailed process-based models that contain numerous pools with complex interactions. For instance, the forest production model allocates the carbon and nitrogen to large wood, foliage, fine branches, and coarse and fine roots. For each of these pools, there are also equivalent pools that represent the amount of dead material. Each type of plant residue is divided into structural and metabolic pools, which are defined on the basis of their lignin and nitrogen content. Within each SOM pool, each time there is mineralization, there is also microbial respiration.

The literature on process-based models has increased sharply in the last few decades. New models were presented to address specific questions, suggest different or advanced modeling approaches or functional relationships, or simply introduce innovative structures to improve the representation of the complexities of the interactions among the processes and effects of environmental factors. Despite the significant evolution, some basic model frameworks remained relatively constant. For instance, for the modeling of photosynthetic rate, the model developed by Farquhar and colleagues in the early 1980s were integrated into many process-based models of forest ecosystems that included the representation of photosynthetic rate. Two basic relationships in Farquhar's model have been widely applied. The regulation of net photosynthetic rate, A_n (μmol CO_2 m^{-2} s^{-1}), is limited by the ribulose-bisphosphate (RUBP) concentration:

$$A_n = J\frac{C_i - \Gamma}{4(C_i + 2\Gamma)}R_d \tag{6}$$

or the activity of ribulose-bisphosphate carboxylase/oxygenase (RuBisCO) at saturating RUBP:

$$A_n = V_c \max \frac{C_i - \Gamma}{C_i + K_c(1 + O/K_o)} - R_d \tag{7}$$

where J (μmol m^{-2} s^{-1}) is the potential electron transport rate, C_i the CO_2 intercellular concentration (μmol mol^{-1}), Γ the CO_2 compensation point (μmol mol^{-1}), R_d the dark respiration rate (μmol CO_2 m^{-2} s^{-1}), V_{cmax} the RuBisCO potential capacity for CO_2 fixation (μmol m^{-2} s^{-1}), K_c the Michaelis–Menten coefficient for carboxylation (μmol mol^{-1}), O the O_2 intercellular concentration (μmol mol^{-1}), and K_o the Michaelis–Menten coefficient for oxygenation (mmol mol^{-1}).

As previously mentioned, the process-based models differ in the amount of details included with respect to input variables and modeled processes. For instance, FOREST-BGC and BIOME-BGC require daily meteorological data (minimum and maximum air temperatures, precipitation, relative humidity, and solar radiation), while CENTURY requires monthly meteorological data (precipitation and mean monthly minimum and maximum temperatures). For process-based models on soil processes, the soil may be considered as a single unit or may be subdivided into horizons. The modeling of PAR interception and distribution within the canopy, including the effect on photosynthetic rate, is another model component that differs among process-based models. For instance, FOREST-BGC considers the canopy as a single three-dimensional layer with homogeneous characteristics ("big-leaf" approach). The stratification of the canopy into at least two sections of sunlit and shaded leaves, the derivation of foliage distribution functions, or the description of the development of individual branches within crowns are "multilayer" approaches used in several models. For instance, the LIGNUM model includes the description of detailed tree architecture, including the development of foliage on individual branches. The multilayer canopy approach implies that the variations in foliage characteristics with canopy position, such as foliage dimensions, area, mass, angle, or nitrogen content, are usually represented and may have a pronounced influence on the degree of precision in predicted PAR interception and photosynthetic rate and on the degree of realism in the scaling of processes. For several tree species, foliage at the top of the canopy is acclimated to full sunlight conditions, while the foliage within the canopy under shade conditions is acclimated to low-sunlight conditions. These differences in acclimation are associated with morphological, physiological, and anatomical characteristics of the foliage. For instance, leaf area or nitrogen concentration may increase from the top to the bottom of the canopy, while leaf biomass and thickness may decrease.

The objectives of the modeling effort must guide the decisions on the complexity of the details to be included, as the number of variables and degree of complexity may require more field measurements for calibration or may influence any scaling exercise. Also, the more variables and parameters in a model the less general it may be. For instance, if a model is developed to examine if nutrient leaching may significantly affect nutrient uptake in soils that contain mineral horizons differing substantially in texture and structure, the subdivision into layers may be entirely justified. However, if the objective of the model is to simulate the productivity of forest ecosystems by including the effect of nutrients in combination with other factors, it may not be necessary to subdivide the soil into different horizons. If a model is intended to simulate how competitive interactions among trees within a forest ecosystem affect carbohydrate partitioning among different sections of individual crowns, stems, and roots, the representation of the variability in foliage characteristics may be important for the modeling of photosynthetic rate. On the other hand, if a model is intended to scale up photosynthetic and respiration rates from the ecosystem to the landscape levels, the use of the "big-leaf" approach may be sufficient.

Gap Models

Gap models, also known as forest succession models, simulate seedling establishment, including their transition to sapling and tree status, and individual-tree growth and mortality. They are very well adapted to simulate the development of mixed uneven-aged forest ecosystems. Several gap models were developed in the last few decades, and the majority of them are descendants of JABOWA, originally developed by Daniel B. Botkin and colleagues in the early 1970s. Among gap models that have received much attention, FORET (developed by Herman H. Shugart in the 1970s and 1980s) and ZELIG and SORTIE (developed by Dean L. Urban and colleagues and Steve W. Pacala and colleagues in the 1990s) are similar in concept to JABOWA. They can simulate the natural course of species replacement for several generations, as well as the succession that is initiated when canopy openings occur in forest ecosystems following the death of a dominant tree. Gap models are a compromise between growth and yield models and process-based models. Biotic and abiotic processes occurring in forest ecosystems are modeled, including competition and the effects of PAR conditions, site fertility, temperature, and water on tree growth and seedling establishment. However, the description of the processes and effects of site factors on ecosystem behavior is much simpler than in process-based models discussed above.

Empirical or semiempirical relationships are used to model the growth of individual trees. For JABOWA-type models, the annual growth rate of individual tree species within a forest ecosystem is modeled using the following basic equation form:

$$\frac{\Delta D_{\text{real}}}{\Delta \text{t}} = \frac{\Delta D_{\text{pot}}}{\Delta \text{t}} \times f(\text{limiting site factors}) \tag{8}$$

where the left-hand term represents the realized annual dbh growth rate, and $\Delta D_{\text{pot}}/\Delta t$ is the maximum or potential dbh growth rate that the tree can achieve under optimal conditions. The relationship for potential growth rate has the following general form:

$$\frac{\Delta D_{\text{pot}}}{\Delta \text{t}} = \frac{GD(1.0 - DH)}{D_{\max} H_{\max}} \times \frac{1}{f(D)} \tag{9}$$

where D is dbh, H stem height, G a growth rate parameter, $D_{\max}$ and $H_{\max}$ the maximum dbh and height that a tree species can reach under optimal conditions, respectively, and $f(D)$ an allometric relationship between dbh and height. The effects of limiting site factors are expressed by functions that describe the influence of abiotic and biotic factors, including PAR, temperature, site fertility, and moisture conditions. These functions constrain the potential growth rate and are based on scalar (0–1) multiplicative relationships. Tolerance or response classes are used to differentiate the response of each species to environmental factors. For instance, ZELIG recognizes five shade-tolerance classes (from tolerant to intolerant), three soil fertility classes (from responsive to stress tolerant), and three soil moisture classes (from drought tolerant to intolerant). The effect of temperature for each species is described by a dimensionless (0,1) response function that scales the growing degree-days computed for a given site relative to the minimum and maximum growing degree-days that exist within the range of distribution of a species. Seedling establishment is modeled stochastically by computing a probability of establishment conditioned by the potential number of seedlings that a site can produce and the prevailing understory PAR conditions, site fertility level, moisture conditions, and growing degree-days. Mortality is also modeled as a stochastic event and may result from natural or stress-related factors.

The advances in computer technology have made it possible to develop integrated modeling tools to simulate forest succession and disturbance at the landscape level. While the JABOWA-type models focus on the simulation of individual-tree development to predict ecosystem dynamics at the forest ecosystem level, forest landscape models simulate the forest dynamics of large regions that include many forest ecosystems. Forest landscape models explicitly consider that ecological processes occur at different scales or units: abiotic and biotic interactions occur among trees within a forest ecosystem as well as among forest ecosystems within a forest region or landscape. Thus, several processes may occur among adjacent or more or less remote forest ecosystems: flow of energy, water and nutrients, species migration or disturbances, such as fire, windthrow, diseases, or insect infestation. One of the objectives in the design of forest landscape models is to integrate the effects of the occurrence of events in individual forest ecosystems on adjacent forest ecosystems. This means that the integration of spatial and temporal complex interactions differing in scale, which may require the use of several variables, must rely on technology, such as geographic information systems for spatialization, in combination with mathematical analysis methods to describe the mechanistic details of the processes. A good example of this relatively recent generation of forest ecosystem models is LANDIS (Fig. 2). This basic diagram illustrates the interactions between the information on species composition and ecological characteristics of the forest ecosystems within a landscape or forest region, the processes that are simulated over time, including species establishment, growth, and death, and the integration of different types of disturbances and management scenarios.

Model Evaluation

Issues or questions related to uncertainty, prediction error, sensitivity, and robustness are becoming more important because models are increasingly used in forest management planning and decision making. Thus, it is important to provide policymakers with quantifiable methods to evaluate the extent to which these issues may affect their judgment or decisions. Models are imperfect representations of reality, which means that their outputs or predictions contain errors or have a degree of uncertainty associated with them. Uncertainty may be caused by model structure, that is, the lack of understanding of biological processes or incorrect mathematical representation, data and parameter estimates, natural variation, and scaling.

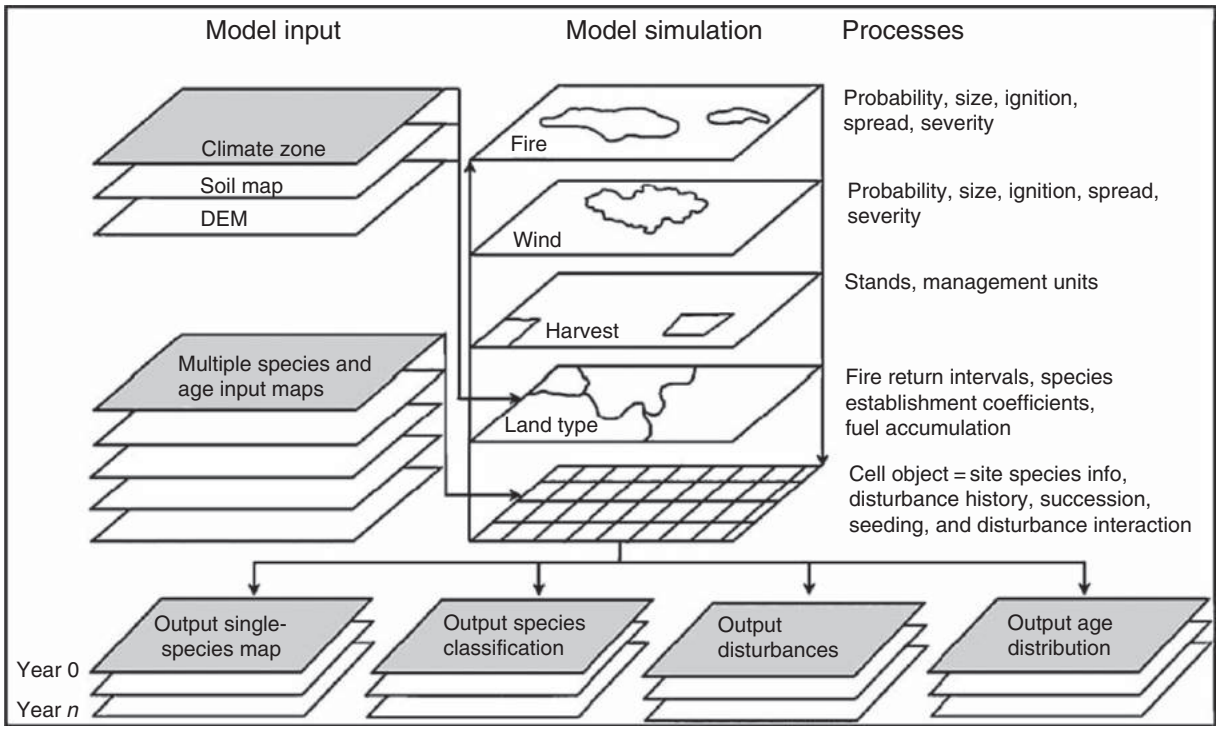

Fig. 2 Basic schematic diagram that illustrates the integrated structure of LANDIS to simulate forest succession and disturbance over landscapes. Reproduced from Mladenoff, D.J. (2004). LANDIS and forest landscape models. *Ecological Modeling* 180, 7–19, with permission from Elsevier.

Uncertainty in the predictions, sensitivity, and robustness have often been evaluated with validation methods. Model validation (the term validation is frequently used interchangeably with verification in the literature, which contributed to maintaining the controversy on what model validation consists of) may include the comparison of model outputs with observations from an independent data set and the examination of the consistency of its logical structure. For instance, the comparison of predictions with observations using historical data is a common validation method. Historical data for forest ecosystems may consist of tree or site variables (e.g., dbh, stem height, foliage, and soil nutrients) measured on the same sample plots at different periods. An essential rule is to conduct the comparison of a model's outputs with data that have not been previously used for its calibration. However, some may argue that this method is simply a statistical validation, and does not allow one to conclude if a model is biologically consistent or realistic. Biological consistency consists in examining the behavior of a model by varying systematically its inputs to represent the variation in widely different initial conditions. This is important for evaluating if the predictions indicate a logically consistent pattern, determining if a model conforms to basic laws of biological growth, or detecting illogical or improper formulation or representation of the underlying processes. For instance, a forest growth model that would predict that the diameter growth of individual trees within an even-aged forest ecosystem increases with increase in stand density (i.e., with the intensity of competition) would be inconsistent, but the statistical fit could be significant. A biological consistency analysis can be conducted simultaneously with a sensitivity analysis, which consists in examining the degree to which the outputs of a model change with variation in input variables or parameters. When the variation in input variables or parameters is extended to their extremes, it allows the modeler to verify the reaction of the model when there is extrapolation.

When a statistical method is used to estimate the parameters of a model, the coefficient of determination (which expresses the proportion of variability in the dependent variable accounted for by the regression on the independent variable(s)) and the mean square error (a measure of dispersion) are usually computed. For more complex models that contain several relationships, other statistics computed from predicted and observed values have been suggested in the forestry literature as quantitative measures to evaluate the performance of growth and yield models in terms of goodness of fit:

$$\text{Mean residual or prediction error} = \sum (y_i - \hat{y}_i)/n \tag{10}$$

$$\text{Root mean square error} = \sqrt{\sum (y_i - \hat{y}_i)^2/n - 1 - p} \tag{11}$$

$$\text{Model efficiency} = \sum (y_i - \hat{y}_i)^2 / \sum (y_i - \overline{y}_i)^2 \tag{12}$$

$$\text{Variance ratio} = \sum (\hat{y}_i - \overline{\hat{y}}_i)^2 / \sum (y_i - \overline{y}_i)^2 \tag{13}$$

where n is the number of samples in the independent data set, y_i are observations, $\hat{y}_i$ predictions, and p the number of independent variables. Several statistical tests exist to validate models, such as the Kolmogorov–Smirnov, χ^2-test, or F-test of a regression.

Summary

Forest models are increasingly being used as research tools to better understand the mechanisms that govern the dynamics of forest ecosystems and as decision-making tools to plan forest management activities and predict the effects of disturbances. Three different types of models were reviewed: growth and yield models, process-based models, and gap models. Each model type is characterized by specific features, including model formulation, complexity of structure, state variables, and required inputs. While growth and yield models aim at predicting tree and stand growth to evaluate the effects of forest management activities, process-based and gap models focus on the simulation of processes and are more flexible for predicting the effects of changing environmental conditions or the natural course of long-term change in species composition. Therefore, when selecting a model type, the intended objectives of a model must be carefully considered.

Fuzzy Models☆

R Wieland, Leibniz Centre for Agricultural Landscape Research (ZALF), Muencheberg, Germany

Introduction

In environmental modeling, biologists or agricultural scientists are often able to describe a process quite well, but find it difficult to construct a mathematical model. One such problem is the modeling of alteration in wildlife-habitat quality caused by climate change, pollution, new management methods in agriculture, etc. A further example is the calculation of agricultural yield for different management strategies under changing climate conditions. Such problems often involve uncertainties. Fuzzy-set modeling can help one to cope with this uncertainty.

Fuzzy-set theory and fuzzy-set control theory provide methods to describe:

- the input ranges for the model
- the output ranges for the model
- a set of rules
- a method for defuzzification

To use fuzzy-set models for environmental modeling a method must be provided to enable use of these models in a spatial context. This can be done as part of a geographic information system (GIS) or with a special software toolbox like the matlab fuzzy toolbox (Sivanandam et al., 2006) or the open source software SAMT.

Fuzzy Sets

Fuzzy sets provide a basis for fuzzy modeling. A fuzzy set is an extension of a classical set. In classical set theory an element either belongs or does not belong to a set. In a fuzzy set an element belongs gradually to a set. The fuzzy set theory traditionally uses the

☆*Change History:* April 2013. R Wieland updated Subsection "Adaptation of the rules", and "Dynamic Simulations" sections, and Figures 7 and 8 are new and Table 2 added.

Table 1 Nutrition quality of crops for a crane fuzzy set

	Good	*Medium*	*Bad*
Maize	0.2	0.8	0
Rye	0.4	0.6	0
Wheat	0.6	0.4	0
Rape	0	0.1	0.9
Barley	0.6	0.4	0
...	...	...	...

Greek letter $\mu \rightarrow [0,1]$ as the membership-function. The value between zero and one describes the degree of membership of the element to the set $\tilde{A}$. A fuzzy set is defined by:

$$\tilde{A} = (x, \mu_A(x)) \mid x \in X \tag{1}$$

Every element $x \in X$ gradually belongs to the set $\tilde{A}$. The value $\mu_A(x) = 0$ means that $x \notin \tilde{A}$ and the value $\mu_A(x) = 1$ means that $x \in \tilde{A}$. All values strictly between zero and one characterize the fuzzy members. In other words, if the membership values are restricted to zero and one, the fuzzy set is a classical set.

Another consequence of this definition is that an element x can belong to different fuzzy sets. For example a biologist may express the quality of nutrition of crops for the crane (grus grus) as in **Table 1**.

This estimation could be part of an model of the habitat quality for the crane. Maize with a membership value of 0.8 belongs to the class "medium nutrition quality" and with 0.2 to the class "good nutrition quality" for example. This description can be used to express uncertainty or used in discussing it with other experts.

Combination of Fuzzy Sets

Fuzzy sets may have to be combined with other fuzzy sets. Common operations are "and", "or" and "not". These operations can be defined as:

Definition 1 (Fuzzy AND Min)

$$x \in \tilde{A} \wedge x \in \tilde{B} \Rightarrow \mu_{A \wedge B}(x) = min\{\mu_A(x), \mu_B(x)\} \tag{2}$$

Definition 2 (Fuzzy OR Max)

$$x \in \tilde{A} \vee x \in \tilde{B} \Rightarrow \mu_{A \vee B}(x) = max\{\mu_A(x), \mu_B(x)\} \tag{3}$$

Definition 3 (Fuzzy NOT)

$$x \notin \tilde{A} \Rightarrow 1 - \mu_A(x) \tag{4}$$

These definitions will be used as parts of fuzzy models. Alternative definitions for fuzzy "and" and "or" are

Definition 3 (Fuzzy AND Prod)

$$x \in \tilde{A} \wedge x \in \tilde{B} \Rightarrow \mu_{A \wedge B}(x) = \mu_A(x) * \mu_B(x) \tag{5}$$

Definition 4 (Fuzzy OR Add)

$$x \in \tilde{A} \vee x \in \tilde{B} \Rightarrow \mu_{A \vee B}(x) = min\{\mu_A(x) + \mu_B(x), 1\} \tag{6}$$

These definitions are based on fuzzy t-norm and t-conorm (Hjek, 1998). In fuzzy models the definitions 5 and 6 often show a better behavior than definitions 1 and 2. This will be explained in greater detail below. (Minimum/maximum and/or was used because simple fixed-point micro-controllers are faster that way; floating-point-PCs are not (multiplication is faster than floating-point comparison).)

Fuzzy Sets for Continuous Inputs

In the definition of fuzzy sets the inputs were given by enumeration. Spatial modeling of ecological precesses often involves inputs which continuous variables such as distance or density functions. This continuous values must be "fuzzified", i.e., the modeler

must specify membership function values for the fuzzy sets. Membership functions with triangular or trapezoidal shape are frequently used. A triangular membership function is defined as:

$$\mu_A(x) = \begin{cases} 0 & : & x \leq x_1 \\ (x - x_1)/(x_2 - x_1) & : & x > x_1 \wedge x \leq x_2 \\ (x_3 - x)/(x_3 - x_2) & : & x > x_2 \wedge x < x_3 \\ 0 & : & x \geq x_3 \end{cases}$$

The lower left edge point is x_1, x_2 the point where the triangle is 1, and x_3 the right hand point of the triangle. This membership function describes fuzzy values, e.g., "about 10". (meaning numbers around 10.) In this example $x_1 = 8$ and $x_3 = 12$. The 10 belongs to this set with $\mu_A(10) = 1$, and 9 belongs to this set with a degree $\mu_A(9) = (9-8)/(10-8) = 1/2$.

Another commonly used membership function type has a trapezoidal shape, and is used to describe ranges. A range is a generalization of classical sets. In the middle of a range, between $[x_2, x_3]$ all values belong to the set with a membership of $\mu_A(x) = 1$. But there are some values between (x_1, x_2) and (x_3, x_4) with a strict fuzziness. This type of membership function is often used in habitat modeling. If an effect of disturbance on a habitat has to be modeled, then this range is often helpful. In the center of the range the animal can tolerate the disturbance, but if the disturbance exceeds a determined level, the reaction may be strong. In a formal way this range can be defined as:

$$\mu_A(x) = \begin{cases} 0 & : & x \leq x_1 \\ (x - x_1)/(x_2 - x_1) & : & x > x_1 \wedge x < x_2 \\ 1 & : & x \geq x_2 \wedge x \leq x_3 \\ (x_4 - x)/(x_4 - x_3) & : & x > x_3 \wedge x < x_4 \\ 0 & : & x \geq x_4 \end{cases}$$

The triangular and the trapezoidal membership functions are simple and useful in modeling environmental processes. More sophisticated membership function types like bell shaped functions are possible but often overrated. A trapezoidal membership can approximate a bell-shaped function quite well, but the bell shape-function is itself an approximation. The ultimate objective is to use fuzzy models to transform expert knowledge into formal knowledge that can be used to perform simulations.

Fuzzy Models

Fuzzy models specify rules in terms of fuzzy sets. A fuzzy rule consists of an antecedent (IF-part) and the consequent (THEN-part). The antecedent combines different inputs using the "and" combination. To express "or" combinations, a set of rules with different inputs but the same output is often used. For example:

$$IF((nutrition \in good) \vee (nutriton \in medium)) \Rightarrow quality = good$$

can be expressed with the following two rules:

$$IF(nutrition \in good) \Rightarrow quality = good$$

$$IF(nutrition \in medium) \Rightarrow quality = good$$

This splitting technique leads to easily understood but larger rule sets. The simpler rules are sometimes advantageous for rule inspection in maintenance of fuzzy models.

Output of Fuzzy Rules

The consequent part can be arranged as a bundle of fuzzy sets or more simply as crisp values. (A crisp value means that every output is linked with an real value: $medium \rightarrow 0.8$; $good \rightarrow 0.2$ for example.) It seems rather curious that the consequent part often is implemented using crisp values, but this has a lot of advantages. Some of which are described later, but a major advantage is based on the sematic. The input carries information about the uncertainty. This uncertainty is modeled using fuzzy sets. The output is a desired value, which has to determined by the modeler. The simplest way to do that, is to provide a crisp value for each output. If the output is modeled using fuzzy sets, this implies that the modeler is uncertain about the consequence. But this is often not true. The modeler knows the output but is not able to determine the fuzziness. It is difficult to determine the x_1 and x_3 of a triangle for an output. With other words the modeler is more or less confident about the value or the output, but he can not determine the fuzziness of it.

The modeler has to define the membership functions $\mu_{ij}(x_i)$ (i counts the inputs, j counts the rules) for the inputs, the membership functions for the outputs (or in our case the output values as crisp values) and the rules for combining the input with the output. The membership functions are indexed for every variable and for the linguistic values. For example the input x_1

may have three membership functions (low, medium, high) so the index j will run from 1 to 3. A typical rule set with three inputs and n rules looks like this:

$$\begin{array}{lcl} \text{IF } \mu_{11}(x_1) \wedge \mu_{21}(x_1) \wedge \mu_{31}(x_3) & \Rightarrow & o_1 \\ \text{IF } \mu_{12}(x_1) \wedge \mu_{22}(x_2) \wedge \mu_{32}(x_3) & \Rightarrow & o_2 \\ \cdots & \cdots & \\ \text{IF } \mu_{1n}(x_1) \wedge \mu_{2n}(x_2) \wedge \mu_{3n}(x_3) & \Rightarrow & o_n \end{array}$$

Remark: every rule uses one selected membership function for every input. The outputs o_k must not be different. This means that rules with different membership functions but the same output exist.

Fuzzy Algorithm

The fuzzy algorithm uses the membership functions and the rules in three steps:

- fuzzification: for every input $\vec{x} = (x_1, x_2, \ldots)$ all membership functions $\mu_{ij}(x_i)$ will be calculated
- inference:
  - assigns a value a_k^m using the minimum or product operator to each rule (k points to the outputs; m points to different rules with the same output k):

$$a_k^m = min\left\{\mu_{1j_m}(x_1), \mu_{2j_m}(x_2), \mu_{3l_m}(x_3)\right\} \quad [7]$$

  - selects the the best rule from the m rules with same output k using maximum operator

$$a_k = max\left\{a_k^1, a_k^2, \cdots\right\} \quad [8]$$

- defuzzification

Defuzzification

The defuzzification algorithm assigns the fuzzy output of the fuzzy inference to one floating point value. This value can be used for further calculation, for example in a spatial context. The realization of the defuzzification algorithm depends on the character of the output values. For crisp outputs the algorithm is simple and fast:

$$o = \frac{\sum_k a_k \times o_k}{\sum_k a_k} \quad [9]$$

In eqn [9] the activity of a rule a_k and its output value o_k are used to calculate the output o of the fuzzy system. The realization is fast, which is a precondition for the usage in a spatial simulation. In a spatial simulation a huge number (up to some millions) of grid cells must be often calculate.

A further advantage of crisp output values is not so obvious. This simple algorithm can produce linear functions as well as nonlinear functions. Using a fuzzy set as output leads to a nonlinear behavior. Most ecological processes are nonlinear, but sometimes a piecewise linear part is essential. The modeler must be able to decide the functional behavior of the model. A more demanding modeling approach using outputs as fuzzy sets can be used at the expense of a bit of nonlinearity in the model.

When using fuzzy sets as outputs there are some possibilities for defuzzification. One of the most commonly used is the so called "center of gravity" method. To understand this method a closer look at the fuzzy inference is necessary. The inference procedure assigns a value a_k^m to each rule. After the selection of the best value for a specified output a_k (eqn [8]), this value is multiplied to the output. In case of fuzzy set output the multiplication "cuts" the fuzzy set. A result of the inference procedure may look like **Figure 1**.

To determine one floating point value from this area the following equation is used:

$$o = \frac{\int_{x_a}^{x_e} \mu(x) \times x dx}{\int_{x_a}^{x_e} \mu(x) dx} \quad [10]$$

The eqn [10] is a generalization of eqn [9]. The center-of- gravity algorithm is numerically more complex than the simple eqn [9]. Additionally the integral in eqn [10] introduces the aforementioned nonlinearity in the system. (This can be checked using a simple fuzzy model with one fuzzy input and one fuzzy output.)

Influence of Fuzzification Method to System Behavior

Many different fuzzification methods are quoted in the literature (Hjek, 1998). Two frequently used methods were introduced above. These methods influence system behavior. That means not only an effect on output value but it introduces some

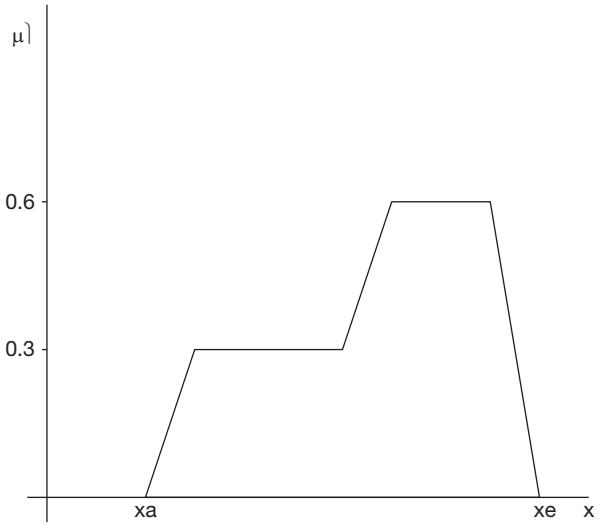

Figure 1 Center of gravity defuzzyfication.

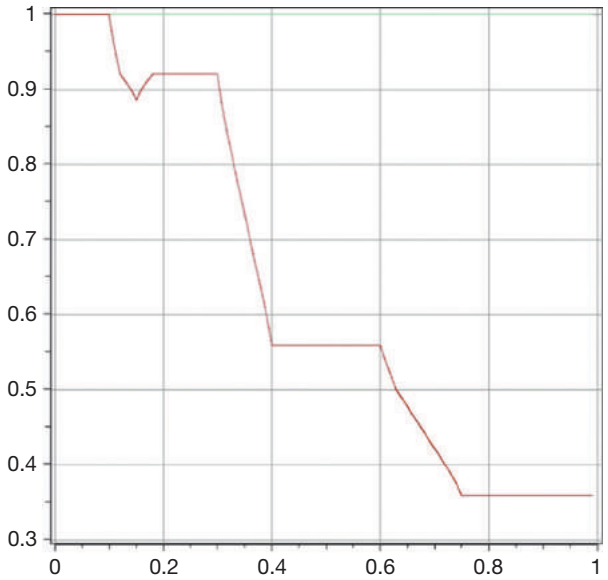

Figure 2 Fuzzy AND Min, x-axis: coverage degree, mean distance to structure = 130 m.

nonlinearity into the system. The FUZZY_AND is often realized as minimum method. This is simple and easy to understand. But sometimes this method introduces some strange behavior in the model. The minimum function cuts the values very strongly. This is sometimes undesirable. The use of the FUZZY_AND Prod is often a better choice. This produces a smoother functional behavior and should be preferred in practical simulations.

This was checked with the fuzzy model for the nutrition quality for the lesser spotted eagle, aquila pomarina, (see below). At first the chart of the model using FUZZY_AND Min was plotted in Figure 2.

Easily visible is the vertex in the upper part of the chart. This can be changed with the use of the FUZZY_AND Prod. This is shown in Figure 3. The last chart looks smoother than the first one.

If the fuzzy model is checked, it can be used as part of a habitat model in a simulation.

Training of Fuzzy Models

A fuzzy system is just a way to formulate heuristically-basis functions for regression and controller functions with a rule table instead of by optimization. The fuzzy modeling approach is a transformation of expert knowledge into a mathematical model. The expert can control this process by defining the membership functions, the outputs and the rules. For modeling tasks like our

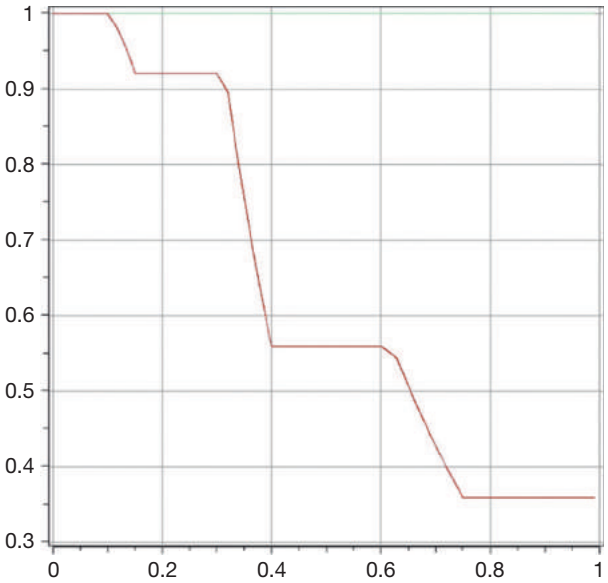

Figure 3 Fuzzy AND Prod, x-axis: coverage degree, mean distance to structure = 130 m.

example is this the only possible way. Usually the expert has lots of experience but little observation data. (Otherwise the modeler should think about a artificial neural network.) When the bird is not as rare as the lesser spotted eagle used in the example below, more data are frequently available. In other investigations the data collection process is part of a project. So the modeler can construct a fuzzy model and wants to enhance it with the collected data set. Often used as an optimization strategy is the minimization of the mean square error (mse) between the modeling output and the observed data:

$$mse = \frac{1}{n}\sum_{i=0}^{n}(y_i - fuzzy(x_{1i},x_{2i},x_{3i}))^2 \qquad [11]$$

y_i is the measured value and the $fuzzy(x_{1i},x_{2i},x_{3i})$ the output of the fuzzy model. There are three possible strategies to train such a fuzzy model:

- to change the membership function for the inputs
- to change the outputs
- to change the rules

Adaptation of Membership Functions

The membership functions are defined by the parameters x_1, x_2, x_3 for triangular shaped membership functions and x_1, x_2, x_3, x_4 for trapezoidal membership functions. These parameters are not independent. Additionally the number of parameters can be large when many membership functions are used. In many simulations it could be shown that this strategy is possible but not very effective and often slow.

Another reason to avoid this is that the expert can see these functions quite clearly. This is caused by the experience with the modeled process. It is not the best idea to start a training procedure by changing this sensitive part of a fuzzy system.

Adaptation of Outputs

The outputs are crisp values. Adaptation of the outputs is simple. The only restriction is that the order of the outputs must not be changed. As training procedure a delta rule can be used (Freeman, 1994). (A delta rule is the standard training rule for artificial neural networks.) The algorithm consists of the following steps:

- determine the active outputs for this input pattern
- calculate the error for every active output
- calculate a delta for these outputs
- change the outputs using the delta rule

All active outputs can be determined using eqn [9]. The error for an output can be calculated as following:

$$error = y_i - fuzzy(x_{1i}, x_{2i}, x_{3i}) \quad [12]$$

With this error the delta can be calculated:

$$\delta_k = a_k * o_k * error * gain \quad [13]$$

The gain is a (small) step rate for the training procedure. The new output follows:

$$o_k = o_k + \delta_k \quad [14]$$

The error determines the direction and strength of the training step. The membership a_k ensures that outputs with small belief are only slightly change.

This training procedure was checked for a yield model. Inputs included soil quality, amount of fertilizer, and water availability. The output was the yield for winter wheat. The fuzzy model consists of 3 inputs with 12 fuzzy sets (5 for soil quality, 4 for the fertilizer, 3 for water). The number of rules equaled 60. The number of training data was 1998. The mean square error of 206.236 before training was reduced to 85.6025 after training. This simple training procedure is effective and very efficient. An alternative training algorithm based on an evolutionary algorithm (Haupt and Haupt, 2004) was implemented but found to be less efficient than the simple delta rule. In contrast to the delta rule the evolutionary algorithm can also be applied to train a rule set.

Adaptation of the Rules

The adaptation of the rules is simple to complete (only a pointer must be changed) but it is a global change in a fuzzy system and must be done with care. (The modeler often wants to control the rules and would not allow an automatically adaptation.) A combination of the outputs is possible and could be used to keep the consistency of the fuzzy system when an output crosses another. To further read about fuzzy adaptation (Nauck et al., 2003), a complete semiautomated training method based on the fuzzy algorithm above is introduced in (Wieland et al., 2011). This method consists of a statistical analysis to support the creation of fuzzy membership functions and an automated rule generation. The big advantage over neural networks (Freeman, 1994) or vector machines (Schlkopf and Smola, 2002) are that the rules can be understood and modified by the modeler. This technique combines learning from data with expert knowledge to a fuzzy model.

Using Fuzzy Models in Spatial Simulation

In a geographic information system the data are stored in form of raster data (uniformly spaced grid cells) or in form of polygons. Grid data cells are more convenient for modeling approaches. An equally spaced grid cell is better suited to make simulation of fluxes with this data model. These simulations are for example important for wind-or water erosion modeling. A fuzzy model needs continuous data as inputs. (An approximation with a discrete set with many members is also O.K.) The spatial information is split into different information layers (maps) each containing a grid. A fuzz modeling approach usually needs two or three maps as inputs to calculate an output grid. The grids contain stored information like soil quality, elevation data, land use data etc. Other data of this type include distances, such as between grid cells and points (nesting places for birds, location of wind energy plant etc.) or between grid cells and linear features (roads, rivers, etc.). Another important example involving continuous data demonstrates the use of the so called moving-window technique, which calculates

$$q_i = f(x, y) = \iint_{A(x, y)} g(x, y) dx dy \quad [15]$$

Here $A(x, y)$ is an area around the point (x, y), and $g(x, y)$ is a function depending on spatial modeling problem. For simple problems, $g(x, y)$ can be the mean or the median for all points in a region $A(x, y)$. This technique produces a spatial abstraction of data at all grid cells. (Not only the value at the point, but also values in the neighborhood of the point are important.)

Before you can start using fuzzy models in spatial context the spatial database must be provided. There are some steps that must be performed:

- select data sources for the project from the GIS data base
- transform the polygons to a grid using an appropriate resolution. (The resolution depends on the modeling task. Every process has its own scale.)
- generate inputs for the fuzzy model using distances and the moving window technique

This task has to be done in a GIS. To apply fuzzy models to this grid data base the modeler should prefer an integrated simulations system. Such a toolbox additionally provides a set of analysis tools. With these tools it is possible to analyze the spatial database, to explain the fuzzy model on concrete points, to control the rule base of the fuzzy model etc. This tools should be also used do perform a validity test, that means the model behavior should be checked against the expected correlations. To further read about a spatial simulation, see (Wieland et al., 2006) and (Mirschel et al., 2006)

Example: Habitat Model of Lesser Spotted Eagle

The lesser spotted eagle is one of the key species in north East Germany. To improve understanding of the fuzzy modeling technique a simplified fuzzy model using the lesser spotted eagle will be explained. (The real model discriminates more details in the habitat structure, but this is not important for understanding.)

Habitat structure

The habitat structure of any animal depends on nutrition, the possibility of reproduction and protection against predators and other dangers. For the lesser spotted eagle this means that:

- When hunting it can either fly or sit and wait. If it hunts in flight, plant cover must not be too dense, so that it can see the prey on the ground. To enable it to sit and wait some "structure elements" to perch on must be available.
- The lesser spotted eagle breeds in a forest. It must be able to reach the hunting area from the nesting place.
- There are no predators in the region, but wind energy plants or roads and railways might be dangerous too.

Fuzzy model nutrition

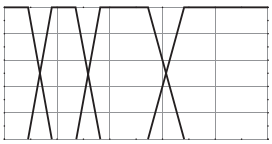
The investigated area is located northeast of Berlin, and measures approximately 18×30 km. Most of the area is used for agriculture but there are also grass lands, forests, lakes and settlements.

Before the fuzzy model "nutrition.fis" can be used the coverage of the soil with plants must be calculated. The coverage depends on the type of crops and therefore on the time of year. The crops covering the soil are shown in Figure 4. As an example the year 1995 and the year day 160 was selected.

Another input for the nutrition part of the habitat model for the lesser spotted eagle is the structure density map. (In this map the mean distance to structure is shown.) A high density of structure can partly compensate a high cover of crop degree because the bird is able to use a structure element (hedge, tree etc.) as hunting point. This input is represented in Figure 5. Remark: this map was produced using moving window technology to generalize from the real structure to a more landscape characteristic.

The output is calculated using a fuzzy model. The two fuzzy inputs degree of coverage and structure density are shown:

Coverage degree [0.000.0.1.000]



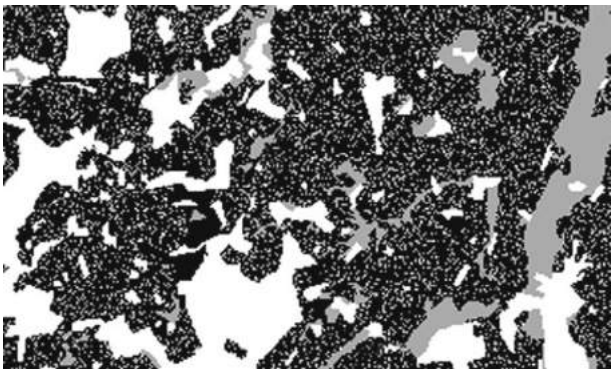


Figure 4 Degree of crop cover, white areas = non food area, gray color: the brighter the color the smaller the coverage degree (the white areas are lakes, forest and settlements).

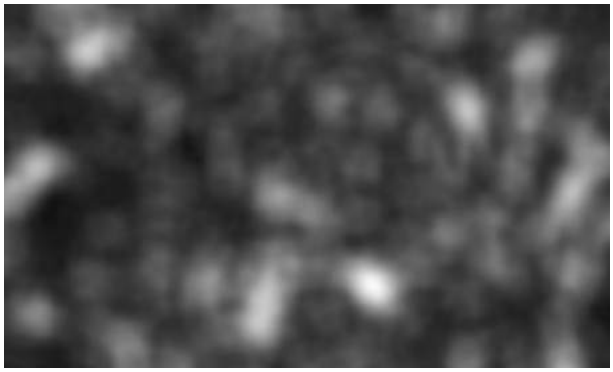

Figure 5 Mean distance to structure elements, the brighter the color the smaller the distance.

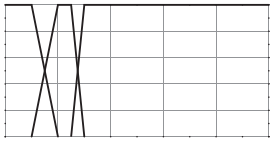
Very_small	−0.100	0.000	0.100	0.200
Small	0.100	0.200	0.300	0.400
Medium	0.300	0.400	0.600	0.750
High	0.600	0.750	1.000	1.100

Mean distance to structure [0.0.1000]



High	−0.1	0	100	200
Medium	100	200	250	300
Small	250	300	1000	1001

As outputs crisp values where used:

Very_small	*Small*	*Medium_small*	*Medium*	*Medium_high*	*High*	*Very_high*
0	0.2	0.4	0.5	0.6	0.8	1

The rule base is very simple. It can be presented as a table:

Coverage degree	*Structure*	*Output*	*Numoutput*	*Weight*
Very_small	High	Very_high	1	1

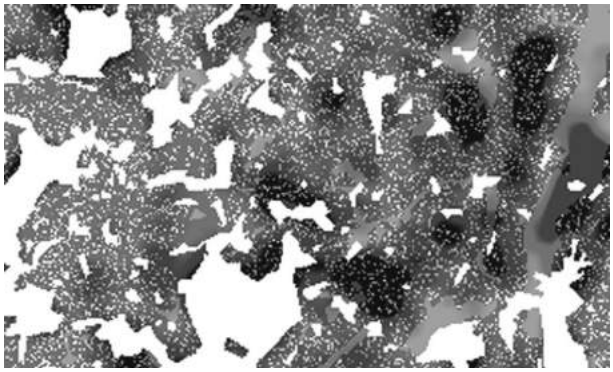


Figure 6 Nutrition quality for the lesser spotted eagle.

Very_small	Medium	Very_high	1	1
Very_small	Small	High	0.8	1
Small	High	Very_high	1	1
Small	Medium	Medium_high	0.6	1
Small	Small	Medium	0.5	1
Medium	High	Medium_small	0.6	1
Medium	Medium	Medium_small	0.4	1
Medium	Small	Small	0.2	1
High	High	Medium_small	0.4	1
High	Medium	Small	0.2	1
High	Small	Very_small	0	1

Sometimes there are contradictory rules. The belief in such a rule can be changed using the weight factor. (This can arise, when more than one expert constructs a rule set.) With this fuzzy model a nutrition quality for lesser spotted eagle can be calculated. The result is shown in Figure 6.

Fuzzy model habitat

The output of the part of the model on nutrition is one input for the calculation of habitat quality. The next input is the distance to the breeding places. These places are located in a forest. The mean distance to the forest can be used to evaluate potential breeding habitat. The last input includes the endangerment caused by wind energy plants. The lesser spotted eagle will avoid areas around wind energy plants. In this sense wind energy plants can shrink the hunting area of the bird. These three inputs are put in a new fuzzy model. The result is the habitat quality of the area. With such a model it is easy to estimate the influence of planned wind energy plants or of some alternative land use modes. The model can be used to optimize the location for new wind energy plants. The big advantage of this modeling approach is that all influences for the habitat quality will be considered. It is not logical to protect the lesser spotted eagle in a region where it can not live.

Simulation of Habitat Quality of the Lesser Spotted Eagle

The habitat model of the lesser potted eagle depends on the degree of vegetation coverage as a dynamic changing value. To determine the habitat quality the simulation has to be repeated over a sequence of points in time (during one breeding session). The resulting habitat quality can be calculated as the minimum for the period which was simulated. (The nutrition condition is especially important in the breeding season from April to June in our region.)

$$q = MIN\{q(t_1), q(t_2), \ldots, q(t_n)\} \quad [16]$$

Dynamic Simulations

Many ecological variables are functions of time. This starts with a simple growth dependency of the coverage degree, as discussed in the example of the lesser spotted eagle. More complicated dependencies include more than one variable, which will be discussed in the Lotka-Volterra model below. In realistic ecological models, the number of time-dependent variables can easily exceed one hundred, as shown in (Abrahamsen and Hansen, 2000). The fuzzy approach can be used to simplify traditional models, making

them more stable and enhancing their accuracy. The most important advantage of dynamic fuzzy models is that ecologists are able to understand and modify all parts of the model. The clear structure of a fuzzy model, consisting of the definition of the membership functions and the rule set, is the key factor for ensuring it is understood. On the other hand, ecologists require a software development system to combine differential equations with fuzzy models. A simple modeling system based on the programming language Python (including "scipy" for solving of differential equations) is available as open source software. This simulator allows a fuzzy model to be analyzed as part of a differential equation. A program combining fuzzy models can then be built as part of a differential equation system with a graphical output to visualize the chart of the solved differential equation. This executable program can be used as the first step for building dynamic fuzzy models. The software is developing very rapidly; efforts are now being made to integrate spatial and dynamic modeling. To find out more about dynamic simulation, see (Deaton and Winebrake, 2000), (Korn, 2013) and (Korn, 2004). An introduction to dynamic fuzzy modeling and how it is applied to landscape modeling is given below.

