Other terms frequently used with relation to endothermy are standard metabolic rate (SMR), resting metabolic rate (RMR), basal metabolic rate (BMR), and field metabolic rate (FMR). SMR is metabolism measured at a particular environmental temperature while an animal is inactive and not digesting or absorbing food. RMR differs from SMR in that an animal may be digesting or absorbing food. BMR is a special case of SMR, when metabolic rate is measured within the thermoneutral zone (TNZ; see below). FMR is metabolic rate of animals in their natural environment. SMR, RMR, and FMR can be used to describe the metabolic rate of both endotherms and ectotherms, but the term BMR applies only to endotherms.

Which Organisms Are Endotherms?

The most familiar groups of endotherms are mammals and birds. Only mammals and birds are endothermic at rest. However, because some endothermic fish (e.g., tunas) must swim continuously to ventilate their gills, these fish might also be

This is an update of M.K. Labocha and J.P. Hayes, Endotherm, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1270–1276.

 doi:10.1016/B978-0-12-409548-9.11221-7

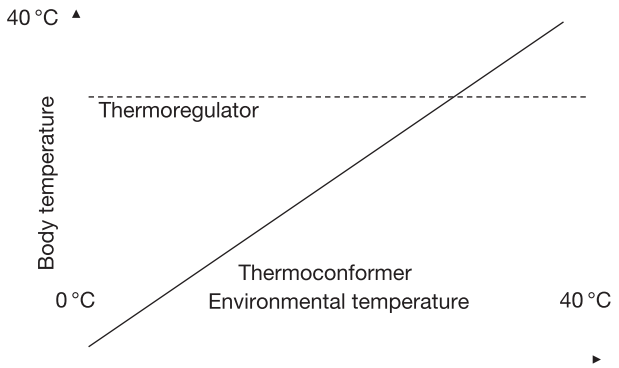

Fig. 1 Change in body temperature of thermoregulators and thermoconformers with environmental temperature change.

considered to be endotherms even at rest or as close to rest as their biology allows. Besides birds and mammals, other endotherms include some species of reptiles (e.g., large sea turtles, brooding pythons), ray-finned fishes (e.g., tunas and billfishes), lamnid sharks, insects (e.g., beetles, dragonflies, cicadas, moths, and bees), gymnosperm plants (i.e., cycads), and flowering plants (e.g., some species from the families Annonaceae, Aracacea, Araceae, Cyclanthaceae, and Rafflesiaceae).

Source of Heat

Mammals and birds differ from other endotherms because they can maintain high body temperature at rest. A high basal metabolism is necessary for mammals and birds to elevate their body temperature above environmental temperature even if the animal is resting. Birds and mammals have much higher standard metabolic rates than ectotherms, and the differences in standard metabolism are associated with different molecular, cellular, and organ characteristics. Compared to ectotherms, birds and mammals have higher mitochondrial volume, greater membrane surface per tissue volume, and higher aerobic enzyme activity. Their cellular membranes have greater ion fluxes, such that physiologists describe the cellular membranes of endotherms as being 'leakier' than those of ectotherms. Indeed, the greater leakiness of cellular membranes has been hypothesized to be one of the major processes responsible for the higher standard metabolic rate of endotherms.

Most endothermic reptiles, fishes, and insects support an elevated body temperature with heat produced by working muscle, and they do not maintain endothermy at rest. So their molecular, cellular, and organ characteristics are more similar to ectotherms than they are to endotherms. Besides producing heat by muscle, endothermic fishes developed vascular countercurrent heat exchangers to reduce heat loss and thereby promote endothermy. Some sea turtles also have countercurrent heat exchangers (in their flippers). In fishes that elevate their brain or eye temperature, the method of heat production varies among species, and the method of heat production is known not for all species. In lamnid sharks, heat is transferred from muscle, whereas billfishes and mackerel produce heat with specialized heater tissues (evolved from ocular muscles). In plants, endothermy is achieved by decoupling ATP generation from heat production via use of an alternative electron-transport mechanism (i.e., cyanide-insensitive respiration).

Endothermy, Metabolic Rate, and Body Size

The metabolic rate necessary to achieve endothermy is influenced by size because heat loss to the environment is roughly proportional to an animal's surface area. Surface area depends on body mass (i.e., for similarly shaped organisms, surface area increases with body mass raised to the power 2/3). Because surface area increases more slowly than body mass, larger animals generally can achieve endothermy with lower metabolic intensities (i.e., metabolic rates per unit mass) (**Table 1**). Indeed, even with low metabolic intensities, animals with very large body masses (e.g., sauropod dinosaurs) may have been endothermic. A lower limit on size of vertebrate endotherms also exists. The smallest vertebrate endotherms are roughly 2 g in mass but the smallest vertebrate ectotherms can be much smaller.

Endothermic Response to Temperature

Endothermic homeotherms alter their metabolic rate in response to environmental temperature (**Fig. 2**). The response to temperature depends in part on how precisely or not endotherms maintain body temperature. Over a range of intermediate temperatures, called the thermal neutral zone (TNZ), metabolic rate remains constant. If body temperature and metabolic rate are constant, but the thermal gradient between the animal and the environment is changed, then the insulation (or its reciprocal conductance) of the animal must change. A typical endothermic homeotherm would have maximal conductance at the upper end

Table 1 Basal metabolic rate (BMR) of some mammals over a large range of body mass

Species	*Common name*	*Body mass (g)*	*BMR (mL O_2 h^{-1})*	*Mass-specific BMR (mL O_2 g^{-1} h^{-1})*
Sorex minutus (Sparti, 1992)	Pygmy shrew	3.3	28.4	8.60
Peromyscus maniculatus (Hinds and Rice-Warner, 1992)	Deer mouse	14.9	44.4	3.00
Clethrionomys glareolus (Labocha *et al.*, 2004)	Bank vole	20.9	52.5	2.50
Petrodromus tetradactylus (Downs and Perrin, 1995)	Four-toed elephant shrew	206.1	179.5	0.87
Erinaceus europaeus (Shkolnik and Schmidt-Nielsen, 1976)	European hedgehog	750.0	337.5	0.45
Fossa fossa (McNab, 1989)	Fanaloka	2260.0	904.0	0.40
Felis pardalis (McNab, 1989)	Ocelot	10,416.0	3229.0	0.31
Antilocapra americana (Wesley *et al.*, 1973)	Pronghorn	37,800.0	9318.0	0.25
Panthera onca (McNab, 1989)	Jaguar	68,900.0	12,402.0	0.18
Alces alces (Renecker and Hudson, 1986)	Moose	325,000.0	51,419.0	0.16

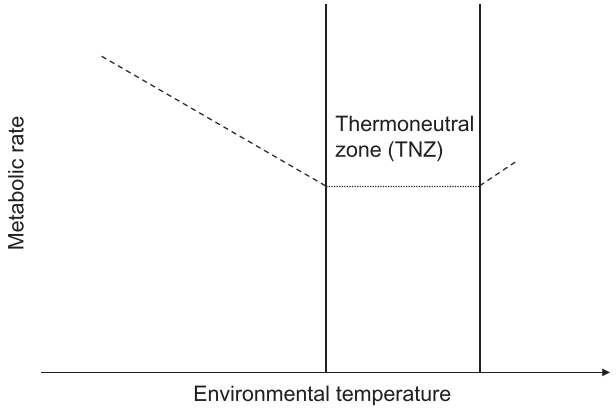

Fig. 2 Change in metabolic rate of endotherms in response to environmental temperature. Other response patterns are possible, but this pattern is roughly typical for endotherms that are strict thermoregulators.

of its TNZ and minimal conductance at the lower end of its TNZ. Above the upper end of the TNZ, metabolic rate and body temperature increase, and the animal may undertake such behaviors as panting to increase evaporative heat loss. Below the lower end of the TNZ, endotherms increase heat production so that they can offset increased heat loss in colder environments; thereby, they balance heat production and heat loss to maintain a constant body temperature (**Fig. 2**).

Endotherms that live in cold environments (e.g., aquatic environments, where the thermal conductivity of the water is many times greater than that of air) tend to be well insulated, and aquatic endotherms tend to be large. Insulation in vertebrates can take the form of fur, feathers, or fat layers. As insulation increases, the TNZ widens and the lower end of the TNZ occurs at lower temperatures. Animals that are very well insulated (the arctic fox is a classic example) have thermal neutral zones that may extend to extremely cold temperatures (e.g., they may experience temperatures as low as $-40^{\circ}C$ or perhaps even lower without having to increase their basal metabolic rate).

High temperatures can present problems for endotherms. When the thermal environment is hot, endotherms must increase evaporation to avoid overheating. Hence, hot environments can be challenging, particularly if ample water is not available.

Benefits and Costs of Endothermy

The ability to control body temperature enables endotherms to live in cold or thermally variable environments yet remain active. On a geographical scale, endotherms can live in regions too cold for most ectotherms. On a temporal scale, endotherms can be active year-round in regions with cold seasons, as well as be active during cold parts of the day or night. Endotherms not only have high SMR, RMR, and FMR, they also have high aerobic capacities (maximal aerobic metabolism). These high aerobic capacities

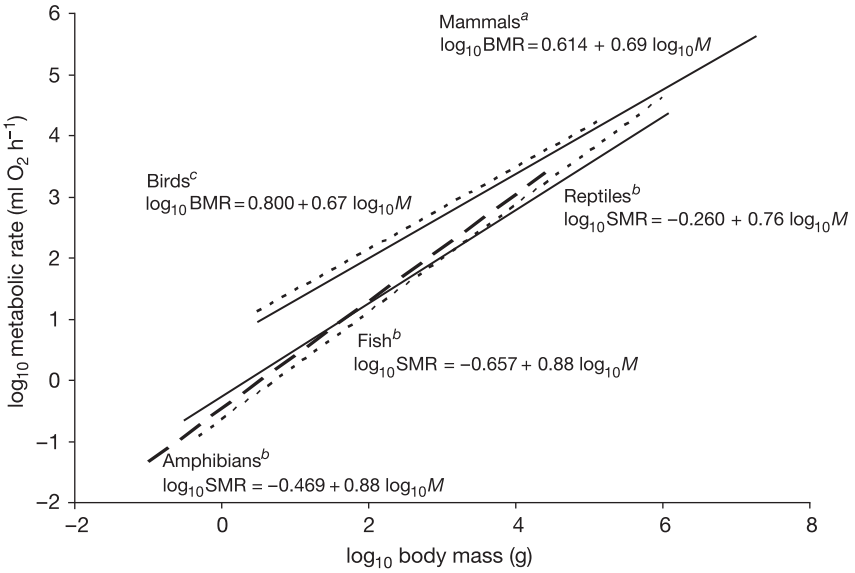

Fig. 3 Relationship between metabolic rate and body mass in vertebrates. The data for amphibians, fish, and reptiles were normalized to 38°C as described in White et al. Equation for birds was recalculated from Watts (used by McKechnie and Wolf) to mL O_2 h^{-1} (Lovegrove, 2000; White et al., 2006; McKechnie and Wolf, 2004).

Table 2 Field metabolic rate (FMR) of endotherms and ectotherms of similar body mass

Species	*Common name*	*Endotherm (ENDO)/ectotherm (ECTO)*	*Body mass (g)*	*FMR (kJ d^{-1})*
Peromyscus maniculatus (Hayes, 1989)	Deer mouse	ENDO	18.0	57.3
Erithacus rubecula (Tatner and Bryant, 1993)	Robin	ENDO	18.7	71.3
Mabuya striata (Nagy and Knight, 1989)	Striped skink	ECTO	19.5	2.9
Thamnophis sirtalis (Peterson *et al.*, 1998)	Common garter snake	ECTO	22.0	5.2
Spermophilus parryi (Nagy, 1994)	Arctic ground squirrel	ENDO	630.0	817.0
Alectoris chukar (Kam *et al.*, 1987)	Chukar	ENDO	440.0	306.2
Tiliqua scincoides (Christian *et al.*, 2003)	Bluetongue lizard	ECTO	574.0	45.7
Aptenodytes patagonicus (Kooyman *et al.*, 1992)	King penguin	ENDO	12,900.0	7410.0
Chelonia mydas (Southwood *et al.*, 2006)	Green sea turtle	ECTO	16,000.0	1867.0

make it possible to sustain vigorous activity for extended time periods. As a result, endotherms can maintain large territories and migrate for long distances.

While there are diverse benefits of endothermy, endothermy also has costs. In particular, endotherms have higher metabolic rates than ectotherms (**Fig. 3**), so they must locate and process more food to provide the energy to sustain higher metabolism. Typically, an endotherm requires much more energy and food than a similar-sized ectotherm (**Table 2**). The cost of endothermy relative to ectothermy changes with environmental temperature. At warm environmental temperatures, the energetic cost of endothermy relative to ectothermy is not as great as at cold environmental temperatures (**Table 3**).

Energetic Influence of Endotherms on Ecosystems

Endothermy is more energetically costly than ectothermy. Because endotherms use more energy than ectotherms, the same amount of food can maintain a larger population of similar-sized ectotherms than endotherms. Moreover, 90% or more of the energy assimilated by endotherms is converted to heat, so only a small percentage of the food energy drawn from the ecosystem by endotherms is converted to biomass (i.e., to grow tissue or produce offspring). In other words, endotherms have lower production efficiency than ectotherms.

Because of the high energetic cost of endothermy, endothermic carnivores require higher prey densities than ectothermic carnivores. In systems with low primary productivity they will be absent or rare. Even folivorous endotherms may be absent in habitats with extremely low productivity.

Table 3 A comparison of metabolic rates of endotherms and ectotherms of similar body mass

Species	*Common name*	*Endotherm (ENDO)/ ectotherm (ECTO)*	*Temperature (°C)*	*Body mass (g)*	*Metabolic rate* ($mL\ O_2\ h^{-1}$)
Dipsosaurus dorsalis (Bennett and Dawson, 1972)	Desert iguana	ECTO	25	35	1.68
Dipsosaurus dorsalis (Bennett and Dawson, 1972)	Desert iguana	ECTO	30	35	2.45
Dipsosaurus dorsalis (Bennett and Dawson, 1972)	Desert iguana	ECTO	35	35	5.25
Dipsosaurus dorsalis (Bennett and Dawson, 1972)	Desert iguana	ECTO	40	35	6.30
Notoryctes caurinus (Withers *et al.*, 2000)	North-western marsupial mole	ENDO	30.8	34	21.4
Phyllostomus discolor (McNab, 1969)	Pale spear-nosed bat	ENDO	34.6	33.5	11.1
Gerbillus allenbyi (Haim, 1984)	Allenby's gerbil	ENDO	36.3	35.3	38.8
Acanthodactylus erythrurus (Pough and Busack, 1978)	Fringe-toed lizard	ECTO	20	9.0	1.17
Acanthodactylus erythrurus (Pough and Busack, 1978)	Fringe-toed lizard	ECTO	25	9.0	1.62
Acanthodactylus erythrurus (Pough and Busack, 1978)	Fringe-toed lizard	ECTO	30	9.0	2.25
Acanthodactylus erythrurus (Pough and Busack, 1978)	Fringe-toed lizard	ECTO	35	9.0	3.15
Crocidura crossei (Sparti, 1990)	Crosse's shrew	ENDO	34.3	10.2	22.4
Perognathus longimembris (Chew *et al.*, 1967)	Little pocket mouse	ENDO	34.7	8.9	9.5
Pteronotus davyi (Bonaccorso *et al.*, 1992)	Davy's naked-backed bat	ENDO	38.8	9.4	24.4

For endotherms, basal metabolic rate is shown. For ectotherms, standard metabolic rate over a range of temperatures is shown.