FUZZY Models as Part of Dynamic Models

In traditional ecological models, differential equations contain algebraic expressions. For example, the well-known Lotka-Volterra model should demonstrate that:

$$\frac{dx}{dt} = \alpha * x - \beta * x * y \quad [17]$$

$$\frac{dy}{dt} = \delta * x * y - \gamma * y \quad [18]$$

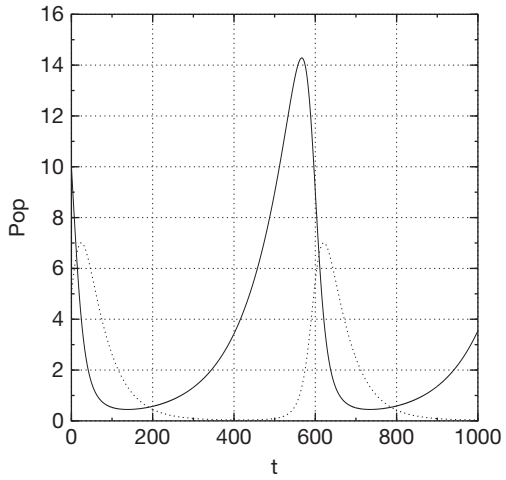

Figure 7 Lotka-Volterra model: prey = black, predator = gray.

Table 2 Subset of fuzzy rules of $f_{predator}(x,y)$

Number	*x (prey)*	*y (predator)*	*Output*
16	High	Zero	sp
17	High	Small	mp
18	High	Medium	hp
19	High	High	sn
20	High	Very_high	mn
21	Very_high	Zero	sp
22	Very_high	Small	mhp
23	Very_high	Medium	hp
24	Very_high	High	mp
25	Very_high	Very_high	sn

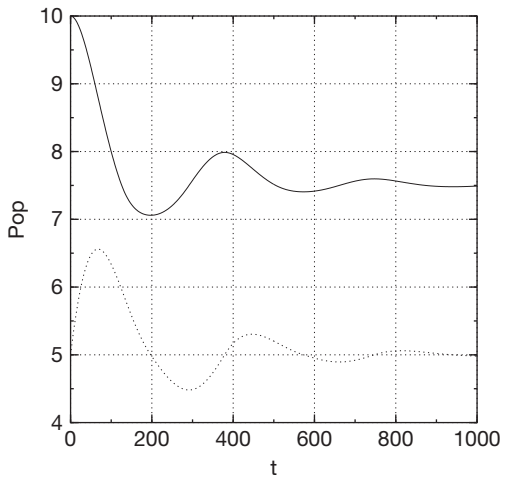

Figure 8 Fuzzy-Lotka-Volterra model: prey = black, predator = gray.

This model describes the interaction between a prey (x) and a predator (y). The prey, which uses a constant nutrition source for growing ($\alpha * x$), is reduced by the predator ($-\gamma * x * y$). The predator depends on the prey ($\delta * x * y$), and is reduced by a constant rate of death ($-\gamma * y$). With the parameters ($\alpha = 0.01$, $\beta = 0.0075$, $\delta = 0.02$ and $\gamma = 0.005$), the starting values for the prey and predator (10.0, 5.0) and the $dt = 0.2$ for 1000 simulation steps produces the following chart with cyclic behavior, see **Figure 7**.

The result of the Lotka-Volterra model appears very "artificial" from an ecological point of view. A stable cycle is very rare in nature. Changing behavior to make it more realistic means changing the model. A fuzzy approach is much easier to understand and adapt here. Firstly, the Lotka-Volterra model is replaced by a set of fuzzy models – one for the prey, the other for the predator.

$$\frac{dx}{dt} = \alpha * f_{prey}(x, y) \quad [19]$$

$$\frac{dy}{dt} = \alpha * f_{predator}(x, y) \quad [20]$$

α is a scaling constant to control the systems behavior. The membership functions are triangular, and are not shown here. However, the rules are interesting. In the fuzzy model $f_{predator}(x,y)$ they combine input x {zero, small, medium, high, very_high} and input y {zero, small, medium, high, very_high} with output {hn = −0.05, mhn = −0.03, mn = −0.02, sn = −0.01, zero = 0.0, sp = 0.01, mp = 0.02, mhp = 0.03, hp = 0.05}. A subset of the rules is shown in **Table 2**.

Rule 25 means that a very_high prey and a very_high predator leads to a small negative (sn) growth of the predator. Ecologists are aware of the fact that, even under optimal conditions, a very large population of predators is often reduced by other factors (by disease, for example). This knowledge can be entered directly into the fuzzy rules. The resulting system behavior is "dampened", making it much more realistic, see **Figure 8**.

As shown in this example, as part of dynamic systems, fuzzy models can make the modeling more flexible, accurate, and easier to understand. A larger application of dynamic fuzzy models to estimate agricultural yield under climate change is given in (Wieland et al., 2013).

Dynamic-System Modeling Part

In order to study how landscape features change over time, the spatial part only requires landscape feature values at fairly widely spaced sampling times (communication times) $t = t0$, $t0 + COMINT$, $t0 + < 2 * COMINT$, . . .; the communication interval *COMINT* could be one day, one month, one year, and so on. The dynamic part, however, can increment the time in smaller steps DT to emulate continuous change. The dynamic part relates current and future data values at each grid point by ordinary differential equations. (We can instead, relate current and future feature values at different sampling times by difference equations, or by combinations of differential and difference equations.)

$$\frac{d}{dt} q_i = f(q_1, q_2, \ldots, p_1, p_2, \ldots, a_1, a_2, \ldots) \forall i \in (1..n) \quad [21]$$

For each grid point, the feature values $q1$, $q2$, . . . *state variables* start with given initial values. $p1$, $p2$, . . . are feature values related to the state variables by *defined-variable assignments*

$$\begin{aligned} p_1 &= g1(p_2,p_3,\ldots;q_1,q_2,\ldots;b1,b2,\ldots;t) \\ p_2 &= g2(p_1,p_3,\ldots;q_1,q_2,\ldots;b_1,b_2,\ldots;t) \\ &\ldots \end{aligned}$$

which may not involve recursive "algebraic loops". $a_1, a_2, \ldots b_1, b_2, \ldots$ are fixed parameter values associated with each grid point. The differential equation system (1) for each grid point is solved by numerical integration to produce time histories of the feature values $q_i = q_i(t)$ and $p_i = p_i(t)$. Such an equation system could, for instance, model the growth of a crop or the population dynamics of competing plant species at a certain point of the landscape.

Summary Fuzzy Modeling

A rule-based system lies at the heart of all fuzzy modeling of ecological problems. The inputs for this system are taken from a GIS describing a landscape or from a dynamic simulation system. The outputs of the model evaluate environmental indicators. The rule set is easy to understand, and should form the basis for discussing the model with other experts. Use of a fuzzy model should be accompanied by a strategy for its further development. This strategy should encompass visualization of the systems behavior, tests on real data sets, sensitivity analysis, etc., including an adaptation using a training algorithm.

The following advice can be offered concerning the development of fuzzy models:

- start with simple models (no more than three inputs, otherwise use two models)
- use triangular or trapezoidal shaped membership functions
- use FUZZY_AND Prod rather than FUZZY_AND Min
- use crisp values as the output type
- use training procedures to enhance the model
- check the model using graphical analysis tools, rule statistics and sensitivity analyses

Introduction

Grasslands

A large proportion of the surface of the Earth is covered with grasslands (Figs. 1 and 2), which are ecosystems where the vegetation component is herbaceous in character, with grasses being predominant. Grasslands can be divided into tropical grasslands that occur in the same regions as savannas, that is, grasslands with scattered individual trees, and temperate grasslands. The major manifestations of temperate grasslands are, for example, the veldts of South Africa, the puszta of Hungary, the pampas of Argentina and Uruguay, the steppes of the former Soviet Union, and the plains and prairies of central North America. Grasslands are important ecosystems because they are frequently used for livestock grazing, they provide important ecosystem services, and may serve as carbon sinks.

Very roughly, grasslands can be classified as natural grasslands where grassland without trees constitutes the vegetation climax, seminatural grasslands which are mostly natural grasslands but modified by low intensity (grazing) management, and man-made grasslands which are either intensively managed natural grasslands that have been substantially altered or secondary grasslands, for example, created by the removal of natural forests for livestock production. The latter is common in temperate, Mediterranean, and tropical regions. In natural grasslands of pristine climax condition, perennial grasses and sedges are dominant and annual grasses are often restricted to locations where perennial plant cover has been disturbed. On the other hand, in seminatural grasslands, grazing often reduces the palatable perennials which are replaced by unpalatable and/or annual grasses.

As one of the world's major ecosystems, grasslands have been an important subject of basic and applied ecological research attempting to understand the ecological processes and factors occurring in grasslands and their effects on grassland dynamics, productivity, and diversity. Grasslands are model ecosystems for basic ecological research to investigate the effects of processes such as competition, seed dispersal, and reproductive strategies on coexistence and diversity. They are of interest in rangeland science where ecological understanding is needed to derive optimal grazing management strategies that maximize fodder or animal production and minimize the risk of degradation. More recently, grassland ecosystems gained interest in climate change ecology because of their importance as carbon sinks.

Overview Over Models of Grasslands

Grasslands are complex ecosystems, and understanding the ecological processes and factors determining its dynamics, productivity, and biodiversity requires use of combined approaches of field measurements, experimentation, data analysis, and modeling. Thus,

ecological models are important tools for ecologists working in grasslands. However, the term "model" has been used in such a variety of contexts that it has become almost meaningless, unless used with some qualifications. In the present context, models may be regarded as a simplified and formalized representation of ecological processes, either using mathematical or computer simulation techniques, which produce, based on a set of assumptions, a quantitative output. Grassland models are as varied as the purposes for which they have been constructed, and cover various spatial and temporal scales and various degrees of detail. Our focus lies on ecological models which are concerned with grassland population and community dynamics with less attention to grassland models of matter and energy flows or biophysical processes. In this article, most grassland models are conceptual, empirical, analytical, or simulation models.

Modeling Questions and Models

In the following, we present an overview over the most important grassland models, structured by their scientific questions rather than by model type. A summary of these models is given in Table 1. The major variables and properties of ecological grassland models are temporal and spatial grassland dynamics and diversity, grassland productivity, water dynamics, and flow of other matter and nutrients. Grazing is a predominant theme in grassland models.

Grassland Dynamics and Processes of Coexistence

An important topic in grassland research, both from theoretical and applied point of view, is the temporal and spatial dynamics of species abundance and composition. In applied rangeland science, the dominant question is how to manage grasslands for maximal long-term domestic livestock production without degrading the grassland to an extent that would make it unsuitable for further grazing. In applied conservation ecology, the main question is how to promote survival of small and fragmented remnants of natural grasslands. A specific conservation problem in central Europe is that an increasing intensification of agriculture leads at the same time to abandonment of former secondary grasslands maintained by grazing. From a more theoretical perspective, grassland ecologists are interested in the processes and factors that determine the dynamics of grasslands and maintain their biodiversity. Grasslands are good systems to study questions of coexistence and biodiversity in sessile organisms (e.g., vascular plants), because they are relatively easy to monitor, and are less complex than tropical forests or coral reefs but still species rich enough for studying questions of coexistence. Another theoretical question in biogeography is why and under which climatic and environmental conditions grasslands can exist.

Succession in Grasslands

Understanding succession, that is, the change in vegetation of an area over time, is fundamental for the theoretical understanding of grasslands as well for an understanding of the reactions of grasslands to management. Models of grassland succession, especially applied models, are mostly based on the Clementsian theory of ecological succession. Models which explicitly deal with spatial structures are more influenced by the work of A. S. Watt in the 1940s, who proposed that plant communities are composed of a mosaic of patches in different states of a natural cycle of disturbance and regeneration.

Rangeland Models

The range succession model. The range succession model based on the Clementsian theory of ecological succession formed the conceptual framework for most grazing management up to the 1980s. It is supposed that, in the absence of grazing, a rangeland has a single persistent state (the climax), whereas grazing causes continuous and reversible transitions of the grassland state along a single, monotonic gradient between an undisturbed climax and an overgrazed subclimax vegetation state. Therefore, the grazing pressure can be made equal and opposite to the successional tendency, producing an equilibrium in the vegetation at a set stocking rate (Fig. 3A). A sustainable yield of livestock products can be harvested from such an equilibrium. The model recognizes that vegetation is affected when rainfall varies from year to year and supposes that grazing and interannual variation in rainfall cause equivalent changes in the vegetation. Therefore, management should respond to drought by reducing grazing.

State-and-transition models. Over the years, however, substantial empirical evidence accumulated of cases where the assumptions of the range succession model were not met, especially in arid and semiarid environments. To deal with the complex dynamics of semiarid and arid ecosystems, scientists such as M. Westoby, B. Walker, and I. Noy-Meir suggested (by the end of the 1980s) that these ecosystems could be described in terms of discrete states and inter-state transitions (Fig. 3C). Transitions could be triggered by natural events (e.g., rainfall, drought, and fire) or by management actions (e.g., removal of herbivores, altered intensity or timing of herbivory, and burning). Changes in range condition are not unidirectional, but multiple pathways of system transitions to alternative states may exist, depending on the particular sequence of driving events (Fig. 3C).

Such state-and-transition models are valuable tools for describing the structure of the ecosystem to identify irreversible transitions and alternate stable states; however, they provide little information applicable to forecasting and prediction. Additional models are needed to quantify the temporal scales of the transitions, to identify rare events that drive semiarid and arid ecosystems, and to improve the user's understanding of ecosystem dynamics over a long temporal scale.

Degradation gradient models. The degradation gradient model combines in some sense the concepts of Clementsian succession and state-and-transition models (Fig. 3B). It is based on the idea that vegetation compositional changes along a grazing gradient are indicative for the ecological condition. This statistical method was developed in the 1990s by O. J. H. Bosch and H. G. Gauch for the semiarid South African grasslands. Key element of the approach is a classification of the species according to their response to grazing as increaser and decreaser species (Fig. 3B). This classification is derived by means of multivariate statistics. Species composition data are collected from grasslands in various stages of degradation. Based on a series of statistical analyses of these data, the degradation gradient is constructed. The model recognizes that irreversible transitions may exist which are caused by soil loss or major changes in floristic composition. This method is used for range assessment where species composition data of a sample is compared to the gradient.

Spatially Explicit Models on Succession and Disturbance in Grasslands

Disturbance can play a major role in structuring grasslands by producing a spatiotemporal mosaic of patches by locally resetting the successional clock after a disturbance. The spatiotemporal distribution of species within the resulting mosaic depends upon an interaction between species' life-history traits and the spatial and temporal structure of the ecological processes controlling species' distributions. The availability of powerful computers and the advent of spatially explicit simulation models revitalized the

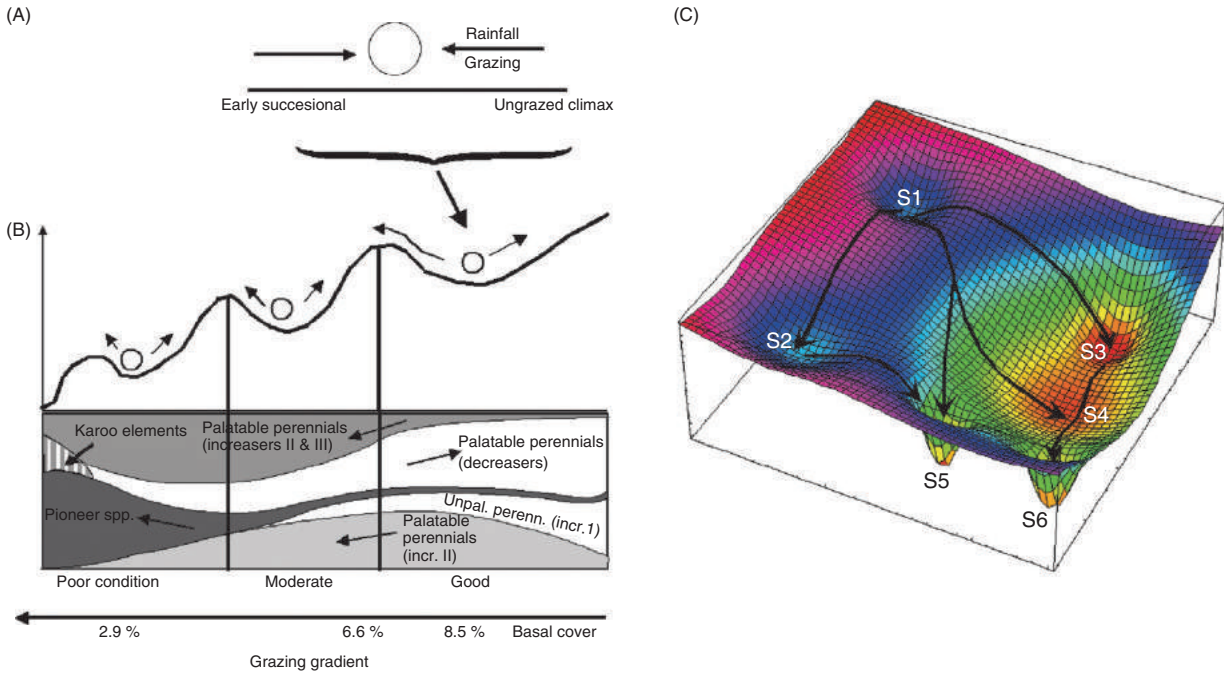

Fig. 3 Illustration of different conceptual rangeland models. (A) Range succession model. Vegetation changes are reversible and unidirectional in response to grazing and rainfall. (B) Degradation gradient model for South African grasslands. The system responds to smaller perturbations (grazing and rainfall) unidirectionally and reversibly as predicted by the range succession. Larger perturbations (drought, overgrazing) may cause the system to cross an irreversible threshold where changes in soil conditions (related to reduced basal cover) and species composition may hinder the system to return. The pathway of degradation is unidirectional. (C) State and transition model. Multiple equilibria and multidirectional pathways of degradation in response to different driving events. S1, S2: Good condition domains; S3, S4: moderate condition domains; and S5, S6: poor condition domain.

conceptual work done by Watts in the 1940s and allowed to elucidate process from patterns. In this line, several spatially explicit plant dynamics models investigate questions related to succession and disturbance.

The Steppe model. D. B. Coffin and W. Lauenroth developed at the end of the 1980s a spatially explicit gap dynamics simulation model (STEPPE) to evaluate the effects of disturbances at the scale of a landscape for a semiarid grassland in north-central Colorado, United States. The approach goes back to spatially implicit gap models of forest succession (see Forest Models). These models simulate succession in a gap left after the death of a large tree. Succession dynamics are then estimated by the average behavior of 50–100 plots of the size of a single large tree. The exact location of each individual is not used to compute competition in these models. However, gap models can be made spatially explicit by linking several individual plots together.

The STEPPE model is a gap model and simulates the establishment, growth, and death of individual grass plants on a small plot ($0.12\ m^2$) through time at an annual time step. Landscapes were simulated either as a collection of independent plots or as a collection of interacting plots. In the 1990s, extending their first approach, W. Lauenroth and colleagues coupled compartment models of nutrient cycling and soil water–plant relation with the STEPPE model. The aim was to understand the interactions between vegetation structure and ecosystem processes across ecosystems. However, the approach of coupling several models was quickly abandoned, probably because of problems with increased model complexity.

A gap model similar to STEPPE was developed at the beginning of the 2000s by D. B. Peters (formerly Coffin). This individual-based, gap dynamics model (ECOTONE) was used to predict the effects of climatic fluctuations on regional patterns of vegetation dynamics, and the effects of disturbance on vegetation dynamics at an arid–semiarid ecotone between shortgrass steppe grassland and a Chihuahuan desert community in central New Mexico, United States.

The Jasper model. K. A. Moloney and S. A. Levin developed in the 1990s a spatially explicit simulation model of a serpentine grassland, focusing primarily on the role of disturbance. The model is hierarchical in design and population dynamics were modeled as occurring within local sites, which were then arranged to form a landscape and interact primarily through seed dispersal. Several components of the disturbance architecture were varied systematically among model runs to determine their impact on population dynamics at the scale of the landscape. Results suggested that predicting the impact of disturbance on ecological communities will require an explicit understanding of at least some aspects of the spatial and temporal architecture of the disturbance regime.

Neural networks. Where long-term site data on species composition and environmental factors are available, an approach using artificial neural networks may be feasible to predict grassland succession. The method takes advantage of the ability of neural networks to learn, recognize, and generalize from patterns contained in the ecological data. In the 1990s, S. S. Tan applied this

approach to a 30-year data set on vegetation changes and climatic factors in grassland communities in Kansas (United States). Their model predicted future community composition using input data on present conditions that have not been used to develop the model. The model performs well for 1–4 year predictions and performance significantly deteriorated from the fifth year on. One disadvantage of the neural networks is that it is purely descriptive and gives little insight into underlying causes and mechanisms of grassland succession. On the other hand, if predictions are required for highly complex systems as they occur in natural rangeland communities, they are an appropriate technique for qualitative analysis and statistical forecasting.

Matrix models. Matrix models of succession are mathematically and conceptually the most straightforward among the succession models. Matrix models are constructed by determining the probability that the vegetation on a local plot will transform to some other vegetation state after a given time interval. To construct the model, the vegetation must be classified into identifiable states. The model consists of a vector representing the state variables of the system and a matrix containing the (usually) constant probabilities of possible state transitions. A question of interest is how a population growth rate depends on factors such as rainfall or grazing. Matrix models provide the means for calculating population growth rates, thereby allowing for an assessment of the influence of different population processes such as seed production and growth and mortality. For example, T. G. O'Connor used in the 1990s stage-structured matrix models to assess the influence of rainfall and grazing on the demography of some African savanna grasses. Results showed that the population growth rates of most species were positively correlated, indicating that an extrinsic force, presumably rainfall, had the greatest effect on population growth.

Optimal Life-History Strategies, Competition, Coexistence, and Biodiversity

A considerable number of models on grassland dynamics and processes are motivated from general theory in ecology and are often put into a spatially explicit context. These models, developing since the mid-1990s, are concerned with tradeoffs in optimal reproduction strategies, and investigate how optimal strategies depend on disturbance and other spatially explicit factors such as a patchy habitat. One early example of this approach is a spatially explicit, two-species simulation model by S. Lavorel to examine the interaction between dispersal, dormancy, and small-scale disturbances on coexistence of two annual plant species in landscapes with varying degree of patchiness. Coexistence patterns depended on the degree of suitability and the patchiness of the landscape, mostly in relation to the interactions between landscape structure and mean dispersal distance.

A model of grassland community dynamics developed in the 2000s by Y. G. Matsinos and A. Y Troumbis aimed to quantify the role of competition and dispersal under disturbance, and investigated the resilience of the communities with respect to gap-creating disturbances that were imposed at different spatial extent. Model results showed that plants with longer seed dispersal distances may have a competitive advantage in their colonization success as compared to the better competitors, especially in the cases of a disturbance-mediated creation of gaps in the landscape. An increase of the species number led to more stable end communities and a higher vegetation cover in the landscape.

A series of papers by S. Schwinning and A. J. Parsons investigated, in the 1990s, coexistence mechanisms for grasses and legumes in grazing systems. This is an important question since legumes fix nitrogen which in turn is beneficial for grasses.

Other questions investigated with spatially explicit models attempt to gain an understanding of clonal growth and ramification of grass tillers in grasslands. For example, E. Winkler and colleagues developed a series of grid-based models of grassland communities to investigate long-term control of species abundances and reproduction strategies in patchy landscapes undergoing disturbances. One example is a study with M. Fischer investigating tradeoffs between sexual and vegetative reproduction of clonal plants. Depending on spatial habitat structure and disturbances, different reproduction strategies lead to different long-term fitness. The model simulated plant population dynamics on a two-dimensional cellular grid consisting of 70×70 square cells. In an extension of this approach, J. Stöcklin and E. Winkler used a spatially explicit, individual-based metapopulation model of *Hieracium pilosella* to examine the consequences of tradeoffs between vegetative and sexual reproduction and between short and far-distance dispersal of seeds. They found that in a spatially heterogeneous landscape, sexual seed production in a clonal plant is advantageous even at the expense of local vegetative growth.

While most of the questions from this section were analyzed by means of grid-based models, advances in analytical modeling made by B. M. Bolker, S. W. Pacala, and others at the end of the 1990s suggested that spatial interactions may be approximated by means of moment equations that describe changes in the mean densities and spatial patterns (covariances) of competing species. The formalism of moment equations is borrowed from physics where it was used to describe phase transitions and is an elegant way to approximate simple spatial dynamics by tracking the dynamics of the first moments (mean densities) and second moments (variances and covariances or spatial covariances) of the spatial distributions of populations. For example, to understand at a general level how plants coexist in communities, Bolker and Pacala studied three different strategies to compete for resources in a spatially variable environment: colonizing new areas, exploiting resources in those areas quickly before other plants arrive, or tolerating competition once other plants arrive. However when adding more realism the moment equations become quickly lengthy, simulations are often required to find an appropriate moment closure.

Spatial Structures in Arid and Semiarid Grasslands

In mesic regions, patchy spatial vegetation patterns arise through the interplay of succession and disturbances. In the past, this has been shown in many studies of patch dynamics for mesic forests and grasslands, for example, summarized in the classic book by S. T. A. Pickett and P. S. White. However, patchy structures are also frequently observed in water-limited arid and semiarid ecosystems,

where distinct banded and spotted vegetation patterns are often found. There are numerous hypotheses on the origin of the distinctive patterning. For example, banded vegetation may be a remnant of more complete vegetation cover diminished by climatic deterioration or by grazing disturbance. Other hypotheses assume these patterns to be natural with downslope water re-allocation from bare areas to vegetated bands as a key-process or are based solely on the intrinsic dynamics of the vegetation without slope-induced anisotropy.

A number of cellular simulation models were developed to investigate the robustness and origin of such patterns. For example, end of the 1990s, D. L. Dunkerley modeled banded vegetation communities in western New South Wales Australian grassland and shrublands to test the hypothesis that water partitioning in spatially unstructured plant communities may lead to the development of banding. The model shows that without any climatic change or external disturbance, strongly developed banding can emerge from an initially random distribution of plants.

Other models used differential equations to search for possible unifying mechanisms to explain these spatial patterns. One hypothesis is that spatial patterns establish themselves through a Turing-like spatial instability depending only on a tradeoff between facilitative and competitive interactions among plants. This hypothesis goes back to the 1950s where A. M. Turing described morphogenesis in chemical systems. These models produce patterns superficially similar to banded and spotted vegetation, which then is taken as evidence for the validity of the underlying hypothesis. However, reproduction of a pattern is not proof that the modeled processes represent the natural processes. Since these top-down models are usually not explicitly related to specific spatial and temporal scales, they are difficult to test and their ecological content remains unclear.

Models on the Impact of Grazing on Grasslands

The impact of grazing on the dynamics and productivity of grasslands has been an important subject of basic and applied ecological research. Theoretical and applied questions are intimately linked since developing sustainable grazing management requires an understanding on the dynamics of the grazing system. Early models on grazing systems were based on the Clementsian theory of ecological succession, and since the 1970s biomass–herbivore grazing systems were modeled in analog to predator–prey models developed one decade earlier. Since the 1980s, however, the equilibrium concept was increasingly challenged, and in the late 1980s nonequilibrium concepts and models emerged which stipulated environmental variation (due to rainfall variability) and spatial heterogeneity. Numerous grazing models have modified the early predator–prey differential equation models, and spatially explicit and rule-based simulation models are increasingly used to analyze specific grazing systems. For a detailed treatment of grazing models, see Grazing Models.

Modeling Primary Production in Grasslands

Regional and global patterns in aboveground net primary production (ANPP) and their determinants have long interested ecologists. Understanding ANPP patterns and controls through time is particularly important in grasslands where grazing is the most important economic activity. Coping with temporal changes in the availability of forage is a prerequisite for the efficient and sustainable use of natural vegetation. More recently, interest in ANPP has intensified as projected global changes in climate, nitrogen deposition, and land use threaten to alter ecosystem carbon and energy flow. Data on primary production are also important to calibrate, parametrize, and evaluate terrestrial biosphere models and for modeling the global carbon cycle.

Regression Models

Early approaches to assess primary production in grasslands, such as the work by H. N. Le Houérou in the 1980s, used empirical models which correlated primary productivity with mean annual precipitation or evapotranspiration. In general, the relationships of production with environmental variables were derived from long-term averages for many sites distributed across environmental gradients (spatial models). ANPP increases linearly along spatial precipitation gradients within the range of 200–1300 mm $year^{-1}$ in North American, South American, and African grasslands.

However, much less is known about the controls of the temporal, inter-annual variation of productivity at a given site (temporal models). Temporal models relating time series of ANPP and annual precipitation for single sites have shown lower slopes (=water use efficiency) and regression coefficients than the spatial models. Additionally, memory and carryover effects, for example, due to storage of carbohydrates in the root system and structural inertia, might play an important role in the functioning of semiarid grasslands. Memory and carryover effects buffer fluctuations in production if wet, productive years alternate with dry, less productive years and amplify fluctuations if wet or dry sequences of several years take place. Identifying and quantifying such memory and carryover effects is an important challenge for global models which mostly use simple linear relationships with precipitation.

Use of Remote Sensing Data

Biomass harvesting is the most common way to estimate ANPP in grasslands, but because of the large effort and the detailed spatial scale, harvesting methods are rather limited in their spatial and temporal extent. Remote-sensing techniques are a fast and nondestructive method for estimating ANPP at a regional scale over longer time periods. NDVI is the most commonly used radiometric index for estimating ANPP in grasslands and the annual summed NDVI can be used as a surrogate for annual ANPP because, in ecosystems dominated by grasses or deciduous life forms, the absorbed photosynthetically active radiation of plant canopies (APAR) and net primary production are directly related. Biomass estimates for grassland using NDVI have been performed, for example, by the group of J. M. Paruelo in the late 1990s and 2000s for the Central Grassland Region of the United States, and for subhumid pampa rangelands and the Patagonia steppes in Argentina. S. D. Prince determined in the early 1990s primary production for Sahelian grasslands.

Additionally, NDVI data allow determination of other important ecosystem characteristics such as the degree of seasonality, and the start and the end of the growing season. Relating NDVI characteristics over regional gradients with climatic and other environmental variables allow for inference on the controls of primary production and ecosystem functioning. Remote-sensing data may also be used to calibrate ecosystem models, for example, by minimizing the difference between the measured and the simulated NDVI. The utility of this approach was demonstrated by a study of Y. S. Nouvellon in the 2000s who coupled a grassland ecosystem model for semiarid perennial grasslands in southeastern Arizona (USA) with Landsat imagery for a 10-year simulation of carbon and water budgets.

Ecosystem Modeling and Flows of Energy and Matter in Grasslands

Although the first interest in ecosystem modeling peaked in the 1970s with the International Biological Program (IBP), it is now having a rebirth with the recent interest in predicting ecosystem effects of global change. In the 1960s and 1970s "big biology" projects were initiated by G. M. Van Dyne to study ecosystems including grasslands. One of the main problems of this big biology project was the attempt to model everything without a clear and focused research question. At the end, the resulting models were nearly as complex as nature itself and they could not be properly analyzed and thus understood. The objective of the IBP grassland simulation model was to simulate biomass dynamics in a variety of grassland types and the response of the system to irrigation, fertilization, and cattle grazing. The model comprises several submodels, that is, abiotic, producers, mammals, grasshoppers, decomposers, nitrogen, and phosphorus. Some of the submodels originally designed to be incorporated into the ELM model never reached this objective but developed a life of their own.

Plant Growth and Production

A number of models, reviewed in detail by J. D. Hanson and colleagues in the mid-1980s, simulated/predicted plant growth and production of grassland ecosystems. For example, the AFRICA model included processes like shoot growth, tillering, root growth, photosynthesis, and nitrogen uptake for single plants. The aim of AFRICA was to model primary production of perennial graminoids and it unites physiological processes and morphometric traits. In a study in the late 1990s, M. B. Coughenour and D.-X. Chen linked models of photosynthesis, plant growth, and biophysical processes with models that simulate water, nutrient, and carbon flows through plant–soil ecosystems. The linked ecosystem model was applied to examine ecosystem-level responses to CO_2, temperature, precipitation, and global-warming scenarios in grasslands of Colorado and Kansas (United States) and Kenya. Using similar ecosystem model approaches, several models have been developed for semiarid perennial grasslands that allow multiyear simulations of plant growth patterns by accounting for carbohydrate storage in root systems and further translocation to aboveground regrowth.

Biochemistry Models

Other models analyzed the soil organic matter dynamics in response to changes in management and climate. These models described the flow of energy and matter (Conceptual Diagrams and Flow Diagrams) in form of balance equations. Following the approach of H. T. Odum, the focus of these models was not on biotic interactions between species but rather on the flows of energy and nutrients, treating plants basically as composers and decomposers.

The most prominent model of this type is the "CENTURY model" (Fig. 4) developed by W. J. Parton in the 1980s. CENTURY is a model of terrestrial biochemistry of grasslands based on the relationships between climate, human management (fire, grazing), soil properties, plant productivity, and decomposition. Studies performed with this model include efforts to link models describing plant and soil responses to the large-scale modeling of global change effects. The model is intended as a generic model whose basic balances of the different flows in grasslands can be calibrated to specific systems. In the 1990s, Parton and colleagues parametrized CENTURY for the world's major grassland types to predict the biomass and soil organic matter dynamics of the grassland biome worldwide.

In the late 1990s, the performance of CENTURY was assessed by T. G. Gilmanov and colleagues using long-term data collected under IBP and at research stations within the former USSR. They found that CENTURY reproduced the seasonal, mid-term, and, in

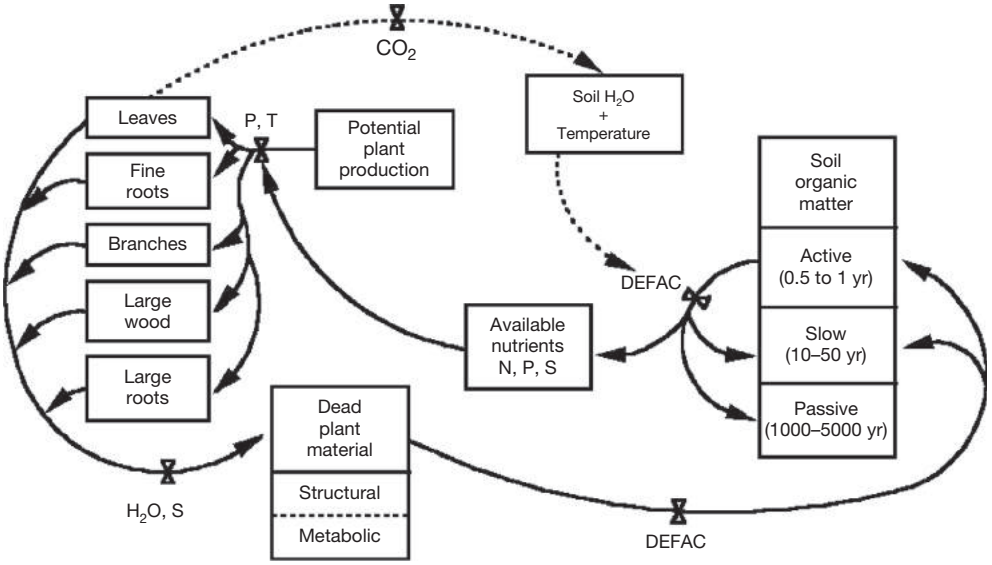

Fig. 4 Flowchart of the CENTURY model. Supplement to Metherell et al., (1993). Century Manual. CENTURY Soil organic matter model environment. Technical documentation. Agroecosystem version 4.0. some cases, long-term dynamics in aboveground biomass in a wide range of grassland ecosystems. Model discrepancies were attributed to changes in species composition and short-term responses to intermittent rainfall that are missed by the monthly timestep of the model. In another application, K. A. Hibbard and colleagues assessed in the 2000s the magnitude of changes in plant and soil carbon and nitrogen pools in a subtropical landscape undergoing succession from grassland to thorn woodland in southern Texas (United States). They linked CENTURY to a transition matrix model and parametrized grass and tree production submodels of CENTURY with field data. The Markov transition matrix model simulated the displacement of grassland communities under land-use practices (heavy livestock grazing, no fire) and climate events.

Water-Balance Models

Other models, such as a model of water balance developed by J. M. Paruelo in the 1990s, calculate the amount of water evaporated from the soil and transpirated by the canopy. Typical questions asked with such models are: What are, on a long-term basis, the magnitude of evaporation, transpiration, and deep percolation in a water-limited steppe? How will elevated CO_2 change the fluxes of soil water to the atmosphere and ground water?

Lake Models☆

Peter Reichert and Johanna Mieleitner, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland

Introduction

Since the 1970s models have been used to predict the water quality of lakes and reservoirs to support their management. Lake models are also used for testing hypotheses in research. Many different approaches and levels of complexity have been and are used to achieve the different goals.

An overview is given of the basic principles of biogeochemical and ecological lake modeling. We start with a brief discussion of the objectives of ecosystems modeling with a particular emphasis on lake modeling. Then we give an overview of important processes in lakes and discuss major difficulties of describing them in lake models. This is followed by an overview of important components of lake models and how different formulations of these components attempt to overcome the problems mentioned in the preceding section. In the next section, we show mathematical process formulations typically used in the biogeochemical and ecological parts of lake models. Finally, by briefly describing a selection of lake models and their application, we provide an overview of different models currently in use and different modeling strategies applied by different research groups. The article focuses on mechanistic lake modeling because they more comprehensively address the objectives discussed in the next section in comparison to empirical and statistical approaches to lake modeling. Empirical and statistical approaches usually provide less insight into mechanisms in the ecosystem. Nevertheless, also these approaches can be useful for analysis and extrapolation of observed behavior.

Objectives of Lake Modeling

There are three main objectives for constructing and using lake models:

1. *Improving the understanding of lake ecosystem function*: Comparing results of simulations of a lake model with measured data provides a test of the hypotheses formulated in the model. Thus, lake models are ideal tools for quantitative testing of hypotheses about lake ecosystem theories. Furthermore, they provide a link from concentrations to fluxes and transformation rates that are much more difficult to measure than concentrations. The formulation of comprehensive lake models can also lead to the identification of knowledge gaps. Finally, performing model simulations and tests stimulates creative thinking about important mechanisms in lake ecosystems.
2. *Summarizing and communicating knowledge about lake ecosystems*: Lake models are perfect communication tools for exchanging quantitatively formulated knowledge about processes in lakes.
3. *Supporting lake ecosystem management*: Lake models can support lake management by predicting the consequences of suggested (alternative) measures. As both our knowledge and its representation in the models are incomplete, a considerable effort must be on quantifying prediction uncertainty if the models are applied for management purposes.

These objectives are essentially the same as in other fields of environmental modeling. However, lake models had a pioneering role in providing insight into the function of natural ecosystems and in model application for environmental management. The two most important reasons for this pioneering role are (1) the severe eutrophication problems many lakes with excessive nutrient input faced in the 1950s and 1960s, and (2) that already simple one- or two-box phosphorus mass-balance models were able to provide essential insights into these problems.

As in other fields of environmental modeling, the lake model to be used depends on the objective of the study. Typically, models for improving the understanding and communicating knowledge must have a higher structural resolution of model components and processes than models for lake management. For management purposes, getting the important mass fluxes correct is usually more important than providing a detailed insight into the substructures at the trophic levels of the food web. However, knowledge gained from more detailed research models often stimulates the development of simpler management models. Also the method of parameter estimation can depend on the objective of the study. For research purposes parameters are often estimated using frequentist techniques to avoid bias due to subjective prejudices. When the model is used for management purposes, there is usually not enough data available to perform a frequentist parameter estimation. In this case prior knowledge is best combined with empirical data using Bayesian techniques.

☆*Change History:* March 2018. Todd M. Swannack made minor changes to the references.

This is an update of P. Reichert and J. Mieleitner, Lake Models, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2068–2080.

Processes to Be Represented in Lake Ecosystem Models

The basis of all biogeochemical and ecological lake models are mass balances of nutrients, dissolved oxygen, and organic compounds—particularly aquatic organisms—in the lake. Fig. 1 shows a graphical representation of biological processes in a lake ecosystem that build, at a certain level of simplification or refinement, the basis of most lake ecosystem transformation process models.

By primary production, nutrients are converted into phytoplankton biomass (in shallow lakes, periphyton may also considerably contribute to primary production). This process requires light and produces dissolved oxygen. Herbivorous zooplankton grazes on phytoplankton. Carnivorous zooplankton feeds on herbivorous zooplankton. Omnivorous zooplankton feeds on herbivorous zooplankton and on phytoplankton. All or some of these plankton classes serve as food for planktivorous fish which again are the food source for carnivorous fish. All these grazing and predation activities require dissolved oxygen and lead to release of particulate organic material (fecal pellets and remainings from sloppy feeding), dissolved organic matter (released from broken cells), and nutrients. Death of all organisms transforms them into particulate organic matter. Furthermore, respiration of organisms transforms biomass into nutrients. Particulate organic matter is hydrolyzed to dissolved organic substances which are mineralized into nutrients. These last two processes are of particular importance in the sediment of the lake. In the presence of dissolved oxygen, mineralization is accompanied by dissolved oxygen consumption. In deeper sediment layers, where all dissolved oxygen diffusing into the sediment from the water column is used up, mineralization requires reducing nitrate, manganese oxide, iron hydroxide, or sulfate. Finally, mineralization is also possible by methanogenesis.

Transport processes lead to partial spatial separation of these transformation processes. Fig. 2 gives an overview of the most important transport processes in a lake or reservoir. Depending on the density of the inflow and on stratification of the lake, the inflow enters the lake at a certain depth (with some entrainment of water from the layers above). As the outflow is not at the same level (at the surface for natural lakes and close to the bottom for many reservoirs), this leads to vertical advection of (part of) the water column. In addition, the water column is mixed by turbulent diffusion. During periods of stratification (usually caused by warmer and less dense water layers laying above colder and denser layers), horizontal mixing is usually much faster than vertical

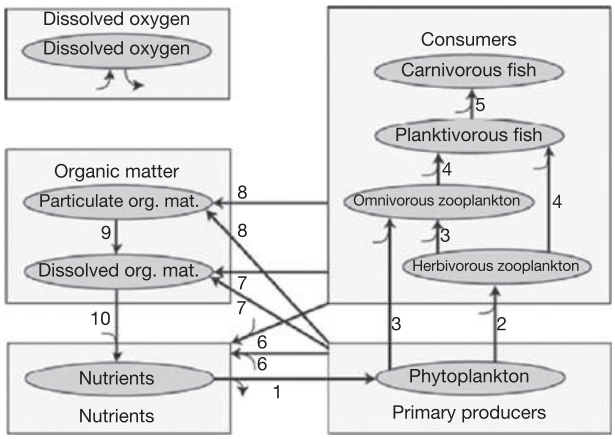

Fig. 1 Overview of important biological processes in the pelagic zone of surfacewaters. Gray ovals represent state variables (chemical compounds or organisms), and arrows represent transformation processes. The following processes are considered: 1, growth of phytoplankton (primary production); 2, growth of herbivorous zooplankton; 3, growth of omnivorous or carnivorous zooplankton; 4, growth of planktivorous fish; 5, growth of carnivorous fish; 6, respiration; 7, release of dissolved organic matter during death, sloppy feeding, and exudation; 8, death; 9, hydrolysis; 10, mineralization. Small arrows indicate oxygen consumption or production.

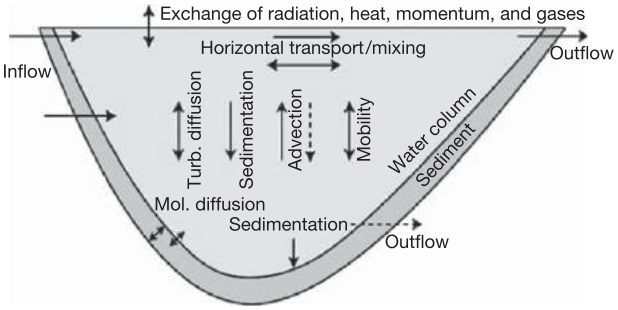

Fig. 2 Important transport and exchange processes in a lake or reservoir.

mixing. Radiation, heat, momentum, dissolved oxygen, carbon dioxide, and molecular nitrogen are exchanged over the lake surface. Due to their mobility, fish, zooplankton, and some phytoplankton species move actively through the water column. Particulate substances are deposited at the surface of the sediment due to sedimentation. Dissolved substances are transported within the sediment porewater and between porewater and lake water by molecular diffusion.

The interaction of transformation and transport processes discussed separately in the previous paragraphs (**Figs. 1** and **2**) often leads to the following typical spatial separation of processes in a lake: primary production of phytoplankton takes place in the upper layer of the lake, where sufficient light is available. This process consumes nutrients. Nutrients are delivered by the inflow and produced by respiration or mineralization either in the epilimnion or in the depth of the lake from where they diffuse to the surface layer. Zooplankton can actively move through the water column. Herbivorous zooplankton feeds on phytoplankton in the surface layer of the lake. Fish dominantly feed on plankton in the surface layer in the pelagial and in the littoral as the light allows them to catch their food. Particulate organic material produced by the organisms is usually sedimenting through the water column much quicker than mineralization takes place. For this reason a large fraction of particulate organic material reaches the sediment where mineralization processes consume dissolved oxygen, nitrate, and other compounds that can be used for the oxidation of organic substances. Due to the small diffusivities in the sediment and often also in the hypolimnion, this leads to large gradients of dissolved oxygen, nitrate, and mineralization products in the sediment and the hypolimnion of the lake. In shallow lakes, benthic organisms and Macrophytes can contribute to substance turnover in a similar way as described here for the pelagial.

A lake ecosystem model should represent the main physical, chemical, and biological processes of the most important substances in the lake and represent the biological communities building the ecosystem.

Difficulties of Lake Ecosystem Modeling

The large number and complicated nature of the processes in a lake ecosystem described in the previous section makes lake ecosystem modeling a very demanding task. However, there are more reasons that even increase the difficulty of building up a lake ecosystem model:

- A lake is a heterogeneous environment consisting of quite different, interconnected habitats (e.g., environmental conditions in the epilimnion, hypolimnion, littoral, and the sediment are significantly different).
- Within each of the trophic levels of the lake ecosystem shown in **Fig. 1**, there are a large number and a high diversity of species that are difficult to describe collectively as well as individually (e.g., there is a huge number of different phytoplankton species which all have the same essential function in **Fig. 1** but differ considerably in their properties).
- The occurrence of many individual species in a lake is highly irregular (some species occur at a high density in particular years and form only a minor contribution to the biomass in other years even under similar driving conditions).
- The properties of species are difficult to extract from lake data and field and laboratory experiments (easily measurable properties such as size and volume are not strongly related to properties relevant for growth and occurrence).
- The species are adaptable so that they can change their properties to some degree in response to the environmental conditions they encountered in the past (e.g., different size, different light dependence, or different elemental composition). This can make even measured properties unreliable when applied to a situation with different environmental condition history.
- There is a strong interaction between mixing on one side and oxygen, nutrient, and biological population dynamics on the other side. These processes are difficult to describe and hard to separate using lake data.
- The interactions between sediment and water column are very important for the lake ecosystem, especially the nutrient release from the sediment. The processes governing these interactions are difficult to quantify.
- Populations of higher organisms have an age distribution. Different age groups of the same species can play entirely different roles in the food web.

Most of these difficulties listed above occur similarly when modeling other ecosystems, particularly aquatic ecosystems. But the generic difficulties related to heterogeneity, adaptability, species richness, and interactions at various levels are even similar when modeling terrestrial ecosystems.

Different lake ecosystem models differ in the degree of simplification or refinement of the food web and transport processes, in the mathematical formulation used for quantifying process rates, and in the way they cope with the difficulties listed above. In the following section, we give an overview of typical approaches grouped according to different components of lake ecosystem models.

Components of Lake Ecosystem Models

In lake ecosystem models different strategies have been applied to deal with the problems described above. The major distinction is the degree of simplification of the physical, biogeochemical, and ecological components of the lake ecosystem and the mathematical formulation of the processes considered in the model. In this section, we give an overview of approaches for physical, biogeochemical, and ecological submodels of lake ecosystem models.

Physical Submodels

Key elements distinguishing physical submodels of lake ecosystem models are the spatial resolution of the model and the description of mixing processes.

Spatial resolution of lake ecosystem models

Already in the early 1970s, it was recognized that simple one-box mass-balance models (mainly for phosphorus contained in phosphate and phytoplankton) are extremely useful for improving the basic understanding of eutrophication processes. Such models represent the whole lake as a mixed reactor and calculate changes in average concentration(s) as a consequence of input, transformation, sedimentation, sediment release, and output. In conjunction with more complex biogeochemical and ecological submodels (see below), such models are still in use today, particularly for shallow lakes with a small degree of stratification.

Thermal stratification suppresses vertical mixing significantly during the summer, when warm, less-dense water layers lay on the top of colder and denser layers. Due to diurnal temperature variations and wind-induced mixing, a frequently mixed surface layer, the epilimnion, builds up on top of the hypolimnion, which is separated from the epilimnion by a zone with a strong temperature gradient and high stability, the metalimnion. Obviously, a simple description of such a system can be obtained with two mixed reactors representing epilimnion and hypolimnion and with an exchange process that is strong during the winter and weak during the summer.

Closing the nutrient cycle in the lake-sediment system requires an extension of the mass balances to the sediment. This can be done by adding an additional mixed reactor describing the sediment, either to a one- or two-box lake model. This makes it possible to describe mineralization of organic particles deposited in the sediment and resulting oxygen consumption and nutrient release. More boxes can be used to describe anoxic and anaerobic mineralization processes in deeper sediment layers.

A better description of mixing in the lake can be achieved by resolving the depth of the lake continuously. Such one-dimensional (1D) lake models are able to resolve the often very strong gradients in vertical concentration profiles of dissolved oxygen, nutrients, and phytoplankton.

Particularly for narrow lakes with a large longitudinal extension and a high throughflow, it may be necessary to resolve the longitudinal dimension as well. This can be the case for reservoirs. Such 2D models are then able to distinguish different vertical profiles along the longitudinal direction of the lake.

The increasing availability of 3D mechanistic mixing models makes it more and more possible to couple such models with biogeochemical and ecological lake models. This leads to a 3D description of all processes in the lake. From the biogeochemical and ecological perspective, such models make it possible to distinguish processes and substance concentrations in the pelagic zone (open water column) from those in the littoral zone (close to the land and sediment) and to resolve concentration gradients across the lake. This can be relevant for the description of increased productivity in the neighborhood of nutrient-delivering inflows.

Description of mixing processes

Options for the description of mixing processes in lakes depend on the spatial resolution of the model described in the previous subsection. Use of box models usually requires an empirical parametrization of mixing processes between the boxes. Models with resolution of the vertical dimension of the lake often also rely on empirical parametrization of mixing processes. Such empirical parametrization of mixing processes is usually calibrated with the aid of temperature profiles in the lake. Such profiles lead to quite reliable estimates of mixing intensity between epilimnion and hypolimnion. However, due to very small temperature gradients, they often do not provide sufficient information for a calibration of mixing processes in the hypolimnion of deep lakes. This leads to the requirement of including profiles of phosphate, nitrate, and/or dissolved oxygen into the calibration process. This can be problematic as there may be nonidentifiability problems between mixing intensity and transformation processes.

Physically based mixing models can be derived for 1D, 2D, and 3D lake models. They describe stratification and mixing caused by heat exchange over the lake surface and by momentum uptake due to wind forcing. Often turbulence due to seiche oscillation is also relevant for lakes. The main advantage of replacing empirical and semiempirical mixing models by such mechanistic mixing and transport models is that this decreases the need for empirical parametrization of the physical part of the ecological lake model. This improves the predictive capability of the models, at least conditionally on assumptions regarding climate forcing.

Biogeochemical Submodels

Biogeochemical submodels differ in the consideration of nutrients, in modeling of the element cycles and exchange with the sediment, and in their description of the mineralization process.

Consideration of nutrients in lake models

The most important elements that can limit phytoplankton growth are phosphorus, nitrogen, carbon, and, for diatoms, silicon. These are usually taken up in the form of phosphate, ammonium or nitrate, carbon dioxide (sometimes also bicarbonate), and silica.

Many lakes are limited by phosphorus during the summer stratification period. This leads to extremely small phosphate concentrations in the epilimnion during summer and makes the consideration of phosphate very important for lake models.

Nitrogen limitation is more difficult to describe than phosphorus limitation, because there are some phytoplankton species that are able to fix nitrogen from dissolved molecular nitrogen. Nitrification of ammonium to nitrate also affects the oxygen budget of the lake. Nitrate is not only important as a nutrient for phytoplankton, it is also important for anoxic mineralization of organic material (primarily in the sediment). This denitrifying mineralization can make the lake a significant sink for nitrate. Quantifying this denitrification capacity of the lake requires consideration of nitrate (and usually also ammonium) in the lake model.

The limiting effect of silica on phytoplankton growth depends on the geology of the watershed (determining silica input) and on the occurrence of diatoms (determining silica consumption). The consideration of silica can be important, if diatoms are distinguished from other functional groups of phytoplankton.

Sometimes also carbon is limiting primary production in lakes. Most phytoplankton species need CO_2 as carbon source. The dependence of the growth rate on the CO_2 concentration varies among species, therefore the depletion of CO_2 can lead to a change in species composition. For example, the dominance of cyanobacteria in hypereutrophic lakes is sometimes caused by CO_2 limitation because cyanobacteria have a very efficient carbon concentration mechanism (CCM). Some species can also use HCO_3^- as carbon source.

Modeling of element cycles and exchange with the sediment

Simple models (with respect to element cycles) treat sedimentation of organic particles as loss from the modeled part of the system and use sediment oxygen demand, phosphate release, and ammonium release as model parameters. With a correct choice of these model parameters, this can lead to reasonable results. However, this decoupling of processes which is very strongly coupled in reality (through mineralization in the sediment) allows an inexperienced model user to work with unreasonable model parameters that violate mass conservation.

For this reason, a more detailed level of description is to model the mass balance of nutrients in the sediment explicitly. This can be done by describing the pools of particulate organic matter, dissolved oxygen, and nutrients in the sediment and calculating sediment oxygen demand and nutrient release by a simple kinetic process.

More detailed sediment models use one or more sediment layers (with different redox conditions) to achieve a more realistic description of the sediment. Particulate organic matter enters the top sediment layer through sedimentation. The mineralization of organic matter to inorganic nutrients in the sediment can be modeled using the same process description as in the water column. The inorganic nutrients produced by mineralization are released into the porewater of the sediment and diffuse into the water column, depending on the concentration difference between the sediment porewater and the water column.

Description of the mineralization process

Among the models which model mineralization explicitly, most do not distinguish hydrolysis of particulate organic matter into dissolved organic matter from mineralization of dissolved organic matter but combine both steps into a single "mineralization" process.

Many models only describe oxic mineralization. Some add denitrifying mineralization, some add further steps with reduction of manganese oxide, iron hydroxide, or sulfate and finally methanogenesis.

Most models parametrize the mineralization process directly without explicitly describing the bacterial community performing the process. This limits the transferability of these models as different bacterial populations in different environments lead to different mineralization rates.

Ecological Submodels

Ecological submodels can be divided into trophic-level models, functional group models, dominant-species models, and adaptive property models. Combinations of some of these model types are also possible.

Trophic-level models

Trophic-level models use the trophic levels of the food web shown in Fig. 1 as state variables without further division. However, some of the trophic levels may be merged and some may be omitted. If higher trophic levels are omitted, their effect on lower levels is considered by increased death rates at the lower levels.

Phytoplankton or periphyton must be considered in each ecological lake model as it is responsible for primary production of biomass out of inorganic nutrients. Phytoplankton consists of hundreds of different species with widely varying properties such as maximum growth rate, edibility, and dependence on light, nutrients, and temperature. In trophic-level models, all these different species are modeled by a single state variable. It seems astonishing that this can work. However, the limitation of primary production by nutrients in many lakes makes production less dependent on formulation and quantification of process kinetics. In such situations, input of nutrients determines production. This may be the explanation why such simple models work astonishingly well.

If zooplankton is considered explicitly it is often modeled as a single state variable or as two state variables representing herbivorous and carnivorous or omnivorous zooplankton. Again, these classes aggregate many different species.

In most ecological lake models, fish are not explicitly modeled. The predation pressure of fish is then quantified by increasing the death rate of zooplankton. To account for changes in predation pressure, a seasonal dependence of such a death rate contribution can be considered.

Functional group models

Functional group models differ from trophic-level models by disaggregating the species within one or several trophic levels into groups with similar properties. Although these groups usually have the same function (given by the trophic level), they are called functional groups.

Criteria for the division of species into functional groups can be (1) ecological properties, such as growth rate, edibility (e.g., size), silica requirement, ability to fix nitrogen, or mobility; (2) taxonomic groups; (3) easily measurable properties, such as maximum extension, volume, etc., which are assumed to correlate with ecological properties. Often different functional groups have similar process formulations, but differ in model parameter values.

Dominant-species models

Dominant-species models make a slightly different approach to model the variability of properties of different species at a given trophic level. Instead of dividing the species at the trophic level exhaustively into functional groups, the key species are modeled individually. If these species can be cultivated in the laboratory, such models have the advantage that essential behavioral parameters such as maximum growth rate or parameters related to nutrient limitation can be measured experimentally. This can decrease the number of calibration parameters of the model significantly. On the other hand, these models have the disadvantage of introducing a large number of additional state variables and still not being able to describe the sum of all species correctly.

A slightly modified version of this type of model uses the properties of a key indicator species to represent functional groups. This leads to a model that combines advantages of the dominant-species model with those of the functional group approach. However, the advantage of using measured properties in the dominant-species approach becomes less strong when applying these to functional groups.

Adaptive property models

Biological species are adaptive. They are able to change their properties, for example, their size, edibility, chlorophyll, or phosphorus content in order to adapt to changing environmental conditions. This is only rarely accounted for in the ecosystem models discussed above (adaptation of phosphorus content is considered in some models). Recently, there have been attempts to include adaptation into aquatic ecosystem models.

One approach is called "structural dynamic models." In this approach, selected properties of species are dynamically changed according to the global criterion of maximization of "exergy." Kinetic parameter values are adapted during the simulation according to exergy maximization.

A second approach identifies "rapid evolution" as the cause for adaptation and (usually) uses an empirical parametrization of this process.

Typical Formulations of Transformation Processes

The temporal change of the concentration, C_X, of a substance or organism, X, in a vertically resolved water column is given by the following differential equation:

$$\frac{\partial C_X}{\partial t} = v_X \frac{\partial C_X}{\partial z} + \frac{\partial}{\partial z}\left(K_z \frac{\partial C_X}{\partial z}\right) + r_X \tag{1}$$

where t is time, z is the vertical coordinate in the lake, v_X is the sum of the advective velocity of the water column and the sedimentation velocity of substance or organism X, K_z is the coefficient of vertical turbulent diffusion, and r_X is the total (net) transformation rate of substance or organism X. The total transformation rate of a substance is the sum of contributions by different processes. The contribution of each process is calculated as the product of the process rate with a substance-specific stoichiometric coefficient. This means that the net transformation rate of substance X is given by

$$r_X = \sum_i v_{i,X} \rho_i \tag{2}$$

where the sum extends over all transformation processes. $v_{i,X}$ is the stoichiometric coefficient of the process i with respect to substance X and ρ_i is the process rate of the process i.

In order to discuss formulations of transformation processes used in the literature, we use a simple, didactic lake model. This lake model contains five state variables: dissolved oxygen, nutrients, phytoplankton, zooplankton, and dead particulate organic material. Compared to Fig. 1, this model aggregates the two functional groups of zooplankton and it omits fish and dissolved organic material. This leads to an aggregation of transformation processes also. We will give formulations of the following processes:

1. Growth of phytoplankton by primary production (gro, ALG)
2. Growth of zooplankton by grazing of phytoplankton (gro, ZOO)

Table 1 Structure of typical formulations of process rates

Process	*Structure of rate formulation*
Growth of phytoplankton	$\rho_{\text{gro, ALG}} = k_{\text{gro, ALG, max, To}} \cdot f_T(T) \cdot f_I(I) \cdot f_N(C_N) \cdot C_{\text{ALG}}$
Growth of zooplankton	$\rho_{\text{gro, ZOO}} = k_{\text{gro, ZOO, max, To}} \cdot f_T(T) \cdot f_{O2}(C_{O2}) \cdot f_g(C_{\text{ALG}}) \cdot C_{\text{ZOO}}$
Respiration of phytoplankton or zooplankton	$\rho_{\text{resp, }i} = k_{\text{resp, }i\text{, To}} \cdot f_T(T) \cdot f_{O2}(C_{O2}) \cdot C_i,\ i = \text{ALG, ZOO}$
Death of phytoplankton or zooplankton	$\rho_{\text{death, }i} = k_{\text{death, }i\text{, To}} \cdot f_T(T) \cdot C_i,\ i = \text{ALG, ZOO}$
Oxic mineralization	$\rho_{\text{miner}} = k_{\text{miner, To}} \cdot f_T(T) \cdot f_{O2}(C_{O2}) \cdot C_{\text{POM}}$

T, temperature; I, light intensity; C_N, nutrient concentration; C_{O2}, dissolved oxygen concentration; C_{ALG}, concentration of phytoplankton; C_{ZOO}, concentration of zooplankton; C_{POM}, concentration of dead particulate organic material; k, specific transformation rates at reference conditions.

3. Respiration of phytoplankton (resp, ALG)
4. Respiration of zooplankton (resp, ZOO)
5. Death of phytoplankton including grazing by zooplankton (death, ALG)
6. Death of zooplankton including predation by fish (death, ZOO)
7. Oxic mineralization of particulate organic material to nutrients including the hydrolysis step to dissolved organic material (miner)

We will now discuss typical formulations of the transformation rates of these processes used in the literature. Transformation rates of substances and organisms are then given by Eq. (2).

Table 1 gives an overview of the structure of typical formulations of these seven process rates. Growth, respiration, and death rates are usually proportional to the concentration of the organism affected by the process. The rate formulation then multiplies this concentration by a specific transformation rate at standard conditions and several modification factors that describe the effect of important influence factors.

Table 2 shows options for the formulation of modification factors used in Table 1 for describing the dependence of process rates on important influence factors.

If several nutrients are limiting, several nutrient limitation terms can be multiplied or the minimum of the limiting factors can be used (Liebig's law).

This short overview should give an idea of how transformation process rates can be formulated. Some models use different or more complicated process formulations or they further divide processes into subprocesses. For example, the growth process of phytoplankton can more realistically be described by a nutrient uptake process into the cell and a growth process on nutrients contained in the cell.

Examples of Ecological Lake Models and Their Application

In this section we give a brief overview of model structures, calibration strategies, and applications of five selected ecological lake models. This overview is far from being complete. Nevertheless, it provides insight into the variety of approaches used in science and management. We will briefly present an aggregated trophic-level lake model (biogeochemical—ecological lake model, BELAMO), two functional group lake models (simulation by means of analytical lake model, SALMO and computational aquatic ecosystem dynamics model, CAEDYM), a dominant-species algal community model (phytoplankton response to environmental change model, PROTECH), and an adaptive property model (structural dynamics model).

BELAMO

The BELAMO represents a relatively simple, aggregated trophic-level lake model with emphasis on biogeochemical cycles rather than ecology. A particular feature is the consideration of closure of element cycles by explicit consideration of mineralization processes in the sediment.

Model overview

BELAMO describes the concentrations of phytoplankton, zooplankton, dissolved oxygen, ammonium, nitrate, phosphate, and degradable and inert dead organic particles in the water column and in the sediment. The model considers growth, respiration, and death of phytoplankton and zooplankton, mineralization, nitrification, and phosphate uptake on sinking particles. The model is 1D and resolves the depth of the lake. The physical processes vertical mixing, advection, sedimentation, mobility of zooplankton, and molecular diffusion in the sediment and across the water sediment interface are considered. Phytoplankton can grow with a variable stoichiometry with respect to phosphorous depending on the phosphate concentration in the water column to describe the low phosphorus content of phytoplankton growing during phosphate-limited periods in summer.

Calibration strategy

BELAMO applications estimate kinetic parameters of transformation processes with the attempt of finding "universal" values across lakes of different trophic state. As all phytoplankton species are aggregated to a single state variable, it is hard to use kinetic

Table 2 Typical formulations of the functions used for describing the dependence of process rates on important influence factors

Term	*Formulations*	*Name/comment*
$f_N(C_N)$	$\frac{C_N}{K_N+C_N}$	Monod
	$\frac{{C_N}^n}{{K_N}^n+{C_N}^n}$	Hill
	$1 - e^{-k_N C_N}$	Exponential
	$\begin{cases} 1 & C_N > 2K_N \\ \frac{C_N}{2K_N} & C_N \le 2K_N \end{cases}$	Blackman
$f_I(I)$	$\frac{I}{K_I+I}$	Monod
	$\left(\frac{I}{I_{opt}}\right)\exp\left(1-\frac{I}{I_{opt}}\right)$	Steele
	$\left(\frac{I}{I_{opt}}\right)^n \exp\left(1-\left(\frac{I}{I_{opt}}\right)^n\right)$	Walker
	$\frac{I}{\sqrt{K_I^2+I^2}}$	Smith
$f_{O2}(C_{O2})$	$\frac{C_{O2}}{K_{O2}+C_{O2}}$	Monod
$f_T(T)$	$\frac{T-T_{min}}{T_{ref}-T_{min}}$	Linear
	$\Theta^{T-T_{ref}}$ with $\Theta = \exp\left(\frac{E}{RT_{ref}T}\right)$	Arrhenius
$f_g(C_{ALG})$	$\frac{C_{ALG}}{K_{ALG}+C_{ALG}}$	Monod
	$1 - \exp(-k_{ALG} \cdot C_{ALG})$	Exponential
	$\begin{cases} \frac{C_{ALG}-C_0}{K_{ALG}+(C_{ALG}-C_0)} & \text{for } C_{ALG} > C_0 \text{ with threshold} \\ 0 & \text{else} \end{cases}$	

parameters measured for selected cultured species in this model. To avoid nonidentifiability problems during the parameter estimation, sensitivity, and identifiability analysis techniques are used.

Model applications

BELAMO so far has been applied to three lakes of different trophic state. It is a research model to summarize knowledge and test hypothesis with a focus on biogeochemical cycles.

Fig. 3 shows measured and calculated profiles of phytoplankton, dissolved oxygen, phosphate, and nitrate in Greifensee.

The profiles clearly demonstrate the yearly cycle of mixing and stratification and its effect on the nutrient cycle. Phytoplankton shows a first maximum in spring, followed by a second in summer. Dissolved oxygen concentrations are nearly uniform in spring; during summer stratification, there is a strong oxygen depletion in the hypolimnion. Phosphate is not limiting phytoplankton growth in spring, but is during the summer and fall months. There is a significant increase in phosphate concentrations in the hypolimnion during the summer and fall months due to mineralization of organic particles in the sediment. Nitrate shows a severe depletion in the deep hypolimnion during the stratification period primarily due to anoxic mineralization in the sediment.

SALMO

SALMO represents a functional group lake model. The emphasis is on a very detailed description of the plankton growth dynamics. Recently SALMO was extended to SALMO-HR (high resolution). In this version the ecological model is coupled to a hydrothermodynamic model of the water column.

Model overview

SALMO describes orthophosphate, dissolved inorganic nitrogen, dissolved oxygen, organic particles, three functional groups of phytoplankton, and zooplankton concentrations in a lake. The processes growth and mortality of phytoplankton and zooplankton and mineralization are considered. Sedimentation of phytoplankton and migration of zooplankton is also modeled.

SALMO was designed to mechanistically describe physical, chemical, and biological processes according to a maximum of generality. The model uses only a small number of state variables but more complex process formulations than other models in order to achieve this goal. Each functional group of phytoplankton is characterized by an indicator species, the properties of which

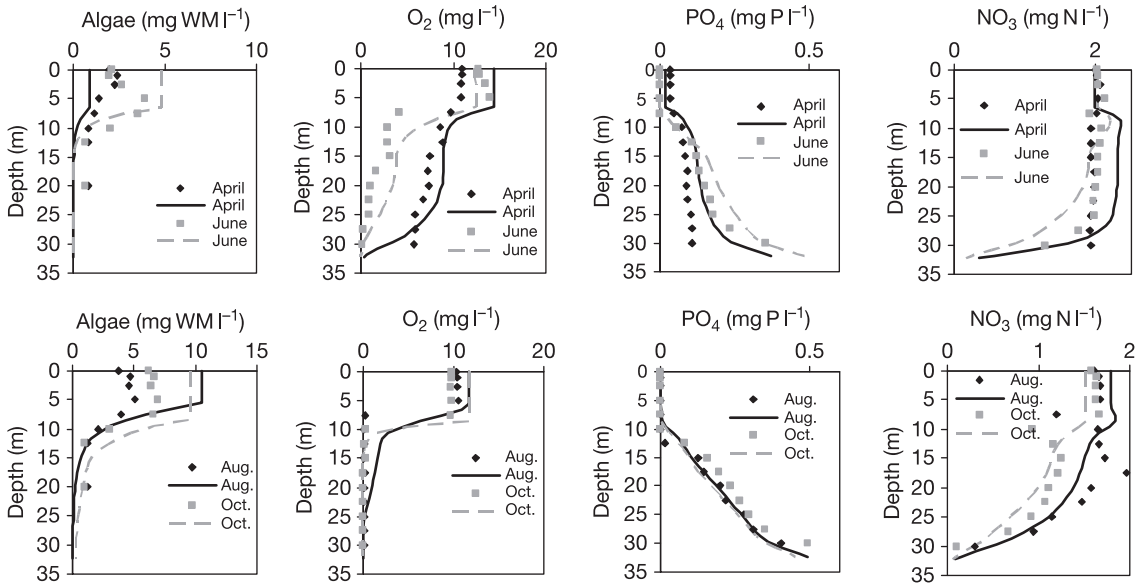

Fig. 3 Lake data (markers) compared with simulation results (lines) of the model BELAMO. Profiles of phytoplankton, dissolved oxygen, phosphate, and nitrate in Greifensee are shown for the year 1989. From Mieleitner, J. and Reichert, P. (2006). Analysis of the transferability of a biogeochemical lake model to lakes of different trophic state. *Ecological Modelling* **194**, 49–61.

were measured or compiled from the literature. Fish are considered implicitly by their predation rate on zooplankton. The nutrient release from the sediment is modeled as an empirical function of oxygen depletion and denitrification.

SALMO describes the water body as two mixed reactors representing the epilimnion and the hypolimnion. The depth of the epilimnion has to be specified as a boundary condition. SALMO-HR uses a very detailed hydrothermodynamic model of the water column.

Calibration strategy

In contrast to most other ecological lake models, the parameters of SALMO are not fitted. Measured values are used for all parameters. The parameter values for phytoplankton growth are determined in the laboratory for key species of each functional group.

This strategy not to calibrate the model has the advantage that the parameters are not adapted to a specific lake at a specific time and the parameters are universal for that reason. This improves the prediction quality and the generality of the model.

Model applications

SALMO is used as a tool to improve the understanding of the ecosystem and to support management decisions. It has been successfully applied to more than 20 lakes and reservoirs of different trophic states and has been used to calculate scenarios for different discharge regimes, climate change scenarios, changing nutrient input, and biomanipulations.

Fig. 4 shows an example of an application of SALMO to the Bautzen Reservoir, Germany. The agreement between calculated and measured concentrations achieved without modifying model parameters is remarkably high. This example shows the interactions between phytoplankton and zooplankton and the depletion of phosphate during the summer.

CAEDYM

The CAEDYM is an ecological model that can be linked to different hydrodynamic models. In our list of example models, CAEDYM represents a functional group lake model of very high degree of resolution of ecosystem variables and processes. This is a chance for a detailed representation of many processes and mass fluxes, but also a challenge with respect to the number of model parameters and to calibration.

Model overview

The ecosystem model implemented in CAEDYM is based on a detailed description of the ecosystem. The user can choose between different ecological configuration options and use a different model for each specific application. CAEDYM can be used for freshwater, estuaries, or coastal waters. The model gives the user a large flexibility in the choice of state variables, processes, and process formulations.

The state variables that can be used include concentrations of dissolved oxygen, ammonium, nitrate, phosphate, silica, dissolved inorganic carbon, quickly and slowly degradable dissolved and particulate organic matter, up to two groups of inorganic suspended

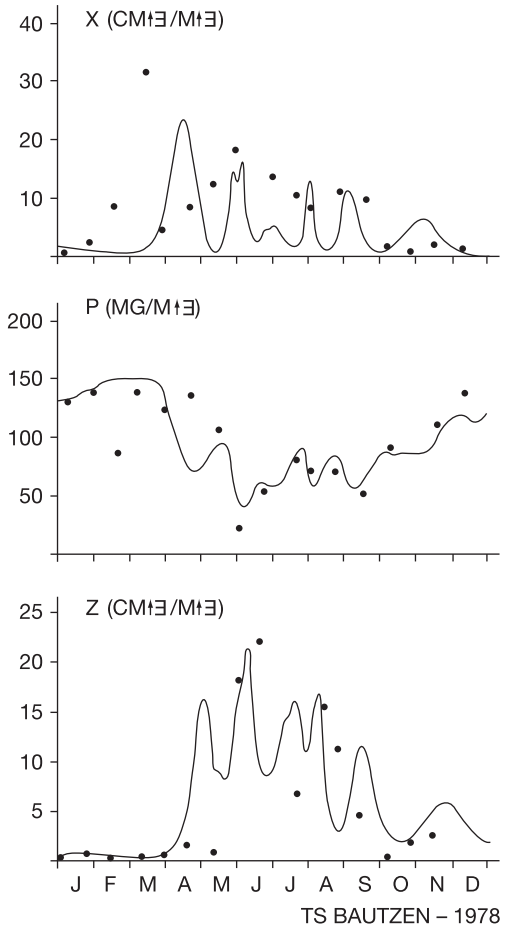

Fig. 4 Application of SALMO to the Bautzen Reservoir. Simulated and measured concentration time series of total phytoplankton biomass (top), dissolved phosphate (middle), and zooplankton (bottom) for the mixed layer of the hypereutrophic Bautzen Reservoir. From Benndorf, J. and Recknagel, F. (1982). Problems of application of the ecological model SALMO to lakes and reservoirs having various trophic states. *Ecological Modelling* **17**, 129–145.

solids, bacteria, up to seven groups of phytoplankton, up to five groups of zooplankton, up to five groups of fish, and pathogens in the water column, up to four groups of benthic macroalgae, seagrass, up to three groups of benthic invertebrates, and up to seven groups of benthic algae and others. The nonliving components in the water column are also modeled in the sediment. Process descriptions for primary production, secondary production, nutrient and metal cycling, and oxygen dynamics and exchange with the sediment are included in the model. CAEDYM can be coupled to 0D, 1D, 2D, and 3D lake hydrodynamics programs. It can be coupled to DYRESM (a 1D hydrodynamic model for lakes and reservoirs) or ELCOM (a 3D hydrodynamic model).

Calibration strategy

CAEDYM studies follow the reductionist approach with a detailed, general lake ecosystem model. Model parameters are fitted, but the attempt is made to find "universal" values that do not depend on the particular application. In typical applications, most parameters are held constant, some are fitted jointly for several systems, and some may need site-specific calibration.

Model applications

CAEDYM has been applied to many lakes and reservoirs. It is used by many research groups and can be downloaded as freeware.

CAEDYM has been used to evaluate different management strategies, to quantify nutrient cycles, and other processes.

Fig. 5 shows an application of the model to the Prospect Reservoir in Sydney, Australia. The simulations qualitatively and quantitatively reproduce the measurements with some problems in the concentrations of phytoplankton.

PROTECH

The PROTECH describes the phytoplankton growth in lakes at the species level. The emphasis of this model is on describing the dynamics of phytoplankton composition in a wide range of different ecosystems.

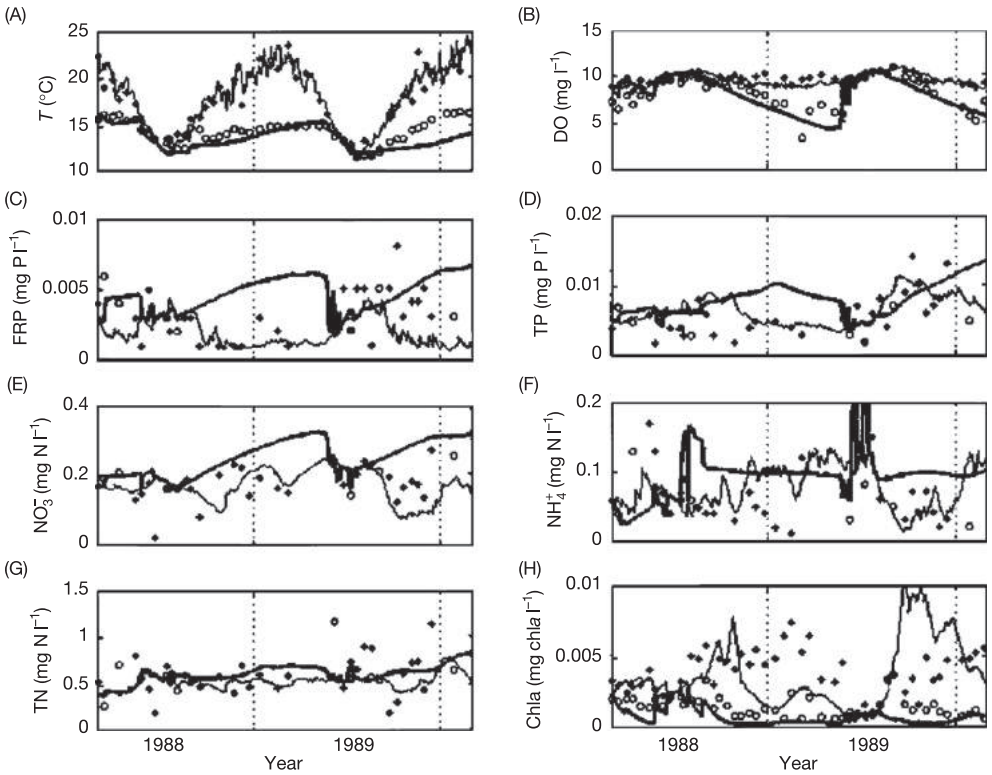

Fig. 5 Simulation results of the model CAEDYM. Comparison of measured time series with 1D simulations of the Prospect Reservoir at 2 m (black symbols, thin line) and 17 m depth (white symbols, thick line). The panels show temperature (a), dissolved oxygen (b), filterable reactive phosphorus (c), total phosphorus (d), nitrate (e), ammonium (f), total nitrogen (g), and chlorophyll *a* (h). From Romero, J. R., Antenucci, J. P., and Imberger, J. (2004). One- and three-dimensional biogeochemical simulations of two differing reservoirs. *Ecological Modelling* **174**, 143–160.

Model overview

PROTECH is designed to make simulations of the dynamic changes in the populations of different species of phytoplankton within a reservoir or lake environment which may be subject to thermal stratification, periodic destratification, and hydraulic exchange.

Chlorophyll *a*, phosphorous, nitrogen, and silica are modeled. The phytoplankton model is very detailed; up to eight species can be selected from a library of 18 phytoplankton species. The effect of zooplankton is described by the death rate of phytoplankton. The maximum growth rate of the different phytoplankton species is calculated using correlations with surface area and volume of the species. Adjustments for temperature dependence, light limitation, and nutrient limitation are made.

The physical model is 1D. It divides the water body into mixed layers.

Calibration strategy

The parameters for the growth of the phytoplankton species are not fitted in PROTECH. However, the choice of considered species is site specific.

Model applications

PROTECH has been applied to different lakes across the world. It has been used to explore ecological theory, to assess the reactions of phytoplankton to changes in temperature and nutrient concentrations, and to support management decisions. It was also coupled to a climate model and to predict the changes in phytoplankton communities due to climate change. Fig. 6 shows a comparison of measured functional groups of phytoplankton with PROTECH simulations. The changes of chlorophyll *a* concentrations of two functional groups are shown. In the spring there is a bloom of *R* species, followed by a period with low phytoplankton concentrations and a bloom of CS species during the summer. The correspondence of the model results with the data is remarkable. In general, the correspondence is better at the functional group level than at the species level.

Structural Dynamic Model

Structural dynamic modeling is an approach that represents an adaptive property model in our list of example models. See more details under Structural Dynamic Models.

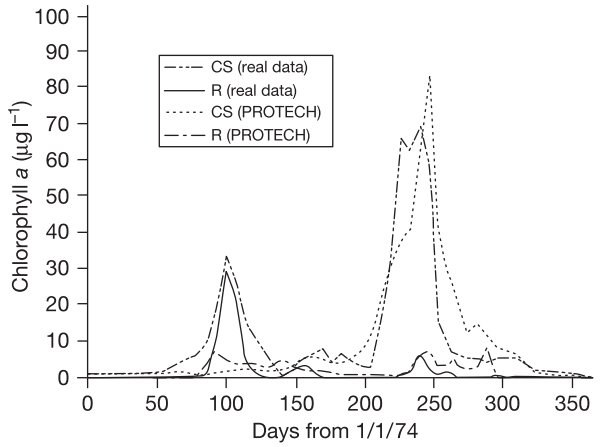

Fig. 6 Time series of data and PROTECH model results for two functional groups of phytoplankton. Phytoplankton is divided into *R*-strategists (ruderals) and a CS-group (intermediate group of competitive *C*-strategists, stress-tolerant *S*-strategists). From Elliott, J. A., Irish, A. E., Reynolds, C. S., and Tett, P. (2000). Modelling freshwater phytoplankton communities: An exercise in validation. *Ecological Modelling* **128**(1), 19–26.

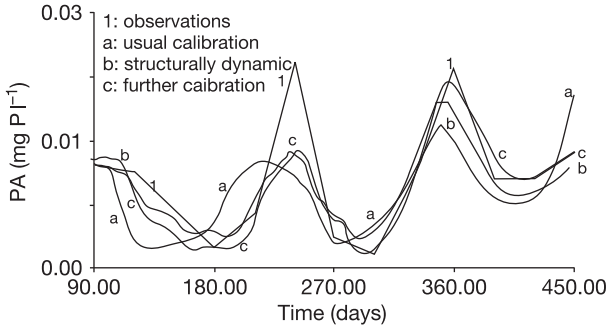

Fig. 7 Time series of phytoplankton. Comparison of data with simulations from Zhang, J., Jorgensen, S. E., Tan, C. O., and Beklioglu, M. (2003). A structurally dynamic modelling—Lake Mogan, Turkey as a case study. *Ecological Modelling* **164**(2), 103–120.

Model overview

Structural dynamics modeling is one of the approaches to consider adaptive processes in ecosystem models. The approach is based on the hypothesis that an ecosystem tends to move away from thermodynamic equilibrium. This is quantified by exergy, defined as the amount of work that a system can perform when it is brought into thermodynamic equilibrium with its environment.

Modeling approach

During the calibration period, some model parameters are adapted dynamically to maximize exergy while reducing the residuals. This leads to time-dependent parameters.

Example application

Fig. 7 shows a comparison of a conventional modeling approach, a structurally dynamic modeling approach, and a further improved simulation with data. It is evident, that the structurally dynamic model fits the data much better than the conventional calibration.

Mediated Modeling and Participatory Modeling

Damon M Hall, University of Missouri, Columbia, MO, United States
Eli D Lazarus, University of Southampton, Southampton, United Kingdom
Jessica L Thompson, Northern Michigan University, Marquette, MI, United States

Introduction: Rise of Participatory Modeling

Understanding the dynamics and interactions of social and ecological systems is critical for managing shared resources and human behaviors towards sustainability. Constructing conceptual representations of systems with complex interactions, multiple feedback loops, and nonlinear dynamics in ways that are useful for decision making is difficult. Any abstracted representation of a system must be accurate to technical experts, accessible to stakeholders, and politically acceptable to decision makers if it is to be used to guide management actions. As policy tools intended to change behavior—the way a given natural resource is used, in this case—system representations must be relevant to those living and working within the system, credible to decision authorities, and legitimate to those within and outside of the decision making process (Clark *et al.*, 2016).

When uncertainty is present, significant changes in shared resource use proposed, or when livelihoods are affected by decision outcomes, a democratic process for representing these systems is best to inform decisions. People intuitively construct a practical understanding of how a particular system they live in works, and how to live within it. These first-hand working "mental models" of the social and ecological systems people live in are made often without explicit analysis or even words (Meadows, 2008; Westervelt and Cohen, 2012). Individuals' mental models and shared "cultural models" are influenced by practices of everyday life forming ideas about how systems work (Paolisso, 2002; Özesmi and Özesmi, 2004; Glynn *et al.*, 2017). Tacit lay conceptualizations of ecological functioning are passed down through social learning, business practices, everyday language, and woven into cultural fabrics of everyday living like farming, ranching, irrigating, fishing, hunting, commuting, and others. Cultural models are often expressed piecemeal in ordinary conversation; circulated in story, shared memories, social norms, and common social meanings (Jones *et al.*, 2011). These mental schemas condition how individuals and societies interact with their environment (Butzer and Endfield, 2012). Integrating lay mental and cultural models with scientific and technical models of how ecological systems work for more complete system understanding for deliberation requires a structured process for developing shared models of systems. This process that depends upon communication.

The process of stakeholder and expert groups constructing integrated and collective representations of coupled social-ecological systems is generally called "participatory modeling." Participatory modeling encompasses several stakeholder-based modeling approaches including mediated modeling (van den Belt, 2004), group modeling (Andersen and Richardson, 1997), group model building, collaborative modeling, comodeling (Levrel *et al.*, 2009), companion modeling (Bousquet *et al.*, 2005; Etienne *et al.*, 2011), participatory simulation, and shared vision planning (Voinov and Bousquet, 2010). Here, we use participatory modeling to describe commonalities among approaches.

Participatory modeling is a practice of coordinated communication of actors' working understandings of how a particular system of interest functions and the organization of these communicated conceptualizations into a shared representation or "model." The process combines collaborative learning, public participation, and system dynamics modeling. The model (a product of the process) may take many forms and is at the discretion of the group driven by the purpose, the system, and the participants (Gray *et al.*, 2018). Ultimately, the model—which may be a conceptual model (image, diagram, statement), computer-based model where functional and/or spatial relationships are made explicit, or a series of negotiated scenarios shared in narrative form—serves as a collaborative tool for communicating diverse understandings about the system of interest for some purpose (social learning, collaboration, decision making) (Röckmann *et al.*, 2012; Henly-Shepard *et al.*, 2015; Seidl, 2015). Ultimately, the modeling process yields a shared understanding of the system enabling groups to work together (**Fig. 1**).

The rise of participatory modeling accompanies three trends within environmental policy and academia. First, the decentralization of environmental decision making and policy that acknowledged the shared nature of environmental quality warrants participation of many stakeholders halting decision making by technical experts alone (technocratic rule) (Fischer, 2000). Environmental decision making is moved from the capital buildings where experts reside into communities where people live. Decentralization recognizes both the right of citizens to participate in environmental decisions that affect them as well as the importance of on-the-ground expertise—local knowledge—which citizens possess that can improve policy via contextualization when incorporated into planning (Berkes *et al.*, 2000; Hall *et al.*, 2012). In the United States, this is exemplified by the National Environmental Policy Act (1969), which mandates government agencies to consult affected citizens before carrying out any actions using federal funds that impact shared natural resources.

The second trend is the intellectual and academic development of systems theory elevated by the advancement of computer technology that enables computer programmers to model complex ecological and social systems with multiple variables, feedback loops, nonlinearities, and emergent properties (Forrester, 1971; Meadows *et al.*, 2004; Liu *et al.*, 2007). This precipitated the

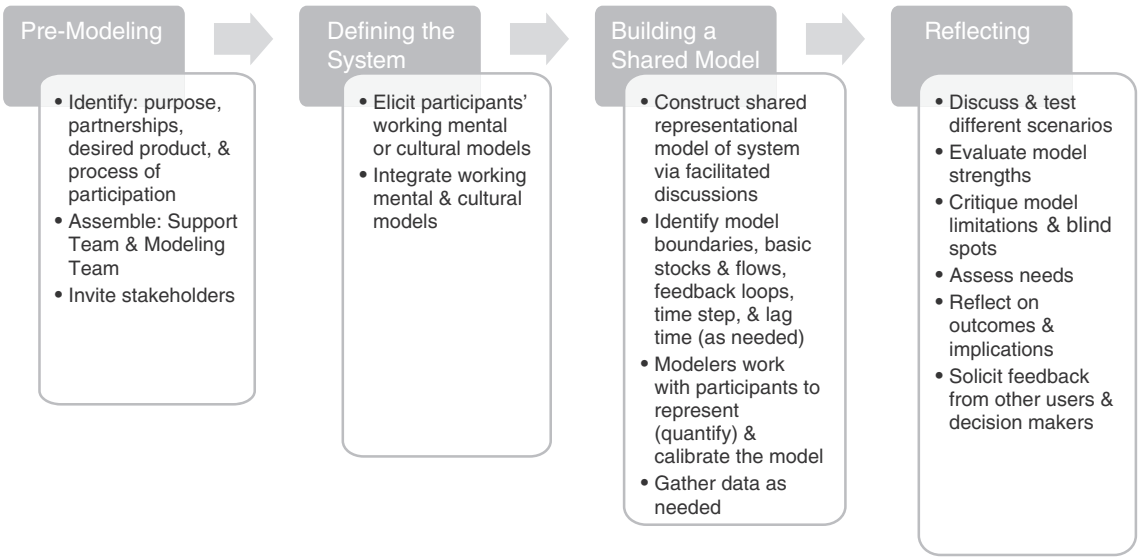

Fig. 1 General modeling process.

development of modeling software (Stella, Fuzzy Cognitive Mapper, GoldSim, POWERSIM, iThink, Simile, Vensim DSS, AnyLogic, others) that facilitated groups' ability to build and animate computer-based systems models collaboratively.

The third trend is the emergence of interdisciplinary research groups like the Resilience Alliance and research fields like sustainability science (Kates *et al.*, 2001; Miller, 2013) explicitly focused on understanding complex systems with the aim of using university research to address pressing sustainability challenges. "Systems thinking" constitutes the central organizing principle of these developing fields (Ostrom, 2009; Wiek *et al.*, 2011). To advance problem solving, requires the integration of social and biophysical sciences (interdisciplinary) and the active participation of public and private sector expertise—stakeholder participation—beyond the university (transdisciplinary) (Gibbons, 1999; Talwar *et al.*, 2011; Mattson *et al.*, 2016). The objective of collaborative problem solving has expedited the maturation of participatory modeling techniques.

Uses of Participatory Modeling

Participatory modeling is used to aid decision making and eventually shape behaviors via informal or formal policy. It is a tool for understanding, conceptualizing, and communicating complex systems to evaluate and improve policy (Schmolke *et al.*, 2010; Voinov *et al.*, 2016). It is increasingly used in environmental management frameworks as it aligns with goals of Ecosystem-based Management, Adaptive Resource Management, and Integrated Water Resources Management (Metcalf *et al.*, 2010; Peterson *et al.*, 2004; Hare, 2011). For example, the European Water Framework Directive calls for integrated water resources management decisions made at the watershed scale and developed with stakeholder participation (Hering *et al.*, 2010)—a good fit for participatory modeling (Carmona *et al.*, 2013; Molina *et al.*, 2011). Participatory modeling has also been use in health care (Vennix, 1999), management (Rouwette and Vennix, 2006; Senge, 2006), and urban water systems (Mirchi *et al.*, 2012).

Models and Participatory Modeling

Models of human–environment dynamics are tools for communicating about complexity (Forrester, 1994). Across all forms, they constitute a way of organizing knowledge (Wierzbicki, 2007). The process of creating a model forces model builders to articulate clearly their held assumptions (Krebs, 2000; Voinov *et al.*, 2014). Effective models describe relationships among system components with a degree of precision not afforded by language alone (Heemskerk *et al.*, 2003; van der Leeuw, 2004).

Models tend to fall into one of two categories (Murray, 2007). Models may be *descriptive*, designed to explain system components and dynamics qualitatively or quantitatively. Models may present a big-picture, simplified, or abstracted perspective of a system for decision groups to improve evaluating problems, assessing management, or testing hypotheses (Grant and Swannack, 2008; Gray *et al.*, 2018). Models may also be used as *predictive* tools, for simulating biophysical systems to forecast trends, evaluate social-ecological interactions under varying management scenarios, to allow comparisons of different technologies on environmental systems, and to anticipate system changes under biophysical or social changes.

It is critical to remember that, regardless of a model's type, a model is a tool—a means to an end—and therefore the purpose of a model should always be made clear throughout a participatory modeling process. Such clarification is especially important in participatory modeling, so that all participants in the problem-solving process work with a shared understanding of the model's

purpose, anticipated uses, and analytical limitations. Clear framing of a model's purpose can thus help address related expectations regarding how the model ultimately informs decision making (Hall *et al.*, 2014).