Evolution of Endothermy

Because endothermy is energetically expensive and evolved more than 100 million years ago (at least in birds and mammals), the selective forces leading to the evolution of endothermy are unclear. The earliest hypotheses to explain the evolution of endothermy postulated that selection for higher resting metabolism led to an expanded thermal niche or increased thermal stability. Later, the aerobic capacity model posited that endothermy evolved as by-product of selection for high aerobic capacity (i.e., maximal oxygen consumption capacity during exercise). Based on data for extant organisms, aerobic capacity was argued to be inescapably correlated with resting metabolism. The newest models suggest that endothermy evolved as consequence of selection for intense parental care. Which of these models for the evolution of endothermy is best is unresolved.

Epiflora and Epifauna☆

Richard B Taylor, University of Auckland, Auckland, New Zealand

Introduction and Definitions

The terms epiflora and epifauna (collectively "epibiota") are usually used to describe nonparasitic organisms living on the surfaces of other organisms (see examples in **Fig. 1**). Some epibiota have an intimate relationship with their host, but for many or perhaps even most species the host is just a surface to which they can attach, shelter from consumers, or gain better access to light or nutrients. These species typically show little host-specificity and may also occur on nonliving surfaces.

Numerous terms have been used to describe surface-dwelling organisms and their hosts (Box 1). Epiphyte, the most familiar of these, usually denotes a terrestrial plant living on another plant, but has also been used in the aquatic literature to describe plants on plants, and animals on plants. Here epiphyte and epiflora are used interchangeably to refer to plants living on other organisms. For aquatic epifauna the term has been broadened to include animals inhabiting nonliving surfaces (but not those forming large-scale habitat like coral reefs). Microorganisms (with the exception of periphyton) and terrestrial animals are not considered here.

Epiflora

Terrestrial epiphytes comprise a taxonomically and morphologically diverse range of relatively large vascular plants (notably bromeliads, orchids, and ferns), and small nonvascular bryophytes (mosses and liverworts), lichens, and free-living algae. Growth forms include creepers, mats, brackets, nests, pendants, and shrubs. Most terrestrial epiphytes are self-contained on the bark or branches of their host, except for hemiepiphytes, which have roots reaching down to the ground. Not considered here are the mistletoes, which are parasitic, and the vines or lianas, which although using other plants for physical support do not have a crown attached to the host.

Aquatic epiflora are composed of red, green, and brown algae, and various other photosynthetic microorganisms. In freshwaters, microscopic, mostly unicellular, periphyton (or "aufwuchs") dominate, while in the ocean macroalgae (seaweeds) are also important. Periphyton grows in thin films, while macroalgal epiphytes take encrusting, sheetlike, or branching forms, the latter two usually attached to their host by a small discoid holdfast or penetrative rhizoids.

Epifauna

Aquatic epifauna can be categorized by the sieve mesh size they are retained on (meiofauna 0.063–0.5 or 1 mm; macrofauna >0.5 or 1 mm), and by whether they are mobile or sessile (attached). Freshwater macrophytes are inhabited by meiofaunal nematodes and macrofaunal gastropods, insect larvae and oligochaete worms (all mobile). Estuarine and marine macrophytes are inhabited by meiofaunal nematodes and harpacticoid copepods, and macrofaunal gastropods, polychaete worms, and amphipod and isopod crustaceans (all mobile), along with sessile hydroids, bryozoans and tube-building polychaetes. Larger marine sessile animals are host to crustaceans (shrimps, crabs, amphipods, isopods), gastropods, pycnogonids, and brittlestars (all mobile). Sessile animals such as sponges and bryozoans may also be present. Animals living on lake and river beds include most of the taxa listed above for freshwater macrophytes, along with crayfish, mysid shrimps, and fishes (all mobile) and bivalves (sessile). The mobile fauna of nonliving marine surfaces includes gastropods, echinoderms (starfishes, brittlestars, sea urchins, sea cucumbers), crustaceans (crabs, lobsters, shrimps, amphipods, isopods, cumaceans), and fishes. The sessile fauna of hard substrata includes ascidians, brachiopods, bryozoans, crustaceans (barnacles), cnidarians (hard and soft corals, sea anemones, gorgonians, hydroids), echinoderms (brittlestars, crinoids, sea cucumbers), tube-building polychaetes, and sponges. On soft sediments common sessile epifaunal taxa include bivalves and sponges, many of which actually grow attached to shells (alive or dead) or cobbles. There is a general trend for the maximum body size of epifaunal individuals to increase from aquatic macrophytes (<1 cm) to sessile invertebrates (several cm) to nonliving surfaces (10s of cm).

Types of Hosts

On land the major hosts for epiphytes are woody vascular plants: the trees and shrubs, with animals (e.g., sloths) a very minor habitat. In freshwaters the main living hosts for both epiflora and epifauna are vascular plants, with bryophytes (mosses and

Box 1 Definitions

Aufwuchs. Microscopic organisms forming a film on aquatic surfaces
Epi-. Living on the surface of
Epibenthos. Organisms living on the surface of a sea-, lake- or river-bed
Epibiota. Organisms living on any surface
Epifauna. Animals living on an aquatic surface
Epiflora. Plants or algae living nonparasitically on surfaces of other organisms
Epilithic. Growing on rock
Epiphyte. Plant or algae living nonparasitically on the surface of another organism
Epizoon. Organism living on the external surface of an animal
Hemiepiphyte. Epiphyte with roots reaching down to the ground
Holoepiphyte. Epiphyte living its entire life cycle as an epiphyte
Liana. Vine rooted in the ground
Macrophyte. Macroscopic aquatic plant or alga
Periphyton. Microscopic organisms forming a film on aquatic surfaces
Phorophyte. Terrestrial plant hosting epiflora

liverworts) and macroalgae less important. In the oceans, the hosts are seaweeds (macroalgae), and seagrasses, mangroves and saltmarshes (all vascular plants), the latter two found only along sheltered coastal and estuarine margins. Marine epiflora also occur on many aquatic animals, both sessile (e.g., sponges, corals) and mobile (e.g., gastropods, turtles). In addition to macrophytes, aquatic epifauna inhabit numerous sessile animals (sponges, bivalves, tunicates, corals, gorgonians, hydroids, bryozoans), and some mobile animals. As noted in the introduction, animals living on the surfaces of marine and estuarine soft sediments (mud, sand, and gravel) and hard bottoms (rocks, wood, and artificial structures such as jetties and shipwrecks) are often termed epifauna, and those inhabiting similar freshwater habitats are also included here for completeness.

Host Attributes

Total abundances, total biomasses and maximum sizes of epibiota individuals tend to increase with host age, size, and structural complexity, for both plant and animal hosts. Epiphyte distributions are often strongly stratified within individual hosts.

Terrestrial host plants tend to be large, rigid, and may live hundreds or even thousands of years, while most aquatic host plants are small, flexible, and live for a decade at most. These factors, along with inherent phylogenetic constraints and the high drag resulting from the greater density of water as a medium, limit the maximum age and size attained by aquatic epiphytes and sessile epifauna. While terrestrial epiphytes can weigh hundreds of kilograms, aquatic epiphytes usually weigh less than a few grams.

Host-Specificity

Restriction to a single host species is rare among epibiota, with many species found on multiple host species or even nonliving surfaces. For instance, many terrestrial epiphytes also grow at ground level on soil or rocks, and most mobile epifaunal taxa found on aquatic macrophytes will also colonize artificial plants, suggesting that for those epibiota there is nothing intrinsically special about the host. Obligate host-specificity is probably commonest among epibiota having a tight mutualistic relationship with their host, e.g., coral-dwelling shrimps and crabs that derive shelter and eat mucous released by their host in exchange for protecting it from crown-of-thorns starfish and other predators. There is little evidence for coevolution of such relationships.

Environmental Gradients

Terrestrial epiphytes are most diverse and abundant in neotropical forests that experience year-round humidity and no frosts. Diversity is lower in the palaeotropics (possibly due to historical aridity), and decreases at higher altitudes and latitudes, but epiphytes can still be important in temperate forests with oceanic climates. Aquatic epiflora are found virtually everywhere their host macrophytes exist, i.e., on sunlit surfaces free of sessile animals or destructive grazers. Epiflora are often abundant in eutrophic waters.

Epifauna occur in all aquatic environments: in lakes and rivers, from the intertidal to ocean trenches, and from tropical to polar latitudes. Densities are usually highest where there is strong net water movement supplying food for filter-feeders. Strong light supports algal growth, which benefits mobile epifauna that eat periphyton, but not sessile epifauna, which are often susceptible to being overgrown. On soft sediments, epifaunal densities tend to decline with increasing depth due to the reduction in food input from the sunlit surface waters, though densities can be locally high where detritus accumulates. Sessile epifauna are often delicate and long-lived, so are vulnerable to physical disturbances like dredging and trawling.

Acquisition of Resources

Solid Substratum

Structures vary greatly in their suitability as a surface to grasp or stick to, with solidity, shape, inclination, aspect, texture, and sediment- and water-holding ability among the important characteristics for epibiota.

Light

In dense forests light at ground level is $< 2\%$ of that falling on the canopy, so epiphytism is the only way that small plants can gain access to strong light for photosynthesis. However, not all terrestrial epiphytes require full sun and some are tolerant of deep shade. Light levels are also greatly reduced under dense aquatic macrophyte beds, but for epiphytes there tends to be less vertical light stratification within hosts than that experienced by their terrestrial counterparts, due to the flexibility of macrophytes subject to water motion.

Water

In the canopies of many forests, precipitation is sporadic and exposure to the wind and sun creates drier conditions than on the forest floor, so water availability strongly affects the growth and survivorship of epiphytes lacking a root connection to the ground. Epiphytes maximize water uptake and minimize loss by (1) rapidly absorbing rain, dew or mist using specialized leaf and root structures, (2) storing water when it is plentiful (in their own tissues, root-mass humus, or "tanks" in the case of bromeliads), and (3) using CAM photosynthesis to reduce losses through transpiration. Many can tolerate severe desiccation. Water availability is obviously not a factor for aquatic epiphytes, except those exposed by low tide or drought.

Nutrients/Food

Nutrients are often in short supply for terrestrial epiphytes, since most have no root connection to the ground and must instead obtain their nutrients from solutes in rain and stemflow water, wind-borne particles, litterfall, carnivory, or animal excrement (especially the waste products of ants living in the root mass or within specialized plant organs). For aquatic organisms, living on surfaces can increase their access to nutrients/food in a number of ways. (1) Organisms obtaining nutrients from the water column, either as ions in solution (epiphytes) or suspended particles (many epifauna), should profit from the increased access to

water flow achieved by living on other organisms that project into the water column, or in the case of epifauna living directly on the seafloor, inhabiting the surface of sediments or rocks rather than living in burrows. Aquatic epiphytes can take up nutrients from the surrounding water across their entire surfaces, so they generally have better access to nutrients than do terrestrial epiphytes. They usually have higher surface: area volume ratios than their host macrophytes, enabling them to take up nutrients more rapidly, but like their hosts they are still potentially limited by C, N, or P. Other food sources available to epifauna are (2) periphyton, for which host surface area is important, (3) trapped detritus, for which host structure is important, and (4) host macrophyte tissue, for which intrinsic host properties such as nutritional value and chemical defenses are important.

Refuge From Consumers

Living in a tree or aquatic macrophyte reduces the threat to epibiota from ground- or seafloor-dwelling consumers. Predation is intense in many aquatic habitats, but epibiota can acquire critical refugia on hosts possessing (1) structural complexity, which reduces the foraging efficiency of predators, and/or (2) chemical defenses against consumers, which provide epibiota with "enemy-free space" where they are safe from incidental consumption or destruction of their host (an "associational defense"). For herbivorous seaweed epifauna, shelter from predators often appears to outweigh food quality as a factor influencing host selection or subsequent survivorship.

Contribution to Ecosystem Diversity, Biomass and Productivity

Epiflora

Worldwide about 27,000 species or 9% of vascular plants are epiphytes, with the proportion up to 50% in tropical forests. About two-thirds of vascular epiphyte species are orchids. Similar figures are unavailable for nonvascular epiphytes. The green biomass of epiphytes may match that of their host trees, though epiphyte productivity is likely to be lower due to resource limitation (see above). In moist tropical forests the habitat complexity, water and food provided by epiphytes is a major contributor to the high diversity of insects and other animals.

The productivity of aquatic epiphytes often exceeds that of their host macrophytes, though in some habitats (e.g., seagrass beds) the dominance of epiphytes may be a recent artifact of anthropogenic eutrophication or the overharvesting of vertebrate herbivores (sirenia, turtles) that once cropped macrophytes before they could be colonized by epiphytes. In aquatic systems, epiflora are usually more suited to direct consumption by herbivores than their vascular plant hosts, which tend to be tougher, and contain less nitrogen than epiflora but more indigestible fiber and secondary metabolites like phenolics.

Epifauna

It is difficult to compare epifaunal diversities among habitats because of variation among studies in the size range of organisms examined and in the number of hosts or area of seafloor sampled. However, some generalizations are possible. For instance, marine epifauna are far more taxonomically diverse than freshwater epifauna, and complex structures host more species than simple ones. In the oceans, species of macrophytes and sessile animals host up to several hundred epifaunal species.

Small organisms are more metabolically active than larger ones (they have higher mass-specific metabolic rates and shorter generation times), and will likely play increasingly greater roles in aquatic ecosystems as larger organisms are progressively removed by fishing. On New Zealand rocky reefs, small (0.5–10 mm) mobile epifauna contribute about 80% of total secondary (animal) production, and probably make similar contributions to total food consumption and nutrient regeneration by animals.

Small mobile epifauna are important trophic links between fishes and primary producers, while suspension-feeding epifauna link pelagic and benthic ecosystems by accelerating the flow of organic matter from the water column to the seafloor.

Interactions

As shown by the aquatic example in Fig. 2, there are numerous ways in which the host, its epiflora and epifauna can potentially interact. Some of the more important interactions are as follows. Sessile epibiota reduce their host's access to light and nutrients, and their additional mass can cause tree branches to break off or aquatic macrophytes to be torn loose by water movement. In an apparent response, some hosts actively discourage epibiota by allelopathy (the release of settlement- or growth-inhibiting chemicals) or by the shedding/sloughing of heavily fouled tissues. There is ample scope for indirect effects, the most important of which is probably the favor that many herbivorous epifauna do their host macrophyte by removing fouling epiphytes – some seaweeds are rapidly smothered by epiphytes in the absence of certain epifaunal grazers. On the other hand, direct grazing by epifauna can seriously damage the host macrophyte, especially when vulnerable tissues or microscopic life stages are targeted.

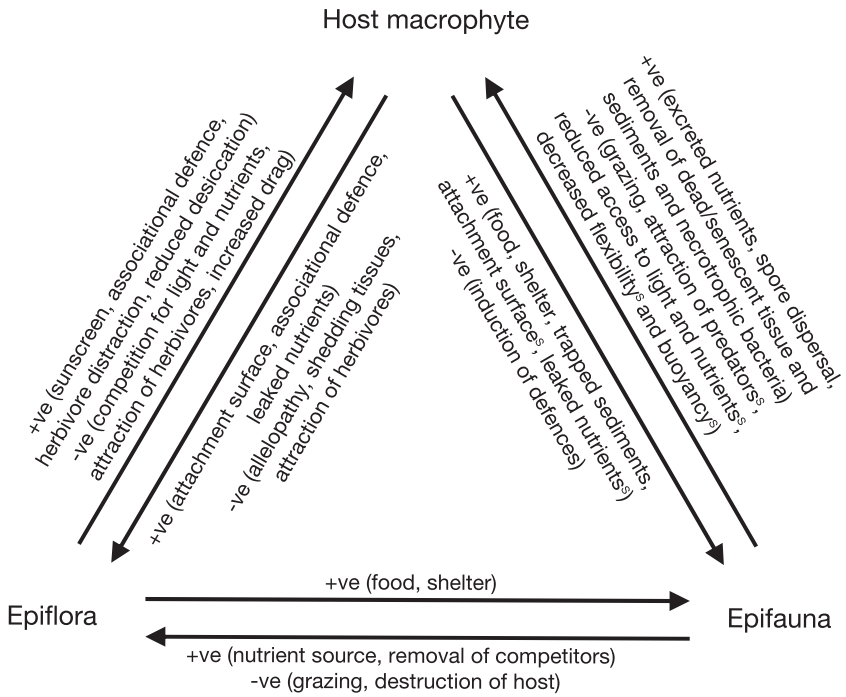

Fig. 2 Summary of potential interactions between aquatic macrophytes, epiflora, and epifauna. A positive effect of one group of organisms on another is denoted by "+ve", and a negative effect by "-ve". Superscripted "S" refers to sessile epifauna.

Trophic Cascades: The Importance of Predators

In aquatic ecosystems, the impact of grazing epifauna on both host macrophytes and their epiflora is often moderated by small predatory fishes (a so-called "trophic cascade").

Several mesocosm experiments have found that fishes prevent epifaunal overgrazing of seaweeds. Interestingly, for seaweed epifaunal taxa feeding on periphyton the main effect of fish predation is to remove the larger epifaunal individuals, which actually results in higher total numbers of epifauna due to the freeing up of the limiting periphyton resource for many more small individuals.

In freshwater macrophyte beds, epifauna appear to have a much greater impact on periphyton than on the host, so by reducing epifaunal densities fish promote periphyton growth and thus decrease host vigor. Fish predation on epifauna may ultimately shift shallow lakes from macrophyte- to phytoplankton-dominated ecosystems.

Light and nutrients also strongly affect primary productivity in aquatic ecosystems, but it is not yet possible to generalize about the relative importances of bottom-up (resource) and top-down (consumer) controls on community structure.

Life Histories

The taxonomic diversity of epibiota is reflected in their wide range of life histories. Some species have complex life cycles with phases that look like they belong to different species (Fig. 3). Epibiota face particular life history challenges. Suitable host species may be short-lived or patchily distributed, making it difficult for individual epibiota to find hosts, grow to maturity and locate mates. If the host has a strongly seasonal life cycle then specialized obligate epibiota need to synchronize their own life cycle accordingly. In common with nonepibiota, tradeoffs in life history traits are to be expected. For example, should offspring be dispersed widely in the hope of finding a vacant settlement site, or settle next to the parent in what may be an overcrowded or deteriorating habitat (such as a rotten tree branch)? Although traits such as self-compatibility may be more frequent in certain epibiota species than related nonepibiota, life histories of epibiota generally reflect their phylogeny much more strongly than their lifestyle, i.e., there is no particular life history mode that is characteristic of epibiota as a whole.

Threats

Human activities affect epibiota in a variety of ways. Like other organisms, epibiota are and will be affected by climate change directly through changing temperature, precipitation (on land) and acidification (in water), and indirectly through altered species interactions. The diverse epiphyte communities in tropical cloud forests are particularly vulnerable to climate change due to their

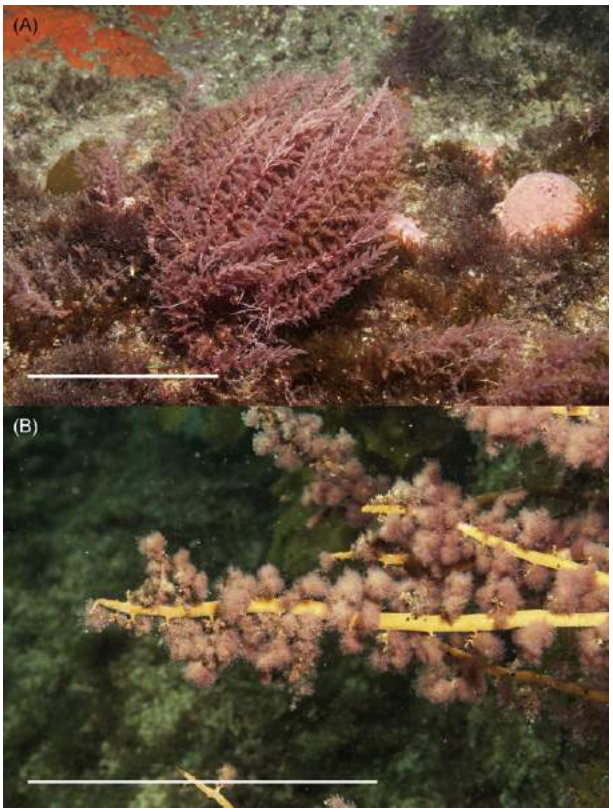

Fig. 3 Alternating life stages of the red alga *Asparagopsis armata*. (A) gametophyte, growing on turfing algae, (B) tetrasporophyte, growing on the brown seaweed *Carpophyllum plumosum*. Both life stages occur mainly as epiphytes. The gametophyte is haploid and dioecious. Sperm from males fertilizes eggs within a carposporangium on the female. The resultant diploid carpospores are released, and germinate into tetrasporophytes. When mature these develop haploid tetraspores via meiosis, which are released and germinate into gametophytes to complete the life cycle. The gametophyte is present in spring and early summer, while the tetrasporophyte is present year-round. Before the life cycle was worked out the tetrasporophyte was assigned to a separate genus and species. White bars represent 100 mm. Photos copyright Richard Taylor.

dependence on atmospheric moisture. Habitat modification, such as the destruction or fragmentation of natural forests, has varying effects on epiphytes. Some species are able to establish in plantation forests, while opening up the forest to wind through fragmentation favors epiphytes that tolerate a drier microclimate, at the expense of species that cannot. In the sea, the effects of dredging and trawling on seafloor epifauna have been compared to the clear-felling of forests on land. Air pollution affects many terrestrial epiphytes, and lichens are even used as indicator species in this regard. In aquatic systems, pollutants such as fine sediments and nutrients have greatly altered many ecosystems. Interestingly, eutrophication (excess nutrients) sometimes favors algal epiphytes over macrophytes, as the high surface area: volume ratio of microalgae and filamentous macroalgae enables them to take up nutrients more rapidly. Many terrestrial epiphytes are heavily harvested for medicinal or ornamental purposes.

Generation Time☆

Enric Cortés, National Oceanographic and Atmospheric Administration, Panama City, FL, United States
Gregor M Cailliet, Moss Landing Marine Laboratories, Moss Landing, CA, United States

Glossary

Cohort In general a collection of individuals that share some trait(s). When referring to generation time, a group of individuals born in the same year (or other unit of time).

Intrinsic rate of population growth The maximum rate at which a population can increase with no resource limitation. It is a constant expressed in year^{-1}. Also known as maximum rate of population increase (r_{max}), Malthusian parameter, or per capita rate of growth.

Life table A schedule of survival probabilities and fecundity, typically at age, that is used to calculate the intrinsic rate of population growth and other demographic parameters, such as generation time.

Projection matrix A mathematical model—a matrix—that projects the population from time t to time $t+1$ assuming constant schedules of survival and reproduction at age (or stage or size). Analogous to a life table.

Stable age distribution A principle of ecology by which the proportions of individuals belonging to different age groups will remain constant generation after generation when the population reproduces in a constant environment with no resource limitation.

Definition of Generation Time

The estimation of generation time, or generation length, is an important part of the demographic analysis of populations because it is a measure of the time required for a newborn to become a parent and this influences a population's potential for growth. The word "generation" is generally defined as the average age at which a female from any given population gives birth to her first female offspring, or the average age of mothers in a population. It is therefore equivalent to the time that it takes a population to increase by a factor equal to the net reproductive output of those females.

There are several definitions of the term generation and ways of calculating its length (generation time) for age-structured populations. The first is to calculate the time T required for a population to increase by a factor of R_0 (its net reproductive rate). Two other definitions include (1) the mean age (μ_1) of the females bearing offspring produced by a cohort over its lifetime (not requiring a stable age distribution) and (2) the mean age ($\overline{A}$) of the females bearing pups produced by a population at the stable age distribution—for this last one, in a stationary population with $\lambda = 1.0$, $\mu_1 = \overline{A}$, where λ is the finite rate of population growth.

Calculation of Generation Time

While the concept of generation and generation time (or length) has been an important, but varying, concept over the years, ways of calculating it have also varied. Generation times can be calculated either through the use of life tables or projection matrices. Early authors defined generation time as the mean length of a generation (or the average time from the birth of a mother to the birth of her first female offspring), and used it as T in the exponential growth equation $N_t = N_0 e^{rT}$. Then, from their definition of the net reproduction rate as $N_t/N_0 = R_0$, they solved for $r = \ln R_0/T$ and $T = \ln R_0/r$. But, it was then pointed out that the mean length of a generation cannot be obtained until the best value of r, the intrinsic rate of population growth, is obtained, which is only possible after iteratively solving the Euler–Lotka equation, which in its discrete form is expressed as $\sum l_x m_x e^{-rx} = 1$,where l_x is the probability of a female being alive at the beginning of age x and m_x is the number of female offspring produced by a female of age x. This ultimately led to the other two expressions of generation time, μ_1 and $\overline{A}$. The first, μ_1, is equal to $\sum x l_x m_x / \sum l_x m_x$, whereas the second, $\overline{A}$, is expressed as $\sum x l_x m_x e^{-rx}$. Both of these equations have commonly been used in many papers and textbooks to explain how to calculate generation times. The above calculations of generation time (and other parameters) involve the creation of life tables—a more classic approach to demography. A relatively more contemporary approach to demography involves the use of Leslie (age-based) or Lefkovitch (stage-based) matrix models.

Demographic analyses are useful for understanding the population dynamics of many organisms and their likely response to exploitation. The role of generation time in these analyses is crucial in understanding the interaction between age- or stage-specific survivorship and reproductive-output functions. Such approaches have been used to produce estimates of generation time for many types of organisms including algae, flowering plants, invertebrates, fishes, reptiles, birds, and mammals.

☆*Change History:* February 2018. E Cortés and GM Cailliet updated Abstract, updated, extended, and added sections to the text, extended the Further Reading, and modified Figure 1.

This is an update of G.M. Cailliet, Generation Time, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1734–1736.

Ecological Considerations

Generation time is positively correlated with body size (see Fig. 1), leading some authors to categorize this as a "generation-time law." The mathematical relationship is that the generation time increases with body size at a power of approximately one-fourth of the body mass, a pattern which appears to hold across taxa. Body size (measured as weight or length) in a variety of organisms is also positively related to reproductive output (e.g., clutch weight or volume, number of eggs per female parent), hatchling weight (egg or other product), gestation (or brood) time, maturation time, and maximum life span. The intrinsic rate of population growth appears to decrease with body size across taxa following the same allometric relationship as generation time, in other words it decreases with body size at a power of approximately one-fourth of the body mass. However, in some taxa it can be either negatively or not related to body size and generation time.

The relationship between generation time and the intrinsic rate of increase with body mass led some authors to define the intrinsic rate per generation (rT), which is a dimensionless quantity because r is measured in years^{-1} and T is measured in years, such that: $rT = a_r M^{-0.25} a_t M^{0.25} = a_r a_t M^0 = a_r a_t$, where M is body mass and a_r and a_t are the constants in the allometric equations for intrinsic population growth rate and generation time, respectively. The intrinsic rate per generation is related to an important reference point in population dynamics of exploited populations, the position of the inflection point of population growth curves, which is a measure of where "maximum sustainable yield" (MSY) or "Catch" can be attained. The relationship between the intrinsic rate per generation and the position of the inflection point of population growth curves is independent of body size. These relationships, often employing size at maturation or first reproduction rather than actual generation times, have also been employed to better understand how the life-history traits of many organisms have evolved.

The intrinsic rate per generation, or product of the allometric constants, has been shown to be approximately equal to 1 in several taxa. This led to two simplified definitions of generation time under ideal conditions and assuming constant adult survival probability (s) and fecundity after the age at first reproduction (α): $\overline{T}_{op} = \alpha + {}^{s}/_{e^r} - s$ and $\overline{T}_{op} \approx {}^{1}/_{e^r} - 1$.