General Process of Participatory Modeling

The process of modeling is determined by the specifics of the purpose, process of participation, partnerships, and the product (see Gray *et al.*, 2018). Nevertheless, collaborative model building typically involves a series of meetings or workshops designed to elicit and integrate working mental or cultural models, then construct and reflect upon the newly assembled shared representational model. This process constitutes social learning (Pahl-Wostl and Hare, 2004; Hare, 2011) akin to collaborative learning, which combines soft systems methodology and alternative dispute resolution via a series of activities that encourage systems thinking, joint learning, and open communication (Daniels and Walker, 2001).

Stakeholders and experts participate in participatory modeling for various reasons. Stakeholders may simply care about a particular environmental system, depend upon its functioning, want an opportunity to influence policy, or want to ensure that the system is not falsely modeled (Voinov and Gaddis, 2008; Gray *et al.*, 2018). Advice abounds about best practices for involving stakeholders in environmental planning that are transferable to participatory modeling (Forester, 1999; Wondolleck and Yaffee, 2000; Carr, 2015; Hall *et al.*, 2016). However they are included, stakeholders should be involved early and throughout the process (Voinov and Gaddis, 2008; van den Belt and Blake, 2015) because model end-users' "confidence in the model, as well as the overall quality of the model, almost always is higher as the result of early and continued dialogue with potential users" (Grant and Swannack, 2008: 92).

Engaging participants in collaborative model building is administered by a support team. A typical support team consists of: a facilitator who is an impartial party that manages the meetings, guides discussions, summarizes, and brings closure to the meetings; a mediator, an impartial third party who remains involved after the meetings and meets with small groups or individuals between meetings; a modeler (or modeling team) who creates an abstract representation of reality; a recorder who documents the meetings; and a gatekeeper who provides information, advice for the process (Thompson *et al.*, 2010).

Participatory modeling workshops proceed iteratively through a series of phases. The first phase includes problem definition, envisioning, risk assessment, and determining scale issues (van den Belt, 2004). The process includes gathering and eliciting participants' mental and cultural models (Andersen and Richardson, 1997; Luna-Reyes *et al.*, 2006). Elicitation can be direct elicitation of models, such as asking people to diagram their understanding of a system, arrange predetermined variables, or spatially map model components. Or indirect elicitation can be used, where researchers extract system representations from interview transcripts (see Jones *et al.*, 2011 for a review of techniques). During the second phase, participants develop a shared conceptual model of the system, which includes basic stocks and flows, boundaries of the model, feedback loops, and lag time. Data analysis and synthesis occur via facilitated discussions. System scientists or modelers work with the participants to quantify and calibrate the model, gathering data as needed. Finally, participants test their model by trying out different scenarios, and evaluating outcomes (van den Belt, 2004). Some key elements for a workshop series might include integration of ecology, economics, social, and cultural aspects of marsh restoration (see Costanza and Daly, 1992); which requires effective stakeholder participation at the appropriate scale and a linked understanding of past, present, and future relationships (see Peterson *et al.*, 2004; Senge, 2006).

Model selection

Different disciplines and professions construct different kinds of models. Disciplinary training exposes adherents to a selection of models as platforms and software move in and out of popularity. Modelers within the support team will have differing familiarities with different modeling software or limits to software licenses. Despite which modeling platform is selected, the model type, a justification for its selection relative to other modeling approaches, and the objectives for its application to the problem at hand, should be explained clearly, taking into consideration the audience's preexisting experience with modeling. Communicating the implicit assumptions their models use is essential for managing participants' and end-users' expectations (Harte, 2002; Jakeman *et al.*, 2006; Schmolke *et al.*, 2010). The following questions are typically discussed: What is a given model for? What output does it produce and from what input? What is known and unknown? How should its results be interpreted? What insights for decision making, policy, or science can the model yield?

Benefits of Participatory Modeling

In their classic work on conflict resolution, Fischer *et al.* (2011) encapsulated their conflict management process as "one text procedure." Similarly, the participatory modeling process focuses stakeholders with multiple types of expertise on creating "one text"—in this case, a model—to serve as a decision support tool. The modeling practice of focusing a group of experts, citizens, and managers on the activity of building a single text, has a variety of benefits.

Group modeling improves understanding of complex systems. Many persons have expertise used to make decisions across economic, educational, science, cultural, nonprofit, and legal sectors. The activity of model building forces explicit discussions of community values and goals among diverse perspectives into a planning or policy tool. The group activity focused on building a

one-text model forces dialogue to make seemingly incommensurate knowledge commensurate. Groups learn about the system through diverse perspectives; the process elucidates data gaps and information needs (Ritzema *et al.*, 2010). This shared understanding of a complex system increases a group's capacity to collaborate. The resulting model provides ways for groups to explore "what if" scenarios of various decisions and policies.

Participatory modeling can improve environmental policy decisions from stakeholders with local expertise and first-hand experience (Röckmann *et al.*, 2012). Local participants are familiar with local dynamics within regulatory frameworks, organizational cultures, and institutional settings. They remember past efforts to solve problems (Hall *et al.*, 2016). They are capable of developing innovative solutions because of their familiarity with what is politically feasible (Voinov and Gaddis, 2008).

Environmental management agents report having limited knowledge about the publics they serve (Senecah, 2004). Model building can serve as a boundary spanning activity between managers, scientists, and citizens improving relationships within the community via regular engagement and deliberation. Even within systems riddled by conflict, group modeling functions as a "focusing device" which keeps diverse stakeholders focused on the issues and not positions (Fischer *et al.*, 2011). Such collaborative, relationship building among citizens, decision makers, and scientists is valuable in bridging the science-society-policy gaps and mitigating antiintellectualism (Hofstadter, 1963) and distrust of science (Mooney and Kirshenbaum, 2010).

The development of participatory modeling reciprocally benefits the environmental policy and academic trends surrounding its emergence. Fifty years after the National Environmental Policy Act forced US agencies to incorporate the public into environmental decisions that affect them, the intended transition from technocratic management towards citizen-advised forms of resource management is still evolving. Participatory modeling is a tool among many for attaining public participation goals and reflecting upon practices of participation (Seidl, 2015). Further, the practice of participatory modeling advances nascent areas of interdisciplinary research in complex systems thinking and sustainability problem solving through the active development of transdisciplinary collaborative practices.

Risks, Challenges, and Considerations

The assumption within decentralization of environmental policy is that the greater involvement of publics in model construction improves model salience with decision audiences. However, models are political. All models have a backdrop of political gains and losses (Allen *et al.*, 2005; Barnaud *et al.*, 2013). Because any accepted system representation effectively denies alternative representations (Burke, 1966), model conceptions can establish—and decommission—entire paradigms of resource management practices, enacting lasting changes in economic, social, cultural, and ecological functioning (Hall *et al.*, 2014). Such models become perceived in terms of how they affect budget priorities, project approval, and policies (Jacobson and Berkley, 2011; Latour, 2004; Radinsky *et al.*, 2017). Democratic processes of decision making in environmental management arenas do not always come to "successful" ends (Layzer, 2008). The public debate surrounding anthropogenic climate change exemplifies how model-generated predictions can have divisive and significant political, social, and economic impacts (Nisbet, 2009; Fischhoff, 2011). Participatory modeling support teams must remain aware of the impacts of models as selected representations (selections) of reality. Models that do not match—or at least somehow acknowledge—a community's shared values, histories, biases, beliefs, and desired futures are expensive in terms of time and money—litigation, enforcement, education, and other incalculable costs of mistrust. Approaches to modeling that involve and incorporate these innate human aspects of understanding our social and physical contexts may yield more robust decision making instruments—and more sustainable management of natural resources (Glynn *et al.*, 2017).

A model is an abstracted simplification of a system (Allen *et al.*, 2005; Murray, 2007; Grant and Swannack, 2008). While this helps render a complex system more tractable for problem formulation, hypothesis testing, or management, it also forces choices about what can and cannot be modeled. Not all elements can fit within a model. The choices of which variables to include are shaped by epistemic choices as well as technological resources (computational resources, modeler capacities, chosen software). Any variables included in the model must be commensurate with other driving variables and their accompanying dynamics. Finding commensurate variables in social-ecological systems is a difficult enough task for the lone academic. Each component (resource, organism, dynamic relationship) contains implicitly held assumptions and meanings that differ among members of a group. Some social variables lack equivocal units in ecological systems—like trust, power, or influence—and do not conveniently fit into the ecological models (see Hall *et al.*, 2015). These epistemic and technical challenges may appear to participants as political gamesmanship. Furthermore, exploratory models of potential future scenarios—typical of participatory modeling exercises—depend on chains of conditional possibilities; even when they are well informed, such models tend to defy standard quantification of "uncertainty" (for a helpful discussion in ecology, see Higgins *et al.*, 2003). This emphasizes the importance of working with interdisciplinary teams where diversity enables solutions to challenges of incommensurability as well as the importance of communicating the limits of modeling software and the role of models in the ultimate decision making (Gray *et al.*, 2018).

Similarly, not all variables can be conceptually reduced to fit the agreed-upon modeling format. (Again, not all elements can fit within a model.) Modeling requires participants to fit their complex, lived knowledge into scientific discursive forms. Using computer models as tools for insight and prediction always raises questions regarding which scale is the "best" for representing the real system most comprehensively. Even the most reductionist models cannot simulate reality in all its detail, and may trade flexibility for complication. Oppositely, abstracted, extremely simplified models tend to be poorly suited to making credible predictive forecasts for specific settings and contexts, and therefore lack utility for decision makers. These trade-offs require

reflection. Further, a reductionist approach to a resource-management issue, for example, requires a focus on particular resources, and therefore also tends to look for, or contributes to the creation of, specialized institutions for the governance of that particular resource (Buytaert *et al.*, 2014). For some decision makers and stakeholders, the necessity of reduction constitutes an over-simplification at best, or a predetermined decision that undermines the democratic promise of the process. Communicating this part of the process and being aware of how all audiences may perceive these "normal practices" of modeling is paramount.

The process of participatory modeling contains embedded assumptions and values that impact policy outcomes (Paolisso and Trombley, 2017). Social systems are difficult to model. Often the social system is not effectively placed within ecological models (Brulle and Dunlap, 2015). For example, for most trained ecologists humans are external or secondary to more interesting organism-environment interactions. When humans are represented, they often appear as impacts. This may be off-putting for a stakeholder within the system whose livelihood is tied to such impacts. Modelers and support teams should consider the effects on participants of their implicit assumptions resembling characterizations of humans as "bad." This has relational consequences for participatory modeling teams of experts, managers, and citizens. Participants more often volunteering their time and attention. Often the most dedicated stakeholders in attendance, have the most at stake, moreso than the nonlocal scientists, support team, and modelers.

The ownership of the modeling tools may influence participatory modeling outcomes. For example, the technology used to build and run models, the ownership of the computer code, and related institutional structures and arrangements likely have an impact on the process and outputs of participatory modeling (Paolisso and Trombley, 2017).

A wide range of activities and expectations are suggested when members of the public are formally invited to engage in "participatory" decision making, no matter the form (Seidl, 2015). Public participation takes a variety of forms (Arnstein, 1969; Greenwood *et al.*, 1993; Stern and Dietz, 2008) with different levels of participation expected from citizens by environmental agencies or modeling conveners. Most stakeholders participate to have influence in the decision making, yet, in a majority of cases, agencies cannot legally share decision authority (Senecah, 2004). This emphasizes the importance of communicating the terms of participation, clarifying the expectations from participants, planners, the model, and the process (Harrison, 2011; Gray *et al.*, 2018; Radinsky *et al.*, 2017). Clarity will improve stakeholder contributions to the model and planning. This includes clarifying when the desired product is the structured social learning that occurs throughout the process of group modeling rather than any model (Voinov and Bousquet, 2010).

Conclusion

For policy to be meaningful, it must speak to how people experience their world. Participatory modeling offers a way to better represent complex social-ecological systems for decision making: representations that integrate technical discourses with citizens' lived knowledge (Fischer, 2000; Collins and Evans, 2008). Utility in modeling does not derive from accuracy alone. Where human systems and environmental systems are integrated in the same model, and that model is intended to facilitate a common understanding among a broad spectrum of users, the clarity with which a model speaks to both decision makers and the people whose behaviors are the targets of any policy changes becomes a vital quality. Thus, for systems of shared social and ecological resources, a model's eloquence is paramount. Model representations, no matter how accurate, cannot not determine what society should do. That challenge requires engaging citizen expertise.

Metapopulation Models☆

Ilkka Hanski† **and Otso Ovaskainen,** University of Helsinki, Helsinki, Finland

Glossary

Detectability The probability of observing an individual or local population that is actually present during the time of a survey.

Extinction debt The number of species that will eventually go extinct due to habitat loss and fragmentation but have not yet had time to do so.

Extinction threshold The critical amount of habitat loss and fragmentation exceeding which leads to metapopulation extinction.

Metapopulation A collection of local populations connected by dispersal.

Patch occupancy model A metapopulation model that is based on classifying patches as empty or occupied and thus ignoring their population sizes.

Introduction

Most landscapes are complex mosaics of many types of habitat. From the viewpoint of a particular species living in such a landscape, only some habitat types, called suitable habitat, provide the resources that are necessary for population growth. The remaining landscape, often called the (landscape) matrix, can only be traversed by migrating individuals. Often the suitable habitat occurs in discrete patches (also called habitat fragments). Individual habitat patches may be occupied by a local population of the focal species, but many patches are likely to be unoccupied at a particular point in time, because a local population went extinct in the past or the patch appeared in the landscape only recently due to, for example, successional changes. The currently unoccupied patches may become colonized in the future. The set of local populations inhabiting the network of habitat patches is called a metapopulation. The local populations are typically connected to other populations by some degree of migration, but how strong this coupling is depends on the structure of the landscape (how far apart the habitat patches are located) as well as on the powers of migration of the species.

Mathematical metapopulation models are used to describe, analyze, and predict the dynamics of metapopulations in fragmented landscapes. This article presents an overview of different kinds of metapopulation models, with an emphasis on spatially realistic models, which can be applied to real metapopulations for the purposes of research, management, and conservation.

Classification of Metapopulation Models

There is no sharp distinction between models for single populations and metapopulations. Classic single-population models assume that individuals interact equally with all other individuals (panmictic population structure). In the other extreme are classic metapopulation models, such as the Levins model described in this article, which assume a set of dynamically independent local populations. But there are also intermediate models. A model involving the spatial coordinates of individuals and limited spatial range of interactions and movements can be viewed as a detailed population model, or it can be considered as a metapopulation model at the landscape level. Such individual-based models for continuous space may exhibit spatial variation in habitat quality and thereby offer a very general framework for population modeling, but their potential to address relevant questions about metapopulation ecology remains largely unstudied and they are not covered in this article. Other models include a description of the genetic structure of the metapopulation, and such models may be used to analyze evolutionary processes in metapopulations. These models too are beyond the scope of this article, which is restricted to ecological metapopulation models.

Stochastic Versus Deterministic Models

Metapopulation dynamics are influenced by four kinds of stochasticity (Table 1): demographic and environmental stochasticity affecting separately each local population, and extinction–colonization and regional stochasticity affecting the entire

Table 1 Four types of stochasticity affecting metapopulation dynamics

Type of stochasticity	*Entity affected*	*Correlation among entities*
Demographic	Individuals in local populations	No
Environmental	Individuals in local populations	Yes
Extinction–colonization	Populations in metapopulations	No
Regional	Populations in metapopulations	Yes

metapopulation. Notice that the latter two forms of stochasticity are analogous to demographic and environmental stochasticity. Metapopulation dynamics are inherently stochastic, because population extinction and colonization are stochastic events, and real metapopulations are additionally affected by regional stochasticity.

Nonetheless, stochasticity is often ignored and instead a deterministic model is constructed and analyzed. An important difference between stochastic and deterministic models is that the former predict a smaller or greater time to metapopulation extinction, whereas the latter predict that for some parameter values the metapopulation persists (has a positive equilibrium) while for other parameter values it goes extinct. For large metapopulations the essential behavior of the metapopulation is well captured by a deterministic model. Namely, if the deterministic model predicts that the metapopulation will persist, the stochastic model will predict that the time until metapopulation extinction is very long.

Discrete-Time Versus Continuous-Time Models

Population models can be constructed by assuming discontinuous changes in population size at discrete time intervals, for instance once a year, or continuous temporal changes in population size. Though in reality the sizes of all populations change continuously, the breeding seasons may be so short that a discrete-time model is warranted, particularly if population regulation influences only certain age classes. In discrete-time metapopulation models with population turnover, extinctions and colonizations occur at time intervals that agree with the life history of the species, for example, colonizations follow the season during which migration occurs.

Number of Populations and Description of Landscape Structure

How many populations does the metapopulation consist of? How is the landscape structure represented in the model? Models may consider only two local populations connected by migration, which represents a minimal metapopulation but is nonetheless sufficient to address some general questions about the role of migration in local dynamics. In the other extreme, other models assume an infinite number of habitat patches to simplify model analysis; these models are typically focused on the processes of population extinction and colonization. The treatment of space can be implicit, explicit, or realistic. In the first case, the model includes no information on the spatial locations of habitat patches and local populations, which implies that all local populations are equally coupled to each other. The archetypal spatially explicit model assumes a regular lattice, where lattice cells represent habitat patches. Finally, spatially realistic models involve a description of habitat patches in terms of their spatial coordinates, areas, qualities, and so forth, in a manner that allows the application of the models to networks of real habitat patches.

Five Kinds of Metapopulation Models

Two-Population Models

The simplest metapopulation model extends models for single populations to two populations coupled by migration. For instance, local dynamics may be modeled with the familiar logistic model, and migration by assuming that a fraction m of individuals migrates to the other population. Migration may greatly influence the size of the metapopulation, depending on the form of population regulation, the difference in the carrying capacities in the two patches, and mortality during migration. If local dynamics are modeled with discrete-time models, which are inherently less stable than continuous-time models, more complex dynamics may emerge. Migration may now stabilize local populations that exhibit complex dynamics in the absence of migration, but migration may also amplify population fluctuations, all depending on the details of the model and the exact parameter values. Even limited amount of migration may bring population fluctuations into synchrony.

The two-population models may be extended to n populations, but typically at the cost of the analysis being restricted to simulations. n-population models have been used to study metapopulation viability for conservation. Such models are appealing

to ecologists and conservationists because of their apparent realism, but because of the typically large number of untested structural model assumptions and unmeasured parameter values one cannot place much confidence on model predictions.

The two-population and *n*-population models have been used to study source-sink population dynamics. Some interesting results include the possibility of sink populations enhancing metapopulation stability when source populations exhibit large fluctuations leading to high risk of extinction. A metapopulation consisting of independent sink populations with temporal variation in growth rate may persist even if long-term growth rate is negative in each population in the absence of migration. Migration among such populations enhances metapopulation growth rate by spreading the risk of locally bad period among many independent populations.

Levins Model

The Levins model has a special significance for metapopulation ecology, as it was with this model that Richard Levins introduced the metapopulation concept in two papers published in 1969 and 1970. The Levins model represents a completely different approach to metapopulation modeling in comparison with the two-population model. The assumptions of the Levins model are: (1) The suitable habitat occurs in infinitely many patches that are equally large and of the same quality. (2) The patches have only two possible states, occupied versus empty, and hence the Levins model is an example of patch occupancy metapopulations models, in which local dynamics are ignored. (3) Local extinctions and colonizations occur independently in different patches. (4) All local populations are equally connected to other populations and patches, which is another way of saying that the model is spatially implicit.

With these assumptions, the size of the metapopulation can be described by the fraction of the currently occupied patches, denoted by $p(t)$. Temporal changes in the value of $p(t)$ are given by

$$\mathrm{d}p(t)/\mathrm{d}t = cp(t)(1 - p[t]) - ep(t) \quad (1)$$

where c and e are colonization and extinction rate parameters. The first term describes the rate of colonization of currently unoccupied patches (fraction 1-p) of all patches, while the second term gives the rate of extinction of currently occupied patches (fraction p). Local extinctions may be due to demographic and environmental stochasticity, but at the metapopulation level local stochasticity is assumed to translate to a constant extinction rate parameter. Note that because the existing local populations are assumed to be identical, they all contribute equally to the rate of colonization, and hence the colonization term is proportional to p as well as to 1-p.

The equilibrium metapopulation size is given by $p^* = 1\text{-}\delta$, where $\delta = e/c$ is called the extinction threshold. In the Levins model a species that can invade a currently unoccupied patch network has a positive equilibrium size in the network, and vice versa (Fig. 1**A**). This is not so in more complex models that may have alternative stable equilibria (see section titled "Population size-structured models"). The basic reproductive number R_0 in the Levins model is given by $R_0 = 1/\delta$, which has to exceed unity for the species to be able to spread into an empty patch network.

The Levins model is a deterministic approximation of a model known as the stochastic logistic model, which is an example of stochastic patch occupancy models. The stochastic logistic model assumes a finite network of n patches. If a patch is occupied, it is assumed to go extinct with a fixed rate $E = e$, while the colonization rate of an empty patch is assumed to depend on the fraction of occupied patches, $C = ck/n$, where k is the number of currently occupied patches. These assumptions define a.

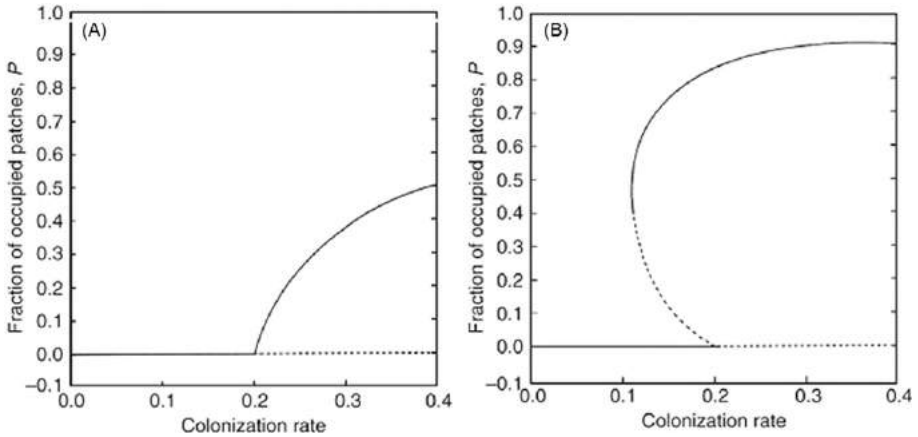

Fig. 1 This figure shows the metapopulation equilibria in relation to increasing colonization rate. Locally stable equilibria are shown by continuous line, unstable equilibria by broken line. (A) In the Levins model, the metapopulation may invade a patch network at the extinction threshold, at which point metapopulation extinction ($p^* = 0$) becomes an unstable equilibrium and only the positive equilibrium is stable. (B) In population size-structured models with strong rescue effect, there are two alternative stable equilibria for some parameter values, in which a metapopulation that is originally sufficiently large may persist in a network that it cannot invade from small size (in the example colonization rate between 0.11 and 0.2). From Hanski, I. (1999). *Metapopulation Ecology.* Oxford: Oxford University Press.

Markov process with metapopulation extinction as an absorbing state, that is, sooner or later the entire metapopulation will go extinct. A key prediction of the model is the mean time to extinction, T. Using a diffusion approximation to analyze the model, which is justified when the number of patches is large, we obtain:

$$T = \sqrt{\frac{2\pi}{n}} \frac{e^{-(n-1)p*}}{p^{*2}(1-p^*)^{n-1}} \tag{2}$$

where p^* is the size of the metapopulation at quasi-equilibrium. Fig. 2 gives the number of patches n that the network must have to make T at least 100 times as long as the expected lifetime of a single local population. For metapopulations with large p^* a modest network of around 10 patches is sufficient to allow long-term persistence, but for rare species (say $p^* < 0.2$) a large network of $n > 100$ is needed for long-term persistence.

The stochastic logistic model includes extinction–colonization stochasticity but no regional stochasticity, which leads to correlated extinctions and colonizations. In the presence of regional stochasticity the mean time to metapopulation extinction does not increase exponentially with increasing n as predicted by Eq. (2) but as a power function of n, the power decreasing with increasing correlation in extinction and colonization rates. This result is analogous to the effects of demographic and environmental stochasticities on the lifetime of single populations.

Population Size-Structured Models

The stochastic logistic model extends the Levins model by incorporating extinction–colonization stochasticity in the model. Population size-structured models represent another type of extension. These models are deterministic and retain the assumption of infinitely many identical and equally connected patches, but the models include a description of local dynamics and migration in the same manner as the two-population models. The simplest structured model divides existing local populations into just two classes, small and large, which is sufficient to model one important new process in comparison with the Levins model: migration from existing large populations (which send out many migrants because they are large) may increase the growth rate in small populations and thereby rescue them from local extinction. At the metapopulation level, the rescue effect leads to the novel prediction of alternative stable equilibria, one of which is metapopulation extinction, the other one a positive metapopulation size (Fig. 1**B**). Therefore, a metapopulation may persist in a network that cannot be invaded from small metapopulation size.

Spatially Realistic Metapopulation Models

An important simplification of the models that have been discussed so far is that they involve no description of the landscape structure, hence it is not possible to apply the models in a quantitative manner to real metapopulations. Real habitat patch networks consist of a finite number of patches that typically differ in their size and quality, and in their spatial connectivities to existing populations, which affect colonization rate.

To model metapopulations in such heterogeneous patch networks, we extend the stochastic logistic model to situations in which the extinction and colonization rates (in continuous-time models) or probabilities (in discrete-time models) are specific to particular habitat patches. This leads to heterogeneous stochastic patch occupancy models. Below, a deterministic approximation of the full stochastic model is discussed, which leads to a family of models with a clear relationship to the Levins model and to models that are helpful for practical applications.

In continuous time, the deterministic model is defined by a set of n equations for a network of n patches,

$$\mathrm{d}p_i(t)/\mathrm{d}t = C_i(\mathbf{p}[t])(1 - p_i[t]) - E_i(\mathbf{p}[t])p_i(t) \tag{3}$$

where $\mathbf{p}$ is a vector of probabilities p_i of each of the n patches being occupied, and C_i and E_i are patch-specific colonization and

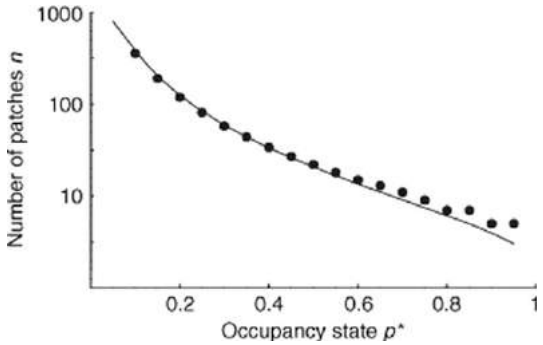

Fig. 2 The number of habitat patches needed to make the mean time to metapopulation extinction at least 100 times longer than the mean time to local extinction. The *dots* show the exact result based on the stochastic logistic model, while the line is based on the approximation given by Eq. (2). From Ovaskainen, O. and Hanski, I. (2003). Extinction threshold in metapopulation models. *Annales Zoologici Fennici* **40**, 81–97.

extinction rates. To link colonization and extinction rates to the structure of the fragmented landscape, we make assumptions of how these rates depend on the properties of the habitat patches, leading to spatially realistic metapopulation theory.

Generally, the extinction risk decreases with increasing patch area A_i, because large patches, when occupied, tend to have large populations with a small risk of extinction. A reasonable parametric assumption is

$$E_i = e/A_i^{\zeta_{ex}}$$

where e and ζ_{ex} are two parameters. The colonization rate increases with connectivity to existing populations, with connectivity defined as a measure of the expected rate of migration from all possible source populations to the focal habitat patch. A reasonable parametric assumption of connectivity is

$$S_i = A_i^{\zeta_{im}} \sum_{j \neq 1} \exp\left(-\alpha d_{ij}\right) A_j^{\zeta_{em}} p_j \tag{4}$$

Thus connectivity of patch i is obtained as a sum of contributions from all other patches from which migrants may arrive. The contribution of patch j increases with its area A_j, scaled by power ζ_{em}; with decreasing distance between patches i and j, with $1/\alpha$ giving the average migration distance; and with the probability of occupancy of patch j, as migrants can only arrive from occupied patches. Immigration to patch i may depend on its own area, scaled to power ζ_{im}. The colonization rate is then defined as $C_i = cS_i$.

The full dynamics of the model is described by the system of n coupled Eq. (3), but its essential behavior can be approximated by just one equation,

$$\mathrm{d}p_\lambda/\mathrm{d}t = c' p_\lambda (1 - p_\lambda) - e' p_\lambda \tag{5}$$

Here metapopulation size is measured as the weighted average of the patch-specific occupancy probabilities p_i, $p_\lambda = \Sigma V_i p_i$, where the weights V_i satisfy $\Sigma V_i = 1$, and they are derived from the relative contributions of individual patches to the capacity of the landscape to support a metapopulation. Large and well-connected patches have larger values of V_i than small and poorly connected patches, because large patches have populations with small risk of extinction and send out many migrants to colonize new patches, especially if they are located close to the other patches. Note that this model is structurally identical with the Levins model, though metapopulation size is measured in a different manner and the colonization and extinction parameters are defined as $c' = c\lambda_M/\omega$ and $e' = e/\omega$, where $\omega = \Sigma V_i A_i$. The new quantity here is λ_M, which is called the metapopulation capacity of the fragmented landscape. Mathematically, λ_M is the leading eigenvalue of a "landscape" matrix, which is constructed with assumptions about how habitat patch areas and connectivities influence extinctions and colonizations. To compute λ_M for a particular landscape one needs to know the scale of connectivity, set by parameter α in Eq. (4) for connectivity, the scaling of immigration, emigration, and extinction rates by patch area (ζ_{im}, ζ_{em}, and ζ_{ex}), and the areas and spatial locations of the habitat patches. The size of the metapopulation at equilibrium is given by

$$p_\lambda^* = 1 - \delta/\lambda_M \tag{6}$$

An attractive feature of the spatially realistic models is the possibility of estimating the values of model parameters with empirical data on the structure of the patch network (patch areas, spatial coordinates, and possibly other information) and spatiotemporal pattern of patch occupancy. Data should preferably be available for several years, including many extinction and colonization events. Having estimated model parameters based on data from a particular landscape, one may predict metapopulation dynamics and persistence in other landscapes, for instance to guide management and conservation actions. The models are most appropriate for highly fragmented landscapes, where all habitat patches are small or relatively small and the respective populations have hence a substantial risk of extinction.

When fitting a metapopulation model to data, it is important to account for the detectability, for example, the possibility that a local population was present but not observed. Failing to account for detectability can lead to biased estimates of colonization and extinction rates. For example, consider a situation in which a local population was actually present in three consequtive years, but it was not observed in the second year. If not accounting for imperfect detectability, the data would suggest that both an extinction and a colonization took place, inflating the estimates of both the extinction rate parameter e and the colonization rate parameter c.

Individual-Based Metapopulation Models

The models described in the previous section "Spatially Realistic Metapopulation Models" classify the patches simply as occupied or empty. While such models can provide many kinds of insights on metapopulation ecology, they lack an explicit connection to individual-level processes. For example, in Eq. (4) the connectivity (and hence colonization rate) of a patch is assumed to increase with the area A_j of a potential source patch, raised to the power of ζ_{em}. The scaling of the patch area with ζ_{em} models two very different proceses at the same time. First, the size of a local population is likely to increase with patch area, making a positive contribution to ζ_{em}. Second, an individual present in a patch is less likely to emigrate from a large patch than from a small patch, making a negative contribution to ζ_{em}. The value of ζ_{em} estimated through a patch occupancy model combines the influences of these two processes, thus failing to separate their roles. More mechanistic insights on connectivity and other components of metapopulation dynamics can be obtained with the help of individual-based models.

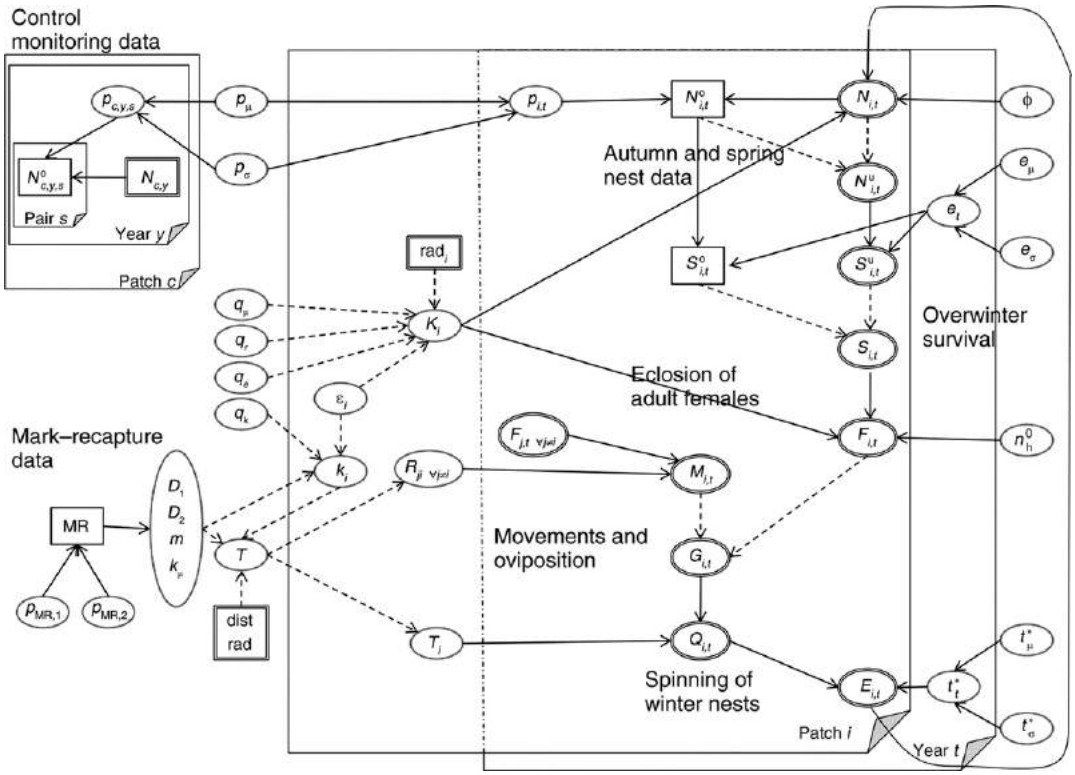

Fig. 3 A graphical description of an individual-based metapopulation model. The quantities in the double ellipses describe the state of the metapopulation (e.g., number of individuals present in each patch), and the quantities in the single ellipses are the parameter values that are estimated. In the single boxes are the observations used to estimate the model, and in the double boxes are the fixed quantities (patch areas and locations). The *full arrows* correspond to stochastic relationships and the *dashed arrows* to deterministic relationships. Imperfect detection is accounted for through an observation model, which describes the probability of observing individuals in mark-recapture studies (used to parameterize the movement part of the model) as well as annual surveys (used to parameterize the demographic part of the model). From Harrison, P.J., Hanski, I. and Ovaskainen, O. (2011). Bayesian state-space modeling of metapopulation dynamics in the Glanville fritillary butterfly. *Ecological Monographs* **81**, 581–598.

If sufficiently rich data are available, it is possible to construct individual-based versions of a spatially realistic metapopulation models and estimate their parameters. Such models are necessarily rather complex, as they generate metapopulation dynamics from individual-level behavior. For example, in the butterfly metapopulation model illustrated in Fig. 3, the individuals move according to a diffusion model both within and between the habitat pacthes, and the emigration rate is controlled by the relucatance of the individuals to leave a patch when encountering its boundary. The demographic part of the model involves the oviposition of eggs by the females, and the survival of the eggs through larvar stages until the eclosion of adult butterflies that form the next generation.

Given the complexity of individual-based models compared to that of patch occupancy models, it is natural to ask what are the additional insights that individual-based models may bring about. First, if parameterized with sufficiently rich data, individual-based models can make more accurate predictions than patch occupancy models, and thus be useful for example, in the conservation context. Second, individual-based models can help to gain a mechanistic understanding on how metapopulation dynamics are generated by the individual-level processes. For example, unlike patch occupancy models, invidual-based models do not involve phenomenological colonization and extinction rate parameters. Instead, a colonization takes place when a migrating individual moves to an empty patch and reproduces there, whereas a local extinction takes place when the last individual in a patch dies or emigrates. Individual-based metapopulation models also work as a natural starting point for studying evolutionary metapopulation dynamics.

Models for Dynamic Landscapes

The vast majority of metapopulation models assume that the landscape structure remains unchanged, only the population sizes and the spatial pattern of habitat occupancy changes. This is a reasonable assumption for many but not all species and landscapes. In particular, metapopulation structures are common in many successional habitats, in which changing habitat quality is an important reason for local extinctions. Human-caused habitat loss and fragmentation are often so fast that one cannot assume

metapopulations to occur at quasi-equilibrium with respect to the current landscape structure, and we may ask how long it takes for a metapopulation to reach the new quasi-equilibrium (which may be metapopulation extinction) following a change in landscape structure. This latter question will be addressed in the section "Transient Dynamics And Extinction Debt" below.

One may extend a stochastic patch occupancy model to include turnover in habitat patches. A general formulation for the stationary probability of occupancy of patch i in a network of n patches is given by

$$J_i = \frac{C_i}{C_i + E_i} \tag{7}$$

J_i is often called the incidence of occupancy, and the model an incidence function model. Assuming that existing patches disappear (which increases the extinction probability of the respective local population) and new patches appear in the landscape, the incidence function may be written as

$$J_i = \frac{C_i - C_i(1 - C_i - E_i)^{age}}{C_i + E_i} \tag{8}$$

where *age* is the age of the patch. Note that initially the patch is always unoccupied ($J_i = 0$ when $age = 0$), while the incidence in old patches (*age* large) approaches the incidence given by Eq. (7). Given data on the ages of the patches in addition to data on patch areas and connectivities and the incidences of occupancy, this model may be parametrized in the same manner as other stochastic patch occupancy models. The size of the metapopulation at quasi-equilibrium is given by the sum of the patchspecific incidences. Given that E_i in Eq. (8) is greater than in Eq. (7), it is clear that landscape dynamics reduce metapopulation size.

Metapopulation Models for Two or More Species

Like all species, species living in fragmented landscapes interact with other species. Metapopulation models have been constructed for competing species and for prey and predator inhabiting the same patch network. This has led to several important results. For instance, a species with a high colonization rate may coexist at the landscape level with a species that is a superior competitor locally, essentially because the former species finds a temporary refuge in those patches that have not yet been colonized by the superior competitor. Similarly, a prey that is driven to extinction locally may persist in a network of habitat patches if it has a sufficiently high colonization rate. Spatially restricted range of movements and ecological interactions may give rise to strongly aggregated spatial distributions of interacting species in the absence of any environmental heterogeneity, which has been studied with continuous-space and discrete-space (lattice) models. The latter are conceptually related to metapopulation models, especially if one assumes that lattice cells (representing habitat patches) are occupied by local populations rather than by single individuals. Spatial pattern formation due to ecological interactions is less likely to be a dominant feature in metapopulation models for fragmented landscapes, because the (fixed or dynamic) spatial variation in habitat quality strongly constrains (meta) population dynamics.

Applications to Landscape Management and Conservation

Habitat Loss and Extinction Threshold

Loss and fragmentation of natural habitats due to human land use is the most important reason for the current catastrophically high rate of loss of biodiversity on Earth. Population viability depends, among other things, on the environmental carrying capacity and hence on the total amount of habitat available. Additionally, the spatial configuration of habitat may influence viability, because most species have limited migration ranges and hence not all habitat in a highly fragmented landscape is readily accessible. Metapopulation models have been used to address the population dynamic consequences of habitat loss and fragmentation.

In the Levins model, habitat loss has been modeled by assuming that fraction 1-h of the habitat patches becomes unsuitable for occupancy and reproduction, while fraction h remains suitable. abitat loss reduces the colonization rate to $cp(h\text{-}p)$, because the model assumes that fraction 1-h of the migrants land on unsuitable habitat and perish (the model thus most literally applies to species with long-range passive migration and no habitat selection). The species persists in a patch network if h exceeds the threshold value δ set by the extinction-proneness and colonization capacity of the species. An interesting implication of this result is that, at equilibrium, the fraction of suitable but unoccupied patches ($h\text{-}p^*$) is constant and equals the amount of habitat at the extinction threshold ($h = \delta$). This is a potentially helpful result, because it suggests a way of measuring the value of the extinction threshold given knowledge of h and p^*. The model is however exceedingly simple and hence not really suitable for quantitative predictions.

The spatially realistic metapopulation models combine the metapopulation perspective of the Levins model with a description of the spatial distribution of habitat in a fragmented landscape and how the landscape structure influences the extinction and colonization processes. In the model described by Eq. (5), the metapopulation capacity λ_M replaces the fraction of suitable patches h in the Levins model, and the threshold condition for metapopulation persistence is accordingly given by $\lambda_M > \delta$. The novelty here is that λ_M takes into account not only the amount of habitat in the landscape but also how the remaining habitat is

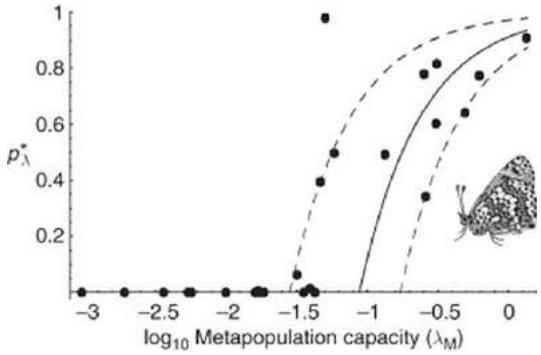

Fig. 4 Metapopulation size of the Glanville fritillary butterfly (*Melitaea cinxia*) as a function of the metapopulation capacity in 25 habitat patch networks. The *vertical axis* shows the size of the butterfly metapopulation based on a survey of habitat patch occupancy in 1 year. The empirical data have been fitted by a spatically realistic model. The result provides a clear empirical example of the extinction threshold. From Hanski, I. and Ovaskainen, O. (2000). The metapopulation capacity of a fragmented landscape. *Nature* **404**, 755–758.

distributed among the individual habitat patches and how the spatial configuration of habitat influences extinction and colonization rates and hence metapopulation viability.

The metapopulation capacity can be computed for multiple landscapes and their relative capacities to support viable metapopulations can be compared even without knowledge of the threshold value δ: the greater the value of λ_M, the better (Fig. 4). One complication is regional stochasticity, which can only be included in the calculations if there is empirical knowledge about the spatial scale and the strength of stochasticity. Without regional stochasticity, it always helps to have as short distances as possible between habitat patches. With regional stochasticity, metapopulation viability is likely to be maximized by intermediate distances between the habitat patches: long enough to reduce the correlation in local dynamics, but not too long to reduce migration too greatly.

Transient Dynamics and Extinction Debt

A change in the structure of a fragmented landscape, for instance a reduction in the area of some habitat patches, will influence the patch-specific extinction and colonization rates, but it takes time before the metapopulation has reached a new quasi-equilibrium following environmental change. The length of the transient period is longer when the change in landscape structure is greater, when the rates of extinction and colonization are lower, and when the new quasi-equilibrium following environmental change is located close to the extinction threshold. The latter result has important implications for conservation. Species that have become endangered due to recent changes in landscape structure are located, by definition, close to their extinction threshold, and hence the length of the transient period in their response to environmental change is predicted to be long. This means that we are likely to underestimate the level of threat to endangered species, because many of them do not occur at quasi-equilibrium with respect to the present landscape structure but are only slowly declining due to past habitat loss and fragmentation.

Considering a community of species, the term extinction debt refers to situations in which, following habitat loss, the threshold condition is not met for some species, but these species have not yet had time to go extinct. More precisely, the extinction debt at a given point in time is the number of extant species that are predicted to go extinct in the future because the threshold condition is not satisfied for them.

Reserve Selection

Setting aside a sufficient amount of habitat as reserves is essential for conservation of biodiversity. Reserve selection should be made in such a manner that a given amount of resources for conservation makes a maximal contribution toward maintaining biodiversity. In the past, making the optimal choice of reserves out of a larger number of potential reserves was typically done by selecting reserves that together would include the largest number of species, without any consideration for the long-term viability of the species. More appropriately, we should ask the question which choice of reserves maintains the largest number of species to the future, taking into account spatiotemporal dynamics of species and possibly and preferably also predicted changes in climate and land use. Metapopulation models can be incorporated into analyses that aim at providing solutions to such questions.

Summary

Metapopulations are assemblages of local populations inhabiting networks of habitat patches in fragmented landscapes. The local populations are coupled by migration among the populations. Metapopulation models are used to describe, analyze, and predict the dynamics of metapopulations. Models have been constructed to investigate the consequences of migration on the pattern and

synchrony of local dynamics, the processes that may lead to spatial pattern formation due to ecological interactions, the persistence of metapopulations in patch networks in a stochastic balance between local extinctions and colonizations, and the response of metapopulations to changing landscape structure. Metapopulation models for highly fragmented landscapes predict an extinction threshold, a critical amount and configuration of habitat that is necessary for long-term metapopulation persistence. The models thus predict that with increasing habitat loss and fragmentation, species will go extinct before all habitat has been lost. Spatially realistic metapopulation models combine a description of landscape structure with a model of the extinction and colonization processes. These models can be parameterized with empirical data and applied to real metapopulations for the purposes of research, management, and conservation.

Model Types: Overview☆

Sven E Jørgensen, Copenhagen University, Copenhagen, Denmark
Todd M Swannack, Texas State University, San Marcos, TX, United States

Introduction: Classification of Ecological Models

An overview of the available ecological models is best provided by presenting different applied classifications of ecological models. Five classifications will be presented, namely:

1. What is modeled: matter, energy, or population
2. Classification of all the models in nine different pairs of models (this classification involves as much as $2^9 = 512$ classes)
3. Type of model employed (11 types given)
4. Type of system modeled; and
5. Type of problem modeled

Modeling Matter, Energy, or Populations

Table 1 shows what is modeled, the organization, and the pattern.

Model Pairs

Models can be classified by nine model type pairs, shown in Table 2. It implies that all models belong to one of 512 classes, corresponding to all combinations of the nine pairs. A model could, for instance, to illustrate this classification, be a research model, that is, deterministic, and at the same time a compartment model, that is, dynamic, nonlinear, causal, distributed, holistic, and spatial; or it could be a management model, that is, stochastic, and at the same time a compartment model, that is, dynamic, linear, lumped, holistic, and nonspatial.