The Use of Generation Time in Conservation and Fisheries

The concept of "generation time" has been used extensively by the International Union for the Conservation of Nature (IUCN) as part of their process of categorizing the status of species and their populations worldwide. They state "Generation length is the

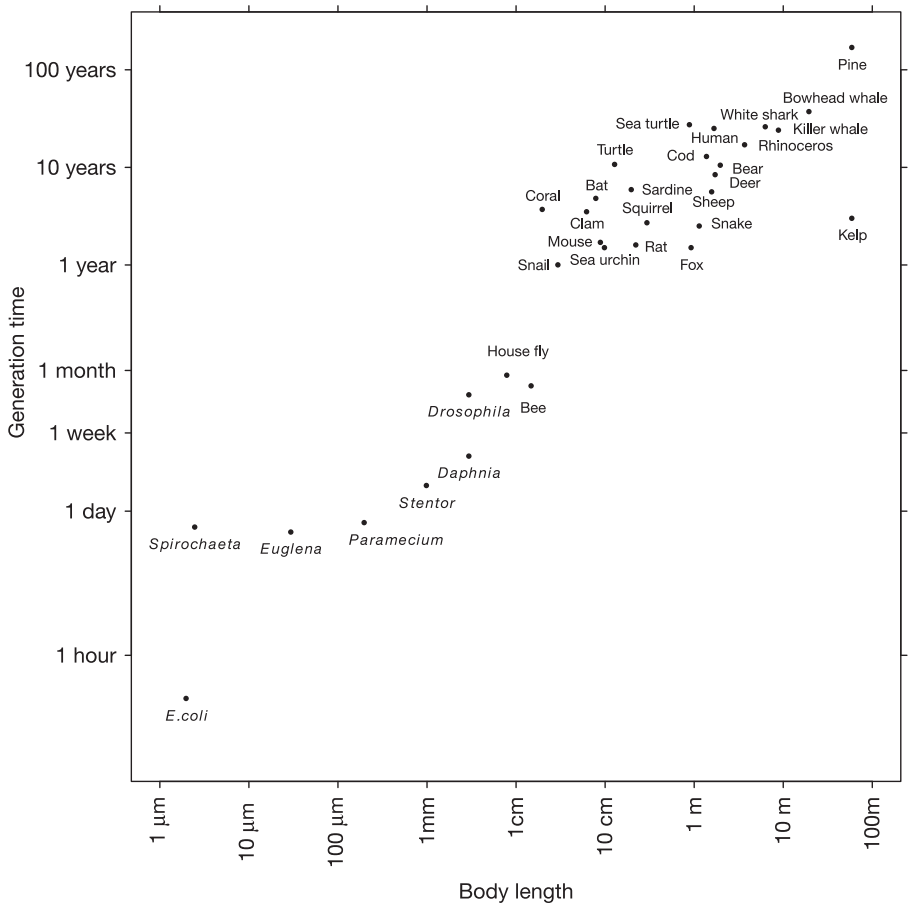

Fig. 1 The relationship between body size and generation time for several groups of living organisms.

average age of parents of the current cohort (i.e., newborn individuals in the population). Generation length therefore reflects the turnover rate of breeding individuals in a population. Generation length is greater than the age at first breeding and less than the age of the oldest breeding individual, except in taxa that breed only once." Generation length is used to categorize the conservation status of species when determining whether they are declining by a certain percentage in abundance "over the last 10 years or three generations, whichever is longer." This enables the IUCN to decide whether a species should be placed on the Red List and categorized as "critically endangered" (CR $\geq$ 90% reduction), "endangered" (EN $\geq$ 70% reduction), or "vulnerable" (VU $\geq$ 50% reduction). Therefore, in this process, the accuracy of both the estimates of population abundance and generation time estimates is extremely important.

Because estimates of age-specific survival and fecundity are often difficult to obtain, the IUCN recommends using two proxies—which are simplifications like the equations for T_{op} we saw in the previous section—to calculate generation time. The first equation assumes constant adult survival and fecundity and infinite lifespan and simplifies to: $T = \alpha + {}^{1}/_{M}$ where M is the instantaneous rate of natural mortality. The second equation is: $\hat{T}_z = \alpha + z(\omega - \alpha)$ where ω is lifespan and therefore $\omega - \alpha$ is a measure of reproductive lifespan, and z is a constant that "depends on survivorship and the relative fecundity of young vs. old individuals in the population." However, it has been found that these proxies can introduce bias and it is preferable to use the traditional definitions of generation time, highlighting the importance of collecting the detailed life history information needed for their computation.

Generation time also comes into play when calculating rebuilding times for overexploited species in fisheries, both in the United States and worldwide. Under precautionary approaches, scientists at the National Marine Fisheries Service (NMFS) of the United States Department of Commerce first calculate the rebuilding time (time it takes for the stock to reach the biomass that produces MSY under zero fishing mortality) and if that rebuilding time exceeds 10 years, then they must add the generation time to it to estimate a new rebuilding period.

Growth Constraints: Michaelis–Menten Equation and Liebig's Law☆

Sven E Jørgensen, Copenhagen University, Copenhagen, Denmark

Glossary

Enzyme kinetics The study of the enzyme-catalyzed reactions that depends on the concentration of the compounds directly interacting with the enzyme and the highest rate achievable by the enzyme that are catalyzed by enzymes.

Rate equation Rate equation is a mathematical formula that shows the effect of changing the concentrations of the reactants on the rate of the reaction.

Reaction rate constant (or coefficient) Reaction rate constant quantifies the rate of a chemical reaction. The value depends on changes on conditions such as temperature or the catalyst.

Substrate The chemical species of interest that is being modified.

Threshold agents The agents that, in a suitable concentrations, promote growth. Nonthreshold agents, in contrast have a negative or no effect on the growth.

What Stops Growth? Liebig's Law

Considering the generalized growth and development phenomenon, we have to ask the question: Why does it not continue indefinitely? What stops growth? Why do the trees not grow to the sky, bacteria not fill the oceans, etc.? The answer is that the elements needed to build the biomass of various species are present only in a limiting amount in the environment/the ecosystems. Liebig's law considers these interactions between the organisms and their growth on the one side and the concentrations of nutrients on the other side. The elementary composition varies from plant to plant and from organism to organism and even the same species may have a different composition in different environments and at different times of the year. There are, however, some basic biochemical processes that require a combination of elements in a certain ratio.

The biochemistry and the biochemical reactions for all organisms on Earth are very similar, although they vary slightly from organism to organism. About 20 elements are necessary to build an organism, sometimes with the addition of one to five more elements. **Table 1** shows an example of the elementary composition of freshwater plants. The relative quantities of the 19 essential elements in plant tissue are shown. The composition is not strictly stoichiometric, as is that of a chemical compound, but may vary between lower and upper values following the composition of different biochemical compounds in the cells. For instance, phytoplankton can contain approximately 0.5%–2.5% of phosphorus and 5%–12% of nitrogen by dry weight.

The required elementary composition of an organism reflects the chemical constraints for growth. Growth implies that the environment delivers the elements—for plants as suitable compounds dissolved in water in contact with the plants, and for animals by the composition of available food. The environment rarely has exactly the same composition as required for growth, which implies that the element less abundant in the environment compared with the need determines the limits to growth. This is expressed in Liebig's law of the minimum (see **Fig. 1**); if a nutrient is at a minimum relative to its use for growth, there is a linear relation between growth and the concentration of the nutrient. If the supply of other factors is at a minimum, further addition of the nutrient in question will not, as shown, influence growth.

Growth and the Limiting Factor(s)

The relationship between growth $v = dw/dt$ (w is weight) and the concentration of the limiting factor is described by the Michaelis–Menten equation, which is also used to give the relation between the concentration of a substrate and the rate of a biochemical reaction:

$$dw/dt = v = ks/(ks + s) \quad (1)$$

where v is the rate (e.g., growth rate), k a rate constant, s the concentration of a substrate, and ks the half-saturation constant. The dimensions of ks and s are the same: kg m^2 or kg m^3. Notice that Eq. **(1)** corresponds to a zero-order reaction when $s > > ks$ and a first-order reaction when $ks > > s$. Growth follows a zero-order reaction when the resources are abundant, while Eq. **(1)** describes the influence of limiting resources on the growth rate ($s < < ks$).

The situation in nature is often not so simple, as two or more resources may be limiting simultaneously. This can be described by

 doi:10.1016/B978-0-12-409548-9.11151-0

Table 1 Average freshwater plant composition on wet basis

Element	*Plant content (%)*
Oxygen	80.5
Hydrogen	9.7
Carbon	6.5
Silicon	1.3
Nitrogen	0.7
Calcium	0.4
Potassium	0.3
Phosphorus	0.08
Magnesium	0.07
Sulfur	0.06
Chlorine	0.06
Sodium	0.04
Iron	0.02
Boron	0.001
Manganese	0.000,7
Zinc	0.000,3
Copper	0.000,1
Molybdenum	0.000,05
Cobalt	0.000,002

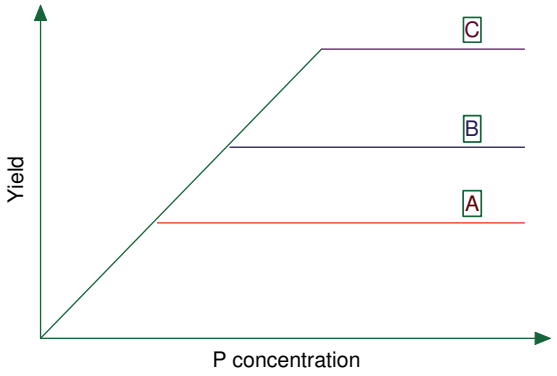

Fig. 1 Illustration of Liebig's law. The phosphorus concentration is plotted against the yield. At a certain concentration another component will be limiting, and a higher P concentration will not increase the yield. The three levels A, B, and C correspond in this case study to three different potassium concentrations.

$$v = K^r(N_1/(ks_1 + N_1))(N_2/(ks_2 + N_2)) \tag{2}$$

where N_1 and N_2 are the nutrient concentrations, K^r is a rate constant, and ks_1 and ks_2 are the half-saturation constants related to N_1 and N_2.

This equation will often limit the description of growth too much and is in disagreement with many observations. Eq. (3) seems to overcome these difficulties:

$$v = K^r \min\,(N_1/(ks_1 + N_1)), (N_2/(ks_2 + N_2)) \tag{3}$$

This expression is in accordance with Liebig's minimum law. Another possibility would be to apply the average of two or more limiting factors, for instance, for two limiting factors (nutrients):

$$v = K^r[(N_1/(ks_1 + N_1)) + (N_2/(ks_2 + N_2))]/2 \tag{4}$$

Finally, it is also possible to use the following expression:

$$v = 2K^r/[((ks_1 + N_1)/N_1) + ((ks_2 + N_2)/N_2)] \tag{5}$$

If one element (nutrient) is limiting, the growth Eq. (1) can be used. It is often the case for lakes, where phosphorus is the limiting nutrient. In coastal areas both phosphorus and nitrogen may be limiting at different parts of the year and it is necessary to apply Eq. (2), (3), (4), or (5). Experience has shown that Eq. (3) and (4) have given the most promising results in the sense that it has been possible to obtain better calibration and validation for models that are based on these two equations.

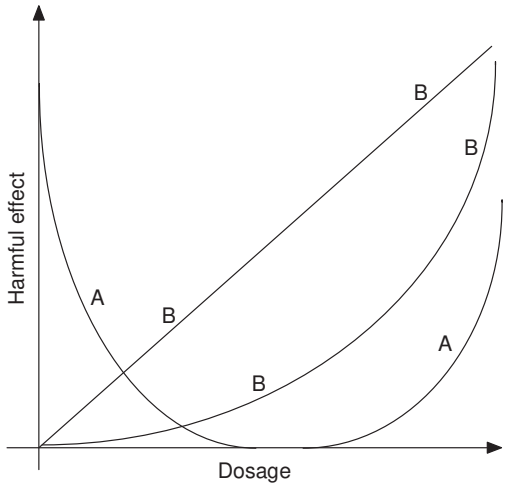

Fig. 2 A indicates threshold agent; B indicates nonthreshold or gradual agent. To have a threshold agent it is sufficient that one of the two A-plots is valid. The two B-plots represent two different dose–response curves.

The Michaelis–Menten equation is extensively applied in ecological models for nutrient-limiting plants' growth, for grazing, and for predation. The equation takes into consideration the needs for growth in form of nutrients or food and the availability of the resources. It is obvious that interactions between growth of organisms and the resources determining the growth are frequently describing the actual situation in an ecosystem, which explains the frequent application of the Michaelis–Menten equations. The same equation is applied frequently in biochemistry to describe the kinetics of biochemical enzymatic processes. The enzymes correspond to the organisms and the substrates correspond to the nutrients or food.

Threshold and Nonthreshold Agents

Following the general terminology, we distinguish between threshold agents, that in a suitable concentration promote growth, and nonthreshold agents, that in all concentrations have a negative or no effect on the growth.

Threshold agents include various nutrients, such as phosphorus, nitrogen, silica, carbon, vitamins, and minerals (calcium, iron, zinc, etc.). When they are added or taken in excess, the organism or the ecosystem can be overstimulated, and the ecological balance may be damaged. Examples are the eutrophication of lakes, streams, and estuaries from fertilizer runoff or municipal wastewater. The threshold level and the type and extent of damage vary widely with different organisms and stresses. The thresholds for some pollutants may be quite high, while for others they may be as low as 1 ppm or even 1 ppb.

The threshold level is often closely related to the concentration found in nature under normal environmental conditions. This shows that the organisms have become adapted to the chemical composition of the environment.

Nonthreshold agents are a number of heavy metals, pesticides, and a number of toxic organic compounds. It is important to determine the noneffect level or noneffect concentration for these compounds to determine at which level or concentration a negative effect on organisms and ecosystems can be expected.

Fig. 2 shows the different effects of threshold and nonthreshold agents. Threshold agents have often harmful effects when they are not present in sufficient quantities to support growth. The range where there chemical composition of organism to the chemical composition of the environment takes place. The biochemistry developed reflects the available elements and compounds. For instance, the role of magnesium and manganese ions and later zinc ions as cofactors for many enzymatic processes could be due to the presence of these ions in a suitable concentration, while other ions could have been used had they been present in an appropriate concentration. The use of calcium in skeletons can be explained more or less in this way.

Growth Models☆

Todd M Swannack, US Army Engineer Research and Development Center, Vicksburg, MS, United States

Introduction

This article presents an overview of the mathematical models of population growth for single-species populations. The first section discusses the models used to model population growth for species with nonoverlapping generations. These models are represented mathematically by linear or nonlinear difference equations. The second section focuses on the models used for species with overlapping generations—these range in complexity from the classic exponential and logistic growth models to models incorporating time lags, or population projection matrices with age (or class)-specific natality and mortality rates. The third section discusses how population growth is affected by the inclusion of stochastic variables.

Discrete Generations

Nonoverlapping generations are common biological phenomenon and population growth is modeled using difference equations. These models all assume that the population size at time $t + 1$ depends only on the conditions at the time t (usually the beginning of each growing or breeding season). The simplest model can be expressed as

$$N_{t+1} = R_0 N_t \tag{1}$$

where N_{t+1} is the population size at time $t + 1$ and N_t is the population size at time t. R_0 is a constant per capita reproductive rate, which is independent of population size. There are three possible outcomes of this model. If $R_0 > 1$ the population will increase geometrically (Fig. 1A), if $R_0 = 1$ the population is at equilibrium (Fig. 1B), and if $R_0 < 1$ the population size will decrease (Fig. 1C).

The above model assumes that R_0 does not change with population size; however, populations do not generally grow at a constant rate. The growth rate of a population should be different for different densities. The simplest assumption regarding this change in reproductive rate based on density is to assume that the R_0 decreases linearly as population size increases. R_0 can be calculated by using a linear equation:

$$R_0 = 1 - B\left(N_t - N_{eq}\right) \tag{2}$$

where $(-)B$ is the slope of the line and N_{eq} is the equilibrium size of the population ($R_0 = 1$ at N_{eq}). Therefore, Eq. (1) can be rewritten as

$$N_{t+1} = \left(1 - B\left(N_t - N_{eq}\right)\right)N_t \tag{3}$$

This model can generate several different behaviors, depending on the value of BN_{eq}. If BN_{eq} is between 0 and 2, the model will converge on N_{eq} either without oscillations ($1 > BN_{eq} > 0$) or with damped oscillations ($2 > BN_{eq} > 1$) (Fig. 2a). If BN_{eq} is between 2 and 2.57, the growth form is stable limit cycles continuing indefinitely (Fig. 2b), and if $BN_{eq} > 2.57$, the population size fluctuates in a nonrepeatable (chaotic) pattern (Fig. 2c).

☆*Change History*: March 2018. Todd M. Swannack updated Reference section.

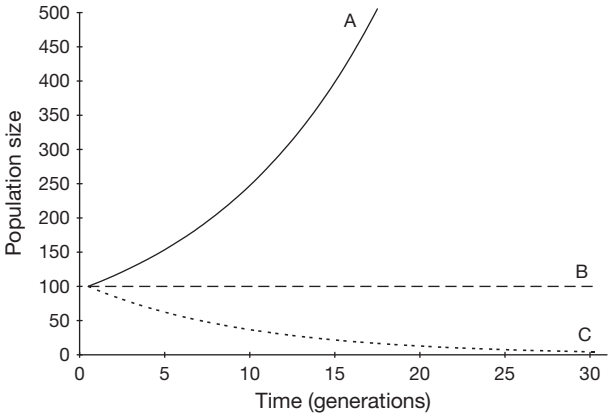

Fig. 1 Population growth for discrete generations using a difference Eq. (1) with $N_0 = 100$. A represents $R_0 = 1.1$; B represents $R_0 = 1.0$, and C represents $R_0 = 0.9$.

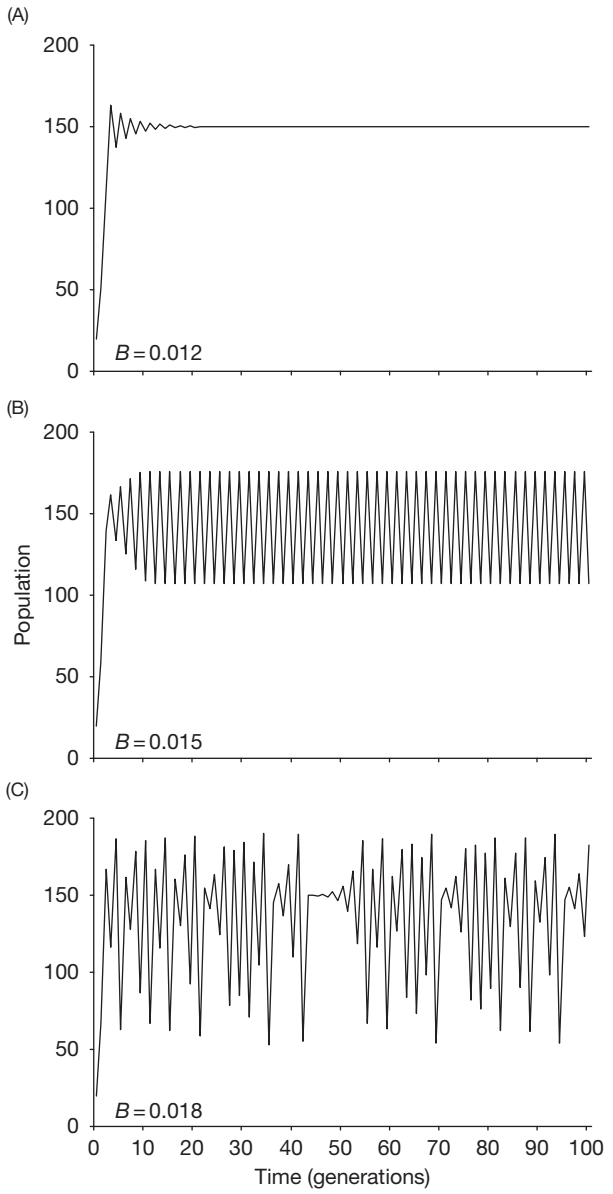

Fig. 2 Population growth with discrete generations and R_0 as a linear function of population density (Eq. 3). The model parameters were $N_0 = 20$, $N_{eq} = 150$, $B = 0.012$ (A), $B = 0.015$ (B), and $B = 0.018$ (C). Modified from Krebs, C. J. (2001). *Ecology*, 5th edn. San Francisco, CA: Benjamin Cummings.

Beverton–Holt Model

The Beverton–Holt model describes discrete-time populations:

$$N_{t+1} = \frac{\lambda N_t}{(1 + bN_t)} \tag{4}$$

where λ represents the finite rate of increase and b is a positive constant. This model approaches a stable equilibrium point for all parameter values and the growth form is analogous to the continuous-time logistic model (Eq. 10).

May Model

Models which assume a nonlinear relationship between the growth rate and the population size can also generate realistic growth forms. One of the simplest nonlinear models (commonly referred to as the May model) is expressed as

$$N_{t+1} = N_t e^{[r(1-N_t/k)]} \tag{5}$$

where e is the base of the natural logarithm, r is the intrinsic rate of increase, and K is the carrying capacity of the environment. This model assumes the relationship between r and N is nonlinear and the growth form exhibited by this model depends on the value of r, K, and the initial value of N. The growth forms of this model are analogous to that of Eq. (3). The model will reach a stable equilibrium at K if $1.99 \geq r \geq 0$, stable limit cycles (with 2, 4, 8, or 16 endpoints) if $2.692 \geq r \geq 2.0$, or become chaotic (nonrepeatable pattern) if $r \geq 2.693$.

Ricker Model

The Ricker model is another nonlinear model which has a wide range of behaviors:

$$N_{t+1} = \lambda N_t e^{bN_t} \tag{6}$$

This model, like Eqs. (4) and (5), can generate growth forms reaching a stable equilibrium point, can oscillate in a repeatable stable limit cycle, and can also generate chaotic, nonrepeating behavior, depending on the initial values of the parameters.

Continuous Generations

Many species have evolved life-history strategies that favor longer lives with multiple reproductive events occurring during the life span. Population growth of these iteroparous species has been commonly modeled using either continuous-time differential equations or population projection matrices.

Birth–Death Model

The simplest model of population growth for species with continuous generations assumes that birth and immigration are combined and death and emigration are combined into a general addition and loss rate, respectively. These rates are constants and the model is represented as

$$\frac{\mathrm{d}N}{\mathrm{d}t} = bN - \mathrm{d}N \tag{7}$$

where b is the instantaneous birth–immigration rate, d is the instantaneous mortality–emigration rate, N is the population size, and $\mathrm{d}N/\mathrm{d}t$ represents the rate of change in N.

Exponential Growth Model

Assuming that in any time interval ($\mathrm{d}t$) an individual can be added to the population either through birth or immigration and in the same interval there is a probability of dying or emigrating, then the instantaneous rate of per capita growth will be

$$r = b - d \tag{8}$$

where r represents the intrinsic rate of growth for the population at time t. The differential equation representing the increase in population size during successive time intervals is

$$\frac{dN}{dt} = rN \tag{9}$$

where N represents the population size and r represents the population's intrinsic capacity for increase (also referred to as the Malthusian parameter). This model assumes that environmental resources are unlimited and r is a constant. The population will increase as long as r is positive (i.e., as long as $b > d$) (Fig. 3A).

Logistic Growth Models

Population growth cannot continue to infinitely large sizes because resources within any environment are finite. The most common population growth model representing growth in a limited environment is a logistic equation (commonly called the Verhulst–Pearl logistic equation) that has a maximum limit at the carrying capacity (K) of the environment:

$$\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right) \tag{10}$$

where r is the intrinsic rate of increase and the $(1 - N/K)$ term represents the effect of individuals in the same population competing for resources (i.e., the effect of intraspecific competition). The growth curve is sigmoid shaped (Fig. 3B). The rate of change in population size is highest at low population sizes and has a value of zero once the population reaches carrying capacity. The Verhulst–Pearl model assumes the population size at time t only depends on the conditions at t, K is a constant, and every new individual decreases the rate of population increase by the fraction $1/K$, causing the decrease in r to be a linear function of N. At any initial value of N, the model will approach K monotonically.

Theta Logistic Model

The Verhulst–Pearl model can be modified by adding an exponent (θ) to the $(1 - N/K)$ term allowing a nonlinear relationship between r and N. The θ-logistic model is as follows:

$$\frac{dN}{dt} = rN\left[1 - \left(\frac{N}{K}\right)^{\theta}\right] \tag{11}$$

where θ controls the shape of the relationship between r and N. The value of θ depends on how individuals of a given population interact at different values of N. The growth form of this model is sigmoid for all values of θ, yet different values of θ have different ecological interpretations. If $\theta > 1$ there is a convex relationship between r and N, inferring that a population grows rapidly until it approaches K then growth slows rapidly. If $\theta = 1$, then the model behaves exactly like Eq. (7) (i.e., the negative effect of each individual is the same, regardless of population size). If $\theta < 1$ then there is a concave relationship between r and N, implying that the per capita reduction in population growth is greater at lower values of N.

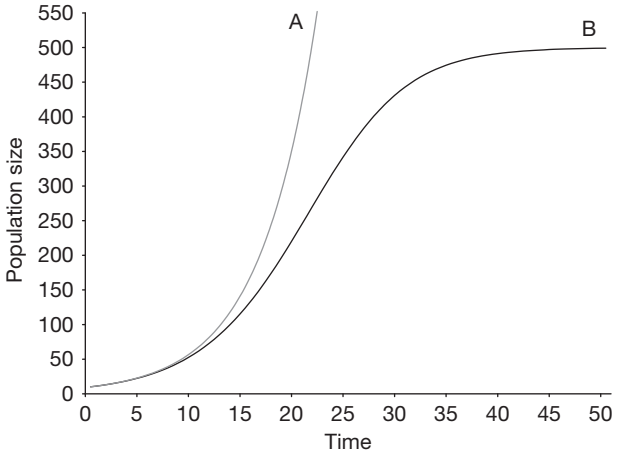

Fig. 3 Population growth forms for species with continuous generations. (A) Exponential (geometric) population growth in an environment with unlimited resources (Eq. 6, $r = 0.085$, $N_0 = 10$). (B) Logistic (sigmoid) population growth in an environment with limited resources (Eq. 7, $r = 0.085$, $K = 500$, $N_0 = 10$).

Time-Lag Models

Time–lag models attempt to create population growth forms which better reflect natural conditions because organisms rarely respond instantaneously to a change in the system. Introducing a time lag into a model can destabilize the model and cause dramatic fluctuations in population size, depending on the length of the time delay. The simplest time-lag model is a modification of the birth and death rate model (Eq. 7):

$$\frac{dN(t)}{dt} = b(N(t-\tau)) - d(N(t)) \tag{12}$$

where b is the instantaneous birth rate, t is the current time, τ represents the time delay (the $N(t-\tau)$ term is the population size at time $t-\tau$), and d is the instantaneous death rate. This model assumes that d is related to the current population size, but that b depends on the population size at time τ.

The Verhulst–Pearl logistic equation can be modified to incorporate time lags:

$$\frac{dN(t)}{dt} = rN_t\left[1 - \frac{N(t-\tau)}{K}\right] \tag{13}$$

where t represents the current time and τ represents the time delay that individuals experience before they are capable of contributing new individuals to the population. The dynamics of this model are controlled by values of the combination $r\tau$. The model will reach a stable equilibrium for $0 < r\tau < e-1$ ($e-1 \approx 0.36788$), damped oscillations for $e-1 < r\tau < \pi/2$, and a stable limit cycle for $r\tau > \pi/2$.

Eq. (13) can be further modified to incorporate more than one time lag:

$$\frac{dN(t)}{dt} = rN(t-\tau_g)\left[1 - \frac{N(t-\tau)}{K}\right] \tag{14}$$

where τ_g is a second time lag. The second time lag will further slow the rate of population increase, but will create patterns of growth similar to those in Fig. 4, that is, the larger the time lag, the larger the amplitude of the oscillations.

Matrix Models

As organisms age, their realized fecundity as well as their survival rates can change. Age-based matrix models separate populations into different age classes and each age class can possess different fecundity and survival rates. Matrix models are useful when hypothesizing about the importance of specific population parameters for certain age classes. Identifying the most sensitive age class is important for management strategies, especially for endangered species.

The most common matrix model is an age-based matrix, commonly referred to as the Leslie matrix. The individuals in a population are separated into classes based on their age (N_x) and each class is assigned a probability of survival (P_x) and a realized fecundity (F_x). F_x and P_x are put into a transition matrix **M** with F_x along the top row of the matrix and P_x along the subdiagonal, and all other elements in **M** are assigned a value of zero (Fig. 5A). Population projections can be made by placing the current number of individuals in each age class into a vector $\boldsymbol{n}$ and obtaining the product of the **M***n* matrices:

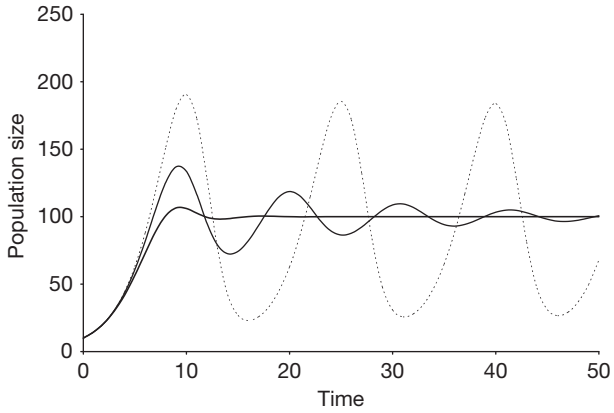

Fig. 4 Population growth of a model with time lags. The *heavy black line* was modeled without a time lag ($\tau = 0$) and reaches a stable equilibrium point, the *light black line* was created with a $\tau = 1$ and exhibits damped oscillations, and the dotted line was created using $\tau = 2$ and exhibits a two-endpoint stable limit cycle.