Eleven Different Model Types/Tools

Ecological modeling, as a tool in environmental management, rose in popularity significantly during the 1970s. In general, three model types were applied at that time, namely population dynamic models with or without age structure represented by matrices, biogeochemical or bioenergetic dynamic models based on differential equations, and static models, corresponding to all differential equations, were zero. The latter type was mainly applied to describe an extreme or average situation.

It was, however, acknowledged that other model types to solve more comprehensive modeling problems were urgently needed. The needs can be formulated as questions:

1. Ecosystems are middle number systems, in the sense that the number of components is orders of magnitude smaller than the number of atoms in a system. All the components are different and that is often important for a proper description of the ecosystem reactions to consider the differences in properties among individuals.
2. Ecosystems and the species that occupy them are adaptable and may change their properties to meet the changes in forcing functions. Furthermore, the species may be replaced by other species better fitted to the combinations of forcing functions. How to account for these changes? Even the interactions and connections among components of the ecosystem (i.e., the ecosystem network) may be changed if more biological components with different properties are replaced by other species. How to account for these structural changes?
3. Can we model a system that has only uncertain observations/data?
4. How to account for stochastic forcing functions and processes?
5. How to develop models for a heterogeneous data set, that is, based on observations from many different ecosystems?
6. How to develop models of ecosystems, when our knowledge is mainly based on a theory or rules/properties/propositions?

☆*Change History*: March 2018. Todd M. Swannack prepared the update. The article was significantly revised from the previous version. The major changes include removing unnecessary text, deleting one table, and adding new model types. The reference section was updated, and a new section on Integrated/Hybrid models was added.

This is an update of S.E. Jørgensen, Model Types: Overview, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008.

Table 1 Classification of models

Modeled/measured	*Organization*	*Pattern*	*Model type*
Number of individuals	Conservations of genes	Life cycles	Biodemographic
Energy	Conservations of energy	Energy flow	Bioenergetic
Mass or concentration	Conservations of mass	Element flow	Biogeochemical

Table 2 Classification by model pairs

Pair 1: Is the model applied for research or management?
Research models
Management models
Pair 2: Is the model deterministic or stochastic?
Deterministic models
Stochastic models
Pair 3: Does the model apply matrices or differential equations?
Matrix models
Compartment models
Pair 4: Are the variables dependent or not on time?
Dynamic models
Static models
Pair 5: Are the equations linear or nonlinear
Linear models
Nonlinear models
Pair 6: Is the model based on causality or is no causality included?
Causal models
Black box models
Pair 7: Are the parameters (the properties of the state variables) dependent on time and/or space or constant?
Distributed models
Lumped models
Pair 8: Is a reductionistic or holistic model approach applied?
Reductionistic models
Holistic models
Pair 9: Is the model considering spatial distribution?
Spatial models
Nonspatial models
Pair 10: Are the equations solved numerically or analytically?
Numerical models
Analytical models
Pair 11: Are the model results discrete or continuous?
Discrete models
Continuous models

7. How to consider toxic substances in the environment? Does development of a toxic substance model require a special model type?
8. How to describe the spatial distribution, which is often crucial for the understanding of ecosystem processes?

Model Types/Tools Available Today

Since the genesis of ecological modeling in the late 1970s, a number of new model types have been developed, due in part to the need to model more complex environments, more integration among disciplines, and significant increases in computing power. Another question is "to what extent have these new model types been applied in ecological modeling?"

The general trend in ecological modeling has been toward models increasing in complexity, with the classical model types, particularly biogeochemical models and population dynamic models, being integrated into more complex model frameworks that combine multiple model types. That is, the principles underlying those models are being applied as useful tools in the development of several different model types. Statistical models are not covered in this section statistics is considered as a tool that can be applied in ecological modeling to give better process description. If a model is based entirely on statistics, it is a so-called black box model, because it has no causality. This section presents different types of ecological models with a strong foundation in the science of ecology.

For historical context, for the period 1975–82, the applications of biogeochemical and bioenergetic dynamic models and population dynamic models are dominant. Fuzzy models, spatial distribution models, structurally dynamic models (SDMs), and models using catastrophe theory were used in the period 1975–82 but their application in ecological modeling was very modest and they were new and untested tools in ecological modeling. Particularly, SDMs, artificial neutral network (ANN), and individual-based models (IBMs) were more extensively applied from 2000 forward, due to increased modeling software availability and a larger need for those types of models in environmental applications. The use of static models, like food web models, is due to wide application software availability that allows modelers to run large, complex simulations in a relatively short period of time—these models are particularly useful for fisheries and various other types of aquatic ecosystems.

Dynamic Models—Biogeochemical and Bioenergetics

Biogeochemical and bioenergetic models generally apply differential equations to express the dynamics. Changes in state variables are expressed as the results of the incoming minus the outgoing substances and the model is therefore based on conservation principles. The process equations are based usually on causality, but can in principle also be a result of a statistic analysis of data. The model type has some clear advantages that make it attractive still to use this model type for the development of many models.

The advantages are as follows:

- most often based on causality;
- based on mass or energy conservation principles;
- easy to understand, interpret, and develop;
- software is readily available (e.g., systems dynamics software);
- easy to use for predictions.

The disadvantages are as follows:

- difficulty developing and parameterizing with heterogeneous data;
- requires relatively good data;
- is difficult to calibrate when it is complex and contains many parameters;
- cannot account for adaptation and changes in species composition.

The advantages and disadvantages define the so-called area of application: for description of the state of an ecosystem, when a good data set is available. A developed model may be applied on different ecosystems of the same type, although calibration and validation should always be carried out for each case study. The model will often but not always take many processes and several state variables into account and require therefore in most cases a good data set. The model type has been extensively applied in environmental management as a powerful tool to understand the reactions of ecosystems to pollutants and to set up prognoses.

Static Models

The model type is a biogeochemical or bioenergetic dynamic model where all the differential equations are set to zero to obtain the values of the state variables corresponding to the static situation. The model provides a *snapshot in time* view of the system, but does not predict or project dynamics forward.

The advantages are as follows:

- requires smaller databases than other types;
- is excellent to give a worse-case or average situation;
- the results are easily validated (and verified).

The disadvantages are:

- does not give any information about dynamics and changes over time;
- prediction with time as independent variable is not possible;
- can only give average or worse-case situations.

This model type will often be used when a static situation is sufficient to give a proper description of an ecological system or to take environmental management decisions.

Population Dynamic Models

This model type is rooted in the Lotka–Volterra model that was developed in the 1920s. Numerous papers have been published about the mathematics behind this model and a number of deviated models. The mathematics of these equation systems is not

very interesting from an ecological modeling point of view, where the focus is a realistic description of ecological populations. Population dynamic models may include age structure, which in most cases is based on matrix calculations.

Population dynamics models can be classified as many different types of models, including individual-based, matrix, statistical, population viability analyses, analytical, among others.

The advantages are as follows:

- fitted to follow the development of a population;
- age structure and impact factors can easily be considered;
- easy to understand, interpret, and develop;
- most often based on causality.

The disadvantages are as follows:

- the conservation principles are sometimes not applied;
- limited to population dynamics;
- require a good database;
- difficult in some situations to calibrate;
- require a relatively homogeneous database.

This model type is typically used to keep a track on the development of a population. The most applied unit is the number of individuals or amount of biomass. Effects of toxic substances on the development of populations can easily be covered by increasing the mortality and decreasing the growth correspondingly. The model type is extensively used in fisheries management, biological opinions of threatened and endangered species, and national parks.

Structurally Dynamic Models

In these models, the parameters, corresponding to the properties of the biological modeling components, change over time to account for adaptation and changes in species composition. It is possible either to use knowledge or artificial intelligence to describe the changes in the parameters. Used most often, however, is a goal function to find the changes of the parameters. Eco-exergy has often been used as goal function in SDMs. By minor changes of the parameters it may be due to adaptation to the changed conditions, but for major changes it is most probably a change in the state variables (i.e., a shift in the species composition), that is causing the changed parameters. It may also be possible to use the approach to a major change in the ecological network, although no reference to this application of the structurally dynamic modeling approach is yet available.

This model type has the following advantages:

- able to account for adaptation;
- able to account for shift in species composition;
- can be used to model biodiversity and ecological niches;
- the parameters determined by the goal functions (a) do not need to be calibrated and (b) are relatively easy to develop and interpret.

The disadvantages of this model type are as follows:

- selection of a goal function needed;
- usually computer time consuming;
- information about structural changes required;
- no available software, programming often needed.

This model type should be applied whenever it is known that structural changes take place. It is also recommended for models that are used in environmental management to make prognoses resulting from major changes in the forcing functions (impacts).

Fuzzy Models

Fuzzy models may either be knowledge based (called the Mamdani type) or data based (called the Sugeno type). The Mamdani-type models are based on a set of linguistic expert formulations, and they are applied when no data are available. The Sugemo type applies an optimization procedure and it is applied when only uncertain data are available.

This model type has the following advantages:

- can be applied on a fuzzy data set;
- can be applied on semiquantitative (linguistic formulations) information;
- can be applied for development of models, where a semiquantitative assessment is sufficient.

This model type has the following disadvantages:

- can hardly be used for more complex model formulations;
- cannot be used where numeric indications are needed;
- fuzzy models based on data are black box models;

This model type should be applied when the data set is fuzzy or only semiquantitative expert knowledge is available, provided of course that the semiquantitative results are sufficient for the ecological description or the environmental management.

Artificial Neural Networks

These types of models can give relationships between state variables and forcing functions based on a heterogeneous database. It is a black box model and is therefore not based on causality; but it gives in most cases very useful models, that can be applied for prognoses, provided that the model has been based on a sufficient big database that allows to find the relationships and to test it afterward on an independent data set.

ANNs including self-organizing maps have the following advantages:

- may be used where other methods must give up;
- easy to apply;
- give a good indication of the certainty due to the application of a test set;
- can be used on a heterogeneous data set;
- give a near-optimum use of the data set.

The disadvantages can be summarized in the following points:

- no causality unless algorithms are introduced or a hybrid between ANN and a normal model is applied;
- cannot replace biogeochemical models based on the conservation principles;
- the accuracy of predictions is sometimes limited.

The advantages and disadvantages of this model type indicate where it would be advantageous to apply ANN, namely where ecological descriptions and understandings are required on the basis of a heterogeneous database, for instance data from several different ecosystems of the same type. It is also often applied beneficially when the database is more homogeneous, for instance, when the focus is on a specific ecosystems, although the modeler should seriously consider to use biogeochemical dynamic models due to their causality. ANN is, however, faster to use and the time-consuming calibration that is needed for biogeochemical models is not needed.

Individual-Based Models (IBMs) and Cellular Automata

This model type can be regarded as a reductionistic approach, as the system-level properties emerge from the interactions of low-level agents (individuals) in the model. Deriving the properties of a system from the properties and interactions among elements of the system. The model type was developed to focus on exploring the theories that ecosystem properties emerge because of the interactions among the individuals (either intra- or inter-specific) within the system. Within this model type, each individual can have different properties, for instance, individuals may have different sizes, which gives a different combination of properties as it is known from the allometric principles. The right combination may be decisive for growth and/or survival in certain situations, as it is known by all modelers. Consequently, a model without the differences among individuals may give a different result.

Cellular automata are systems of cells interacting in a simple way but displaying complex overall behavior. They are usually characterized by a few salient features. Cellular automata form a class of spatio-dynamical models where time, space, and states are discrete. The genesis of IBMs came from the cellular automaton approach, (although there are IBMs that are not cellular automaton models, and cellular automaton models that are not IBMs).

Advantages of this type of model are as follows:

- able to account for individuality;
- able to account for adaptation within the spectrum of properties;
- software is available, although the choice is more limited than for biogeochemical dynamic models;
- spatial distribution can be covered.

The disadvantages are as follows:

- if many properties are considered, the models get very complex;
- requires a large amount of data to calibrate and validate the models.
- Models require rigorous evaluation and can be difficult to communicate to non-modelers

As mentioned under the characteristics above, we know that the individuals have different properties and that may sometimes be crucial for the model results. In such cases, the IBMs are absolutely needed and the cellular automata can often be considered a proper ecological modeling approach.

Spatial Models

As the individual differences may be crucial for the model results, the spatial differences of the forcing functions, nonbiological state variables, and biological state variables may be decisive for the model results, too. Furthermore, it may be required to obtain model results that reveal the spatial differences, because they may be needed to understand the ecological reactions or to make a proper environmental management. Models that give the spatial differences must of course also consider the spatial differences in the processes, forcing functions, and state variables. It can therefore be concluded that there is an urgent need for inclusion of the spatial differences in ecological models.

There are a number of possibilities to cover the spatial differences in the development of an ecological model. It is not possible to cover them all; but as mentioned under IBMs, cellular automata may be used in this context. Geographic information system (GIS) is another possible approach that can also be considered a convenient method to present the model results. For aquatic ecosystems, the ultimate spatial model would give a three-dimensional (3-D) description of the processes, forcing functions, and state variables and is often a question about a good description of the hydrodynamics.

Spatial models offer the following advantages:

- cover spatial distribution, that is often of importance in ecology;
- the results can be presented in many informative ways, for instance, GIS.

The disadvantages are as follows:

- require usually a huge database, giving information about the spatial distribution;
- calibration and validation are difficult and time consuming;
- a very complex model is usually needed to give a proper description of the spatial patterns.

The spatial models are applied whenever it is required that the results include the spatial distribution, because it is decisive or the spatial distribution is crucial for the model results.

Ecotoxicological Models

Ecotoxicological models are in principle not representing a model type, as biogeochemical models or population dynamic models are applied widely in ecotoxicology. It is, however, preferable to treat ecotoxicological models as a separate model type, because

1. Our knowledge of the parameters is limited and estimation methods are therefore needed and have been developed.
2. Due to the use of safety factors and the limited knowledge of the parameters, ecotoxicological models are often simple. In particular, the so-called fugacity models illustrate this feature.
3. They include often an effect component.

The advantages of this model type are as follows:

- It is tailored to ecotoxicological problems.
- It is in most cases simple to use.
- It includes often an effect component or can easily be interpreted to quantify the effect.

The disadvantages are as follows:

- The number of parameters needed to develop models for all toxic substances is very high and we know only at the most 1% of these parameters.
- It implies that we need estimation methods that inevitably have a high uncertainty. The model results have therefore also a high uncertainty.
- Inclusion of an effect component requires knowledge of the effect, which is also limited.

The area of application is in this case obvious: to solve ecotoxicological research and management problems and perform environmental risk assessment for the application of chemicals.

Stochastic Models

This model type is characterized by an element of randomness. The randomness could be the forcing functions, particularly the climatic forcing functions, or it could be the model parameters. The randomness is in both cases caused by a limitation in our

Table 3 Model types applicable to different data sets

Description of data set	*Model type recommended*
High quality, homogeneous	Biogeochemical/bioenergetic dynamic models; or population dynamic models
High quality, heterogeneous	ANN
Only typical or average values	Static models
Uncertain data	Fuzzy models
No data, only rules	Fuzzy models, rule-based models
Important to utilize data set	ANN

knowledge. We can for instance not know the temperature the fifth of May next year at a given location, but we know how the normal distribution of the temperature has been for instance the last hundred years and can use the normal distribution to represent the temperature on this date. Similarly, many of the parameters in our models are dependent on random forcing functions or on factors that we hardly can include in our model without making it too complex. A normal distribution of these parameters is known and by use of Monte Carlo simulations based on this knowledge, it is possible to consider the randomness. By running the model several times, it becomes possible to obtain the uncertainty of the model results. A stochastic model may be a biogeochemical/bioenergetic model, a spatial model, a structural dynamic model, an IBM, or a population dynamic model. There are no differences among these model types on how a model can be made a stochastic model.

This model type has the following advantages:

- able to consider the randomness of forcing functions or processes;
- the uncertainty of the model results is easily obtained by running the model many times.

This model type has the following disadvantages:

- it is necessary to know the distribution of the random model elements;
- has a high complexity and requires much computer time.

It is recommended to apply stochastic models whenever the randomness of forcing functions or processes is significant.

Integrated/Hybrid Models

Hybrid, or integrated, models can in principle be developed by any combination of two of the previously listed ten model types. The underlying concept for integrated modeling is that combining models from different disciplines captures the strengths of each model within the modeling suite (e.g., integrating a hydrodynamic model developed by a hydro-dynamicist and a population dynamics model developed by an ecologist). Similarly, integrating models reduces the need to develop new models for every situation. Model integration is a considerable undertaking. Common issues include: discipline-specific approaches for dealing with spatio-temporal dynamics, underlying assumptions of each model may be incompatible, communicating among the disciplines can take time, input/output requirements are must be designed a priori.

Which Model Types are Recommended to Solve Which Problems?

As mentioned in the introduction, new model types were provoked by the model problems that became clear in the early to mid-1970s when ecological modeling started to be applied more extensively as a tool in environmental management. Biogeochemical/bioenergetic dynamic models and population dynamic models had some shortcomings which the ecological modelers have tried to solve for the last 30 years by development of new model types. Today, the shortcomings have been at least partially eliminated. Further improvements will be possible by development of hybrid models or even new model types, but a solution to the problem formulated in the introduction is available today. Consequently, it is possible to indicate which model type is the best choice in a given model situation, which is defined by the data, and the combination of problem and system. It is possible to indicate with the 11 model types in hand which solution should be used when we know the (1) the available data sets and (2) the combination of problem and system. "Which model type should be applied in which context?" is answered in **Tables 3** and **4**, covering respectively the different data sets and different problem/system combinations.

Which Environmental Problems Have Been Modeled?

Table 5 gives an overview of the environmental problems that have been modeled. Notice that many models have been focusing on a problem for a specific ecosystem and are therefore included in both table overviews. There are of course also models that focus on a specific problem without considering the ecosystem, for instance, fishery, the greenhouse effect, and acid rain, and

Table 4 Model type applicable to different problems/systems

Problem/system	*Model type to be recommended*
Distribution of matter or energy[a]	Biogeochemical/bioenergetic dynamic models
Development of populations[a]	Population dynamic models
Toxic compounds: distribution and effect	Ecotoxicological models
Individuality important	IBM
Structural changes may occur	Structurally dynamic models
Forcing functions and/or processes stochastic	Stochastic models
Spatial distribution important	Spatial models

[a]ANN could also be applied if causality is less important and optimum data utilization is important. Hybrid models may be applied to combine causality with good data utilization.

Modeling Dispersal Processes for Ecological Systems

Adam Duarte, Oregon State University, Corvallis, OR, United States
Ivana Mali, Eastern New Mexico University, Portales, NM, United States

Glossary

Breeding dispersal The unidirectional movement of an individual from one breeding site to an alternate breeding site.
Census Complete count of the number of individuals or species within a sampling unit.
Detection probability (p) The probability a species is detected, given the sampling unit is occupied by the species.
Emigration The process by which an individual disperses out of a population.
Immigration The process by which an individual disperses into a population.
Natal dispersal The unidirectional movement of an individual from its natal site to the area where it breeds for the first time.
Occupancy probability (ψ) The probability a sampling unit contains at least one individual of a species.

Introduction

Dispersal is a vital life-history strategy that has implications for gene flow, resource competition, population dynamics, and the distribution of species (Clobert *et al.*, 2001). Despite its importance, dispersal is also one of the hardest parameters to estimate. Therefore, dispersal processes are often poorly understood, particularly for rare and elusive species. Also, while dispersal has a clear definition within an ecological context (i.e., the unidirectional movement of an individual), dispersal modeling is less definitive because it is largely grounded on the spatial and temporal dimensions of data and the model that is simulating the process. In light of this uncertainty, we dedicated this article to the introduction of some of the commonly used approaches to estimate movement at various spatial resolutions and follow the structure of Kendall and Nichols (2004) by arranging estimation procedures into two broad categories: direct and indirect methods. We also offer a brief overview on how this information can be integrated to model dispersal processes.

Direct Methods

Direct methods to estimate dispersal require the collection of data on individual movements. Such data can arise through the use of mesocosm studies, behavioral studies that observe a focal animal over a period of time, the tracking of a focal animal over time with the aid of technology, and through the individual marking and subsequent recapture/resighting of marked individuals. Each of these approaches comes with a set of constraints (i.e., cost, sample size limitations, etc.) and provides a different resolution of information concerning dispersal processes.

Mesocosms

Mesocosms are controlled experiments that take place in natural environments. Due to logistical constraints, mesocosm experiments centered on mechanisms of dispersal are usually implemented for smaller-sized animals (i.e., invertebrates, fish, amphibians, and reptiles). Despite such constraints, mesocosms can provide the highest resolution dispersal information; for example, describing natal dispersal of juvenile amphibians from ponds into different habitat types, testing the evacuation hypothesis of individuals from disturbed to more suitable habitats, examining how different substrate types and weather patterns affect movement behavior, assessing how presence of predators affect prey dispersal, and documenting the effects of intraspecific competition on movement. Mesocosm studies often involve a physical barrier that outlines the study area beyond which an organism cannot disperse (i.e., an enclosure; **Fig. 1**). Therefore, it is important to define the appropriate scale at which animals are to be monitored and the scale of treatments. Additional barriers are typically constructed between the treatments either with corridors that accommodate dispersal or with passive traps that capture individuals attempting to disperse (i.e., pitfall traps).

The highest resolution data is obtained by continuously monitoring corridors through which individuals move. This can be achieved by using game cameras and other devices such as stationary chip readers that recognize uniquely marked individuals. In addition to evidence of movement, downloaded data provide the date and time an individual moved into a different spatial subunit. Ideally, the system should only consist of marked/known individuals and be able to record movement events with absolute certainty, where detection probability is equal to 1. Generalized linear models with different error distributions (i.e., Poisson, normal, binomial, etc.) can be fit to these data to link explanatory variables to the number of movement events

 doi:10.1016/B978-0-12-409548-9.10573-1

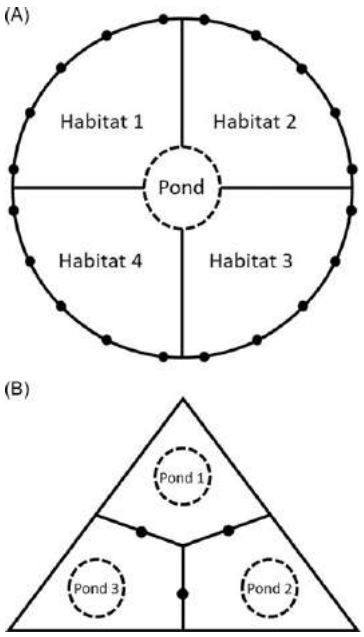

Fig. 1 Two mesocosm experimental designs where *dashed lines* represent ponds, *solid lines* represent barriers to dispersal (i.e., drift or horse fences) and *filled dots* along the barriers present either trap placements (i.e., pitfall traps) or dispersal corridors with some type of monitoring device (i.e., a game camera or chip reader). For example, design A can be used to monitor dispersal of juvenile amphibians into different habitat types while design B can be used to study interpond movement of semiaquatic organisms.

(i.e., count data), a single dispersal event or the chosen terrain to move on during dispersal (i.e., binary [0 or 1] data), the distance moved (i.e., continuous data), etc. In the case where data are collected from the same set of individuals across time, generalized linear mixed models should be fit, where the individual animal identification is treated as a random effect to accommodate potentially nonindependent movement data. That is, an individual is more likely to move the same as itself than it is to share the same behavioral response across multiple individuals, and the analysis should incorporate the hierarchical structure in the data.

Focal Animal Sampling

Focal animal sampling might be one of the oldest methods to monitor movement and consists of direct observations of an individual over a set period of time. Usually if multiple organisms are being observed within a group, each individual is observed during separate time intervals so that the observer is focused on a single animal at a time. However, if an organism is gregarious (i.e., dolphins, elk, etc.), focal-group surveys are conducted where the same set of animals is observed until the end of the survey. A set of behavioral categories to be monitored is usually preestablished. For example, the focus of the study might be distance of focal individual movement between food sites, movement directionality, whether an individual moves independently or as part of a group, or simply total distance traveled.

With technological advancements, research has greatly shifted toward radio telemetry and global positioning system (GPS) devices to monitor focal animals (reviewed in Millspaugh and Marzluff, 2001). Very-high frequency (VHF) radio tracking has become a conventional method to monitor individual movements and requires ecologists acquire a signal via hand-held antenna from a transmitter attached to an animal. Locating marked individuals is done via triangulation (**Fig. 2**), with ecologists traveling either on ground (i.e., afoot, truck, all-terrain vehicle, etc.) or using aerial vehicles (i.e., helicopter, fixed-winged aircraft, etc.). Importantly, aerial vehicles can expand the signal horizon. More advanced GPS tracking technology relies on GPS orbiting satellites to detect signals emitted from a GPS receiver attached to an animal. GPS units can be programmed to record an animal's location at specific time intervals, and data are retrieved either by recapturing the animal to regain access to the GPS receiver or by remote download to a portable hand-held receiver. Finally, satellite-tracking telemetry relies on polar-orbiting Argos satellites to receive signals from platform transmitter terminals (PTTs), which receive the data from GPS satellites. These terminals are located on drifting buoys, ships, or fixed land locations. Argos satellite data are uploaded to several processing centers (i.e., Toulouse, France and Landover, United States of America), which distribute the data worldwide. Therefore, GPS and satellite telemetry are often combined, where an animal is equipped with a GPS/satellite device and the data are transmitted to Argos satellite every few days. While GPS technologies increase the resolution of data and decrease labor requirements, they can substantially increase equipment costs. Ecologists also have to take into account the weight of the transmitter and battery life. In particular, it is recommended that the transmitter is less than 5%–10% of an animal's body mass. Data obtained from focal animal sampling can be used to examine movement rates, migration patterns, and dispersal or space use patterns. Home range can be determined using minimum convex polygon (MCP), bivariate normal probabilistic model, harmonic mean, or kernel density model.

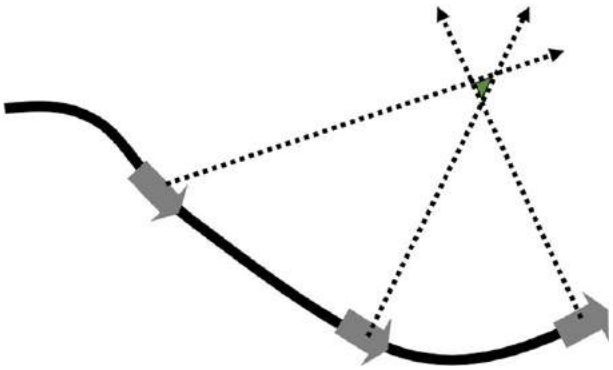

Fig. 2 An example of locating a radio-collared animal via triangulation where the *solid line* represents a surveyor's path, *gray arrows* represent points along the path where a surveyor detected a signal via hand-held antenna, and *dashed lines* represent the direction (i.e., bearing) of the signal from the surveyor's location. The space between where the directional signals intersect, *green triangle*, is the approximate location of the animal.

High-resolution data obtained from GPS devices allow for more sophisticated statistical methods of analyzing daily movement paths and understanding the relationship between movement patterns and environmental factors. First-passage time analysis uses high-resolution data from GPS devices to quantify the time it takes an animal to move through circles with radii that represent evenly spaced points along a movement trajectory (Fauchald and Tveraa, 2003). First-passage times reflect the search effort of an individual at each point. A high first-passage time reflects slower movement representing an encamped area, while a low first-passage time represents faster and straight line movements. To use this method, ecologists have to determine the scale at which the first-passage analysis should be conducted. The results of this technique are dependent on the size of the radius, as an increase in the size of the radius will likely lead to more windings of the pathway within each circle. This increase in tortuosity will probably be much larger in areas with more physical barriers to movement when compared to areas where the animals are able to move unidirectional. Thus, it is assumed that the relative variance of fist-passage times for all points along the path will increase with increasing radii. One approach to determine the appropriate radius (r) is to estimate first-passage times with a range of r values and calculate the variance of log-transformed first-passage times. The r that yields the highest variance represents the scale at which the analysis should probably be conducted.

Brownian bridge movement models (BBMMs) use discrete location data obtained at short time intervals from GPS devices to estimate movement path and model the utilization distribution (*UD*) of individuals (Horne *et al.*, 2007). The BBMM requires sequential location data, estimated error associated with location data, and grid-cell size assigned for the output *UD*. It is assumed that location errors correspond to a bivariate normal distribution and movement between successive locations is random but conditional on the starting and ending locations. The BBMM is dependent on the time between locations, the distance between locations, and the Brownian motion variance (σ_m^2). Brownian motion variance is related to the animal's mobility and represents the diffusiveness or irregularity of movement. This parameter is estimated from the trajectory, which is based on an average of all available movement data. While BBMMs assume homogeneous movement behavior across individual animals, dynamic Brownian bridge movement models (dBBMMs) relax this assumption by allowing σ_m^2 to vary along a path, which enables the estimator to accommodate behavioral heterogeneity in σ_m^2 (Kranstauber *et al.*, 2012). These models can be used to quantify circadian patterns of habitat use and correlated movement patterns among habitat types.

Multistate Models

Multistate models enable ecologists to estimate stochastic transitions between states (Schwarz, 2005). Here, states denote discrete classifications that describe the current condition of an animal. These states can represent an individual's reproductive status, sex, size, disease status, geographic location, occupied habitat type, and much more. When estimating movement parameters, geographic states are typically the states of interest; however, combinations of multiple types of states can also be modeled. Estimating transition probabilities among geographic states requires that animals are monitored in different sites or sample units. Although this model is typically fit to capture–recapture/resight data where recapture/resight probabilities are explicitly modeled to account for imperfect detection, it can also be fit to "known fate" data from VHF or GPS devices. This approach operates under a few assumptions. Specifically, individuals have homogeneous recapture/resighting and survival probabilities, marks are not lost or overlooked, sample occasions are instantaneous or occur over short time periods and individuals are released immediately, all emigration out of the sample units is permanent (but see Kendall and Nichols, 2002), the fate of individuals is independent from each other, states are recorded without error (but see Conn and Cooch, 2009), all individuals in state r at time t have equal movement probabilities, movement and recapture/resight probabilities are only related to the current state and not related to the past location of the individual (but see Hestbeck *et al.*, 1991), and all individuals transition at the same time. It is also worth noting that if permanent emigration out of the sample units is prevalent the survival parameter represents apparent survival, not

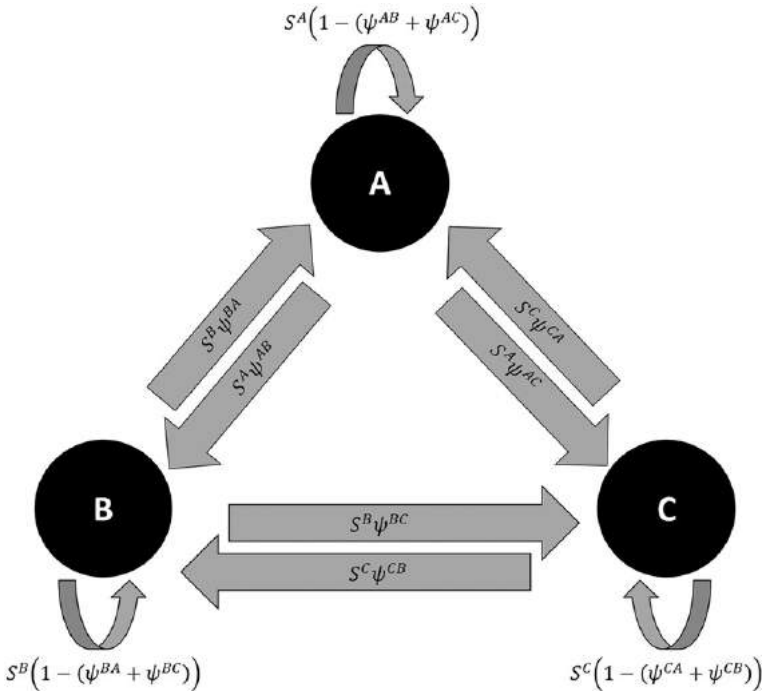

Fig. 3 Graphical depiction of the state transitions for a multistate model with only 3 states. Note that the model also estimates the probability of recapture/resight in each state.

true survival. Apparent survival is the probability that an individual survives and does not permanently emigrate out of the sample units from one occasion to the next.

Here, we focus on a simple example where individuals are sampled on 3 occasions and classified into 1 of 3 states on each occasion, representing sample units A, B, and C (**Fig. 3**). Note that an individual can only belong to 1 state at a time. Let us say you captured and uniquely marked an individual in sample unit C on the first occasion, you reencountered the same individual in sample unit A during the second occasion, and you also reencountered the same individual during the third occasion but the individual was in sample unit B. That individual would have an encounter history of "C, A, B", and the probability statement for this encounter history is $\Pr(h = \text{CAB}) = S^{\text{C}}\psi^{\text{CA}}p^{\text{A}}S^{\text{A}}\psi^{\text{AB}}p^{\text{B}}$, where S^{C} is the probability of surviving through the interval between the first and second occasion, ψ^{CA} is the probability of transitioning from state C to state A, p^{A} is the probability of recapturing/resighting the individual at sample unit A, S^{A} is the probability of surviving through the interval between the second and third occasion, ψ^{AB} is the probability of transitioning from state A to state B, and p^{B} is the probability of recapturing/resighting the individual at sample unit B. What if an individual is captured and uniquely marked on the first occasion in sample unit B, not encountered during the second occasion, and reencountered in sample unit A during the third occasion? Well, the encounter history for that individual is "B, 0, A", and the probability statement for this encounter history is $\Pr(h = \text{B0A}) = S^{\text{B}}(1-(\psi^{\text{BA}}+\psi^{\text{BC}}))(1-p^{\text{B}})S^{\text{B}}\psi^{\text{BA}}p^{\text{A}}+S^{\text{B}}\psi^{\text{BA}}(1-p^{\text{A}})S^{\text{A}}(1-(\psi^{\text{AB}}+\psi^{\text{AC}}))p^{\text{A}}+S^{\text{B}}\psi^{\text{BC}}(1-p^{\text{C}})S^{\text{C}}\psi^{\text{CA}}p^{\text{A}}$, where the terms are defined above. We can see how the complexity of the probability statement for the encounter history increases dramatically when individuals are not encountered on every occasion because we have to consider each potential pathway when going from state B in occasion 1 to state A in occasion 3 (see **Fig. 3**). We can learn a few things by looking at these probability statements. First, we see that the survival between occasions is dependent on the conditions the individual experiences at the state prior to the gap between occasions. That is, if an individual transitions from state A to state B the survival parameter is linked to the location the individual came from (i.e., state A) and is not related to the location the individual travels to (i.e., state B). The individual has to survive and then decide to move or not. Second, we see that the transition probabilities must sum to 1 with respect to each state. That is, if the probability of transitioning from state A to B (ψ^{AB}) is 0.45 and the probability of transitioning from state A to C (ψ^{AC}) is 0.15, the probability of remaining in state A (ψ^{AA}) is $1-(0.45+0.15)$ or 0.40. Thus, in practice we typically estimate the last transition using subtraction. Each of the probability parameters (i.e., S, ψ, and p) can be related to explanatory variables using separate logistic regressions to better understand what factors are related to survival, movement, and recapture/resight probability. One thing to consider, however, is that the number of estimated transition probabilities increases substantially with an increasing number of potential states. Specifically, the number of transitions to be estimated is the number of states squared. So, even when only considering 3 states there are 9 transition probabilities to be estimated. Therefore, this model requires a relatively large amount of data and for the data to contain observations of individuals that move between the states to estimate all of the parameters accurately. If data are robust enough to support fitting these models, multistate models are extremely versatile and have been applied across disciplines.

The above approach enables ecologists to estimate the probability of individuals moving between states or locations. However, it may be of interest to use a 2-step approach in order to estimate the probability of leaving a sample unit (π) and the probability of settling in a recipient sample unit given the individual survived and left the sample unit it was located in during the previous occasion (μ). In fact, Grosbois and Tavecchia (2003) proposed the "$\pi\mu$-parameterization" of multistate models to do just that. Using the example from above, we can rewrite the probability statements for the respective encounter history of "C, A, B" and "B, 0, A" as $\Pr(h = \text{CAB}) = S^{C}\pi^{C}\mu^{CA}p^{A}S^{A}\pi^{A}\mu^{AB}p^{B}$ and $\Pr(h = \text{B0A}) = S^{B}(1 - \pi^{B})(1 - p^{B})S^{B}\pi^{B}\mu^{BA}p^{A} + S^{B}\pi^{B}\mu^{BA}(1 - p^{A})S^{A}(1 - \pi^{A})p^{A} + S^{B}\pi^{B}(1 - \mu^{BA})(1 - p^{C})S^{C}\pi^{C}\mu^{CA}p^{A}$, where the terms are defined above. We see that the probability statements are virtually identical and survival is still dependent on the conditions the individual experiences at the state prior to the gap between the occasions. The difference is that the ψ parameter is replaced by π and μ (or just π when the individual does not emigrate), and the probability of leaving a sample unit and settling in another sample unit can each be related to different explanatory variables using separate logistic regressions. Since π and μ are both probabilities, they are each constrained to sum to 1. That is, π is the probability of emigrating from a given sample unit and $1 - \pi$ is its complement (i.e., site fidelity). Since there are only 3 sample units in this example, if an individual transitions from state B to state A the probability is μ^{BA}, and if an individual transitions from state B to state C the probability is $1 - \mu^{BA}$. Grosbois and Tavecchia (2003) noted that if π and μ are interpreted at the population scale, instead of individual scale, they represent emigration and immigration probabilities, respectively. Importantly, the $\pi\mu$-parameterization of multistate models contains the same set of assumptions as the original ψ-parameterization described above.

Spatial Capture–Recapture Models

Spatial capture–recapture models are a type of capture–recapture model that explicitly model the movement of individuals. Notably, the original focus of spatial capture–recapture models was to derive more accurate density estimates for animal populations by incorporating spatially explicit individual encounter history data and estimating the number of individual activity centers within an area of interest (reviewed in Royle *et al.*, 2014). Ergon and Gardner (2014) extended spatial capture–recapture models to incorporate capture–recapture data collected within fixed trapping grids using the robust design (**Fig. 4**). The robust-design spatial capture–recapture model treats individual activity centers during the first season as independent and uniformly distributed. During the following season, however, change in an individual's activity center is modeled using trigonometric functions that assume dispersal occurs in a random direction and at a random distance. Using the model they developed, ecologists can estimate dispersal distances. Moreover, the estimated survival parameters are more biologically meaningful because the approach allows for better separation of emigration and survival—see the above section concerning apparent survival. Schaub and Royle (2014) approached the apparent survival "problem" differently, but still used concepts from the spatial capture–recapture literature. Specifically, they developed a spatial generalization of the Cormack–Jolly–Seber (CJS) model, which allows for the joint estimation of dispersal distance, emigration rate, and survival probability. Importantly, the spatial CJS model does not require fixed trapping locations or data to be sampled using the robust design to be fit. This approach treats dispersal as a random walk and models dispersal variances using a normal distribution, which can then be used to estimate dispersal distances. It should be noted that, like all of the other techniques introduced in this article, both of these approaches require the sample space to be appropriate in order to examine dispersal for a specific study species.

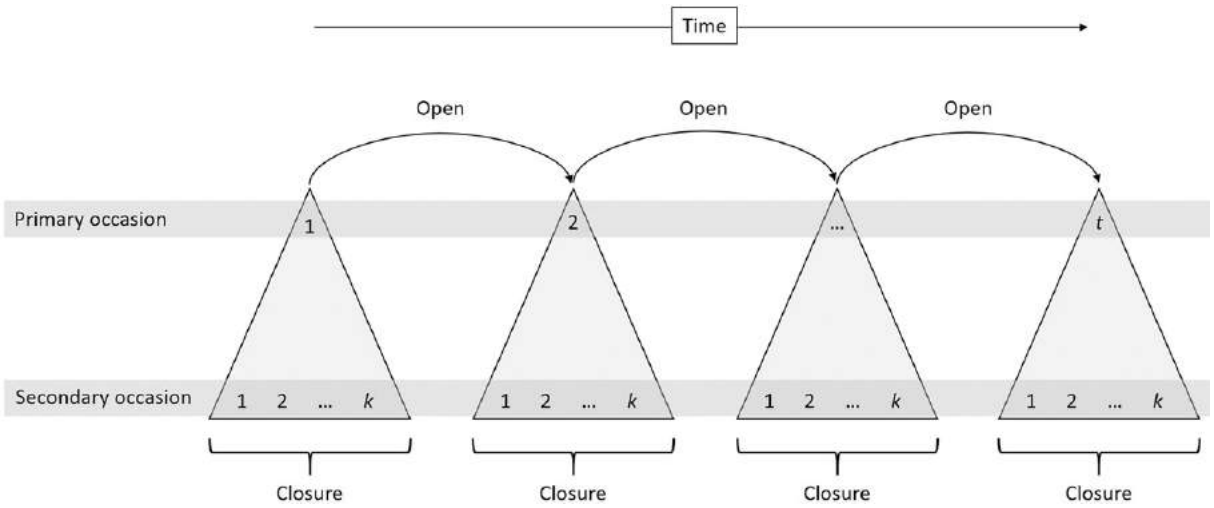

Fig. 4 Illustration of the robust-design sample design. Note that the population is closed (i.e., no loss or addition of individuals) across secondary occasions within a primary occasion, but is open between primary occasions.

Indirect Methods

Indirect methods to estimate dispersal parameters do not require direct data on individuals. Although appealing from a logistical perspective, indirect methods typically do not provide the same resolution of information concerning dispersal processes. Nevertheless, given the logistical constraints associated with most monitoring programs, indirect methods comprise some of the most commonly applied approaches in the field. Moreover, as technology and analytical techniques are further developed and refined, these indirect methods are becoming more useful to understand and model dispersal processes.

Correlated Abundances

Examining for time-lagged correlations in abundance of multiple populations is a method to indirectly study dispersal at large spatial scales (Tittler *et al.*, 2006). If, for example, populations are undergoing source–sink dynamics or asymmetrical dispersal among populations, we can expect abundances to be related across populations over time. That is, if abundance is high in a source population in a given year, we would expect an increase in abundance in the sink population during a subsequent year. Importantly, the time lag in correlations (if present) will vary based on the life history of the study species. The distances over which correlations in abundances occur can be interpreted as the distances over which dispersal occurs. This is perhaps the simplest approach to indirectly study dispersal and, as expected, the information it provides is also coarser than other approaches. Moreover, although simple from a statistical analysis perspective, this approach requires intensive monitoring of multiple populations to reliably estimate abundances and that those data are collected over an extended period of time.

Spatial Dynamic Occupancy Models

Spatial dynamic occupancy models are another indirect method to quantify dispersal. Briefly, dynamic occupancy models leverage replicated detection/nondetection survey data that are collected across seasons using the robust design, where closure within a primary occasion means the occupancy state of a sample unit does not change. The model can estimate the initial occupancy probability (ψ) in the first season of monitoring, detection probability (p) each season, and the occupancy state in subsequent seasons as a result of colonization probability (γ) and local extinction probability (ϵ) as follows:

$$z_{i,1} \sim Bernoulli(\psi_i)$$

$$z_{i,t+1} \sim Bernoulli\left(z_{i,t}\left(1-\varepsilon_{i,t}\right)+\left(1-z_{i,t}\right)\gamma_{i,t}\right) \text{ and}$$

$$\gamma_{i,k,t}|z_{i,t} \sim Bernoulli\left(z_{i,t}p_{i,k,t}\right)$$

where y represents the detection/nondetection data for each site i, during survey k, within season t (i.e., detected [1] or not detected [0]), and z is the latent (partially observed) true occupancy state. Notably, this method accounts for false-negative detections (i.e., imperfect detection) by explicitly modeling the detection process. The probability parameters are linked to potential explanatory variables using separate logistic regressions. In spatial dynamic occupancy models, colonization probability is typically linked to ecological dispersal processes. For example, Risk *et al.* (2011) modeled colonization as:

$$\gamma_{i,t} = \frac{S_{i,t}^2}{S_{i,t}^2 + \delta^2}$$

where δ^2 is a parameter creating a sigmoid-shaped colonization probability function and S is a connectivity metric, which is:

$$S_{i,t} = \sum_{j \neq i}^{m} z_{j,t-1} A_j^{\beta} e^{-\alpha d_{i,j}}$$

where connectivity is related to the area (A) of neighboring occupied sites (i.e., $z_{j,\ t-1}A_j^{\beta}$) and is inversely related to intersite distance between the focal site and its neighbors (i.e., $e^{-\alpha d_{i,\ j}}$). Their approach assumes larger sites have a greater population size and thus contribute more to connectivity. Sutherland *et al.* (2014) used this same rationale, except they calculated colonization and connectivity as:

$$\gamma_{i,t} = 1 - e^{-S_{i,t}}$$

$$S_{i,t} = \delta \sum_{i \neq j} N_{j,t-1}^{*} e^{-\alpha d_{i,j}}$$

where δ is the population-level per capita effective dispersal rate and they replaced $z_{j,\ t-1}A_j^{\beta}$ with the actual juvenile abundances of neighboring sites in the previous season ($N_{j,\ t-1}^{*}$). Chandler *et al.* (2015) approached the problem differently in that colonization was solely related to intersite distance. Specifically, they modeled the probability site i is colonized by at least 1 individual from neighbor j as:

$$\rho_{i,j,t} = z_{j,t-1}\rho_0 e^{-d_{i,j}^2 / 2\sigma^2}$$

where ρ_0 is the baseline colonization probability and σ is the rate of decay in the colonization probability as a function of intersite distance ($d_{i,j}$). This approach assumes a Gaussian kernel for dispersal. The probability that a site is colonized by at least 1 neighbor is then:

$$\gamma_{i,t} = 1 - \left\{ \prod_{j=1}^{M} 1 - \rho_{i,j,t} \right\}$$

where all terms are defined above. Broms *et al.* (2016) modified the base structure of a dynamic occupancy model when developing a spatial dynamic occupancy model. Specifically, their approach models site occupancy after the first season as:

$$z_{i,t+1} \sim Bernoulli\left(z_{i,t}\left(1-\varepsilon_{i,t}\right) + \left(1-z_{i,t}\right) I_{N_{i,t}} \overline{d}_{i,t} + \left(1-z_{i,t}\right)\left(1-I_{N_{i,t}}\right)\gamma_{i,t}\right)$$

where $I_{N_{i,t}}$ indicates whether at least 1 neighbor is occupied (1) or not (0) the previous season and the neighborhood size is specified by the user. Thus, if a site is not occupied it can be colonized by long-distance colonization (γ) if its neighbors are not occupied or by a local neighbor colonization ($\overline{d}$) if at least 1 neighbor is occupied. Neighbor colonization is then modeled as:

$$\overline{d}_{i,t} = 1 - e^{\hat{z}_{N_{i,t}} \log\left(1-d_i\right)}$$

where $\hat{z}_{N_{i,t}}$ indicates if neighbor j is occupied and d_i is the probability site i will be colonized by neighbor j. The approach is flexible as to how d_i is modeled and is largely governed by the objective of the study. Each of these spatial dynamic occupancy models approaches the task of modeling dispersal among occupied and unoccupied sites differently, but we note that each model is parameterized such that if a neighbor is not occupied the previous season it does not contribute to the cumulative colonization probability of a focal site. We also note that each approach requires slightly different data in addition to the typical replicate detection/nondetection data needed to fit traditional dynamic occupancy models.

Integrated Population Models

Integrated population models are an approach to borrow strength across multiple datasets by combining their likelihoods into a single analysis to study population dynamics (reviewed in Schaub and Abadi, 2011). The integration of multiple, but related, datasets within a single analysis enables ecologists to incorporate and estimate complex ecological relationships because relationships among model parameters are constrained to agree with each other since data are fit simultaneously. For example, if data are available to estimate apparent survival, fecundity, and population change for a target population, ecologists can exploit the direct link between the parameters that govern temporal population dynamics (i.e., recruitment, survival, emigration, and immigration) to estimate immigration without having explicit data on movement. That is, if you know how many individuals enter the population through reproduction, how many individuals stay in the population through apparent survival parameters, and how the population abundance changes across time, you can estimate the missing parameter, immigration (**Fig. 5**). Importantly, this approach can also accommodate prior information when using a Bayesian framework if data deficiencies exist for survival or reproduction and the objective is to estimate immigration, albeit the hypotheses that can be evaluated become much more limited. Although these models require a relatively substantial amount of data to be fit, they overcome the logistical challenge associated with estimating dispersal parameters for species that are capable of traveling large distances because only a single target population needs to be monitored.

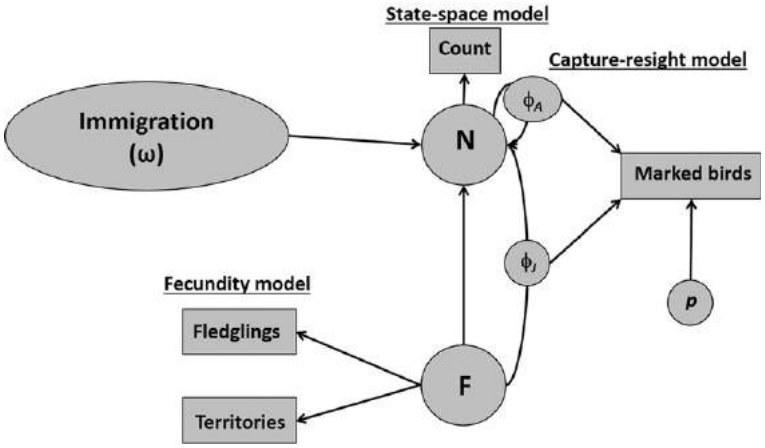

Fig. 5 Graphical depiction of the type of data that can be incorporated within an integrated population model to estimate immigration. Note that this figure depicts a monitoring program that might be implemented for a territorial avian species, but other submodels can be incorporated for different data types and different taxa.

Genetic and Isotope Analysis

Data on gene flow can also be used to infer dispersal. Ecologists can use allozyme, microsatellite, restriction fragment length polymorphism (RFLP), single-nucleotide polymorphism (SNP), and other genotype data to estimate gene flow among populations. There are at least 2 methods of estimating migration parameters. The coalescent approach uses genealogical information contained in deoxyribonucleic acid (DNA) sequences to estimate long-term migration parameters. These traditional indirect estimators of gene flow rely on the assumption that population sizes and migration rates are constant and that populations persist for a time period sufficient to achieve genetic equilibrium. The second approach uses multilocus genotype to estimate short-term migrations (Faubet *et al.*, 2007). This approach uses Bayesian methods to estimate the posterior probability distributions of allele frequencies, migrant proportions, and individual immigrant ancestries. This method also operates under fewer assumptions than the coalescent approach, allowing genotype frequencies to deviate from the Hardy–Weinberg equilibrium. Simulation experiments have shown that with sufficient differentiation among populations and sufficient number of loci, ecologists can derive accurate estimates of recent migration rates using multilocus genotypes (Wilson and Rannala, 2003).

The use of environmental DNA (eDNA) is a relatively novel approach to study dispersal. eDNA is DNA that is collected from the environment, such as soil and water samples, rather than directly from the study species. The presence/absence and even quantitative comparisons of eDNA from a study species in various habitats (i.e., different stretches of the rivers and lakes or freshwater vs. marine environments) can provide information concerning migration routes and potential barriers to movement (Erickson *et al.*, 2016).

The presence of naturally occurring stable isotopes in animal tissues (i.e., carbon [δ^{13}C], nitrogen [δ^{15}N], and deuterium [δD]) can also be used to trace migration (reviewed in Hobson, 1999). Briefly, this approach relies on differential concentration of stable isotopes in different food webs. For example, if differences between food webs exist and they are spatially clustered, organisms moving between geographic regions can carry information on the location of previous feeding. This information can be used to understand movements between different types of habitat (e.g., mesic and xeric, inshore and offshore, marine and freshwater, etc.). Moreover, δD levels in plants and organisms at higher trophic levels vary predictably across continents with growing season precipitation (Cormie *et al.*, 1994). Thus, this stable isotope can be used to study large-scale migration patterns.

Integrating Information to Model Dispersal

Despite the growing number of methods to study dispersal, estimating dispersal is difficult in even the best of cases. Thus, modeling dispersal often requires the integration of any and all available information. Importantly, the objectives of the project should govern what modeling approach is used and, by extension, the data and estimates that are required.

If the objective is to model dispersal corridors, for example, least-cost path (LCP) analysis is a useful modeling approach. LCP analysis uses a geographic information system (GIS) to predict animal movement across landscapes. It involves the use of multiple raster shapefiles that contain information for spatially explicit environmental factors hypothesized to influence movement (i.e., elevation, slope, habitat type, etc.). Combining these raster data using some weighted measure, the user develops a cost or friction surface raster layer, where an individual is more likely to traverse across a cell that contains a lower cell value. The cost surface layer can then be used to identify the most likely (i.e., the least costly) path between multiple locations. LCP analysis is best implemented in combination with the other methods described in previous sections of this article. For instance, information from mesocosms or focal animal sampling can be scaled up to landscape levels using LCP analysis. Also, LCP analysis has been used to explain genetic distances between populations, and ecologists can depict which landscape types are more or less costly for dispersal by identifying genetic immigrant ancestry in different populations (Wang *et al.*, 2009). If there is previous knowledge of established populations, ecologists can study how animals might have dispersed from established populations to newly colonized regions of suitable habitat (LaRue and Nielsen, 2008). Similarly, if Euclidean distance is not as biologically relevant, LCP analysis might also be implemented to develop the intersite distance matrix used when fitting spatial dynamic occupancy models.

When simulating population dynamics using spatially explicit population models, the available information concerning dispersal processes are useful in developing dispersal submodels. For example, Bonnot *et al.* (2011) used the observed distance in correlated abundances reported by Tittler et al. (2006) to specify the dispersal-distance limitation within their simulations. Alternatively, Duarte *et al.*, (2016) used results from genetic and occupancy studies, integrated population models, and capture–recapture analyses to support the use of dispersal submodels without a dispersal-distance limitation and with relatively high dispersal rates compared to previous modeling efforts for their study species. On the other hand, if data are lacking ecologists could also simulate population dynamics with dispersal submodels containing a variety of dispersal-related hypotheses (i.e., density dependence, dispersal cost on survival, no dispersal, dispersal-distance limitations, etc.) to evaluate their influence on projected population dynamics (Horne *et al.*, 2011).

It is important to keep in mind that each of the above approaches provides dispersal information at different resolutions, which may influence how these data are integrated to simulate dispersal in ecological models. For example, spatial dynamic occupancy models differ from the other methods introduced in this article in that the dispersal parameters are related to at least 1 individual colonizing a neighboring site, which is the dispersal probability of the species not an individual within a population. Also, integrated population models provide an estimate of immigration or the number/rate of individuals entering a target population, rather than emigrants leaving a target population or dispersal distances. Again, mesocosm studies are typically conducted at

smaller spatial scales and therefore require the assumption that the observed processes can be scaled up to the larger landscape. Genetic and isotope analyses enable ecologists to have a better understanding of migration rates, how far dispersal occurs and what habitats are used, but the information provided is coarse and can sometimes lack information concerning the mechanisms governing dispersal. Correlation in abundances also provide coarse information concerning dispersal distances, and it should be noted that the time-lagged correlations may be spurious or related to some other population process. Finally, although capture–recapture data and location data from VHF and GPS devices provide high-resolution dispersal information, these approaches can be costly and in some cases not practical at the spatial scales needed to document dispersal events for a study species because of logistical challenges and sample size requirements. This is not to say these approaches do not have merit, but we include this information to highlight that careful consideration should be invested to evaluate which approach or set of approaches best match the objectives and resources of a specific project before implementation.

Ultimately, the use of a sensitivity analysis is paramount to highlight the influence of model assumptions on model results, particularly given dispersal processes have high ecological importance and at the same time dispersal estimates are difficult to obtain. Indeed, it should be standard practice to evaluate the outcome of various dispersal-related rulesets or range in input values, especially if they are not empirically based estimates. Within natural resource management decision making, some rulesets or range of input values may drive the optimal management policies based on simulation results, while others will not affect it at all. Identifying key uncertainties that influence what decision is considered optimal based on simulation results is vital when managers rely on these results to help inform real-world management decision making. Importantly, if modeling efforts are integrated with monitoring programs using an adaptive management framework these uncertainties can be explicitly incorporated into the decision-making process and reduced over time.

Modules and Integrated Modeling☆

Alexey Voinov, University of Technology Sydney, Sydney, NSW, Australia
Paul A Fishwick, University of Florida, Gainesville, FL, United States

Glossary

Integrated model Integrated modeling is the method that is developing to bring together diverse types information, theories, and data originating from scientific areas that are different not just because they study different objects and systems, but because they are doing that in very different ways, using different languages, assumptions, scales, and techniques.

Integronsters Modular constructs that are perfectly valid as software products but ugly and useless as models.

Module A model that is presented as an encapsulated, self-contained independent unit that can be used to construct a more complex models, by linking (coupling) it with other modules.

Introduction

As increasingly more ecological models are developed, it becomes clear that in many cases we are "reinventing-the-wheel." The problem is that models are often developed as nonreusable "one-off" items, or worse, that models are "black boxes" that contain code that by its very nature contains no suitable level of abstraction by which phenomena can be properly understood. One way to avoid that is to build a general ecosystem model, which in theory could eliminate the need for continuous remaking of models for different systems and/or sites. One such model, the general ecosystem model (GEM) has been designed to simulate a variety of ecosystem types using a fixed model structure. Such "generality" logically lead to one of the broader objectives in ecosystem research: with a standard structure for developing a (model) synthesis of a system, comparisons among systems may be facilitated. The model was to be generally applied to ecosystems that range from wetlands to upland forests. It was to provide at least two useful functions in synthesizing our broader understanding of ecosystem properties. One involves using the model as a quantitative template for comparisons of the different controls on each ecosystem, including the process-related parameters to which the systems are most sensitive. Secondly, a simulation model, which is general in process, orientation, and structure, could provide a tool to analyze the influence of scale on actual and perceived ecosystem structure. Object-orientation provides one example of such a structure with ecosystems being natural phenomena for this type of design. Other models, such as CENTURY for example, can claim to be of the same kind of functionality, providing for a wide range of processes that can be parameterized for very different locations and ecosystem types.

However, the general approach turned out to be somewhat insufficient to cover all the possible variety in ecosystem processes and attributes that come into play when going from one ecosystem type to another, and from one scale to another. Modeling is a goal driven process, and different goals in most cases will require different models. There is too much ecological variability to be represented efficiently within the framework of one general model. Either something important gets missed, or the model becomes too redundant to be handled efficiently especially within the framework of larger spatially explicit models. Similarly, when changing scale and resolution, different sets of variables and processes come into focus. Certain processes that could be considered at equilibrium at a weekly time scale need be disintegrated and considered in dynamic at an hourly time scale. For example, ponding of surface water after a rainfall event is an important process at fine temporal resolution, but may become redundant if the time step is large enough to make all the surface water either removed by overland flows, or infiltrated. Daily net primary productivity fluctuations, that are important in a model of crop growth, may be less important in a forest model that is to be run over decades with only average annual climatic data available. Once again the general approach may result in either insufficiency or redundancy.

The modular approach is a logical extension of the general approach. In this case instead of creating a model general enough to represent all the variety of ecological systems under different environmental conditions, we develop a library of modules simulating various components of ecosystems or entire ecosystems under various assumptions and resolutions. In this case the challenge is to put the modules together, using consistent and appropriate scales of process complexity, and make them talk to each other within a framework of a full model. We avoid the "reinventing-the-wheel" by keeping much of the model structure and replacing only the parts that need to be modified under the particular goals of model implementation.

☆*Change History*: March 2018. Alexey Voinov introduced small edits in the text of the article including citations.

This is an update of A.A. Voinov and P.A. Fishwick, Modules in Modeling, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2419–2425.

 doi:10.1016/B978-0-12-409548-9.11142-X

The modular approach directly leads to integrated modeling, when whole models become modules, or components that can be further reconnected, recoupled to build representations of most complex systems.

Modularity

The concept of modularity gained strong momentum with the wide spread of the object oriented (OO) approach in software development. Engineers and computer designers realized some time ago that it is cheaper and more efficient to build devices made of replaceable units. So if you run out of space on your hard disk you can easily take it out and plug in a new bigger one. Similarly, you can swap your CD reader for a DVD reader. The same kind of functionality came with OO software, where pieces of your code became self-contained and self-sufficient and could be easily plugged into other programs or replaced by other components providing the same or improved functionality.

The next logical step was to apply the same concepts to modeling. But this required specific design criteria and rules for building and maintaining models. The features of *decomposability* and *composability* are the most important ones. The decomposability criterion requires that a module should be an independent, stand-alone submodel that can be analyzed separately. On the other hand the composability criterion requires that modules can be put together to represent more complex systems.

Decomposability is mostly attained in the conceptual level, when modules are identified among the variety of processes and variables that describe the system. There is a lot of arbitrariness in choosing the modules. The choice may be driven either by purely logical, physical, ecological considerations about how the system operates, or by quantitative analysis of the whole system, when certain variables and processes are identified as rather independent from the other ones.

The composability of modules is usually treated as a software problem. That aspect is resolved by use of wrappers that enable modules to publish their functions and services using a common high-level interface specification language (the federation approach). The other alternative is the design of model specification formalism that draws on the object-oriented methodology and embeds modules within the context of a specific modeling environment that provides all the software tools essential for simulation development and execution (the specification approach). In both cases as models find themselves in the realm of software developers the gap between the engineering and the research views on models and their performance starts to grow.

From the software engineering viewpoint the exponential growth of computer performance offers unlimited resources for the development of new modeling systems. With the advent of the Internet the vision was to assemble models from building blocks connected over the Web and distributed over a network of computers. New languages and development tools started to appear to facilitate this process, in many cases even faster than their user-communities managed to develop.

On the other hand from the research viewpoint, if a model is to be a useful simplification of reality it should enable a more profound understanding of the system of interest. It is more important as a tool for understanding the processes and systems, than for merely simulating them. In this context there is a more limited demand for the overwhelming complexity of modeling systems. The existing software may remain on the shelf if it does not really help understand the systems. This is probably especially pertinent to models in biology and ecology, where in contrast to physical science or engineering, the models are much more loose and tend to "black-box" much of the underlying complexity due to the difficulty of parameterization and simulation of all the mechanisms from a first-principal basis. They may require a good deal of analysis, calibration, and modifications, before they may be actually used. In this case the focus is on model and module transparency and openness. For research purposes it is much more important to know all the nuts and bolts of a module to use it appropriately. The "plug-and-play" feature that is so much advocated by some software developers becomes of lower priority. In a way it may even be misleading, creating the illusion of simplicity of model construction from prefabricated components, with no real understanding of process, scale, and interaction.

Major requirements for a modular model are as follows:

- *Expandability*. The modules should be designed in such a way that new modules could be easily added and existing modules modified.
- *Scalability*. There should be some clear idea of scale attached to each module. Either a module is designed only for a specific scale, and this scale is clearly identified, or the scale is incapsulated in the module so that it can adjust depending on the scale used in other modules.
- *Transparency*. Modules should be easy to explore and understand. This is a prerequisite of them being reused. Documentation is crucial.

Object-Oriented Modeling

Object orientation is a style of modeling and software engineering. In a general sense, OO takes specific metaphors associated with how physical objects are characterized, and uses these metaphors as a tool for model design, and ultimately programming design and implementation. This physical metaphor has a natural fit within a topic such as ecosystems since the spatial extent of the ecosystem as well as all species residing in that space can be seen as "objects." One develops an "object-oriented model" and then locates a suitable programming language that embodies OO as its primary architecture. The OO approach uses two fundamental ideas: *encapsulation* and *inheritance*. With encapsulation, it is possible to locate computer code and data "within" an object so that

the code and data become addressable and located by first querying the object for its contents. Code within an object is termed a "method" or "behavior" and data is an "attribute." With inheritance, objects become leaf-nodes on a tree whose root represents the most abstract category (or "class") and whose children represent subcategories (or "subclasses").

An example of encapsulation and inheritance can be seen by taking the domain of fish. The shark and stonefish are two types of "fish." One then can define an OO class called "Fish" and two subclasses called "Shark" and "Stonefish." One aspect of building this hierarchy is to take advantage of the process of inheritance, but before discussing that we first need to employ encapsulation in this example. A fish is composed of a skeleton, a central-nervous system, skin, and internal organs, among many other parts. These parts make up a hierarchy that defines encapsulation. It is reasonable to imagine that to obtain attribute information on the type and format of a skeleton, one would get this by going directly to a specific, unique fish—perhaps a specific shark we'll call shark_1032 for lack of a better identifier. Inside of the object shark_1032, we can find all information that this object encapsulates: the size of the object, its skeletal components, and so forth. Now, getting back to the issue of inheritance, it seems clear from the biological taxonomy of fish that both sharks and stonefish both have skeletons. So, we can move the data structure that contains the data for a skeleton and place it in the "Fish" class. The classes Shark and Stonefish inherit all methods and attributes of Fish. Often, this process is termed inheritance of derived classes (Shark, Stonefish) from the base class (Fish).

So, not only does OO design support a new way of thinking about modularity, it supports encapsulation of attributes and methods as well as ways in which these are "moved" (i.e., inherited-by) other components. It is worth closing this section with a description of how OO differs from prior ways of thinking about program design as well as where all of this new thought will lead in the future. Prior to OO, while most real world scenarios were described using words such as "objects" and "attributes," programs were defined in terms of procedures that encapsulated information in the form of simple and complex data. The computer language FORTRAN is a good example of this: the language was composed of functions and subroutines, and data were stored either globally (i.e., for all subroutines to use) or locally (i.e., within that particular subroutine). Procedural approaches such as the one used in FORTRAN are still used in OO (i.e., a method); however, the key difference in the evolution of programming is the introduction of additional encapsulation of objects, either of the physical variety (i.e., "shark_1032") or the conceptual variety (i.e., "budget").

Examples

Flexible modeling system (FMS)

FMS is a software framework developed by the Geophysical Fluid Dynamics Laboratory (GFDL), which is a NOAA climate modeling center at Princeton. It supports the efficient development, construction, execution, and scientific interpretation of atmospheric, oceanic, and climate system models. It is an outgrowth of the MOM family of climatic models, with the latest one—MOM4. The goal is to provide the international climate research community with a repository for robust and well-documented methods to simulate the ocean climate system. Researchers are invited to support the existing modules and provide various modules that are absent from MOM4, yet may enhance the simulation integrity (e.g., a new physical parameterization or new advection scheme) or increase the model's functionality.

FMS comprises the following:

1. A software infrastructure for constructing and running models. This infrastructure includes software to handle parallelization, input, and output, data exchange between various model grids, orchestration of the time stepping, makefiles, and simple sample run scripts. This infrastructure should largely insulate FMS users from machine-specific details.
2. A standardization of the interfaces between various component models.
3. Software for standardizing, coordinating, and improving diagnostic calculations of FMS-based models, and input data preparation for such models. Common preprocessing and postprocessing software are included to the extent that the needed functionality cannot be adequately provided by available third-party software.
4. Contributed component models that are subjected to a rigorous software quality review and improvement process.
5. A standardized technique for version control and dissemination of the software and documentation.

FMS is a software framework. The FMS developers make it clear that their system does not include the determination of model configurations, parameter settings, or the choice of modules. The development of new component models is a scientific concern that is outside of the direct purview of FMS. Nonetheless, infrastructural changes to enable such developments are within the scope of FMS. The collaborative software review process of contributed models is therefore an essential facet of FMS. The quality review and improvement process includes consideration of (A) compliance with FMS interface and documentation standards to ensure portability and interoperability, (B) understandability (clarity and consistency of documentation, comments, interfaces, and code), and (C) general computational efficiency without algorithmic changes.

As a software framework, it has certain clear requirements that contributed code must meet:

1. Clean modular Fortran 90 code that minimally touches other parts of the model
2. Satisfaction of the FMS code specifications outlined in the FMS Developers' Manual
3. Compatibility with the MOM4 test cases
4. Thorough and pedagogical documentation of the module
5. Comments within the code emulating other parts of the model

Object modeling system (OMS)

OMS is the outgrowth of the modular modeling system (MMS) developed by G. Leavesley and his colleagues in USGS. OMS is developed by USDA and is described as a framework for modeling that can be used to develop, support, and apply any dynamic model, but specifically it is focused in the environmental and natural-resource management disciplines. It uses a module library that contains modules for simulating a variety of physical processes. These are primarily water, energy, chemical, and biological processes. A model is created by selectively coupling appropriate modules from the library to create a suitable model for a desired application. When existing modules do not provide appropriate process algorithms, new modules can be developed.

The conceptual framework for OMS has three major components: preprocess, model, and postprocess. A system supervisor, in the form of a window-based graphical user interface (GUI), provides user access to all the components and features of OMS. There are versions that work under UNIX and Windows operating systems. The GUI provides an interactive environment for users to access model-component features, apply selected options, and graphically display simulation and analysis results.

The *preprocess component* includes the tools used to input, analyze, and prepare spatial and time-series data for use in model applications. A goal in the development of the preprocess component is to take advantage of the wide variety of existing data-preparation and analysis tools and to provide the ability to add new tools as they become available. The time-series and other data that are needed to run the model have to be prepared as a single flat ascii file. Procedures are being developed to interface models with a variety of commercial and user-defined data bases, such as SQL type data bases (Oracle and Ingres) and for the HEC-DSS database. NetCDF is another data format that is supported. These are being used in real time applications with the Bureau of Reclamation and the Natural Resources Conservation Service.

The *model component* is the core of the system and includes the tools to selectively link process modules from the module library to build a model and to interact with this model to perform a variety of simulation and analysis tasks. The module library contains a variety of compatible modules for simulating water, energy, and biogeochemical processes. Several modules for a given process may be present, each representing an alternative conceptualization or approach to simulating that process. OMS requires rewriting modules in Java or C# to be then inserted into the system library.

Modules are located in both read-only directories, where tested, documented, and approved code reside, and in user-defined work directories where new modules are being developed. The user selects and links modules from these directories to create a specific model using an interactive, graphical, model-builder tool. Modules are linked by coupling the outputs of user-selected modules to the required inputs of other user-selected modules. Tools are provided to display a module's input requirements and to list all modules available that will satisfy each of these inputs. When the inputs for all modules are satisfied, a model is complete.

When a model is executed, the user is interfaced with the model through a series of pull-down menus in the GUI, which provide the links to a variety of system features. These include the ability to (1) select and edit parameter files and data files, (2) select a number of model execution options such as a basic run, an optimization run, or a sensitivity analysis run, and (3) select a variety of statistical and graphical analyses of simulation output. During a basic run, up to four graphical display windows can be opened to display any of the variables that have been declared in the model modules. As many as 10 variables can be displayed in each window and plotted results can be output in HPGL or PostScript formats either to a digital file or to a printer.

The *postprocess* component provides a number of tools to display and analyze model results, and to pass results to management models or other types of software. Model output can also be directed to user-specific analysis programs using an ascii flat-file format. Some postprocessing capabilities interact directly with the model component. The parameter-optimization and sensitivity-analysis tools are provided to optimize selected model parameters and evaluate the extent to which uncertainty in model parameters affects uncertainty in simulation results. A geographic information system (GIS) interface is developed to provide tools for the analysis and manipulation of spatial data in the preprocess, model, and postprocess components of OMS. Pre- and postprocessing interfaces are being developed as generic interfaces to support a variety of applications, such as the Arc/Info GIS package. Another candidate support package is the Geospatial Library for Environmental Modeling (GEOLEM).

While the GUI is targeted at a broad range of model users, any updates of the system, and additions of new modules or interfaces require good programming skills.

Community surface dynamics modeling system (CSDMS)

Funded by the National Science Foundation, the University of Colorado-Boulder is developing a modular modeling system to advance fundamental earth system science, and repositories for data, models and numerical tools, and educational use. They are leveraging the Department of Energy's Common Component Architecture (CCA) used by the National Laboratory system, and interacting with other efforts, including OpenMI and OMS, to lay out their system. The core of the system is the basic model interface (BMI), a library specification to simplify the coupling of models. In this context an interface is a named set of functions with prescribed function names, argument types, and return types. The BMI functions make the model self-describing and fully controllable by a modeling framework or application. By design, the BMI functions are straightforward to implement in any language and use only simple (universal) data types. While the CSDMS model coupling framework supports C, C++, Fortran, Java, and Python, a BMI can described for any language. CSDMS provides example bindings for BMI in each of the above languages. Also by design, the BMI functions are noninvasive. This means that a BMI-compliant model does not make any calls to other components or tools and is not modified to use any framework-specific data structures. BMI therefore introduces no dependencies into a model and the model can still be used in a stand-alone manner.

BMI specifies:

- Model control functions
- Model information functions
- Time functions
- Variable information functions
- Variable getter and setter functions
- Model grids

In a prefabricated model, the issues of scale consistency are taken care of by the model developers beforehand. Now with the modular approach, the challenge of combining the modules in such a way that they match the complexity of the modeled system and are mutually consistent becomes the task of the library user. Once again this added concern is the price that is paid for the added flexibility and optimality of the resulting models. In theory, we can envision modeling systems that would keep track of the scales and resolutions of the various processes involved, and automatically allow links with only such modules that would match these scales. In practice, with all the complexity and uncertainty associated with ecological and socio-economic systems, it may still be a while until such modeling tools appear. There is always a risk of creating so-called "integronsters" when modules are coupled in a way that may be correct from the formal point of view of units and variables, but makes little sense from the point of view of matching reality. Model transparency is a very important prerequisite of modularity, especially if the modules are to be used in a research context.

Community Modeling

The modular approach is usually a result of collaboration between different groups of modelers as long as they can agree to subscribe to the same set of rules or specifications. At the same time, the modular architecture can significantly empower this kind of community modeling, calling for new members joining the group and contributing their resources in mutually acceptable formats.

MMS, for example, began as a cooperative research effort between the U.S. Geological Survey (USGS) and the University of Colorado's Center for Advanced Decision Support for Water and Environmental Systems (CADSWES). Later on interest in the MMS concepts was expressed by many other national and international agencies and organizations. Agreements established with several of these groups have provided new ideas for system enhancement and the contribution of resources, in terms of money and/or people, to add these enhancements to the system. In addition, these groups continue to contribute their modeling expertise to the system by converting their models to MMS modules and by providing test sites for system evaluation and development. Other partners contributing to the MMS development include the U.S. Bureau of Reclamation (BOR), the Electrical Power Research Institute (EPRI), the TERRA Laboratory, which is a joint Agricultural Research Service (ARS)-Forest Service (FS)-USGS consortium that was formed to facilitate the development of decision support systems for terrestrial ecosystem problems, and others.

The FMS is mostly developed under the auspice of GFDL at NOAA, however its code is provided at GForge (after 2002, before that it was developed as a SourceForge project), which means that it is open for a broad community of programmers and modelers to contribute modules and interfaces.

However in most cases we are still talking about fairly closed communities built around a set of rules and ideas that define the system architecture. The modular systems remain mostly a product of the core group of developers who subscribe to the same more or less limited set of standards and specifications. Apparently a truly flexible and modular system, widely accepted by a range of model development and application organizations, is yet to be developed.

Participatory and Collaborative Modeling

Modular model architecture becomes especially attractive when models are part of a collaborative, participatory modeling process. In this case stakeholders are engaged in the modeling process, and the model itself becomes a tool for deliberations, joint knowledge building, understanding, and decision making. Modularity is very promising in this context because it offers much transparency to the process and allows "on-the-fly" modifications to the overall modeling structure to accommodate the needs and desires of the stakeholder community.

The idea of collaborative modeling is vital to the future success of the modeling enterprise: providing ways in which different scientists can work together, perhaps within a shared space. Some new technologies on the horizon offer possibilities for collaborative modeling. In particular the domain of multiuser games and environments allow an arbitrary number of participants to interact with shared objects. These environments are "object-oriented" by their very nature since "in world," one has an inventory composed of objects and each object contains scripts used to identify behaviors that the object can adopt. However it is still important to realize that modular collaborative modeling goes beyond the software challenges. In addition to new software tools it requires acceptance of new research paradigms promoting open source and open model development, data sharing, and participatory modeling efforts.

Parameterization☆

Alexey Voinov, University of Technology Sydney, Sydney, NSW, Australia

Glossary

Boundary conditions These describe the spatial and temporal boundaries of a system. For a spatially homogeneous system we have only *initial conditions*, that describe the state of the variables at time $t = 0$, when we start the model. For spatially distributed systems we may need to define the conditions along the boundary, as well as the geometry of the boundary itself. These are known as *boundary conditions*.

Constants or parameters in a narrow sense These are measured or calibrated quantities that describe the rates of processes in a process-based model. In empirical models these are the constants that are statistically derived based on empirical observations. We may want to distinguish between real constants, such as gravity, g, and, say, half-saturation coefficient, K, in the Michaelis-Menten function. While both of them take on constant values in a particular model run, g will be always the same from one run to another, but K may change quite substantially while we calibrate the model. Even if K comes from observations, it will normally be measured with certain error, so the exact value will not be really known.

Control functions Control functions are also parameters, except that they are allowed to change to see how their change affects systems dynamics. It is like tuning the knob on a radio set. At every time the knob is dialed to a certain position, but you know that it may vary and will result in different performance of the system.

Forcing functions These are parameters that describe the effect of the outside world upon the system. These may change in time or space, but they do not respond to changes within the system. They are external to it, driven by processes in the higher hierarchical levels. Climatic conditions, rainfall, temperature certainly affect the growth of tomatoes in the garden, but the tomatoes hardly affect the temperature or the rainfall patterns. If we build a model of tomato growth, the temperature will be a forcing function.

Parameterization is the process of finding the right parameter values for a model. In process based modeling it is assumed that parameters have some meaning, some physical or ecological sense. This also means that for most of such parameters some maximal and minimal values can be produced, limiting the size of the space when choosing parameter values. Empirical models are certainly also driven by parameters, but here parameters are simply values that are calibrated and cannot be measured in experiments. There are also no restrictions on the domains from which the parameter values can be chosen.

Note that in some texts parameters will be assumed only in the narrow sense of coefficients that may sometimes change, like the growth rate or half-saturation values. However this may be somewhat confusing, since forcing functions are also such parameters if they are fixed. Suppose we want to run a model with temperature held constant and equal to the mean over a certain period of time, say the 6 months of the growth season for a crop. Then suppose later on we want to feed into the model the actual data that we have measured for temperature. So now it is no longer a constant but changes every day according to the recorded time series. Does this mean that temperature will no longer be a parameter? For any given moment it will still be a constant. It will only change from time to time according to the data available. It would make sense to still treat it as a parameter, except now it will be no longer constant but will change accordingly.

Suppose now that we approximate the course of temperatures by a sine function with some constants that control the amplitude and the period. Now temperature will no longer be a parameter. Instead temperature will be an intermediate variable, while we will have two new parameters in the sine function that specify temperature—one parameter ($B = 4$) will make the period equal to 6 months, the other parameter (A) will define the amplitude and make the temperature change from a minimal value (0) to the maximal value (40, if $A = 20$) and back over this period of time, like in the function:

$$\text{Temperature} = A^{*}\text{Sin}\,(t^{*}B^{*}\pi/365 + 3^{*}\pi/2) + A.$$

Here t is time, π—is a constant $\pi = 3.14$, A, and B are parameters. If we change B, $B = 2$, then the period will change from 6 to 12 months.

For process based models, there may be a number of ways to determine model parameters, including the following.

1. Measurements in situ are probably the best way since they define the value of exactly what is assumed in the model. However such measurements are the most labor and cost intensive, and they also come with large margins of error. Besides in many cases such measurements may be risky or not be possible at all, if a parameter represents some aggregated value or an extreme

 doi:10.1016/B978-0-12-409548-9.11120-0

condition, that may not occur in reality (say, the maximal temperature for a population to tolerate—it may differ from one organism to another, and such conditions may be hard to find in reality).

2. Experiments in lab (in vitro) are usually performed when in situ experiments are impossible. Say we take an organism and expose it to high temperatures to find out the limits of its tolerance. We can create such conditions artificially in a lab, but we cannot change the temperature for the whole ecosystem.
3. Values from previous studies found from literature, web searches or personal communications. If data are available for similar systems it certainly makes sense to use them. However always keep in mind that there are no two identical ecosystems, so most likely there will be some error in the parameters borrowed from another case study.
4. Calibration (ref to the entry on calibration and validation). When we know what the model output should look like, we can always tweak some of the parameters to make the model perform best. For empirical models this and literature search are the only ways to identify parameter values.
5. Basic laws, say conservation principles and therefore mass and energy balances
6. Allometric principles, stoichiometry, and other chemical, physical etc. properties. Basic and derived laws may help establish relationships between parameters, and therefore identify at least some of them based on the other ones already measured or estimated.

Note that in all cases there is a considerable level of uncertainty present in the values assigned to various model parameters. Further testing and tedious analysis of the model is the only way to decrease the error margin and deal with this uncertainty.

With proliferation of various sensors and automatic monitoring, we are increasingly entering the era of Big Data when more information about the system can be inferred by only looking at its overall performance paying less attention to the system structure, the processes that drive the system, and the parameters that control those processes. It is yet to be seen if this kind of modeling will replace the more theory rooted process based models that have been previously used in population ecology and ecosystem studies.

Sensitivity, Calibration, Validation, Verification☆

Alexey Voinov, University of Technology Sydney, Ultimo, NSW, Australia

Glossary

Calibration Changing model parameters or functions in attempt to match a certain existing data set. Calibration can be conducted as a trial-and-error process by manually changing certain model parts, or it can be formulated as an optimization task, when the computer will minimize the difference between data and model output by adjusting model parameters.

Sensitivity analysis Analyzing how the model reacts to changes in model parameters. The model output may change quite considerably when modifying certain parameters, while other parameters may have very little impact on it. This helps understand which parameters and processes are most important and deserve more attention when calibrating the model.

Validation Comparing model output to some independent data set, which has not been used previously for model calibration.

Verification Carefully checking the model for internal inconsistencies, errors and bugs.

Introduction

Once the model is formulated and formalized, some rigorous model testing is in order. The major steps that are usually assumed are called sensitivity analysis, calibration, validation and verification. While the first two can be well formalized and are quite standard in any modeling effort, the validation and verification stages are designed to assess the level of "truth" that the model delivers, and therefore tend to be more vague and controversial. There has been a good deal of discussion about what a good model is, and whether it is feasible at all to claim that the model is true in any sense. One can argue that for an open system, where conditions constantly change it is not even possible to design a model that would represent reality, since the reality is constantly changing with additional factors brought in all the time. The model then can only represent the situation that it has been designed for, and is very much limited by the conditions and factors that were included.

Nevertheless some model testing is definitely in order and some models are still better than others. In spite of much leeway in the definitions of what a good model is, the model testing and analysis is an important stage, which can tell us much about the system, even if it does not really tell us how "true" the model is.

Sensitivity

If no analytical analysis is possible, we have to turn to numerical methods. The numerical solution of the model requires all parameters to take on certain values, and as a result is dependent on parameters that have been specified. These include coefficients, or constants, initial conditions, forcing function, and control parameters. Some parameters do not matter much. We can vary them quite significantly, but will not see any large changes in the model dynamics. However other parameters may have a very significant effect on the model performance. Even small changes in their values result in dramatically different solutions.

Analyzing model performance under various conditions is called *sensitivity analysis*. If we start modifying a parameter and keep rerunning the model, instead of a single trajectory, we will be generating a bunch of trajectories (**Fig. 1**). Similarly we can start changing the initial conditions or even some of the formalizations in the process descriptions. By comparing the model output we get an idea of the most essential parameters or factors in the model. We will also get a better feeling of the role of individual parameters and processes in how the model output is formed, what parameters affect what variables, and in which ranges the parameters may be allowed to vary. This is very important because in contrast to an analytical solution, where we could find an equation relating model output to the input parameters, with numerical models we do not have any other way to learn what is the connection between the various parameters and the model output, except than rerunning the model.

Eventually when we get sufficient confidence in the model performance and collect evidence of the model being actually adequate to the system that it represents, we can further sensitivity analysis to the point, when we make conclusions about the sensitivity of the original system to certain processes and factors. It will be then those processes that should get the most attention in experimental research, and which may become important management tools if we intend to modify the system behavior to match certain criteria.

☆*Change History*: March 2018. Alexey Voinov introduced small edits in the text of the article including citations.

This is an update of A.A. Voinov, Sensitivity, Calibration, Validation, Verification, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3221–3227.

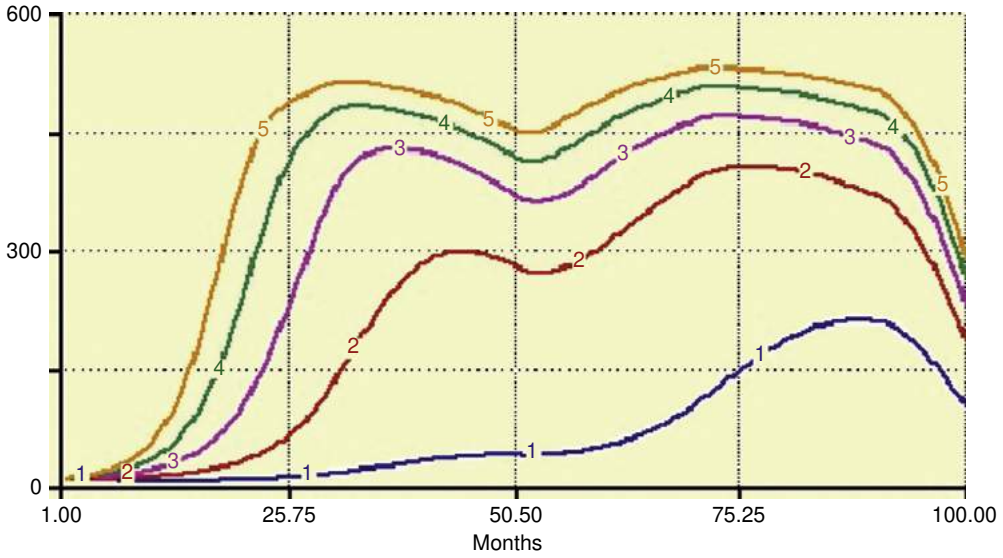

Fig. 1 Analysis of sensitivity in a simple population model.

A full sensitivity analysis of a model is a difficult task, since changing parameters one by one and in combinations may produce entirely different results. But even a partial analysis that will look at some parameters is certainly better than nothing. It will also be of great help for the next step of model analysis, which is calibration.

Calibration

The next thing you will want to do analyzing the model is to compare its output to the other data that is available about the system. In many cases we may have better data about the dependent variables in the model than data about the independent variables or parameters. For instance, USGS provides quite extensive data sets for water flows measured over a network of river gages. For a stream hydrology model that is to produce river flow dynamics, we will most likely have quite good information about the flows, but poor data about the hydrologic coefficients, such as infiltration, transpiration and evaporation rates, etc. By solving an inverse problem we will be determining the values of parameters such that the model output will be as close as possible to the observed data. This process of model refinement in attempt to match a certain existing data set is called *model calibration*. We compare the model output to the data points, and start changing the model parameters or structure in order to get a fit as close as possible.

Sensitivity analysis may have already informed us what are the parameters that need be modified to produce a certain change in model trajectories. Now we actually change them in such a way that the trajectory of the model output matches the data "close enough". How close?—It depends upon the level of confidence in the data we have and upon the goals of the study. It also depends on the model that we built. Sometimes we find very difficult to produce the change in the model output that is needed to get the trajectories closer to the data points. Sometimes it is simply impossible, and we have to find other ways to fix the model, either digging into its structure, or realizing that we have misinterpreted something in the conceptual model, or the time or space scales. Modeling is an iterative process and it is perfectly fine to go back and reevaluate our assumptions and formalizations.

Note that the data set used for calibration, in a way, is also a model of the process observed. The data are also a simplification of the real process and they may also contain errors, they are never perfect, and besides they have been collected with a certain goal in mind, which does not necessarily has to match the goal of the newly built numerical model. We may call these monitoring results an experimental model or a *data model*. In this process of calibration we are actually comparing two models, and modifying one of them (simulation) to better match the other one (data).

When comparing models, it makes sense to think of a measure of their closeness, or a measure of the fit of the simulation model to the data model. This comparison is important for both calibration and further testing of the model (validation, verification). In all these analyses we would want to see how far the model results deviate from the other information we have about the system (both qualitative and quantitative). We may call this measure the *error model*. There may be very different ways to represent this error, but they all have in common one feature, which is that they represent the distance between two models, in this case, the data model and the formal model. The very simplest error model is "eyeballing", or visual comparison. That is when you simply look at the graphs and decide whether they are close enough or not.

However, this may become difficult as we get closer to the target, or when the graph is closer in one time range for one set of parameters, and closer in a different time range for another set of parameters. In those cases visual comparisons can fail. Mathematical formulas can then become useful. One simple formula for the error model is:

Table 1 Available variable tests in the MPI software package

Test	*Description*
BOUNDS	Percentage of points falling into a reference interval
WBOUNDS	Like BOUNDS, weighted according to distance of outliers from nearest limit of interval
CINT	Proportion of points falling into 95% confidence interval of reference data
WCINT	Like CINT, weighted according to distance of outliers
THEIL	Coefficient of inequality between paired data
DBK	Result of simultaneous test of slope = 1, intercept = 0 in linear regression of observed vs. simulated data
STEADY	Steady-state, done as piecewise linear regression and test of slopes
INCREASE	Monotonic increase, done as piecewise linear regression and test of slopes
DECREASE	Monotonic decrease, done as piecewise linear regression and test of slopes
TREND	Known trend, intended as slope of linear regression line
FREQ	Compares the structure of autocorrelation of simulated and observed data to identify common frequencies of oscillation, or looks for specified periods in the simulated data
ERRCOMP	Concordance between the simulated data error composition and specified admissible percentages of mean, variance, and random error

$$E = \sum_{i=1}^{n} \frac{(x_i - y_i)^2}{y_i^2}$$

where y_i are the data points, and x_i are the values in the model output that correspond in time or space to the data points.

Very often the metric used to compare the models is the Pearson moment product correlation coefficient,

$$r = \frac{n \sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i}{\sqrt{\left[n \sum_{i=1}^{n} x_i^2 - \left(\sum_{i=1}^{n} x_i\right)^2\right]\left[n \sum_{i=1}^{n} y_i^2 - \left(\sum_{i=1}^{n} y_i\right)^2\right]}}$$

or the R^2 *value*, which is equal to r^2.

There may be many other ways to estimate the error model. For example a Model Performance Index was proposed that incorporates some 12 metrics to estimate the deviation between the two time series (**Table 1**).

There are many other statistical tools that are available, say, in Excel, in R or in other statistical software packages that may be further used for a refinement of these comparisons.

There is a difference in calibrating empirical and process based models. In empirical models, we entirely rely on the information that we have in the data sets. We come up with some type of equation and then quite mechanically adjust the parameters in attempt to reproduce the data as well as possible. All the information we know about the system is in the data, and the parameters usually can take any values as long as the error model is minimal.

In process based models calibration is different since we are restricted by the ecological, physical or chemical meaning of the parameters that we change. Besides there are usually some estimates for the size of the parameters: they are rarely precisely measured but at least the order of magnitude or a range is usually known. Moreover there are other factors that may play a role, such as confidence in the available estimates for the parameter; sensitivity of the model to a parameter, etc. These are important considerations in the calibration process.

At the bottom of any calibration we have an optimization problem: we seek a minimum for the error model. In most cases, we have certain parameters which values are known and others that are only estimated within a certain domain of change. We call the latter ones—"free" parameters. They are the ones to change in the model in order to minimize the value of the error. To perform optimization we first formulate a *goal function* (also called *objective function*). Then we try to make this function as large or as little as we can by changing different parameters that are involved. In case of calibration the goal function is the error model $\mathbf{E = f(P, C, R)}$, described as a function of the parameter vector **P**, the vector of initial conditions **C** and the vector of restrictions **R**. We then try to find a minimum:

$$\mathbf{\min E}$$

over the space of the free parameters **P** and initial conditions **C**, making sure that the restrictions **R** (such as a requirement that all state variables are positive), hold. There is rarely a model that would allow this task to be solved analytically. It is usually a numerical procedure that requires certain fairly complicated software to be employed.

There are different ways to solve this problem. One approach is to do it manually with the so-called *trial and error* method or *educated guess* approach. The model is run, then a parameter is changed, then the model is rerun, output is compared, the same or another parameter is changed, and so on. It may seem quite tiresome and boring, but actually this process is extremely useful to understand how the system works. Playing with the parameters you learn how they affect output (as in the sensitivity analysis stage), but you also understand the synergetic effects that parameters may have. In some cases you get quite unexpected behavior, and it takes some thought and analysis to explain yourself how and why the specific change in parameters had this effect. If you

cannot find any reasonable explanation, chances are that there is a bug in the model. A closer look at the equations may solve the problem: something may have been missed, or entered with a wrong sign, or some effect was not accounted for.

In addition to the educated guess approach, there are also formal mathematical methods that are available for calibration. They are usually based on the solution of the so-called optimization problem.