(A)

$$\mathbf{M}_A = \begin{bmatrix} F_0 & F_1 & F_2 & \dots & F_{m-1} & F_m \\ P_0 & 0 & 0 & \dots & 0 & 0 \\ 0 & P_1 & 0 & \dots & 0 & 0 \\ 0 & 0 & P_2 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & P_{m-1} & 0 \end{bmatrix} \quad \mathbf{n}_A = \begin{bmatrix} N_0 \\ N_1 \\ N_2 \\ \vdots \\ N_{m-1} \\ N_m \end{bmatrix}$$

(B)

$$\mathbf{M}_B = \begin{bmatrix} G_1 & F_2 & F_3 & \dots & F_{m-1} & F_m \\ P_1 & G_2 & 0 & \dots & 0 & 0 \\ 0 & P_2 & G_3 & \dots & 0 & 0 \\ 0 & 0 & P_3 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & G_{m-1} & 0 \\ 0 & 0 & 0 & \dots & P_{m-1} & G_m \end{bmatrix} \quad \mathbf{n}_B = \begin{bmatrix} N_1 \\ N_2 \\ N_3 \\ \vdots \\ N_{m-1} \\ N_m \end{bmatrix}$$

Fig. 5 Population projection matrices. (A) An age-structured Leslie matrix ($\mathbf{M}_A$) and a vector ($\mathbf{n}_A$) of the number of the individuals in each age-class. (B) A stage-based matrix ($\mathbf{M}_B$) and a vector ($\mathbf{n}_B$) of the number of the individuals in each age class. Subscripts represent the age or size class with m being the oldest or largest class, respectively.

$$\mathbf{M}\mathbf{n}_t = \mathbf{n}_{t+1} \tag{15}$$

where $\mathbf{n}_t$ is the vector whose elements are the number of individuals in each age class, and $\mathbf{n}_{t+1}$ is the vector containing the number of individuals in each age class at time $t + 1$.

For some species, size or stage of development may be better indicators of an individual's fecundity and survival rate. These models do not assume that every individual leaves the class at every time step. The probability an individual will survive and remain in class x during the next time step is G_x. Stage-based matrices incorporate this term along the diagonal in the transition matrix $\mathbf{M}$. P_x is defined as the probability that an individual will move into the succeeding class $x + 1$. The P_x elements are placed along the subdiagonal in the transition matrix $\mathbf{M}$ (Fig. 5b). F_x is defined the same as in the Leslie matrix and population projections are calculated the same as above. The standard stage-based matrix model assumes that the first size class is not reproductively mature and any the remaining classes each have a specific realized fecundity.

Stochastic Models

Deterministic models of population growth allow the population size at time $t + 1$ to be calculated based on the knowledge of N_t plus the other factors that are included in the models. Stochastic models attempt to include the probabilistic nature of biological systems by representing one (or more than one) variable in the given model as a random variable. Natural populations can start at the same size but due to chance increase or decrease at different rates based on the value of the random variable at each time step. Any variable in a model that has any degree of uncertainty can be parametrized as a random variable. Stochastic variables can be based on a probability of occurrence (i.e., probability of breeding at any given time step, or probability of having a certain number

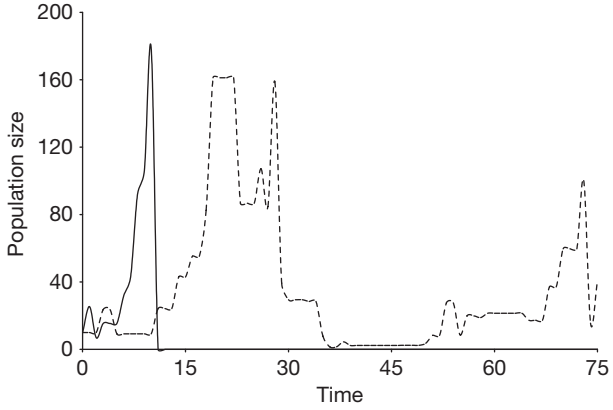

Fig. 6 Two simulations of a hypothetical population using a stochastic birth–death model. The probability of birth or death occurring at each time step was 0.5. The rest of the parameters were: $N_0 = 1.2$, $b = 1.2$, $d = 0.8$.

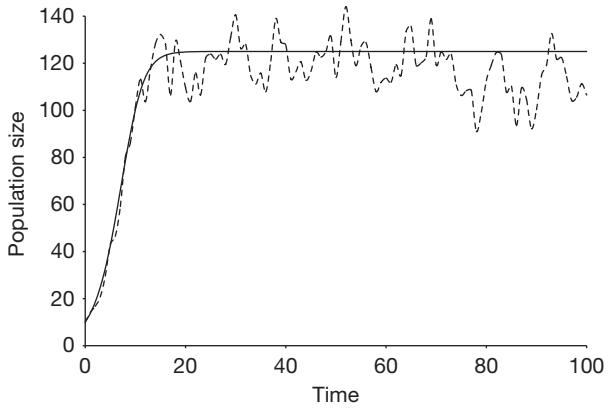

Fig. 7 Population growth for a deterministic model (*heavy line*) and model with the birth rate was a random variable (*dotted line*) chosen from a normal distribution with a mean of 1.2 and a standard deviation of 0.1.

of offspring during a given reproductive bout). These probabilities are generally assigned based on previous knowledge of the system. Stochastic models where both births and deaths occur randomly allow for a chance of extinction. Fig. 6 depicts two simulations of a random birth–death model (Eq. 7) where the probability of births and deaths occurring during a given time step was 0.5 (probabilities of occurrence were independent of each other). This representation exemplifies the nature of stochastic population models for small population sizes. The first simulation went extinct after 10 time steps while the second simulation did not go extinct during the simulation. Small populations are at a greater risk of extinction due to their inability to rebound after a catastrophic event. Stochastic models are often used to estimate the probability of extinction for a given population. This probability is based on several repetitions of the same stochastic model.

Random variables can also be chosen from a frequency distribution of historical data or from a statistical distribution fitted to historical data—Fig. 7 was created using the latter case, depicting growth curves for a hypothetical population created with both deterministic and random models. The same parameters were used except for the random model the birth rate was chosen at the beginning of each time step from a normal distribution with a mean of 1.2 and standard deviation of 0.1 while the birth rate for the deterministic model was 1.2. The population size of the stochastic model oscillates around K but does not converge on a single equilibrium point.

Summary

Population growth for a single-species population can be modeled in a variety of ways. Populations will grow exponentially if the per capita reproductive rate is constant and independent of population size. Simple difference equations used to model populations with discrete generations can generate complex behaviors including converging on an equilibrium population size, limit cycles, and chaos. The most common model used to estimate growth in populations with overlapping generations is the Verhulst–Pearl logistic equation where population growth stops at the carrying capacity. The Verhulst–Pearl model has restrictive assumptions, and was modified into the θ-logistic model which relaxes the assumptions of the relationship between the intrinsic rate of increase and population size. Time–lag models allow for the future population size to be dependent on a population size in the past. Adding a time lag to a model can destabilize it and cause fluctuations in population size, the amplitude of the fluctuations depending on the length of the time lag. Age- or size-based matrices group individuals into classes with each class having its own natality and mortality rates, and these models can project the future number of individuals for each class. Stochasticity can be parametrized into any model and the outcome will no longer be deterministic and will better reflect the probabilistic nature of biological populations.

Habitat

J Stamps, University of California, Davis, CA, USA

Introduction

'Habitat' can be defined as a location in which a particular organism is able to conduct activities which contribute to survival and/or reproduction. This definition emphasizes the notion that the term habitat is organism-specific; that is, it focuses on the biotic and abiotic factors that affect the survival or reproduction of a particular type of organism, and on the areas that contain these factors. In addition, the term 'habitat' focuses on particular areas within a larger landscape. In contrast, the related term 'niche' considers the range of environmental conditions which allow the members of a species to live and reproduce, but does not specify the areas where these conditions exist.

The term habitat can refer to locations at several different spatial scales. At the largest spatial scale, habitat refers to large geographic areas in which the members of a population are able to survive and reproduce. At a medium spatial scale, habitat refers to areas in which a single member of a population is able to survive and reproduce. And finally, at a small spatial scale, habitat refers to areas in which a single member of a population can conduct particular activities (e.g., foraging, shelter, offspring production). Often, the term 'microhabitat' is used to refer to areas in which organisms conduct particular activities, while the term 'macrohabitat' refers to areas used by populations or species.

Implied in the concept of habitat at the intermediate (individual) level is that it contains all of the biotic and abiotic factors which affect survival and reproduction, throughout the life of that individual. However, it is frequently difficult (if not impossible) for humans to identify and measure all of the factors that affect survival and reproduction for taxa of interest. As a result, researchers interested in defining habitat for a particular species usually take 'shortcuts', trying to find factors that humans can readily measure which might be related to the factors which determine whether or not an organism is able to live and reproduce in a given area. Some examples of the shortcuts used by humans to describe habitat include using vegetation species or structural features to describe habitat for birds, using type of soil or incline to describe habitat for trees, or using salinity or distance from the sea to describe habitat for organisms that live in estuaries. In these and comparable cases, researchers assume that the factors they are using to describe habitat either have strong direct effects on survival and reproduction, or that they are strongly correlated with other biotic and abiotic factors that affect survival and reproduction.

If these assumptions are valid, then surrogate measures of habitat can be reasonably successful. Thus, if a particular plant community provides a particular species of bird with nest-sites, food, water, protection from predators and inclement weather, and locations appropriate for social activities, then the space-use patterns of that species might map relatively closely onto the spatial distribution of that plant community. The assumption that some features of a habitat are more important than others is implicit in the term 'habitat-forming species', which refers to organisms that create habitat that can be used by other organisms. For instance, certain species of sea anemones provide habitat to anemonefish, which are able to live, grow, and reproduce within the protection of their tentacles. At a broader spatial scale, 'foundation species' create areas that are capable of supporting an entire community of other organisms. An obvious example are the corals which provide food, shelter from predators, protection from wave action, and other benefits to the large array of organisms that are only able to make a living on coral reefs.

However, while it is tempting to assume that one can determine habitat for one species by mapping the distributions of other organisms, this practice can sometimes lead one astray. Even if the members of a species only occur in association with another organism, this does not mean that every area that contains that organism will support members of that species. For instance, the presence or absence of avian brood parasites (e.g., cowbirds) in a landscape can have a major impact on the reproduction and sustainability of avian populations in that area, but vegetation maps alone are unlikely to reveal whether or not avian brood parasites are present in a particular region.

Given the considerable uncertainty that exists when humans attempt to describe habitats, there can be quite a gap between our notion of what constitutes a habitat and the constellation of biotic and abiotic factors which determine whether the members of a species would be able to sustain themselves in a given area. This uncertainty is one reason for use of the phrase 'suitable habitat', which ecologists often use to refer to areas which actually do contain the factors which determine whether an area can be used by the members of a population.

The Importance of 'Empty' Suitable Habitat

As a practical matter, empiricists begin studies of the habitat of a given organism by focusing on the areas in which it currently lives and reproduces. However, an area can provide suitable habitat for an organism without currently being occupied by any members of that species. The assumption that a habitat can be suitable but empty lies at the heart of many important concepts in basic and applied ecology. Metapopulation biology is based on the assumption that populations live in patches linked by dispersal, and that

at any given time, some of the patches in a given landscape may be unoccupied. Similarly, restoration ecology is based on the premise that humans can change previously unusable habitat into habitat that is suitable for a given species, but that newly suitable habitat will remain empty until it is colonized (either artificially, via translocations, or naturally, via dispersal) by the members of that species.

The concept of empty, suitable habitat is also relevant to range shifts and range expansions, topics of particular interest for applied ecologists in this era of global warming. Many areas which currently sustain the members of a given species may become unsuitable in the future, as a result of changes in temperature, rainfall, and all of the changes in biotic factors that can occur as an indirect result of climate change. Conversely, other regions which currently lack any members of a given species may become suitable for them within a few decades, as a result of the direct and indirect effects of global warming. While it is difficult to predict how climate change will affect the ranges of particular species, the geographic locations of suitable habitat are already beginning to shift for many organisms, and they are likely to shift even more in the coming years. As a result, ecological models which are based on the assumption that habitats are fixed in space across long periods of ecological and evolutionary time are gradually giving way to new approaches which acknowledge temporal shifts of habitat across the landscape.

Habitat Quality

Besides simply asking whether or not a habitat can support an organism, we can further categorize suitable habitats based on their 'quality', where the quality of a given habitat can be defined as the fitness an individual can expect if it lives in that habitat, after controlling for any positive or negative effects of conspecifics on fitness. In practice, habitat quality can be estimated by measuring fitness components of organisms living in different types of habitats at the same population density, or by controlling statistically for positive and negative relationships between population density and fitness.

Habitat quality measured at the spatial scales that are relevant to individuals has important implications for habitat quality at the larger spatial scales that are relevant to populations and species. For instance, if habitat type A supports higher individual survivorship and reproduction than habitat type B at any given population density, then habitat A will contribute more new biomass and more new recruits to the population than habitat type B per unit area. Hence, accurately estimating habitat quality is a major concern both for basic ecologists interested in the effects of habitat features on population dynamics, and for applied ecologists interested in identifying the locations with the largest potential impact on endangered or pest species.

As should be apparent from the previous section, population density should not be used as a surrogate for habitat quality. Although organisms sometimes accumulate in high-quality habitats, there are plenty of situations in which this does not occur. Indeed, the best habitats from the perspective of individual survival and reproduction may be areas which currently contain moderate to low population densities, or even areas which currently do not contain any members of the species. Every decade or so, ecologists write influential articles explaining the various reasons why population density should not be equated with habitat quality. Unfortunately, however, this practice is still fairly common, perhaps because it is easier for humans to estimate the number of organisms living at a given location than to measure the survivorship and reproductive success of those organisms.

Habitat Selection

Another interesting implication of the notion that habitats vary in quality is that we would expect organisms to evolve physiological or behavioral processes which increase their chances of finding, recognizing, and using higher-quality habitats. In fact, mechanisms for habitat selection are nearly ubiquitous in the natural world. Even sessile organisms exhibit habitat selection, albeit at the smaller spatial scales. Examples of microhabitat selection by sessile organisms include plants growing toward the light, or cnidarian colonies growing in directions that enhance the flow of nutrient-rich water past their foraging polyps. However, the champions of habitat selection are mobile animals. In fact, one of the major advantages of mobility in animals is that it allows them to select different microhabitats or habitats in which to conduct different activities, instead of attempting to maximize every component of fitness at a single location. Animals are able to forage in some microhabitats which contain food and safety from predators, rest in other microhabitats which feature favorable abiotic features (temperature, moisture, light, etc.) and biotic features (protection from predators and ectoparasites), advertise for potential mates in microhabitats in which communication signals can be perceived over long distances, etc. At larger spatial scales, individuals can select some types of habitat for long-term use during reproductive periods (breeding home ranges or territories), other types of habitat for long-term use when they are not reproductive (e.g., juvenile home ranges, wintering areas), and still other types of habitat to use when traveling over long distances (migration or dispersal).

Just as habitat can be defined at different spatial scales, habitat selection can occur at the level of microhabitats, individuals, or populations. In each situation, habitat selection refers to the behavioral processes by which individuals choose particular locations for conducting particular types of activities. At the smaller spatial scales, habitat selection refers to the processes by which animals choose microhabitats to use for foraging, offspring production (e.g., oviposition or nest-site selection), courtship or mating, sleeping, or other activities. At medium spatial scales, habitat selection refers to the choice of areas in which individuals will spend extended periods of time, for example, the choice by natal dispersers of a new patch of habitat in which to establish a home range or territory. Finally, at larger (population level) spatial scales, habitat selection refers to the processes by which different

individuals in the same population select a place in which to live. At this spatial scale, interactions between individuals within the population often play a major role in habitat selection. For instance, in some species newcomers are attracted to areas which already contain conspecifics (conspecific attraction), so that even if different areas contain the same biotic and abiotic features, newcomers are more likely to settle in areas that already contain members of their own species.