Some modeling systems have the functionality to solve the optimization problem and do the curve fitting for models. One such package is *Madonna*. One big advantage of Madonna is that it can also take Stella equations almost as is and run them under its own shell. Madonna also has a nice graphic user interface of its own. So you may as well start putting your model together directly in Madonna, if you expect some optimization to be needed.

The calibration problem may not have a unique solution. There may be several parameter vectors **P** that deliver the same or almost the same minima to the optimization task. In that case it may be unclear what parameters to choose for the model. Other considerations and restrictions may be used to make the decision.

If we have done our best finding the values for all the parameters in the simulation model and yet still the error is inappropriately large, this means that something is wrong in one of the models that we are comparing. Either the conceptual model needs to be revised (the structure changed or the equations modified), or the chosen scales were incorrect and we need to reconsider the spatial or temporal resolution. Alternatively, the data is wrong, which also happens quite often and cannot be dismissed.

To conclude, there are different ways to describe systems by means of models. There are different models that may be built. *The process of adjustment of one model to match the output from another model is called calibration*. This is probably the most general definition. In most cases we would speak of calibration as the process of fitting the model output to the available data points or "curve fitting". In this case it is the data model that is used to calibrate the mathematical model.

Note that there is hardly any reason to always give preference to the data model. The uncertainty in the data model may be as high as the uncertainty in the simulation model. The mathematical model may in fact cover areas that are not yet presented in data at all. However in most cases we will have data models precede mathematical models, and, at least initially, assume that the data models convey our knowledge about the system.

Empirical models are entirely based on data models, they may be considered as "extensions" of the data models. They attempt to generalize the data available and present them in a different form. The process-based models, in addition to knowledge about the modeled system, may also employ information about similar systems studied elsewhere or they may incorporate theoretical knowledge about processes involved. In a way these process-based models can be even better than the data available for the particular system that is modeled. Therefore we may hope that process based models will be performing better outside of the data domains that were used for their calibration. So perhaps it will be easier to apply process-based models to other similar systems, than empirical models, which would require a whole new calibration effort.

Testing

Now we have a simulation model that represents the data set close enough. Does this mean that we have a reliable model of the system, which we can use for forecast or management? Did we really capture the essence of the system behavior, do we really understand how the system works or we have simply tweaked a set of parameters to produce the needed output? Are we representing the system and the processes in it, or, as in empirical models, we only see an artifact of the data set used?

We build process-based models with the presumption that they describe the guts of the system and therefore are general enough to be reapplied in different conditions, since they actually describe how the system works. That would be indeed true if all the parameters in the process formulations could be measured in experiment and then simply substituted into the model. However usually this data is nonexistent or imprecise for all of the parameters.

The solution we found was to approximate the parameter values based on the data we had about the dynamics of state variables, or flows. That was the model calibration procedure. We were solving an inverse problem: finding the parameters based on the dynamics of the unknowns. This would be fine if we could really solve that problem and find the exact values for the parameters. However, in most cases that is also impossible, and, instead, we are finding approximate solutions that come from model fitting. But then how is this different from the fitting we do when we deal with empirical models? In that case, we also had a curve equation with unknown coefficients, which we determined empirically by finding the best combination of parameters that made the model output as close as possible to the data.

The only difference is that instead of some kind of generic equation in the empirical models (say, a polynomial of some form), in process-based models we have particular equations that have some ecological meaning. These equations that display certain behavior by themselves, no matter what parameters are inserted. A polynomial can generate pretty much arbitrary dynamics as long as the right coefficients are chosen. But, say, a classic predator–prey system will always produce a certain type of dynamics, no matter what coefficients we insert. So we may conclude that to a large extent, we are building a good model as long as we chose the right dynamic equations to describe our system.

On top of the basic dynamic equations we overlay the many other descriptions for the processes that need to be included in the model. These may be the limiting factors, describing the modifying effect of temperature, light or other external conditions. There may be some other details that we wish to add to the system. However if these processes are not studied in an experiment, and if the related coefficients are not measured, their role in the model is not any different than that of the coefficients that we have in an

empirical model. In both cases we figure out their values based on a time-series of model output, in both cases the values are approximate, and uncertain. They are only as good as they are the best ones found: we can never be sure that a better parameter set does not exist.

So the bottom line is that there is a good deal of empiricism in most process based models, and the more parameters we have estimated in the calibration process, the more empiricism is involved, the less applicable the model will be in situations outside the existing data range. How can we make sure that we have really captured the essence of the system dynamics, and can reproduce the system behavior beyond the domain that we have already studied?

To answer all these questions, the model needs to undergo a process of vigorous testing. There is and probably will never be a definite procedure for model testing and comparisons. The obvious reason is that models are built for various purposes; their goals may be very different. Moreover these goals may easily change when the project is already underway. There is no reason why goal setting should be left out of the iterative modeling process. As we start generating new knowledge and understanding with a model, its goals may very well modify. We may start asking new questions and will need to modify the model, even while it has not been yet brought to perfection.

Besides, most of the ecological systems are open, which makes their modeling similar to shooting at a moving target. While we study the system and built a model of it, it already evolves. It evolves even more when we start administering control, when we try to manage the ecosystem. As a result models can very well become obsolete even before they are used to produce results. We are modeling the system as it was until a year ago, but during the last year because of some external conditions (say, global climate change) the system has already evolved and the model is no longer relevant.

Nevertheless there are several procedures of model testing that became part of good modeling practice and should be certainly encouraged. Ironically in various applications you may find the names for these processes used interchangeably, which can only add to the confusion. Model testing is probably a more neutral and general term.

One way to test the model is to compare its output with some independent data set, which has not been used previously for model calibration. This is important to make sure that the model output is not an artifact of the model formalization, and that the processes in the model indeed represent reality, and are not just empirical constructs based on the calibrated parameters. This process is called validation. There is no agreed procedure of model validation (verification in some texts), especially when models become complex and difficult to parameterize and analyze.

One way is to run the model for spatial or temporal domains that were not used for building the model. We can run the model for places and time periods, for which we either did not have data, or deliberately set that data aside and have not used it for model calibration. We may have the luxury to wait until the new data sets are acquired, making our predictions first and then comparing them to what we measure. Or we set aside a part of the data set that is already available and pretend that we do not know it while constructing the model. Then, when the model is built and calibrated based on the remaining data, we will want to bring the other portion of data into light and see if we have equally well matched this other data set. This time we do not do any calibration, we do not tweak model parameters or functions, we only compare and estimate the error model. If the error is small, we may conclude that the model is good, and may have certain confidence in applying the model for future predictions.

In reality, unfortunately, it rarely happens like this. First of all, the temptation is too strong to use all the data available when building the model. As a result we usually do not have sufficient data sets for a true validation. Besides, even when the validation is undertaken, in most cases it proves to be less accurate than the calibration and therefore the researcher is likely to jump into model modifications and improvements to make the validation result look better. However this immediately defeats the purpose of validation. Once you started using the validation data set for model adjustments you have abandoned your validation attempts and went back to further calibration.

Actually this became quite standard in many on-going modeling projects and is called data assimilation. Special procedures are designed to constantly update and improve models based on the incoming flow of new experimental data. This becomes crucial for complex open system (which is most usually the case for ecological and socioeconomic systems), which is always changing and evolving. As a result the data set considered for calibration and collected during one period may not be representing quite the same system as the one that produced the other data set that is intended for validation. We might be calibrating a model of one system, and then trying to validate the same model but for a different system.

Another important step in model analysis is *verification*. A model is verified when it is scrupulously checked for all sort of internal inconsistencies, errors and bugs. These can be in the equations chosen, in the units used, or in links and connections. These can be simply programming bugs in the code that is used to solve the model on the computer. They may be conceptual, when wrong data sets are used to drive the model. Once again, there is hardly a prescribed method to weed them out. Just check and recheck. Run the model and rerun it. Test it and test again.

One efficient method of model testing is to run the model with extreme values of forcing functions and parameters. There are always certain ranges where the forcing functions can vary. Suppose we are talking about temperature. Make the temperature as high as it can get in this system, or as low as it can be. See what happens to the model. Will it still perform reasonably well? Will the output stay within certain plausible values? Or will the model crash? If so, try figure out why. Is it something you can explain? If yes, then probably the model can be still salvaged and you may simply need to remember that the forcing function should stay within certain allowed limits. If the behavior cannot be explained, keep digging—most likely there is something wrong.

Another important check is based on first principles, such as mass and energy conservation. Make sure that there is a mass balance in the model, that nothing gets created from nowhere and nothing is lost.

The bottom line of all this testing is that there is no perfect model. It is hardly possible to get a perfect calibration, and the validation results will likely be even worse. No matter how long you spend debugging the model and the code there will always be another bug, another imperfection. Does this mean that this is all futile? By no means! As long as you get new understanding of the system, as long as the model helps communicate understanding to others and helps manage and control the system—you are on the right path, and the efforts will be fruitful. *Any model that is useful—is a good model.*

Spatial Models and Geographic Information Systems☆

Arnab Banerjee and Santanu Ray, Visva-Bharati University, Santiniketan, India

Introduction

Models are representation of investigated objects for purposes of description, explanation, simulation, or forecast. Spatial models are complicated by the fact that they include information about position, possible topological connections and attributes of the recorded objects. Spatial modeling of ecological phenomena has always been an important issue in ecology. The mutual influence of patterns and processes of ecosystems are manifested in the spatial distribution of ecosystems at different scales, which has long been the main component of spatial models. A spatial model is a mechanism for assembling spatial knowledge from a range of sources and presenting conclusion based on that knowledge in readily used form. Spatial modeling is the process of constructing a model incorporating space, which can be identified into areal interpolation and surface modeling.

Areal interpolation is the transformation of data between different sets of areal units. The set of zones, for which data are available, are termed source zones. The second set of zones, for which estimates need to be derived, are termed target zones. The third set of zones, for which auxiliary information can be incorporated in the interpolation process, are termed control zones. The methods of areal interpolation based on alternative hypotheses include radially symmetric kernel functions, maximally smooth estimation, piecewise approximation, uniform target-zone densities and uniform control-zone densities.

Surface modeling is the process of numerically representing a planetary surface (Earth or other planets) by grids with known coordinates in an arbitrary coordinate system. Surface modeling is aimed at formulating an ecological object in a grid system, in which each grid cell contains an estimate of the ecological object that is representative for that particular location. Representing data in grid form have the following advantages: (1) regular grid can be easily reaggregated to any areal arrangement required; (2) producing ecological data in grid form is one way of ensuring compatibility between heterogeneous data sets; (3) data in grid form make multiresolution and multisource information fusion easier; and (4) converting data into grid form can provide a way of avoiding some of the problems imposed by artificial political boundaries.

Spatial modeling occurred in the 1960s with general availability of computers, but the tools offered by current geographical information systems (GIS) have appeared to be of little interest for spatial modeling because GIS has been restricted to producing cartographic products rather than spatial models.

☆*Change History*: April 2018. A Banerjee and S Ray updated this article. Figs. 1–4 are newly added, sections "Introduction, Geographical Information System, Historical Development of GIS, Direct Modeling Problem, GIS Data Type, Summary (highly modified)"were updated and "Traditional Approaches, Some Recent Applications of Spatial Modeling (and corresponding subsections), Further Reading" were new sections.

Geographical Information System

There are many definitions of GIS. For instance, GIS can be defined as a powerful set of tools for collecting, storing, retrieving at will, transforming and displaying spatial data from the real world (Burrough, 1986); as an information technology storing, analyzing, and displaying both spatial and nonspatial data (Parker, 1988); a set of computer-based systems for managing geographic data and using them to solve spatial problems (Lo and Yeung, 2003) and also GIS can be defined as a tool for performing operations on geographic data that are too tedious or expensive or inaccurate if performed by hand (Longley et al., 2011). In general, GIS integrates hardware and software to capture, organize, and display geographically referenced data thus allowing for inquiring, interpreting, and imagining the data through visualization that helps in understanding relationships or patterns in the form of maps, charts, and reports.

Historical Development of GIS

The origin of GIS as a computer-dependent application can be traced back to the 1940s and the 1950s when successful data storage, management and processing techniques were successfully implemented. In the early 1960s, R. F. Tomlinson conceptualized the first GIS—Canada GIS—to address the needs of land and resource information management of the federal government of Canada, which became operational much later in 1971. In 1963, H. H. Fisher took advantage of computational techniques to make simple maps by printing statistical values on a grid of plain paper including a set of modules for analyzing data, manipulating them to produce choropleth or isoline interpolations, with the results displayed in many ways using overprinting of line-printer characters to produce suitable gray scales. In spite of the adaptation to advanced computer techniques in 1960s, the cartographers were mostly limited to automatic drafting of maps; fundamental attitudes of traditional cartography gained no evident benefits from the new computer technology.

In the early 1970s, the Swedish Land Data Bank was developed to automate land and property registration; the Local Authority Management Information System and the Joint Information System were developed in Britain and used by local governments to control and monitor land use. By the late 1970s, there had been considerable investments in the development and application of computer-assisted cartography, with hundreds of new computer programs and systems being developed for various mapping applications. Parallel developments in automated data capture, data analysis and presentation in related fields have resulted in emergence of general purpose GIS with the primary focus being map data processing while spatial analysis functionality was rather limited.

Topological principles in cartography (Corbett, 1979)—a milestone of GIS development—by which geographical data can be stored in a simple structure that is capable of representing structure (what they are), position (where they are) and spatial association with one another. In 1982, the release of vector-based ArcInfo GIS software package by Environmental Systems Research Institute, allowed storage of graphic data in topological structure and attributing the same in tabular structure. By the late 1980s, many other GIS software packages were developed by using a similar data model.

In the 1990s, with advances in operating systems, computer graphics technology, data management, increased computer–human interaction and improved graphical user interface design, GIS became multiplatform applications that could be utilized on different classes of computers as stand-alone applications and as time-sharing systems. Development of Web GIS has allowed expensive data and software to be shared. Standardization in interfaces between data programs and other programs has made it much easier to provide the functionality for handling large amounts of data. GIS has been considerably developed in many aspects. Much knowledge on how to set up computer mapping and GIS projects efficiently has emerged. The basic functionality required for handling spatial data has been widely accepted. Although these advances have promoted the considerable development of GIS and the development of GIS has entered the "age of geographical information infrastructure," the basic spatial models used in modern GIS are little different from those of 20 years ago.

Shifting of focus towards emerging conservation paradigms from single species to multispecies approaches all focus on applications of interdisciplinary methodologies including the incorporation of GIS in ecological modeling. Various applications of GIS technologies have shifted the traditional approaches and uses of this to a newer horizon.

The restrictive effects of space–time constraints (Kwan, 2001) on accessibility research originally proposed by (Hägerstraand, 1970) was later incorporated as space–time prisms (Lenntorp, 1976) mapping onto geographical space (Burns, 1979; Villoria, 1989; Dijst and Vidakovic, 2000). Development of space–time accessibility measures utilizing the GIS-based computational strategies and techniques (Kim and Kwan, 2003; Kwan, 1999, 2010; Miller, 2010) and subsequently the development of action space models and detailed examinations of spatial variation of opportunity based choice (Dijst et al., 2002) are two examples of such applications of temporal-spatial framework.

Spatial autocorrelation in ecology is not infrequent and it serves as the base assumption for a multitude of ecological theories and models (Legendre and Fortin, 1989) describing the positive autocorrelation in species abundance. Two different approaches incorporate space into ecological analysis (Legendre, 1993) which are: "raw data approach" that describe the relation of a species with its environment (partial regression—univariate when considering individual species) or "constrained ordination" for community analysis (multivariate case) (Borcard et al., 1992; Legendre and Legendre, 1998). A combination of ecological distances between sampled data with spatial distribution (obtained through GIS technique interpolation) can be represented by a "matrix approach" that combines the distribution of species with its environment and geographical distances and boundaries.

The crucial role of remote sensing in mapping the variations of areal extent and spatial patterns of mangroves has been observed in the late 1990s and also in early 2000s (Heumann, 2011) allowing for detailed characterization of the same in order to understand and contribute to proper management strategies. In spite of the vast applicability of remote sensing, it had been—in this case—primarily targeted to map the areal extent and pattern change at a local scale. The potential for improved accuracy of classification of land cover as well as characterization of various aspects including leaf/foliage area, canopy structure, species composition and abundance were shown through wide scale applications of GIS in the late 2000s and early 2010s owing to the rapid development of newer sensors and systems (Gillespie et al., 2008; Wooster, 2007).

New systems like LiDAR systems (IcsSAT/GLAS), satellite sensors like VHR systems (very high resolution), for example, Quickbird, IKONOS, GeoEye-1, Worldview-2, ALSO PRISM, and synthetic aperture radar satellites (ALOS PALSAR, ASAR ENVISAT, and also Radarsar Satellites), hyper-spectral airborne visible/infrared imaging spectrometer (AVRIS), TOPSAR and AIRSAR (polymeric SAR) as well as various commercial wave-form LiDAR systems, all have contributed to recent developments of remote sensing technologies and applications. With the potential capability of improved accuracy of classification, species detection and estimation of foliage arrangement (canopy height, leaf coverage, etc.) these newer techniques have contributed to the rapid development in the field of GIS and its application in ecology (Heumann, 2011).

Recent advances in remote sensing techniques and sensor technologies and improved geographical imaging techniques have demonstrated plausible and feasible accurate classification techniques that were previously unavailable with only the handful of traditional techniques at the disposal of the researchers. Newer improved data types can now be gathered with these modern approaches and they can be overlapped with some of the traditional findings in order to facilitate exploitation of various new alleys that were otherwise previously limited to simple cartographical applications. While such data fusion has been achieved in relation to mangrove ecology (Wang and Sousa, 2009) and some more recent implementation to map spatial patterns of carbon metabolism and its relation to landscape indices (FRAC—fractional dimensional index) combining them with mathematical statistics (Xia et al., 2017), these paths can be ventured into more deeply to gain further insight into additional elaborate uses of GIS and relating that to answer an even broader spectrum of ecological problems. In spite of the advances and increase in free access to imagery and data storage, over the recent years, intensive involvement, training and accessibility to required technological infrastructure is required to enable this technology to be used and developed further to address more specific and intricate ecological questions.

Error Problem of GIS

Errors are ubiquitous in current GIS. The word, error, can be used in a variety of senses. Unwin, 1995 defined it as the difference between reality and representation of the reality. Defined in this way, error is related to accuracy. Accuracy is the degree with the values or descriptions of the real-world features that they represent.

When field data are incorporated into a GIS, a common mistake is to assume that the error can be simply equated to the measurement error at the sampled points and quoted as a simple global statement, which does not address the spatial variation. Monckton, 1994 criticized that the spatially uniform error assumption was untenable. A complete specification of the error should include not only the spatial field of its mean but also its variance and spatial dependence. The problems of error and uncertainty in field models have been proved to be much hard-addressed in principle using well-developed theory.

The process of integrating remote sensing data into a GIS usually includes five steps, viz. data acquisition, data processing, data analysis, error assessment, and final product presentation. Error may accumulate throughout the process in an additive or multiplicative fashion. Data acquisition error may be from geometric aspects, sensor system, platforms, ground control, and/or scene considerations. Data processing error may be caused by geometric rectification such as resampling and data conversion such as from raster to vector format and from vector to raster format. Data analysis error may be from classification systems, data generalization, and quantitative analysis of relationships between data variables and the subsequent inferences that may be developed. Error of error assessment might be mainly produced by expression of locational accuracy, discrete multivariate and reporting standards. Final product presentation error includes attribute error and spatial error that may be introduced through the use of base maps with different scales, different national horizontal datum in the source materials and different minimum mapping units which are then resampled to a final minimum mapping unit.

The errors can be distinguished into inherent ones and operational ones. The inherent error is the error present in source documents. The operational error is accumulated through data capture and manipulation functions of a GIS. The inherent errors include errors from sampling and attribute errors in data source. Operational errors include positional errors and identification errors. Positional errors stem from inaccuracies in the horizontal placement of boundaries and identification errors occur when there is a mislabeling of areas on thematic maps. Spatial models as simulations of the real world often simplify the complexity of the real world and are therefore obviously open to errors. The inherent errors can be propagated through the simulation process and become manifest in the final products. Although there are many types and sources of error and uncertainty in geographical data and their processing, the problem is not simply technical and it arises from an evident inability of GIS. Integration of data from different sources and indifferent formats, at different original scales, plus inherent errors, can yield a product of questionable accuracy. Manipulation of thematic overlays within GIS to derive model variables are susceptible to inherent and operational errors, from which results may have such error margins as to be useless for specific applications. Any decision based on such products would thus be flawed.

Multiscale Problem

Ecosystems are constantly changing, not only over space but also in time. The understanding of spatial and temporal processes and their interrelations is central to the understanding of the complex behavior of real ecosystems. Relevant processes might span over several temporal and spatial scales. Therefore, tools for modeling such processes should also be able to operate on diverse spatial and temporal scales.

The issues of ecological modeling are involved at various scales. At each scale, a set of spatially explicit indicators needs to be identified to characterize the extent, pressures, condition, trends and scenarios of ecosystem types and land-use patterns as well as the underlying structural features of ecosystems. For any size patch of the Earth's surface that we choose to define as an ecosystem, there will be a set of factors external to the ecosystem that influence how it functions and in turn, there will be flows of material and energy that extend beyond the ecosystem. The larger the scale, the more inclusive it is of these flows of material and energy. However, studies undertaken at larger scales lose the site specificity that policymakers often need. In other words, there is no single scale at which we can obtain a full understanding of ecosystems.

Scale issue is an inherent part of ecology. While in the early 1950s to the early 1970s, many ecologists tried to incorporate scale in environmental biology in the early 1970s to the 1980s, many ecologists focused increasing attention on the problem of spatial scale. In the 1990s, scale problem became the central problem in ecology, for unifying population biology and ecosystem science, and marrying basic ecology and applied ecology.

The explosion of interest in scale has created many methods for scaling. For instance, interpolation brings multiple phenomena measured at different resolutions into a common coordinate grid with a single size. Multiple-variable scaling method simultaneously examines each variable at different scales. Spatially explicit models are simply maps of actual or simulated phenomena to demonstrate scale-sensitive issues. Fractal geometry is used to treat the dependence of various phenomena on scales. Resampling techniques are used to frame samples within a hierarchical framework to assess how scale and sequence of assembly affect ecosystem characteristics. Geostatistical techniques employ knowledge of the spatial covariance to produce a spatial model. Neural models are developed to test scale effects resulting from changes in grain size and spatial structure. Hierarchy theory is employed to address issues of spatial scale, which implies that an ecosystem is composed of interacting components and is itself a component of a larger system. However, they are not generalized in GIS as module.

Real-Time Problem of GIS

Time can be characterized as the fourth dimension of the physical space–time continuum. From the human point of view, a concrete system can move in any direction on the spatial dimension, but only forward on the temporal dimension. Static objects can be defined as objects that do not change in a short time period. GIS systems generally deal with static information. However, in many situations, the information in GIS applications does change dynamically. Quite often, it is desirable to combine static information with dynamic information. Studies show that major impediments to the analysis of spatial data arise from a lack of well-documented methods in terms of error accumulation; errors that may occur due to the static representation of dynamic ecosystem components suggest that a real-time method must be developed. Methods of assessing the accuracy of dynamic images are also inadequate and must be further researched.

Real time means momentary, that is, the same moment as it happens. In real-time systems, this implies momentary updates. However, it is impossible to get momentary updates, there is always some delay. The acceptable delay length for a real-time system depends on how dynamic the processes are and how time-critical the decisions are. Rapid development of computing technology in recent years has enabled real-time spatial analysis and real-time data visualization to become realizable, although current GIS software and interfaces do not encompass the set of technical and real-time functions.

GIS provides powerful functionality for spatial analysis, data overlay, and storage. These spatially oriented systems lack the ability to represent temporal dynamics and their concepts of ecosystems are static. In other words, GIS prefers a static view and generally lacks the representation of dynamics. The current generation of commercial GIS is unable to facilitate real-time decision making without significant modifications or integration with external models.

In general, the technology of digital geographies has found that the representation of change in time is extremely hard to handle. GIS today remains a technology for static data, which is a major impediment to its use in spatial modeling.

Direct Modeling Problem

Some researchers have noted that GIS has been restricted to producing cartographic products rather than spatial modeling. GIS was conventionally developed using a hybrid approach that handled graphical and descriptive geographical data separately. This georelational data model was the norm for GIS implementation until the late 1990s. GIS was usually used as means of overlaying maps. Almost all mathematical models are too complex to be run directly from present state-of-the-art GIS. They often run outside the GIS. In these cases, GIS is used to supply the input data at an appropriate resolution and to display the results graphically in combination with other relevant spatial data.

Integration of GIS and simulation models can be categorized into loose coupling and deep coupling. Most integration is in the loose coupling category that integrates GIS with simulation models through exchanging data files. This approach often requires human intervention, which can become a barrier in automating the operation process. The deep coupling approach

links GIS and simulation models with a common user interface, in which GIS and simulation models can remain, in fact, separate systems.

A management system of ecological modelbase (MSEM) with 3055 models has been developed in order to find a solution for direct modeling problem. Usually, there are two ways to develop MSEM. One is the model management techniques, including database approach, structured modeling approach, object-oriented approach, and knowledge-based approach. Another one is model management in GIS software such as ModelBuilder in ArcGIS. The first way can efficiently manage the models, but requires great code creation to handle spatial data. The second way can utilize GIS to manipulate spatial data, but it does not support building complex mathematical models. Therefore, an object-oriented framework for MSEM is developed, in which models are abstracted to model class and model instance. Model class and model instance are represented as objects. Spatial data and mathematical equation are parsed by Model Engine that is composed of mathematical library and SMTS (Satellite Modem Termination System) component. Integration of SMTS and MSEM would solve the direct modeling problem existing in current GIS. SMTS finds solutions to the error problem, real-time problem, direct modeling problem, and multiscale problem of the current GIS. However, SMTS involve huge computation cost and very slow computational speed because it must solve a partial differential equation set for simulating each lattice of a surface, which has limited wider application of SMTS.

GIS Data Type

One aspect of GIS that is of utmost importance is the type of data that can be generated for the specific purpose that a study demands. These data may be of topographical or topological nature. The topographical data or topography is generated through digital elevation models (DEM) that can describe some spatial information and topological data or simply topology, that can use terrain attributes for describing spatial distribution.

Fig. 1 below shows the representation of a contour map (structure above) that is used for describing the surface topology and topography (structure below).

GIS data can be of the following types, viz. raster or grid based data, triangular irregular networks or vector- or contour-based line networks. Fig. 2 below shows examples of (A) Grid and (B) TIN representation of topographical data.

The grid based approach utilizes grid cell or raster information and is made up of regularly spaced lines that represent a collection of small rectangles containing dots that characterizes the central coordinate—based upon which, each of these rectangles (area) are defined. An example of this is the raster-based GIS of the Geographic Resource Analysis Support System or GRASS (Pentland and Cuthbert, 1971).

TIN or triangular irregular networks (Fig. 2 b) relies upon determination of significant peaks and valley points that are translated into a collection of irregularly spaced points connected by lines producing a patchwork of triangles (planar facets) based on several algorithms. Delaunay triangles are one of the most widely used techniques and ARCINFO is one of the most commonly used commercial systems alongside ADAPT—Areal Design and Planning Tool (Grayman et al., 1975).

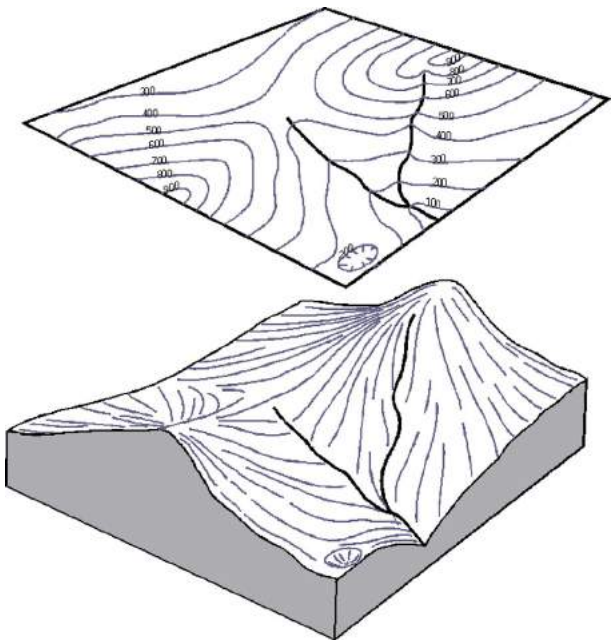

Fig. 1 Example of contour map showing topographic map and corresponding surface. Source: www.cita.utoronto.ca/~murray/GLG130/Exercises/EXE2html.html.

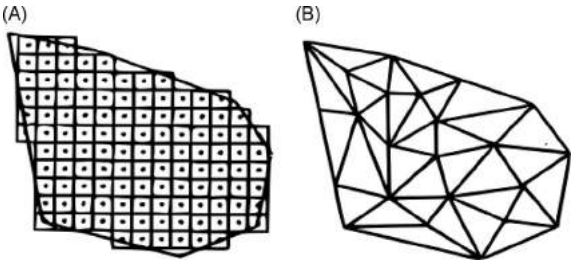

Fig. 2 Representation of Grid (A) and TIN (B) (DeVantier and Feldman, 1993).

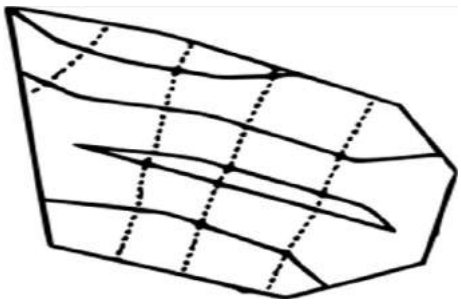

Fig. 3 Representation of vector-based or contour-based diagram (DeVantier and Feldman, 1993).

A contour- or vector-based line network diagram (Fig. 3 below) on the other hand uses digital representation of a point-to-point set (vectors) that can be stored as a digital line graph or DLG. These require a greater magnitude of data as compared to the above two methods but are useful in presenting inherent important attributes (Moore et al., 1991, 1988).

Traditional Approaches

Traditional approaches such as aerial photography (AP) and legacy high resolution systems like Landsat and SPOT are the most commonly used approaches (Newton et al., 2009) for mapping and assessment of mangroves.

Fine grain AP can be successfully used to detect and map individual species as shown by the work of Dahdouh-Guebas et al. (2006). Limited areal extent, relatively high costs of data acquisition over large geographic areas and the possible inconsistencies seen in data collected such as uneven brightness and parallax distortion are the main limitations of using AP. However, these drawbacks can be overcome by the use of satellite based remote sensing. In fact, high resolution satellite imagery (i.e., spatial resolution between 5 and 100 m) such as Landsat (MSS, TM, or ETM+), SPOT (HVR, HRVIR, or HRG), ASTER, or IRS (1C or 1D) have been used by Béland et al. (2006), Benfield et al. (2005), Al Habshi et al. (2007), and so on.

Techniques such as visual interpretation, hybrid classification, unsupervised/supervised classification, and so on have been used to detect and delineate mangroves.

Application of multispectral imagery that includes preprocessing steps such as spectral transformations such as principal components analysis (PCA) or tassel-cap transformation (Crist and Cicone, 1984) or spectral vegetation indices such as normalized difference vegetation index (NDVI) or simple ratio (SR) is another common approach for the classification of mangroves.

In recent times authors such as Gillespie et al. (2008) and Wooster (2007) developed new types of satellite sensors such as very high resolution (VHR) systems (e.g., Quickbird, IKONOS, GeoEye-1 Worldview-2, and ALOS PRISM), synthetic aperture radar systems (e.g., ALOS PALSAR, ASAR ENVISAT, and the Radarsat satellites), and LiDAR systems such as IceSAT/GLAS. Airborne sensors like the hyperspectral airborne visible/infrared imaging spectrometer (AVIRIS), TOPSAR, and AIRSAR (Polarmetric SAR) and various commercial wave-form LiDAR systems have been used to demonstrate the potential for satellite-based sensors. New analysis techniques like the object-based image analysis (OBIA), and image texture metrics, such as lacunarity, use spatial information to improve image classification that has applications in both modern and traditional remote sensing imagery.

Some Recent Applications of Spatial Modeling

Depending upon the capabilities of current GIS systems and owing to the vast availability of data, question arises as to how these are to be represented while evaluating accessibility. Methodological progresses alongside the evolution of theoretical arguments relate to acute perception and explanation of underlying dimensions about the investigated entity thus presenting refinements in the

analysis of spatial interactions and also various facets of its applications. With the increasing dissemination of GIS techniques and advances in statistical methodologies, these advances are becoming more accessible to the common mass (Fischer and Reismann, 2002; Congdon, 2000).

Transportation

Several workers have dealt with applications of accessibility research in transportation and network analysis through the use of matrices measuring connectivity. For example, evaluation of public transit by the use of location–allocation models alongside coverage models focuses on ensuring increased coverage as well as time efficiency and spacing (Wirasinghe and Ghoneim, 1981; Gleason, 1975). Such accessibility research delves in examining not only the geographical distribution and movement of individuals, spatial interaction and population potential, but also patterns of friendship and transmission nets (Cohen and Barabási, 2002; Kwan et al., 2003).

Mangrove Ecosystem

Remote sensing plays a crucial role in the study of mangrove ecology, its management and conservation through the mapping of areal extent and recognizing pattern changes at local scales. Mangroves have unique features like wide dispersal, fast rates of growth, where light acts as a limiting resource and the terrestrial trees have uniform crown shape and prolonged flowering period. These systems provide an wide array of ecosystem services like carbon sequestration, biodiversity support, filtering out pollution and also have the potential to reduce impacts of natural calamities like tsunamis and hurricanes (Alongi, 2002). Hence several studies over the years have been dedicated towards the successful and proper understanding of such systems. Remote sensing plays a critical role in tracking anthropogenic deforestation, impact of natural calamities, effects of conservation projects like reforestation initiatives and also coastal dynamics (Giri et al. 2007; Doyle et al., 2009; Al Habshi et al. 2007; Sirikulchayanon et al., 2008; Lee and Yeh, 2009).

Mapping and Extent

Newer types of imagery like VHR, Hyperspectral Imagery, SAR, etc. helps in overcoming the limitations of multispectral remote sensing in terms of spatial resolution or spectral resolution of sensors, or the inability of optical sensors to penetrate cloud cover.

- VHR imagery like Quickbird or IKONOS is able to reduce the number of mixed pixels.
- Hyperspectral imagery such as HYPERION can potentially detect fine differences in spectral signatures.
- SAR imagery from sensors such as Radarsat or ASAR ENVISAT can penetrate cloud cover.

Even though VHR is capable of and has been used to map mangrove extent, authors such as Giri et al.(2007) and Howari et al. (2009) have used less expensive and coarser resolution imagery over a large area and checked its accuracy using VHR to map a smaller geographic area.

Approaches such as an object-based image analysis (OBIA) or a data fusion to integrate different types of data have been recently developed to improve the accuracy of mapping the extent or detecting the changes over time of mangrove. As its name suggests OBIA uses objects (a group of pixels) instead of individual pixels for image analysis. The pixels are grouped based on image properties or GIS data through an image segmentation process.

Species Composition

Based on biotic and abiotic factors, species in a mangrove exhibit strong zonation patterns which can be used as indicators of geomorphic and environmental changes (Souza Filho and Paradella, 2005). VHR and hyperspectral imagery are among a number of other methods that has been used recently to map mangrove species. Sensors such as Quickbird and IKONOS are used almost exclusively along with satellite-based VHR because of their long-mission life and substantial archived imagery. The spectral information available from Quickbird and IKONOS is limited to the blue, green, red and near-infrared bands which is similar to those of Landsat TM or ETM+. However, due to the very high spatial resolution, the number and effect of mixed pixels may be reduced, which will provide sufficient details for image structure analysis in order to determine canopy structure. Though both sensors are useful for mapping species, IKONOS panchromatic and multispectral data outperformed Quickbird data for texture analysis and MLC, respectively (Wang et al., 2004). Although field studies are limited, lab experiments by Vaiphasa et al. (2005, 2007) indicate that discrimination between multiple species is possible with the inclusion of a genetic algorithm to find the hyperspectral channels that can differentiate between all the species present.

Leaf Area and Canopy Closure

Evapotranspiration, carbon cycling, habitat conditions and forest health can be assessed from bio physical parameters such as leaf area and canopy closure (Kercher and Chambers, 2001; Kovacs et al., 2008). Empirical relationships between ground based

measurements and VHR spectral vegetation indices or SAR backscatter has been utilized to estimate leaf area index (LAI). Kovacs et al. (2004) found strong significant relationships between LAI of red and white mangroves and the simple ratio (SR) and the normalized difference vegetation index (NDVI) using IKONOS; both the indices produced similar results. Spectral vegetation indices from Quickbird sensor produced results similar to the previous IKONOS studies (Kovacs et al., 2009). A stronger relation was observed by Kovacs et al. (2008) between cross polarimetric C-band SAR data and LAI ($r^2 = 0.82$) than the VHR spectral relationships from their earlier studies.

Height and Biomass

Tree and forest biomass estimates can provide a lot of information about the carbon storage and cycling in forests (Litton et al., 2007). Biomass can be estimated

- *Directly* using PolSAR
- *Indirectly* using VHR, SAR Interferometry (InSAR), stereo imagery or LiDAR

Studies by authors such as Lucas et al. (2007), Mougin et al. (1999) demonstrate the potential of SAR to estimate canopy characteristics.

The values and differences of horizontal, vertical and cross-polarizations are used as SAR signal by PolSAR methods to relate with different forest components.

Best estimates of tree height and above ground biomass are given by P-band PolSAR; however, HV polarization of L-Band SAR performs quite well.

Fatoyinbo et al. (2008) and Simard et al.(2008, 2006) demonstrated that Shuttle Topographic Radar Mission (SRTM)—a globally available InSAR digital surface model, provides reasonable estimates of mangrove canopy heights. Though SRTM DSM can be calibrated using field measurements (Fatoyinbo et al., 2008; Simard et al., 2008), vertical canopy structure can be better characterized by air borne LiDAR (Simard et al., 2006) or space-borne LiDAR from IceSAT/GLAS (Simard et al., 2008).

Health Service Access

Extensive use of GIS has been focused on in the health sector for more than a couple of decades to acquire information on the spatial patterns of disease and their correlation with environmental factors, patterns of health service provisions and planning new facilities for making these services more available to the common mass, through various techniques like spatial clustering, and standard GIS functionality like buffering, overlay analyses and network analyses (relying of catchment generation at physical distances of providers and recipients and also the distribution of patients) (Higgs and Gould, 2001; Gatrell and Senior, 1999). Fig. 4 (Higgs, 2004) shows the regions of accessibility to healthcare facilities in Wales and is an example of how to use these kind of study data to potentially improve management, utilization and proper upgradation of such services.

Summary

Simultaneous treatments of issues arising in the representation, selection of methodology and last but not the least—application of GIS techniques have not yet been fully resolved and thus present some form or the other dependability issues that hinder a wider acceptance and successful utilization of GIS technology.

Recent advances have demonstrated an improvement of accuracy with respect to classification, estimation, mapping and measurements. Constant development of comparatively newer imagery techniques like, for example, VHR and SAR generates newer types of data that can stand out on its own as well as play along nicely with some more orthodox traditional approaches. Like VHR and SAR, another method that outperforms its predecessor is OBIA—generating much more accurate data rather than the pixel-based, raster form classification of the past. Classification on the basis of hierarchical rule based systems can be used in conjunction with this new methodology.

Advanced Land Imager (ALI) similar to Landsat TM and ETM sensors with additional blue, NIR and SWIR bands and also HYPERION (hyperspectral HYPERION has 220 bands in the visible, NIR and SWIR spectra) on the EO-1 platform can produce images that—though coarser—can be used in conjunction with Landsat-compatible sensors to detect changes, mapping individual species, estimate photosynthetic activities of a forest and also determine its health.

A good number of traditional GIS methods for conventional ecosystem studies have yet to be explored more deeply in order to expand the range of their usage; for example, spectral unmixing techniques that are used in terrestrial forest studies can be extended to mangrove systems as well in order to get a better idea and explanation of the role of background members (soil and water).

Technological advancements have led to the launch of more than a few up-to-date cutting-edge sensors like ALOS PALSAR, PRISM, Radersat-2, Worldview-2, and some others, that presents newer opportunities to map and present data with additional resolution that allows a researcher to delve deep into newer frontiers that were previously unexplored due to lack of technology or due to the excessive cost involved in such methodology.

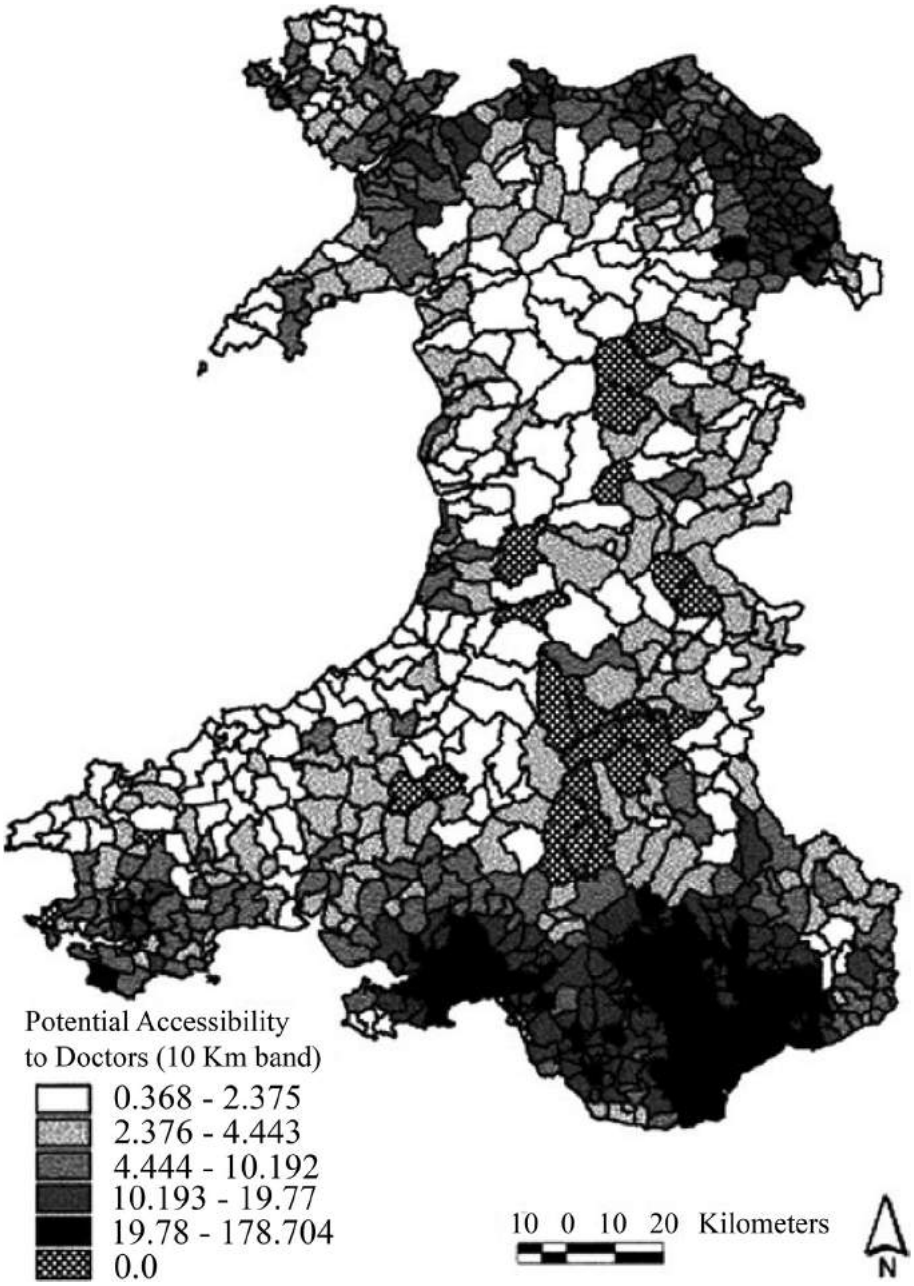

Fig. 4 Potential accessibility to healthcare services in Wales. From Higgs, G. (2004). A literature review of the use of GIS-based measures of access to health care services. *Health Services and Outcomes Research Methodology*, **5**(2), 119–139.

Similarly, newer and advanced VHR sensors like GeoEye-1, having four multispectral bands and higher resolutions provides fresher perspectives and improved opportunities allow further investigation into ecosystems using image texture.

Climate change models has seen the development and use of STMS and YUE-HASM techniques that have considerably reduced computational time and have also improved accuracy and this might be advanced to meet the real time problems of direct modeling and also multiscale problems.

These technological advancements coupled with improved data integration techniques has improved classification accuracy though further in-depth research should be focused in these directions so as to eliminate erroneous occurrences and also to increase efficiency in storing, processing data and analyzing the outputs. Further improved model building strategies and rigorous application of the same is required to expand the horizon on this frontier of research.

Species Distribution Modeling

Adam Duarte and Steven L Whitlock, Oregon Cooperative Fish and Wildlife Research Unit, Oregon State University, Corvallis, OR, United States
James T Peterson, U.S. Geological Survey, Oregon Cooperative Fish and Wildlife Research Unit, Oregon State University, Corvallis, OR, United States

Glossary

Census Complete count of the number of individuals or species within a sampling unit.
Detection probability (p) The probability a species is detected, given the sampling unit is occupied by the species.
Occupancy probability (ψ) The probability a sampling unit contains at least one individual of a species.
Species distribution The spatial arrangement of a species across a landscape.
Species distribution model A spatially explicit, quantitative model that relates occurrence data to landscape characteristics for a focal species.

Introduction

Understanding factors governing spatiotemporal heterogeneity in the distribution of species is a fundamental task in ecology. Quantifying how species occurrence is related to environmental factors using species distribution models (SDMs) enables ecologists to make model-based predictions of species occurrence (Fig. 1) and contribute to the fields of biogeography, evolutionary ecology, invasive species ecology, conservation biology, and natural resource management. Excellent reviews of the ecological and evolutionary processes captured by SDMs are available in the peer-reviewed literature (see Elith and Leathwick, 2009 and citations therein). However, given the utility of SDMs in ecology, it is not surprising that multiple approaches are utilized to leverage different types of data to develop SDMs. In this article, we offer a brief overview of some of the more widely used approaches to develop SDMs, and we organize these methods by the type of data required to fit these models, including presence-only data, presence/absence data, and replicate detection/nondetection data.