Habitat Selection versus Habitat Use

As a practical matter, it is much easier to study the behavioral processes responsible for habitat selection at smaller than at larger spatial scales. Many species will express reasonably natural microhabitat selection behavior under controlled conditions in the laboratory or in field enclosures, so we know quite a bit about how animals select foraging sites, oviposition sites, shelter sites, etc. However, it is much more challenging to design and conduct elegant experiments of habitat selection at larger spatial scales. As a result, researchers interested in habitat selection at the level of individuals and populations often estimate habitat selection indirectly, by comparing the habitat features of areas actually used by individuals or groups of individuals with habitat features at points in the same region that have been randomly chosen by the researcher. The implicit assumption here is that any difference between the two distributions reflects active habitat choice by the individuals in that population. However, this assumption is often problematical. For instance, the habitat-use patterns of new recruits in marine fish and invertebrates are strongly affected by habitat-specific mortality immediately after settlement. As a result, nonrandom distributions of new recruits across the landscape often have more to do with differential mortality than they do with differential settlement, or movement by new arrivals to preferred habitats.

Several authors have suggested using the term 'habitat use' rather than 'habitat selection' to refer to nonrandom spatial distributions of animals and other mobile organisms in heterogeneous landscapes. Habitat use carries no implicit assumptions about the processes which are responsible for associations between organisms and particular habitat features, and instead simply indicates habitat features which are associated with the space-use patterns of the organism of interest. As was indicated earlier in this article, identifying the factors which are associated with the habitat-use patterns of a given organism is an important first step toward identifying the factors that are required to support individuals and populations of any given organism.

Irene Martins*, University of Coimbra, Coimbra, Portugal

Introduction

Ernst Haeckel coined the word "oecology" in 1866 for a new science, but relevant observations and ideas had already been accumulating since the ancient Greeks. The balance of nature was the first ecological idea; Carl Linnaeus expanded it beyond animals to include plants and named it *Oeconomia Naturae*. Specialized sciences began to emerge in the early 1800s; among the earliest was phytogeography, founded by Alexander von Humboldt. Evolutionary theories by Lamarck and Charles Darwin were relevant to ecological ideas, since Lamarck thought species evolve rather than become extinct; Darwin saw competition as a cause of extinction. The roots of the main ecological specializations—plant ecology, animal ecology, limnology, and marine ecology—emerged in the 1800s, and limnology and plant ecology became organized by the 1890s. These four specializations were developed throughout the 1900s, as were new ones—primarily population ecology and ecosystem ecology. Ecological societies and journals came to the fore in the 1900s, as did institutions and specialized schools in various universities. Biogeochemistry arose in Russia (the USSR) in the early 1900s, and the Gaia theory arose in 1972. After the Second World War, environmentalism became important in all countries, and ecologists were needed as consultants. The International Biological Program (1964–74) produced many publications on ecosystems throughout the world.

Natural History

Antiquity and Middle Ages

The earliest ecological concept was the balance of nature, which arose from observations by Herodotus that predatory animals have fewer offspring than their prey and by Plato that each species has means to survive. Later, the sciences of zoology and botany were founded at Aristotle's school, the Lyceum. Supposedly, Aristotle wrote the zoological treatises and Theophrastos the botanical treatises; more likely, Theophrastos organized and compiled all of them. In Roman times, these sciences were abstracted in Pliny's *Natural History* and then remained part of a science of natural history.

During the Middle ages, ancient natural history knowledge was recovered and expanded. Emperor Friedrich II recorded careful observations on raptors and their prey in his treatise on falconry. Scholastic Albertus Magnus wrote two lengthy encyclopedias on the natural history of plants and on animals, synthesizing ancient Arabic and contemporary European knowledge (including his own observations).

Scientific Revolution in the 1500s and the 1600s

During the 1500s, Albertus' encyclopedic tradition was continued by Italian, French, and German herbalists, and the Swiss scholar Conrad Gessner (Fig. 1) wrote natural histories of both animals and plants but only published the former before he died of plague in 1565. Two Italian physicians made important contributions to contagion theory: Girolamo Fracastoro (Fig. 2) published *De contagione* (1546) and Girolamo Gambuccini published the first book on parasitic worms (1547). Aldrovandi and Penny wrote encyclopedias on insects in the late 1500s which were published in the 1600s. Scientific societies arose in mid-1600s and published both books and periodicals which included natural history. Francesco Redi's, John Ray's, and Antoni van Leeuwenhoek's publications were especially important for natural history (Figs. 3–5). All three, for example, studied animal parasites. John Graunt, William Petty, and Matthew Hale advanced human demography in the late 1600s.

The 1700s

Luigi Ferdinando Marsigli published the first treatise on what we call "oceanography" in 1725, *Histoire physique de la mer*, which included information on temperature, salinity, tides, currents, depth contours, and marine plants and animals. He realized that further studies required organized efforts. That began with Captain James Cook's three world exploration voyages, 1768–79, with accompanying naturalists. René Antoine de Réaumur (Fig. 6) made detailed and precise studies of the life histories of insects and

☆*Change History*: April 2018. Frank Egerton updated to include female ecologists.

other invertebrates in his *Histoire des insects* (6 vols., 1734–42). The balance of nature concept was originally limited to animals. Carl Linnaeus (**Fig. 7**) named the concept "economy of nature" and broadened it to include plants—in dissertations which his students defended for their degrees, but which were essentially written by him. His *Oeconomia Naturae* (1749) was the first attempt to organize an ecological science. Linnaeus believed in the stability of species, and his economy of nature concept was not as dynamic as post-Darwinian ecology became, but he believed that members of each species flourish or not within a cycle of plant succession. In *Philosophia Botanica* (1751), he itemized 25 different stations (habitats) of plants. His contemporary, Georges Louis

Fig. 6 René Antoine de Réaumur (1683–1757).

Fig. 7 Carl Linnaeus (1707–78).

Fig. 8 Georges Louis Leclerc, Comte de Buffon (1707–88).

Leclerc, Comte de Buffon (Fig. 8), with collaborators, wrote a large *Histoire naturelle* (44 vols., 1749–1804, though his contributions ended with his death in 1788). Linnaeus and Buffon received many plants and animals from explorers in distant places, and they struggled to explain the similarities and differences among species. Buffon developed a speculative theory that a limited number of species arose initially in a small area, and as their populations increased, they spread out into the rest of the world and were modified into new species by their new surroundings. Clergyman Gilbert White (Fig. 9) published *The Natural History and Antiquities of Selborne* (1789) that contains accurate observations on locations and habits of local plants and animals; it became the most widely read work on natural history. Investigators of different kinds of "airs" tested them on plants and animals, beginning

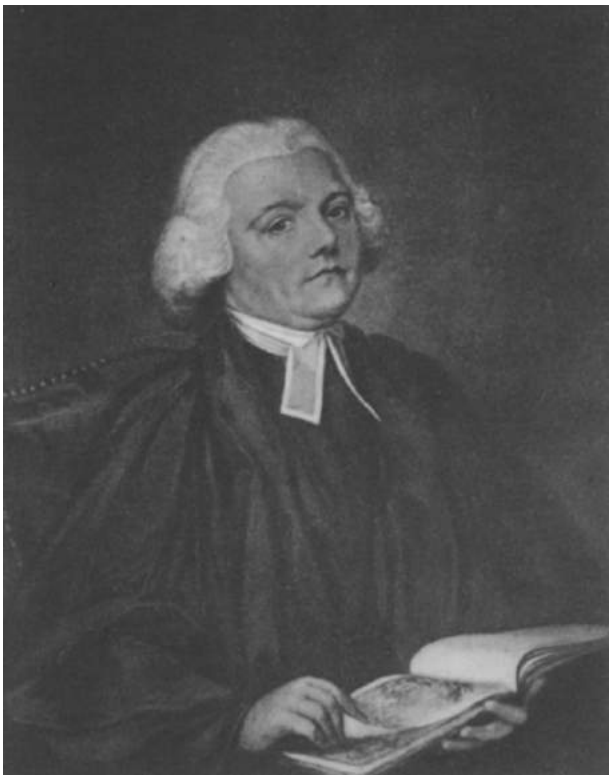

Fig. 9 Gilbert White (1720–93).

with Stephen Hales, the founder of plant physiology, and culminating with Joseph Priestley and Jan Ingen-Housz, who discovered that plants in sunlight produce a gas (named "oxygen" by Antoine Laurent Lavoisier) that animals need for respiration. This was new evidence of the balance of nature.

Specialized Sciences

The 1800s

Early in the century, Alexander von Humboldt (**Fig. 10**) became famous for his investigations and publications. He used inherited wealth to fund 5 years of exploration in Latin America, and then spent two decades in Paris, publishing his findings. "Humboldtian science" involved correlations between plant associations (e.g., grasslands, rain forests, tundra) and environmental factors (e.g., temperature, precipitation, topography), which he carefully measured to understand the distribution and abundance of species of plants and animals. He was the effective founder of phytogeography, emphasizing distribution of vegetation rather than floristics.

In 1809, Lamarck (**Fig. 11**) published his theory of evolution, arguing that species do not become extinct; they become different species. August de Candolle (**Fig. 12**), who rejected Lamarck's theory, emphasized (1820) competition between species as important for determining distributions and extinctions. His writings were used by geologist Charles Lyell (1832), who believed in the stability of species and that fossils do represent extinct species.

Hewett C. Watson (**Fig. 13**), founder of British phytogeography, was strongly influenced by Humboldt and Lamarck but not by de Candolle. He investigated the variability of British plant species in different parts of their ranges, and also compared the British and Azores Island floras.

Charles Darwin (**Fig. 14**), who read widely, was already familiar with the argument for the importance of competition in nature before he read in 1837 Thomas R. Malthus' *Essay on the Principle of Population* (1798, 5th edn. 1825). Darwin's theory of evolution by natural selection focused attention on the struggle of organisms against biotic and abiotic environmental forces. In such a revolutionary book as *On the Origin of Species* (1859), one might expect Darwin to reject the balance of nature concept, since the struggle for existence can cause extinctions. However, his famous cats–mice–bees–clover story seemed to support the balance concept. It was Alfred Russel Wallace who, thinking of extinctions, asked "Where is the balance?"

A Darwin disciple, Ernst Haeckel (**Fig. 15**), in 1866 expressed the need for a new science, "oecology." In 1870, he explained, "By oecology we mean the body of knowledge concerning the economy of nature—the investigation of the total relations of the animal both to its inorganic and to its organic environment." It took about three more decades for ecological sciences to begin to

Fig. 10 Alexander von Humboldt (1769–1859).

Fig. 11 Jean Baptiste de Lamarck (1744–1829).

organize, but meanwhile, various ecological ideas were elaborated. Darwin's theory of evolution included positive relations between individuals and between species, but the emphasis seemed to be on the negative relations of competition, predation, and parasitism. Several authors explored positive relations: Anton de Bary coined the word "symbiosis" and wrote a book on it (1869); P. J. van Beneden defined mutalism in his book *Les commensaux et les parasites* (1875); Alfred Espinas described diverse forms of mutualism in *Des sociétés animals* (1878); and Peter Kropotkin wrote on both animals and humans in *Mutual Aid* (1902).

Fig. 12 August-Pyramus de Candolle (1778–1841).

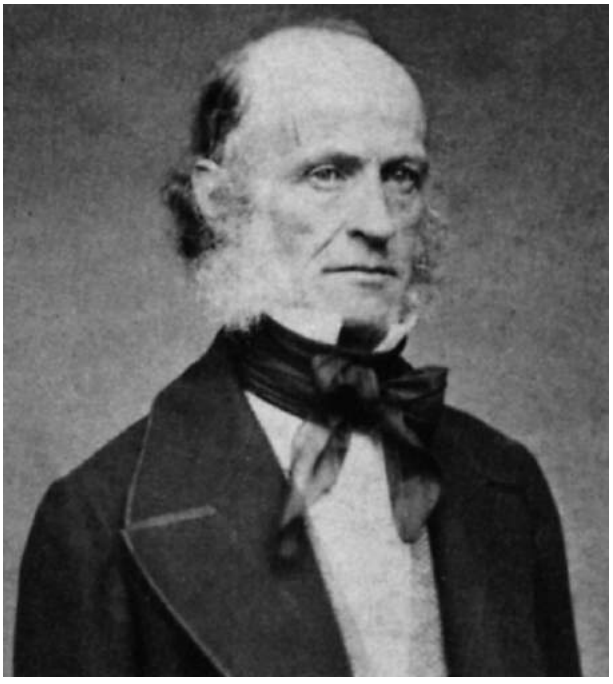

Fig. 13 Hewett Cottrell Watson (1804–81).

Parasitology and the germ theory of disease were important developments in the late 1800s, but their relevance for ecology was little developed.

Edward Forbes (Fig. 16) began studying marine animals in the 1830s and published many works concerning the distribution of species in relation to depth and other factors. He postulated the existence of an "azotic" zone in the depths of the sea. J. J. Coste established a marine zoology laboratory at Concarneau, France, in 1859; more influential was Anton Dohrn's Stazione Zoologica,

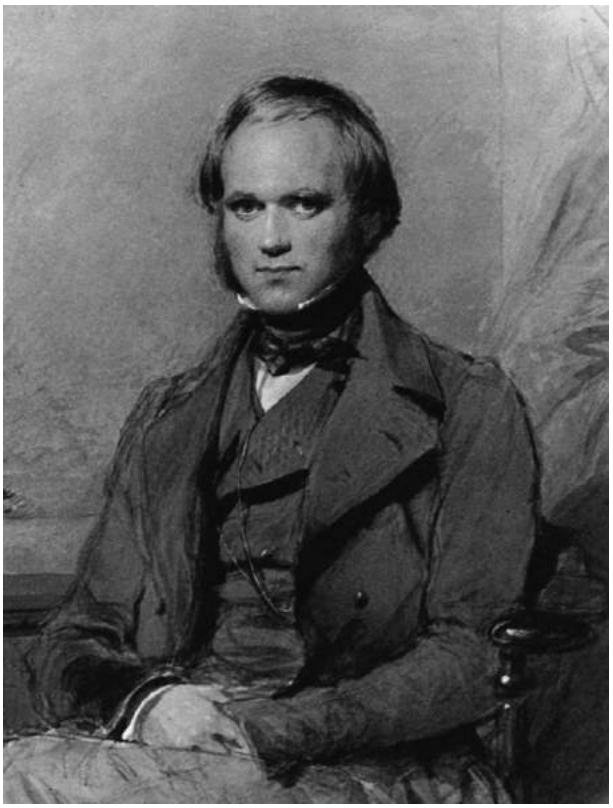

Fig. 14 Charles Robert Darwin (1809–82).