Models for Presence-Only Data

The minimum information required for developing an SDM is a series of locations where a species is known to be present, which is often referred to as presence-only data. Presence-only data typically arise when a random subset of the total number of potential sample units is surveyed and only successful species encounters (i.e., positive detections) are recorded. This is a typical data collection process when data are gathered from natural history museum specimens, herbarium records, and opportunistic encounters. Presence-only data can be related to landscape-scale environmental predictors or covariates to develop SDMs when

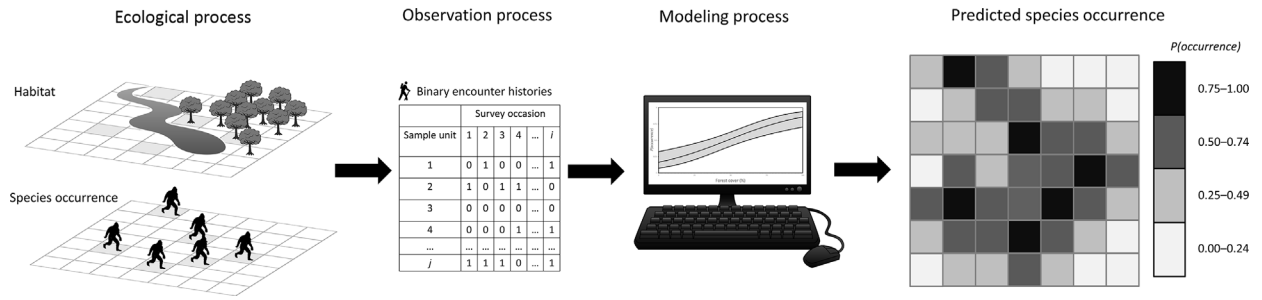

Fig. 1 Illustration of the different components involved when developing species distribution models.

these data are not compromised by sample selection or survey bias. That is, these data need to be collected using a random spatial sample design and patterns in species' detection probabilities need to be constant across sample units—or contain only random heterogeneity—to result in unbiased estimates of species occurrence.

MaxEnt

MaxEnt (e.g., Phillips et al., 2006) is probably the most widely used software package to develop SDMs from presence-only data, despite that it was often referred to as a "black box" method among ecologists for years. The lack of clear understanding was probably related to the program being originally developed in a less familiar machine-learning framework. Fortunately, MaxEnt has since been described in great detail using more familiar statistical terminology (see Elith et al., 2011), providing some clarity to the behind-the-scenes processes. Briefly, users input grid-based spatial environmental data and presence-only records into MaxEnt. The program randomly generates background locations, although this can be further specified outside of the default settings. These background locations may or may not overlap with the presence-only data based on random chance and allow the program to identify the full suite of environmental conditions a species could potentially occupy within the area of interest. MaxEnt examines all pairwise combinations of environmental covariates and the location points, both observed presence and background points, to estimate the conditional probability density of covariates at each observed presence location ($f_1(z)$) and the unconditional probability density of covariates at each background point location ($f(z)$). MaxEnt minimizes the relative entropy between the two probability densities as:

$$f_1(z) = f(z)e^{\eta(z)}$$

where $\eta(z)$ represents a log-linear model that contains a vector of environmental covariates and constrains $f_1(z)$ to sum to 1. MaxEnt has proven to be a useful program to develop SDMs from presence-only data. As Merow et al. (2013) noted, a major limitation of MaxEnt applications is that users rarely deviate from the default settings to ensure the application matches the nuances of a particular dataset or species. In response to this issue, they provided ecologists with a thorough overview of the program options and how to decide among model settings. Such information should be reviewed prior to fitting models in MaxEnt. It is also worth noting that estimates from MaxEnt cannot be reliably interpreted as occurrence probability, but instead are interpreted as indices of habitat suitability.

MaxLike

While MaxEnt has been widely used among ecologists, indices of habitat suitability may not be reliable proxies of occurrence probabilities. As an alternative, Royle et al. (2012) developed MaxLike. MaxLike also relates presence-only data to a vector of environmental covariates. What distinguishes MaxLike from MaxEnt is that MaxLike uses a likelihood-based analysis to fit a logit-linear model to link environmental covariates to presence locations, does not generate background location points, and the output estimates are directly interpretable as occurrence probabilities. Interestingly, they demonstrated that estimates from MaxLike are consistent with the estimates of logit-linear models that are fit to presence/absence data (see "Logistic regression model" section), although they noted MaxLike requires datasets with larger sample sizes. Indeed, smaller sample sizes will result in larger uncertainties (i.e., standard deviations) in the model parameter estimates (Fitzpatrick et al., 2013). The relationship between sample sizes and the precision of the estimates naturally leads one to ask how large the sample size needs to be in order to produce accurate estimates of occurrence probabilities when fitting models in MaxLike. To answer this question, Merow and Silander (2014) simulated presence-only data with variable sample sizes, and their simulations suggested MaxLike estimates were biased and imprecise when samples sizes fell below approximately 1000. Nevertheless, when rescaling the values to relative occurrence probabilities their simulations suggest that MaxLike produced accurate estimates for much smaller sample sizes (approximately 200).

Fitting Models for Presence-Only Data

Given their availability, it is not surprising presence-only data are frequently used to develop SDMs. The application of MaxEnt and MaxLike to analyze presence-only data is continuously increasing in the SDM literature, and it should be noted that the use of

MaxEnt versus MaxLike is somewhat of a contentious issue. In particular, the statistical assumptions imbedded in each of the methods are a primary focus in debates (see Royle et al., 2012; Phillips and Elith, 2013). From a practical perspective, comparisons between the estimates from MaxEnt and MaxLike have been conducted. Similar to Royle et al. (2012), Fitzpatrick et al. (2013) found MaxLike outperformed MaxEnt based on several evaluation metrics. In contrast, Merow and Silander (2014) found a great deal of agreement between MaxEnt and MaxLike after rescaling the estimates from both approaches to relative values. It seems that if data are collected in a manner in which statistical assumptions are met and sample sizes are sufficient, both of these approaches have merits when developing SDMs from presence-only data. Therefore, we encourage ecologists to review these papers, and others, if making the choice between the two methods. Regardless, we stress that presence-only models notoriously produce biased SDMs if sample selection or survey biases are existent in the data and not accounted for during analyses. Unfortunately, these issues are prevalent and often ignored when developing SDMs from presence-only data. We also stress that absence data, if available, should not be discarded in order to use the modeling approaches introduced in this section. If information on the presence and absence of a species is available, ecologists should consider fitting the models described in the subsequent sections.

Models for Presence/Absence Data

Presence/absence data are also commonly used to develop SDMs. These data transpire when both successful and unsuccessful species encounters are recorded during surveys of a random subset of the total number of potential sample units or by generating pseudo-absence data points and combining them with presence-only data. Similar to models for presence-only data, the approaches described in this section are also only valuable to the development of SDMs when the data are not compromised by sample selection or survey bias. Thus, if presence-only data were collected in such a way that they are compromised by these biases, the newly created presence/pseudo-absence data do not overcome these issues. Indeed, there is no shortcut around establishing a robust sample design prior to data collection to develop reliable model-based predictions for SDMs.

Regression Models

Regression models are a useful approach to develop SDMs from presence/absence data. In linear regression models, a response variable is modeled as a linear function of one or more explanatory variables and parameters. Linear models take the basic form:

$$Y_i = \beta_0 + \beta_1 x_{1,i} + \ldots + \beta_Z x_{Z,i} \ldots$$

where Y is the value of the response (a.k.a. dependent) variable, x_1 and x_Z are the values of the explanatory variables for observation i, β_0 is the intercept, and β_1 and β_Z are the model coefficients. There are several types of linear models that are broadly defined as generalized linear models (GLMs) and the use of each type depends on the characteristics of the response to be modeled. Species presence and absence are binary responses (i.e., 1 or 0), so fitting presence/absence data with a GLM requires the use of a Bernoulli error distribution and the predicted response is a probability of presence or occurrence. Although linear models require the likely violated assumption of perfect (100%) detection, the linear modeling concepts discussed in this section form the basis for more sophisticated models that explicitly model species detection and occurrence (see "Models for Replicate Detection/Nondetection Data" section).

Logistic regression model

Linear regression approaches that model species probabilities of occurrence must produce predictions that are bounded by zero and one (i.e., probabilities cannot be negative and cannot exceed one). To keep probabilities within these bounds, GLMs with a Bernoulli error distribution generally employ one of two link functions: the log-log link and the more widely used logistic link that takes the form:

$$\eta = \ln\left(\frac{p}{1-p}\right)$$

where η is the log odds of presence, ln is the natural logarithm, and p is the probability of presence. The linear logistic regression model (a.k.a. logit-linear model) is then:

$$\eta_i = \beta_0 + \beta_1 x_{1,i} + \ldots + \beta_Z x_{Z,i}$$

where the terms are described above. For logit-linear models, the linear combinations of variables are on a log-odds scale and require the use of odds ratios (e^{β_Z}) or scaled odds ratios ($e^{\beta_Z x'_Z}$, where x'_Z is a unit scalar) to interpret the magnitude of the effect size of each parameter (Hosmer and Lemeshow, 1989). To estimate presence probabilities ($\hat{p}$) with logit-linear models, the predicted log odds of presence ($\hat{\eta}$) are calculated using the linear combination of parameter estimates and corresponding explanatory variables and back transformed using the inverse logit link function as:

$$\hat{p} = \frac{1}{1+e^{-\hat{\eta}}}$$

where the terms are defined above. The logit link and logit-linear models are used in a variety of SDMs as shown in the following sections.

Generalized additive model

Generalized additive models (GAMs) combine the properties of two estimators, GLMs and additive models (Hastie and Tibshirani, 1990). The logit-linear GAMs estimate the log odds of a linear combination of variables as:

$$\eta_i = \beta_0 + f_1(x_{1,i}) + \ldots + f_Z(x_{Z,i})$$

where η_i and β_0 are defined above and f_Z is an unspecified smoothing function for explanatory variable Z that can be either parametric or nonparametric. Parametric GAMs generally employ penalized splines for the smoothing function, which can be thought of as a piecewise continuous polynomial function that is delimited by knots. Nonparametric GAMs typically use kernel smoothers to approximate the relation between the log odds and the explanatory variable and also require multiple parameters to define $f_Z(x_{Z,i})$. Thus, each smoothing function in a GAM can use multiple parameters to define the relationship between the log odds and each explanatory variable (Z), whereas a GLM uses a single parameter for each Z (Fig. 2). This suggests that GAMs can account for potential nonlinearities in the estimated relationships; however, it also means that GAMs have a tendency to overfit the data, which reduces the accuracy of the models when applied to data not used to fit the model (i.e., out-of-sample prediction).

Generalized linear mixed models

The logit-linear GLM and GAM are appropriate for examining the relationship between the response and explanatory variables when all observations (i) are independent. Nonindependent errors can arise in any number of ways but, in the context of SDMs, it is often related to spatial and temporal dependence (a.k.a. autocorrelation). For instance when samples are collected within different geographic areas (e.g., bird species detected in multiple riparian sample plots nested within multiple watersheds), samples from the same geographic area may be more similar to each other due to measured or unmeasured factors and may therefore be dependent. Statistical dependence can arise from a variety of factors, including the fact that the sample units share the attributes of the area they are nested within (e.g., same elevation or aspect) and simply due to the fact that they may share a common history. Nonindependent errors can lead to biased low estimates of variance, biased measures of model fit, biased parameter estimates, or all of the above. The incorporation of the error structure (i.e., the dependence) into a linear model is required to account for nonindependent errors. To illustrate, we begin with the logistic regression model from "Logistic regression model" section and assume that J groups (e.g., forested stands) were randomly selected from the entire population of groups and multiple sample units (e.g., amphibian traps) are randomly selected therein. The relationship between the response and explanatory variables in group (j) can be represented by:

$$\eta_i = \beta_{0j} + \beta_{1j}\, x_{1,i,j} + \ldots + \beta_{Zj} x_{Z,i,j}$$

where the variables are defined above. The parameter estimates (i.e., the β_{Zj}) can be treated as fixed, in which their value is assumed equal across groups (e.g., $\beta_{01} = \beta_{02} = \beta_{03}$), which is equivalent to the logistic regression model in "Logistic regression model" section. The parameters can also be treated as randomly varying in which their values differ among groups (e.g., $\beta_{01} \neq \beta_{02} \neq \beta_{03}$). Thus, models with randomly varying parameters differ from the GLM in that each group can have a unique parameter (Fig. 3). Randomly varying parameters are usually assumed to be normally distributed among groups, but other distributions, such as the gamma, can be used to approximate the variability among groups. This means that GLMs with randomly varying parameters can contain mixtures of statistical distributions, which give rise to their name generalized linear mixed models (GLMMs; Stroup, 2012).

Given the GLMM above, the influence of group-level characteristics (i.e., explanatory variables) on the response can be examined by modeling the group-specific parameters (i.e., β_{Zj}) as a function of the group characteristics:

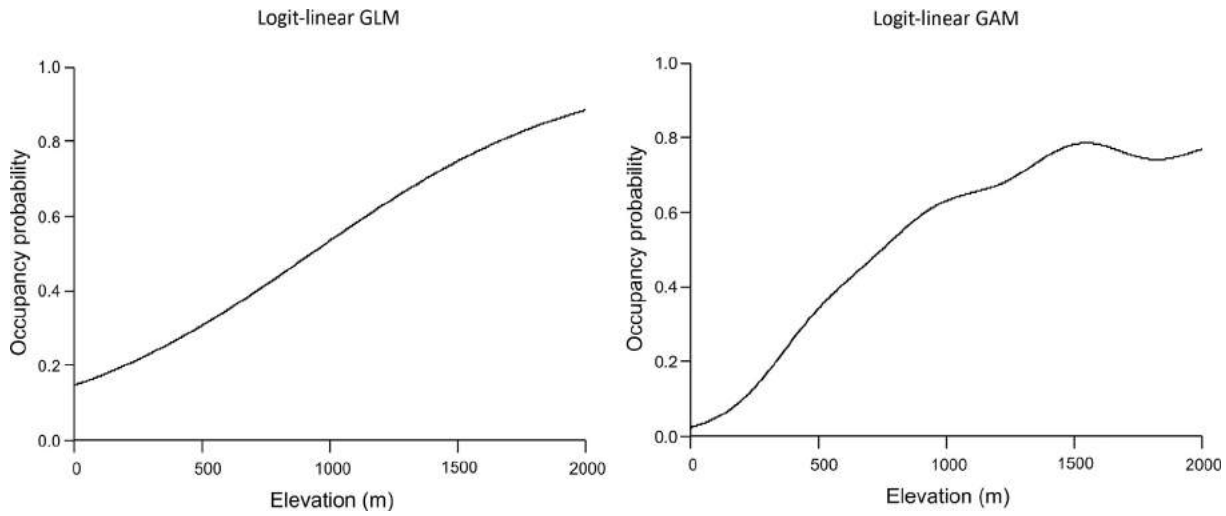

Fig. 2 Comparative illustration between a logit-linear generalized linear model (GLM) and a logit-linear generalized additive model (GAM).

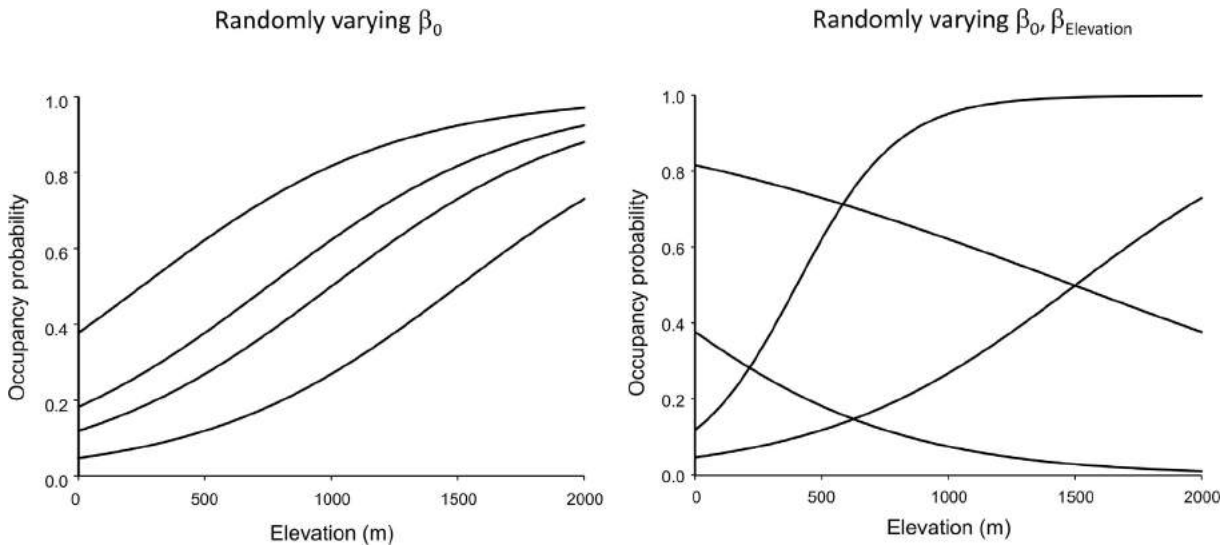

Fig. 3 Illustration of a generalized linear mixed model (GLMM) with randomly varying intercepts (*left panel*) and randomly varying intercepts and model coefficients (*right panel*).

$$\beta_{0j} = \gamma_{00} + \gamma_{01} W_{1,j} + \ldots + \gamma_{0S} W_{S,j} + u_{0j}$$
$$\beta_{1j} = \gamma_{10} + \gamma_{11} W_{1,j} + \ldots + \gamma_{1S} W_{S,j} + u_{1j}$$
$$\beta_{qj} = \gamma_{q0} + \gamma_{q1} W_{1,j} + \ldots + \gamma_{qS_q} W_{S_q,j} + u_{qj}$$

where $\gamma_{00} \ldots \gamma_{qS_q}$ are the fixed effects, $u_{0j}, \ldots u_{qj}$ are the random effects, and W_{Sqj} are the group-level explanatory variables for group j. The random components $u_{0j}, \ldots u_{qj}$ represent the unique effect associated with each group that is unexplained in the model and is typically assumed to be normally distributed, $N(0, \tau_{qq})$.

The fixed parameters of a logit-linear GLMM can be interpreted using odds and scaled odds ratios. The random effects, however, are more difficult to interpret because of the logit link function and mixture of statistical distributions. One approach is to interpret the fixed effects by conditioning on the random effects (Goldstein, 1995) or averaging over all possible values of the random effects via a "population average" or "marginal" model (Diggle et al., 1994). Alternatively, a median odds ratio (MOR) can be used as a point estimate of the magnitude of the random effect in terms of odds. It has the desirable property of being directly comparable to fixed effects (i.e., odds ratios) and is estimated as:

$$MOR = med\left\{e^{|wv|}\right\}$$

where *med* denotes the median of the distribution and $w = \sqrt{2\tau}$, τ is the variance of the random effect, and v is normally distributed with a mean of 0 and variance of 1 (Larsen et al., 2000).

Occurrence probabilities can be estimated with logit-linear GLMs using the predicted log odds and inverse logit link function as described above. However, the group-specific random effects u_{qj} should be used to predict the log odds for groups that were included in the model fitting dataset. For observations from groups not included in modeling fitting (i.e., out-of-sample prediction), the fixed effects should be used to predict the expected probability of occurrence, but the variation among groups (i.e., the random effect variances, τ_{qq}) should be included in measures of uncertainty (e.g., confidence limits). The latter is best implemented in a Bayesian modeling framework.

Tree-Based Methods

Predictions of species occurrence from tree-based methods are dissimilar to the methods discussed in the previous sections in that they are not generated from an explicit model that was fit to a dataset. Instead, tree-based methods predict occurrence probabilities from an algorithm that has been trained by a dataset through a process known as "learning." Tree-based methods come from the realm of machine learning, which is a relatively young field that combines elements of computer science and statistics (Hastie et al., 2009). This approach relies heavily on the application of algorithms, usually for extracting information from large datasets. A practical difference between machine-learning approaches and the traditional statistical methods common to ecology is in the role that the analyst plays in dictating the potential functional relationships between explanatory and response variables. The predominant approach to data analysis in ecology involves first explicitly defining a model or set of models (each of which is linked to an a priori hypothesis), and then fitting those models to data. Conversely, the ecologist who applies a tree-based method chooses the explanatory variables to include, sets several tuning parameters, and the algorithm automatically identifies influential functional

relationships between explanatory and response variables. Unsurprisingly, there is some philosophical debate between advocates of the two methods, which was briefly introduced in "Fitting Models for Presence-Only Data" section. Arguments in favor of tree-based SDMs are that these methods can reveal patterns ecologists did not initially consider (e.g., thresholds and nonlinear responses; Merow et al., 2014), do not require distributional assumptions (i.e., nonparametric), and commonly outperform traditional regression models based on out-of-sample cross-validation (Elith and Leathwick, 2009). Proponents of the traditional statistical approaches assert that failure to predefine model structures can result in spurious conclusions regarding the importance and effect of habitat variables (Burnham and Anderson, 1998). The case has also been made that better out-of-sample prediction does not imply that the model is generalizable (Wenger and Olden, 2012). Debates aside, a simpler deciding factor for whether to apply tree-based methods versus regression methods is the relative importance that one places on prediction versus explanation of species-habitat associations for a particular study (Elith and Leathwick, 2009). Tree-based models are better for prediction of species occurrence at a particular place and time, but interpreting the specific effect of habitat variables is more difficult.

Classification trees

One of the simplest tree-based methods is a classification tree (De'ath and Fabricius, 2000). Classification trees are used to predict the class (i.e., a categorical value) to which a response belongs based on the values of the associated explanatory variables. SDMs typically use classification trees (rather than regression trees that predict continuous responses) because the desired prediction is whether or not the species is present in a defined area. A classification tree is built by sequentially identifying values of explanatory variables that split responses into the most homogenous possible groupings, which are known as nodes. The algorithm decides on the variable to split and the placement of the split by maximizing a value known as the Gini index. The Gini index is a measure of the purity of each grouping that results from the splits, where a grouping that contains only a single class is considered pure. The index also rewards splits that divide the data into larger groupings. The algorithm carries out additional splits until the data are partitioned such that all of the terminal nodes contain responses from only a single class (Fig. 4). Once a tree is created, it can be used to classify independent data with the same explanatory variables. Although, in practice the distal nodes of the tree are usually "pruned" or "trimmed" to avoid overfitting. While the process of performing binary partitions of data appears simple, the resulting classification tree can represent elaborate nonlinear relationships and interactions between explanatory variables and responses. Also, classification trees do not produce parameters that describe the shape of the functional relationships in the same manner as a traditional regression model (e.g., intercepts and coefficients). Although classification trees have been used to develop SDMs, more advanced tree-based methods that have better predictive performance are typically the focus in the SDM literature. These newer tree-based methods improve upon the classification tree approach by generating multiple classification trees with some built-in randomization of variables to minimize poor predictions caused by overfitting. Approaches that work by aggregating information across multiple trees are referred to as ensemble methods and two widely implemented methods that fall into this category are random forests ("Random forests" section) and boosted trees ("Boosted trees" section).

Random forests

Random forests are an extension of classification trees and have been increasingly used to develop SDMs in the last decade (Cutler et al., 2007). The algorithm relies heavily on bootstrap aggregation, which is commonly referred to as "bagging" in the machine-learning literature. Bootstrapping is the practice of iteratively sampling from the observed data with replacement to create

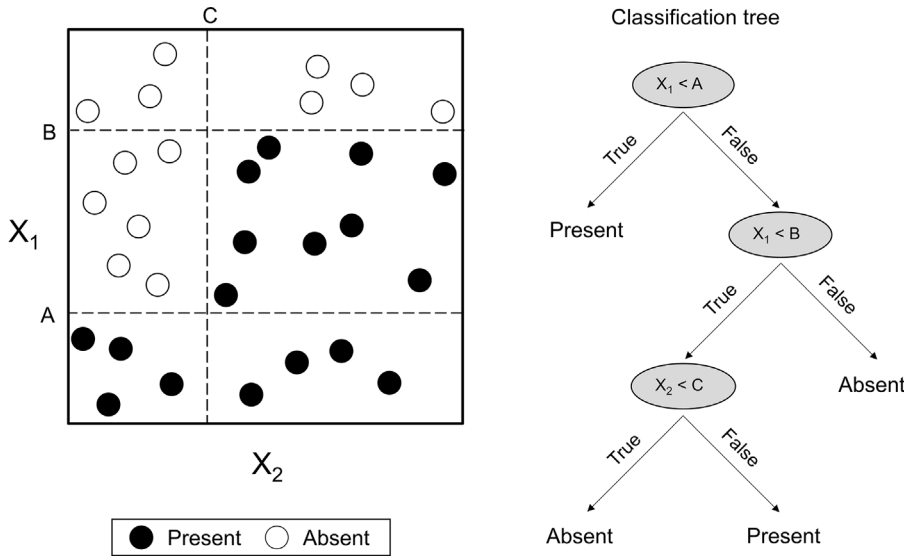

Fig. 4 Illustration of a classification tree for predicting the presence and absence of a species based on two explanatory variables (X_1 and X_2). The data are shown on the *left panel* and the tree on the *right panel*. Letters A, B, and C correspond to the probable locations of sequential splits for this dataset.

a series of artificial datasets or bootstrap samples. The variation among bootstrap samples approximates sample variation of the full dataset, so it is as though each bootstrap sample were an entirely new dataset generated by the same random process that created the full dataset. The first step of the random forest algorithm is to generate a large number (i.e., 100s or 1000s) of bootstrap samples. Unique observations that are included in each bootstrap sample are the "in-bag" data and the observations not sampled are the "out-of-bag" data. The second step is to generate a full classification tree for each of the in-bag datasets, using only a subset of the explanatory variables (e.g., the square root of the total number of variables). The individual classification trees are used to predict their corresponding out-of-bag samples. Predictions of out-of-bag observations across all trees are accumulated and error rates are computed for each observation. The random forest's predicted value for a given observation is the class that was predicted out-of-sample at the highest frequency for that observation. Given the number of trees involved in the prediction process, the results of a random forest are visualized and summarized in a manner that differs from classification trees. The overall influence of explanatory variables within the model is assessed using a variable importance statistic, which is calculated through permutation and is essentially the relative loss in classification accuracy that would occur if the explanatory variable were absent from the dataset. Another method for interpreting and visualizing the results of a random forest is through the use of partial dependence plots. Partial dependence plots illustrate the functional relationships between one or two explanatory variables and the response, averaging over all other explanatory variables. Notably, relationships depicted in these plots can sometimes appear jagged and discontinuous relative to those estimated by regression models (Fig. 5). The complex functions depicted in these plots are a result of the many latent interactions among variables in the random forest. The nature of these interactions can sometimes be difficult to disentangle without creating a large number of plots, and even when the relationships are apparent it can be difficult to ascribe biological meaning to the functional relationships that are identified. The ability to characterize many latent interactions is what gives the random forest algorithm the flexibility to make good predictions, but these latent interactions can also make it difficult to make inferences regarding effects of explanatory variables on species occurrence.

Boosted trees

Boosted regression/classification trees are another ensemble method for predicting the probability of occurrence for species across landscapes (De'ath, 2007; Elith et al., 2008). Unlike the random forest algorithm, the boosted classification tree approach does not draw bootstrap samples. Instead, this approach adds trees to the forest one by one. The initial tree attempts to classify the entire dataset, then the second tree is added in an attempt to correct misclassifications, then the third tree is added to correct remaining misclassifications, and so on. The three tuning parameters that are used to control the operation of the algorithm are the number of trees, the learning rate, and the tree complexity (a.k.a. depth). The number of trees dictates the stopping point of the algorithm. Learning rate dictates the contribution of each tree to the linear combination of trees and is typically set between 0.0001 and 0.1, where a lower learning rate requires a greater number of trees to achieve good predictive performance. Usually tree complexity is doubled whenever the learning rate is halved. The tree depth controls the number of nodes in each classification tree, which affects the order of interactions that can be modeled. For example, trees with a complexity of 1 allow only a single split, which means that the algorithm will only consider additive effects. The recommended method for determining tuning parameters is to run the algorithm on random subsets of data, while systematically applying different combinations of settings and evaluating how well the withheld data are predicted in each scenario. The optimal settings are those which jointly minimize the misclassification rate. Once the preferred settings are identified, the tailored algorithm can be fit to the full dataset and interpreted. Interpretation of boosted regression tree output also consists of estimating variable importance statistics and partial dependence plots.

Models for Replicate Detection/Nondetection Data

Although the SDM approaches discussed so far are useful, they all have a critical weakness in that they do not account for imperfect detection. Detection is considered perfect if ecologists are guaranteed to detect a species in a sample unit, given that the sample unit is occupied. When monitoring a species or community a census is rarely, if ever, conducted, and encounter data both at the individual and species level are biased by imperfect detection. Therefore, the terms "presence-only" and "presence/absence" are misnomers. As the desire to acknowledge imperfect detection escalates, these terms have generally, and more accurately, been replaced by "detection-only" and "detection/nondetection." There is not a straightforward way to disentangle the occurrence state and measurement errors (i.e., false-positive and false-negative detections) using the approaches introduced above. Fortunately, imperfect detection can be statistically accounted for through the use of occupancy models. Occupancy models explicitly link the occupancy state and the observation process, allowing for the disentanglement of these complicated processes. Here, we offer a brief introduction to single-season, multiseason, and dynamic occupancy models. A thorough overview of these models and their extensions can be found in MacKenzie et al. (2017).

Occupancy models contain a few assumptions that should be listed. First, the occupancy state cannot change within a season, but it can change across seasons. Second, detection probabilities must be independent across sample units and survey occasions if occupancy is to be estimated. Third, this approach assumes that heterogeneity in occupancy and detection probability can be explained using covariates or is constant. Last, the occupancy models introduced herein assume false-positive detections do not occur, but see Chambert et al. (2015). A balanced sample design is not required to fit these models, meaning the sample units can be surveyed a variable number of times; however, a greater number of replicate surveys (both spatial and temporal) tend to lead to more accurate estimates.

Single-Season and Multiseason Occupancy Models

Single-season occupancy models were first described by MacKenzie et al. (2002) and Tyre et al. (2003). They realized that if detection/nondetection data across multiple sample units were collected in replicates within a timeframe that the occupancy state within sample units was static, information concerning both occupancy probability (ψ) and detection probability (p) is contained in the species encounter history. Occupancy probability is the probability that a randomly selected sample unit within the larger study area (i.e., the collection of sample units) is occupied by a species, and detection probability is the probability of obtaining a positive detection for that species, given the sample unit is occupied. For example, let us say a sample unit was surveyed three times and the recorded encounter history was "101". Given the species was encountered during at least one survey, we know the sample unit was occupied by the species during all surveys. Therefore, we can be certain that the encounter history reflects the species was detected during the first and third surveys, but not detected during the second survey despite the sample unit being occupied (i.e., a false-negative detection) or $\Pr(h = 101) = \psi p_1(1 - p_2)p_3$. However, what if the encounter history was "000," indicating the species was not detected in sample unit during all three surveys? In this case, it is possible the sample unit was occupied but we failed to detect the species or that the sample unit was unoccupied during the study period. This can be written as $\Pr(h = 000) = \psi(1 - p_1)(1 - p_2)(1 - p_3) + (1 - \psi)$. These processes can be linked hierarchically within occupancy models using coupled Bernoulli processes:

$$z_i \sim \text{Bernoulli}(\psi)$$

$$y_{i,j}|z_i \sim \text{Bernoulli}(z_i p)$$

where y represents the encounter history data for sample unit i and survey j, and z is the latent (partially observed) occupancy state for sample unit i. These equations tell us that whether we detect the species or not on each survey is conditional on the occupancy state of the sample unit and detection probability. Also, the occupancy state for each sample unit is linked to some probability of occupancy. The above example assumes both occupancy and detection probabilities are constant, which is hardly ever the question of interest. This can be modified, however, by relating these probabilities to explanatory variables using separate logit-linear models (see "Logistic regression model" section). Importantly, identical explanatory variables are not fit for each regression, but they can share a subset of explanatory variables. Also note that variation in occupancy is restricted to sample unit covariates since it is static within a season, whereas variation in detection can vary by sample unit and survey. If sample units are surveyed over multiple seasons, one approach to fitting a multiseason occupancy model is to treat each season's data as independent and simply add a covariate for occupancy probability and, perhaps, detection probability that indicates the season the surveys took place. This approach is useful in that it allows ecologists to borrow strength across all of the data, rather than fitting separate single-season occupancy models to each season's data. Importantly, the replicate detection/nondetection data must be collected using a robust design to apply this approach, where the occupancy state does not change within a season (Fig. 6).

Dynamic Occupancy Models

Sometimes our interests are focused on separating patterns from process, where we are less concerned with what is correlated with occurrence and are more interested in what factors govern distributional changes across time. A dynamic occupancy model is one approach to achieve this objective (MacKenzie et al., 2003; Royle and Kéry, 2007). Dynamic occupancy models are similar to the

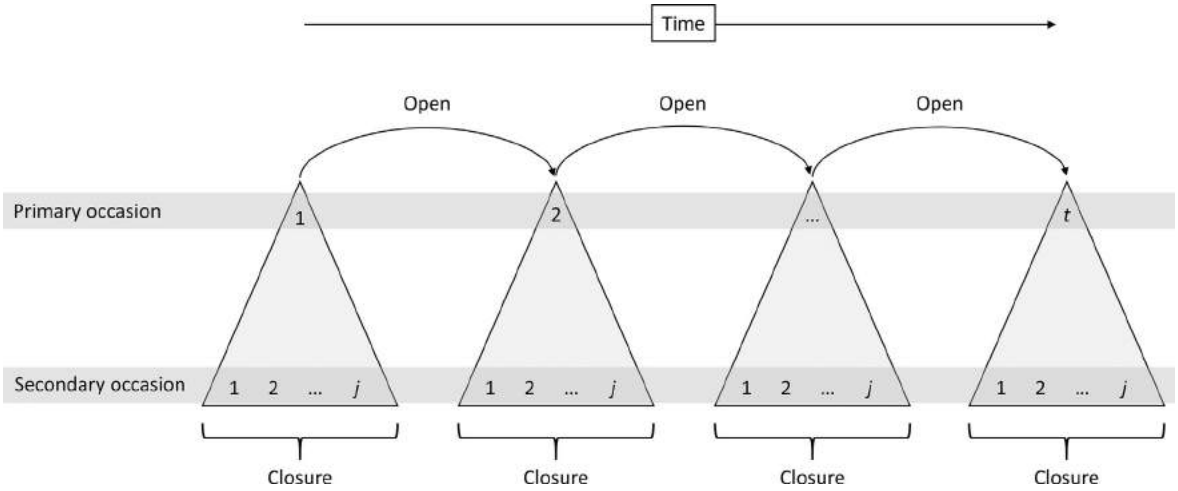

Fig. 6 Illustration of the robust design sample design. Note that the occupancy state of a sample unit does not change across secondary occasions within a primary occasion, but the sample unit can undergo local extinction or colonization between primary occasions.

occupancy models described in the "Single-Season and MultiSeason Occupancy Models" section (in fact they are an extension), except occupancy following the first season uses a first-order Markov model to accommodate temporal autocorrelation in the data. That is, it is likely that at a given sample unit the occupancy state in season $t + 1$ is related to the occupancy state in season t. Like simpler multiseason occupancy models, data must be collected using the robust design to fit this model (see Fig. 6). Dynamic occupancy models contain a couple of extra parameters when compared to simpler occupancy models. In particular, the model estimates the initial occupancy probability (ψ) in the first season, detection probability (p), and the occupancy state in subsequent time periods as a result of colonization (γ) and local extinction (ε) probabilities. For consistency and clarity, here is a dynamic occupancy model written in algebra:

$$z_{i,1} \sim \text{Bernoulli}(\psi)$$

$$z_{i,t+1} \sim \text{Bernoulli}(z_{i,t}(1-\varepsilon) + (1-z_{i,t})\gamma)$$

$$y_{i,j,t}|z_{i,t} \sim \text{Bernoulli}(z_{i,t}p)$$

where the terms are defined above. We see the difference here is the inclusion of a season (t) index and the explicit link between occupancy states across seasons. Similar to the simpler occupancy models described above, all four of these parameters (i.e., ψ, p, ε, and γ) can be related to explanatory variables using separate logit-linear models. Also, occupancy probability in season $t + 1$ can be estimated as $\psi_{t+1} = \psi_t(1-\varepsilon) + (1-\psi_t)\gamma$. It should be noted that local extinction probability is sometimes exchanged for local persistence probability (ϕ). In such cases, "$(1-\varepsilon)$" is replaced by "ϕ" in the equations above. The decision to model local extinction or local persistence is largely dependent on the story you want to tell. That is, are you interested in what causes populations to wink out (a.k.a. local extinction) or what leads local populations to remain intact (a.k.a. local persistence) across seasons? Both approaches are useful ways to describe occupancy dynamics.

Going Forward

Each of the approaches introduced in this article has contributed significantly to our ability to model the distribution of species, and extensions to these methods are being developed rapidly. Notably, there are an increasing number of studies that model spatially explicit abundances (reviewed in Kéry and Royle, 2016) or integrate multiple data sources (e.g., Coates et al., 2016; Fletcher et al., 2016) to develop SDMs, which were not introduced herein. Given the growing number of tools within an ecologist's toolbox, choosing among the different approaches can be daunting, but there are a few things to consider when choosing among the available methods. Axiomatically, fitting a more complicated model requires more robust data (i.e., datasets with larger sample sizes) to support the estimation of a greater number of parameters. Therefore, we stress that the question of interest is the most important thing to consider when choosing among the methods, and the simplest approach that can achieve the desired objective is often the best approach. Moreover, it is beneficial to have objectives in mind before data collection takes place. Otherwise data in hand will dictate what analyses are possible, which may or may not align with the objectives. Similarly, establishing objectives before data collection takes place allows ecologists to simulate monitoring data under various sample designs and establish more efficient and effective monitoring programs. After all, the reliability of an SDM is directly tied to the quality of the data that was used to develop it, no matter what analytical method is used. In our view, analytical methods that account for imperfect detection are always preferred over the alternative methods, if possible, to explicitly and reliably model the state of interest (i.e., species

occurrence). Complicating the estimated relationships with measurement errors, such as false-negative detections, can lead to uninterpretable results that provide little usefulness within ecological research. Finally, each of these methods contains a set of assumptions that should be carefully considered prior to data analysis. The approaches we present herein do not form an exhaustive list and we are unable to cover each approach in great detail. Nevertheless, we hope this article proves to be a useful primer of widely used methods to model the distribution of species and encourages readers to explore these topics in greater detail.

Statistical Inference

Daniel M Wolcott, University of Central Missouri, Warrensburg, MO, United States
Adam Duarte, Oregon State University, Corvallis, OR, United States
Floyd W Weckerly, Texas State University, San Marcos, TX, United States

Glossary

Bias Processes or procedures that consistently result in measurements that differ from the true or correct value.
Inductive reasoning Making a scientifically valid conclusion about a large unknown entity from only a part of the unknown entity.
Maximum likelihood estimation The omnibus estimation approach that assumes large sample size.
Precision The repeatability of a measurement taken multiple times.
Probability The science of uncertainty with values that range from 0 to 1, inclusively.
Repeated measures Observations that are repeatedly measured through time and when subjected to different treatments.
Restricted maximum likelihood estimation Using maximum likelihood estimation on small data sets where estimation relies on using some of the observed data.
Statistics The science of analyzing data.

Introduction

Simply put, statistical methods are used by ecologists to detect patterns in data. If patterns are detected, then the ecologist might also want to predict. Prediction is particularly useful for visualizing the estimated relationships.

Fundamental to the correct application of statistical methods, is an understanding of words and terms such as observation, variable, sample, random sample, population, statistics, parameters, and sample error. An observation is the basic unit. By definition an observation is independent, meaning that each observation has its own information unconnected to the information in any other observation. Replicates or experimental units are synonymous with observations. Characteristics measured from observations are called variables. It is the numerical values of variables that are actually analyzed, and it is convenient to classify variables to assist in choosing the appropriate statistical method, which is largely governed by whether a variable is categorical or numeric. Numeric variables are further classified into continuous or discrete because of different mathematical characteristics (Fig. 1). Continuous variables have infinite possible values between end points and discrete variables are restricted to integer values (e.g., 0, 1, 2, etc.). The population (usually denoted as N) is all the observations of interest and can be quite large or infinite in size. Because it is often not practical to measure variables from all observations of a population, a random subset of observations (usually denoted as n) is selected. The random subset of observations that are drawn from the population is the sample. To, hopefully, obtain a sample that is a microcosm of the population, observations should be selected without any known bias (i.e., a random sample). For example, if we wanted to know if male and female deer were different in body mass at the Kerr Wildlife Management Area, the observation would be the individual deer, the variables measured from each deer would be sex and body mass, the sample would be the collection of deer that were randomly selected and measured, and the population would be all the deer on the Kerr Wildlife Management Area. Clear definitions of these basic terms are needed as the foundation to understand statistical inference.

The essence of statistical inference is making a conclusion about the large unknown and unknowable (population) from the known (random sample). As such, inductive reasoning is required so that a valid conclusion is obtained. Integral to making statistical inferences is accommodating sample error—which is from the sampling process—and using distributions (Fig. 1). The practical consequence is that sample statistics (e.g., mean and variance) almost always will not be identical, but are hopefully close to, their corresponding parameters (population mean and variance). In other words, the data analyst strives for statistical estimates that are precise and unbiased. Using a simple example, a valid inference about a population mean can be made from a 95% confidence interval of a sample mean. The confidence interval is patently estimated to accommodate sample error, and it is a representation of the uncertainty associated with the point estimate. Notably, the interval is more likely to correctly inform about the population mean when the sample data is unbiased and sufficiently large.

Distributions

There are a number of distributions that are used in statistical inference to model uncertainty. We describe six distributions that are often used (Fig. 1). The binomial and Poisson are discrete distributions. Values of these distributions have a lower limit of zero and upper limits that can be quite large. The values are integers. The binomial distribution is one of the most widely

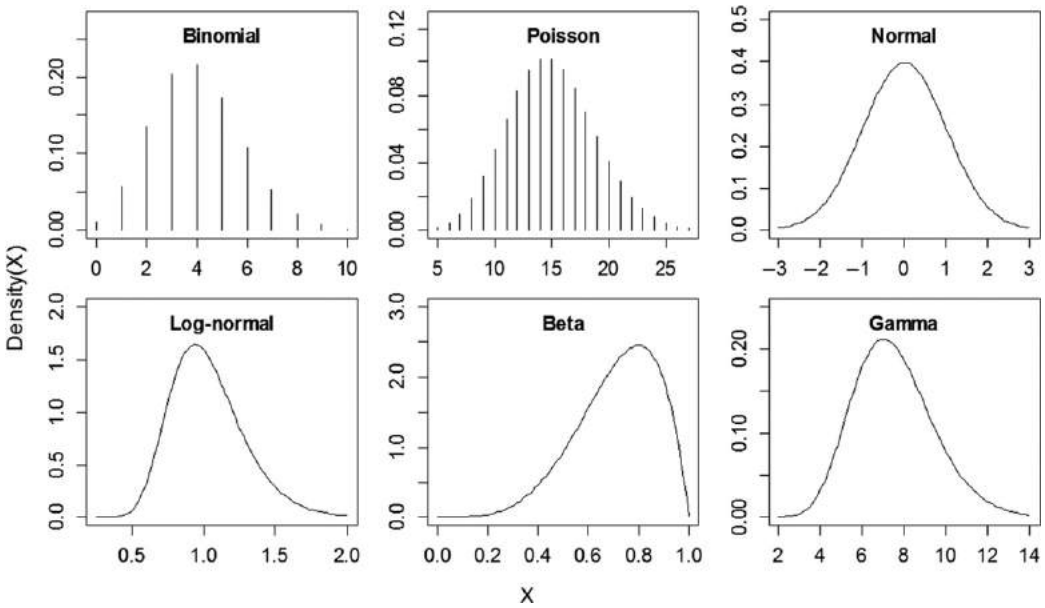

Fig. 1 Examples of six distributions used in statistical inference. Each distribution can have a variety of shapes. Two of the distributions are discrete and the remaining four are continuous. Because the discrete distributions can only have integers for *x* values, vertical lines were used instead of a smooth curve.

implemented distributions for ecological studies focused on the distribution and abundance of animal populations. The key property of the binomial are trials, which by definition are independent. Each trial has two mutually exclusive outcomes. Often, one of the outcomes is of interest and labeled a success. For example, a binomial distribution can be used to describe whether an individual female deer (the trial) gave birth to one or more young in a year (the success) or not. With knowledge about the probability of success it is possible to use the binomial distribution to predict the probability of success for a given set of scenarios. The Poisson distribution is sometimes labeled the distribution of rare events. Imagine you are counting fish at a weir and it is likely that there will be thousands of fish that pass through the weir in a day. One of your tasks is to note if the observed fish are tagged, but there might be three tagged fish counted in a day. For the binomial distribution, the probability of success would be very small and not a convenient application because of the extra variation in the data from the few successes relative to the number of trials. A convenient alternative is the Poisson distribution. The defining feature of the Poisson distribution is the equality between the mean and variance. This distribution is frequently used for modeling population abundances because there usually is small variance among counts of a small population and large variance among counts of an abundant population.

The remaining four distributions are continuous distributions. The normal or Gaussian distribution is a widely used distribution for at least three main reasons. One reason has to do with symmetry. If you superimpose a vertical line through the mean or the peak of the distribution, the right half is a mirror image of the left half. Second, values of the distribution can be negative or positive. Third, the bell-shape of the distribution is useful for describing the sampling process and it matches the distribution of numerous ecological patterns. The normal distribution can be described from knowing the mean and standard deviation. The remaining three continuous distributions are useful in particular settings. The lognormal distribution is a right skewed distribution that becomes more symmetrical with larger means. The lognormal is useful when populations grow exponentially or when the mean is close to zero but the values are constrained to be positive. The beta distribution ranges from 0 to 1 and has two shape parameters that are used to calculate mean and variance. Because the beta distribution ranges from 0 to 1, it is suited for modeling probabilities or proportions. Last but not least is the gamma distribution. The gamma distribution ranges from 0 to values that are quite large. It is a distribution of waiting times until a certain number of events occur. For example, the length of time it takes for three deer to die. The mean and variance are calculated from a shape parameter and a length per event or scale parameter.

Regression Models

General linear models are popular statistical methods (Bolker, 2008). Three conditions (assumptions) define a general linear model, which should be met in the response variable: independence, normality and homoscedasticity (similar variances). It is important to note that the assumption of normality is often misunderstood as a requirement for data to be distributed normally. Instead, normality refers to an error distribution (assessed from residuals, value of variable minus mean of variable) (see Kéry and Hatfield, 2003).