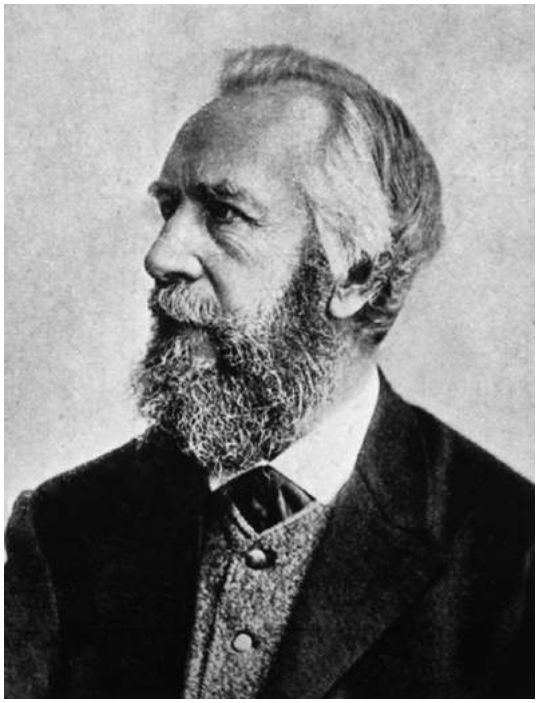

Fig. 15 Ernst Heinrich Haeckel (1834–1919).

established at Naples in 1872. The latter influenced Spencer Fullerton Baird to obtain funds for a US Fish Commission Laboratory at Woods Hole, Massachusetts, in 1884. In 1888, the independent Woods Hole Oceanographic Institution opened nearby. Charles

Fig. 16 Edward Forbes, Jr. (1815–54).

Wyville Thomson (**Fig. 17**) was the first student of deep oceanic life, and his book, *The Depths of the Sea* (1872), helped him become head naturalist on the worldwide voyage of the HMS Challenger (1872–76), and later he directed publication of 50 large volumes of its scientific reports (1885–95). Impressive discoveries of this expedition inspired other countries to sponsor oceanographic voyages. Karl Möbius (German 1877, English 1883) studied oyster beds to assist in their management. He argued that an oyster bed is a "community of living beings, a collection of species and a massing of individuals, which find here everything necessary for their growth and continuance." His study was influential for developing the concept of a biotic community.

American zoologist Stephen A. Forbes (**Fig. 18**) wrote an influential essay, "The Lake as a Microcosm" (1887), which may have been influenced by Möbius' essay, and which used the balance of nature concept to explain the apparent stability of species in a lake despite competition and predation. Meanwhile, since the 1860s, the Swiss zoologist François Alphonse Forel (**Fig. 19**) devoted his research to the life in Lake Geneva and the environmental conditions. His studies culminated in a three-volume paradigm treatise on this research (1892–1904), which he named as "limnology," and he published the first textbook on it in 1901.

Although Swiss botanist Carl Schröter first introduced the terms "autecology" and "synecology" in 1910, those subjects already existed by the 1890s. A strong German tradition in plant physiology and phytogeography led to the development of plant autecology, and when a botanical congress in Madison, Wisconsin, in 1893 adopted the term "ecology," "autecology" was meant. However, the first plant ecology treatise, by Eugenius Warming (**Fig. 20**), *Plantesamfund* (1895), was on synecology, based on his lectures in the first course ever taught in ecology, at the University of Copenhagen. Also in 1895 S. A. Forbes claimed that "economic entomology is simply applied ecology."

Due to strong gender discrimination, women attempting to make a career in natural sciences faced strong antagonism. This was the case of Emilie Snethlage (1868–1929) (**Fig. 21**), a pioneer in fieldwork and ornithology in the Amazonian region. Initially, Emilie worked as a governess in Germany, Ireland, and England, until 1899, when she received a small inheritance and decided to enter the University of Berlin to fulfill her youthful dream: study natural history. However, as a woman, she could only attend lectures hidden behind a screen, she could not speak, and she had to enter and leave lecture rooms 15 min before and after male students. In spite all this, Emilie earned a doctorate in 1904, under supervision of August Weismann. She worked as zoological assistant at the Berlin Natural History Museum until hired by Emilio Goeldi at the Natural History Museum in Belém, Brazil. In 1914, she became the museum director. Between 1908 and 1928, she undertook numerous field expeditions in the Amazon forest and other remote regions in Brazil to study natural history, zoogeography, and ethnology, and describing numerous new species of tropical birds. In some expeditions, only Indians from local tribes accompanied her, through risky regions. Between 1905 and 1928, she published more than 35 scientific papers and books, one of which was the first Catalogue of Amazonian Birds (1914). The Madeira Parakeet (*Pyrrhura snethlageae*), described in 2002, was named in her honor.

Libbie Henrietta Hyman's (1888–1969) (**Fig. 22**) graduated from Fort Dodge High School in 1905, and one of her teachers obtained a scholarship for her at the University of Chicago, where she majored in zoology, under the direction of Professor Charles

Fig. 17 Charles Wyville Thomson (1830–82).

Fig. 18 Stephen Alfred Forbes (1844–1930).

M. Child (B.S. 1910). Child's focus and hers was on invertebrates (PhD 1915). Her dissertation was published a year later. In graduate school, she worked as a laboratory assistant in several zoology courses, and she continued to be Child's assistant after receiving her PhD. She was dissatisfied with available manuals for introductory courses and published "A Laboratory Manual for Elementary Zoology" (University of Chicago Press, 1919, edn. 2, 1929) and "A Laboratory Manual for Comparative Anatomy" (University of Chicago Press, 1922, edn. 2, 1942). In 1940, she began publishing her magnum opus, "The Invertebrates" (6 vols., 1940–67, over 4000 pages). She became the leading invertebrate zoologist of North America and received numerous honors from scientific societies.

The 1900s

Specializations

Four specializations of ecology that emerged during the late 1800s—plant ecology, animal ecology, limnology, and marine ecology—persisted throughout the 1900s, but other specializations also arose, most notably population ecology and ecosystem ecology (**Fig. 23**). Population ecology focused primarily on animals, but both plant and animal ecologists developed ecosystem ecology.

American plant ecologists Frederic E. Clements and Henry Chandler Cowles (**Figs. 24** and **25**) led the investigation of plant communities. Clements wrote the first ecology textbook in English (1905), which was used in the US and in the British Empire. Clements believed plant communities were united into a "superorganism," but in 1917H. A. Gleason questioned the existence of biotic communities, and in 1926 he developed "The Individualistic Concept of the Plant Association." Arthur G. Tansley (**Fig. 26**) at Oxford University challenged the concept of a community being a superorganism in "The Use and Abuse of Vegetational Concepts and Terms' in 1935. Gleason's perspective was adopted in the later 1940s by John T. Curtis (**Fig. 27**) in his school of plant ecology at the University of Wisconsin, where they collected quantitative data for gradient analysis to document a "continuum" of plant species distributions.

Emma Lucy Braun (1889–1971) (**Fig. 28**) was one of 50 botanists awarded a Certificate of Merit by a jubilee committee of the Botanical Society of America "for her contribution to our knowledge of the origin and structure of the Eastern American deciduous forest. Her critical evaluation of the works of others, her capacity to observe correctly in the field and to interpret forcefully have given biogeographers a new point of departure." One of her papers, "The Development of Association and Climax Concepts, Their Use in Interpretation of the Deciduous Forest" is in 50 years of Botany: Golden Jubilee Volume of the Botanical Society of America (1958). For a 1994 symposium on "The Eastern Deciduous Forest since E. Lucy Braun 1950," Ronald Stuckey compiled an 83-page booklet of biographical accounts, maps, and photographs. Lucy published four books and 180 articles. She was vice president of ESA in 1938 and president in 1950—the first woman to hold either office.

She was also the first woman president of the Ohio Academy of Science (1933–34).

In plant ecology, Verona Margaret Conway (1910–1986) (**Fig. 29**) was one of the initiator of studies linking field observations and experimentation, and applying mathematical analysis to environmental physics. She studied processes changing sedge-dominated vegetation into grassland. She studied submerged parts of sedges and the air-spaces through which gases diffuse, thus going from anatomy to ecology. She explained influence of annual temperature changes on waterlogged peat, leading to blanket peats.

Margaret Bryan Davis (1931–2014) (**Fig. 30**) study, "Climatic Changes in Southern Connecticut Recorded by Pollen Deposition at Rogers Lake" (1969) was the only paper by a woman included in Foundations of Ecology: Classic Papers with Commentaries (Real and Brown 1991:650–663). Her social skills were evident in popularity as an advisor to graduate students and her service on national and international committees, leading to her election as president of the American Quaternary

Fig. 20 Johannes Eugenius Warming (1841–1924). Courtesy of Hunt Institute for Botanical Documentation.

Association (1978), National Academy of Sciences (1982) and ESA (1987–88). She was the third woman to serve as ESA president, and she also received its Eminent Ecologist Award (1993). She was also a mentor of women students and faculty members, having spent a quarter of her scientific efforts on these issues.

In limnology there was a strong interest in classifying lakes according to their biological productivity and in measuring their physical and chemical qualities. American leadership was by Edward A. Birge and Chauncey Juday at the University of Wisconsin; for many Wisconsin lakes, they studied temperature stratification, light penetration, dissolved minerals, and hydrogen ion concentration. Arthur D. Hasler (**Fig. 31**), who succeeded them, emphasized experimental limnology and fish ecology. G. Evelyn Hutchinson (**Fig. 32**) of Yale University published an encyclopedic *Treatise on Limnology* (1957–67). In Europe, the leading limnologist was August Thienemann (**Fig. 33**), at the Hydrobiologische Anstalt at Lake Plön and at the University of Kiel. He studied the physical qualities of north German lakes and their invertebrate fauna, and in 1928–29, to make comparisons, he led an expedition to Indonesia to study life in tropical lakes.

Emmaline Moore (1872–1963) (**Fig. 34**) led a survey of the physical, chemical, and biological aspects of Lake George, to determine how to increase fish productivity. That survey was successful and next came a survey of the 60,000 square miles of the New York watershed. In 1926 she became Director of the Biological Survey and chief aquatic biologist. The Survey performed biological surveys of lakes and rivers (1927–40), all published, which in 1996 were still the most comprehensive surveys of any state's water and aquatic resources. In 1928 she became the first woman president of the American Fisheries Society.

The first attempts to organize animal ecology was by Charles C. Adams, who taught animal ecology at the University of Illinois and published a *Guide to the Study of Animal Ecology* (1913), and by Victor E. Shelford (**Fig. 35**), who taught animal ecology at the University of Chicago and published *Animal Communities in Temperate America as Illustrated in the Chicago Region* (1913). A more sweeping synthesis was by Charles Elton (**Fig. 36**) of Oxford University, whose *Animal Ecology* (1927) explained the dynamics of food chains and transformed Joseph Grinnell's descriptive concept (1917) of the niche of California thrashers into a functional concept.

In 1939, Clements and Shelford collaborated on a textbook, *Bio-Ecology*, which sought to bridge the gaps between their specializations. It helped, though the specializations persisted. In 1949, five Chicago animal ecologists—Warder C. Allee, Alfred E.

Emerson, Orlando Park, Thomas Park, and Karl P. Schmidt—collaborated on the most detailed and comprehensive synthesis ever written (including two historical chapters), *Principles of Animal Ecology*, which emphasized cooperation in nature.

Marine ecology focused on estimating the abundance of plankton, at the bottom of the food chain, and fish at the top, seeking in both cases causes of fluctuation in abundance.

Marie Lebour (1876–1971) (**Fig. 37**) was an expert on planktonic stages of marine animals, pioneering the use of a newly invented plunger jar for studying eggs and larvae of krill in the North Atlantic, Bermuda, and Antarctica. She specialized on dinoflagellates and diatoms, publishing the first two comprehensive books in English on them: The dinoflagellates of Northern Seas (1925) and The Planktonic Diatoms of Northern Seas (1930). She joined the staff of the Marine Biological Association's Laboratory at Plymouth in 1915, where she remained until 1946, then an honorary staff member until 1964. Marie Lebour discovered at least 28 new marine species and published more than 175 scientific papers.

Ruth Dixon Turner (1914–2000) (**Fig. 38**) received her PhD from Harvard University in 1954, with a dissertation on Teredinidae (shipworms, marine bivalve molluscs), which remains a standard work to this day. In 1971, Ruth Turner became the first woman to dive in the deep-sea submersible ALVIN. This was only the first of many deep-sea dives to study long-term biodeterioration and species diversity in the deep-ocean. In 1976 she became Professor of Biology—being one of Harvard's first tenured women professors-, Curator of Malacology at the Museum of Comparative Zoology and joint editor of the journal *Johnsonia*. In 1992, Ruth Turner—who continued to SCUBA dive until her 70s—received the Diver of the year award from the Boston Sea Rovers. She was also named Woman Pioneer in Oceanography by the Woods Hole Oceanographic Institution, an award given only once before—to Turner's long-time hero, Mary Sears (1905–97), also of Harvard University. Ruth Turner has over 200 scientific publications.

Eugenie Clark (1922–2015) (**Fig. 39**) was an expert on shark behavior and tropical fishes. She was a pioneer in the field of SCUBA diving for research purposes. Her first memoir, Lady with a Spear (1953) described her adventures collecting fish in the South Pacific and in the Red Sea. It was very popular and translated into seven languages. Her second book, The Lady and the Sharks (1969) described her experiences there (1955–66). She then spent the rest of her career on the faculty of the University of Maryland.

In France Katharina Mangold-Wirz (1922–2003) (**Fig. 40**) was a pioneer in the domain of embryonic development and life cycle in relation to environmental conditions, that she applied to cephalopods. Her work on cephalopod ecology led the way for other marine eco-physiologists. After her death, two new cephalopod species were named after her: *Microeledone mangoldi* (2004) and *Asperoteuthis mangoldae* (2007).

Advances in commercial fishing technology after the Second World War created an industry that could deplete oceans and great lakes of their resources, and ecologists and fishery biologists were needed to explain the level of harvesting that can be sustained. The same is true for shellfish, which must also be protected from pollution. Hasler's study of homing instinct in salmon facilitated development of "salmon farming."

Tansley named and defined the "ecosystem" concept in 1935 but did not lay its foundation. (Instead, he completed his large monograph, *The British Islands and Their Vegetation*, in 1939.) Raymond L. Lindeman, a Midwestern postdoctoral student under Hutchison, developed the ecosystem concept in the most important ecological article ever published, "The Trophic-Dynamic Aspect of Ecology" (1942). It includes both original research and a synthesis of previous literature. Lindeman died, but Hutchinson got it published. After the Second World War, the brothers Eugene and Howard Thomas Odum (Fig. 41) led in studies on

Fig. 28 Emma Lucy Braun (1889–1971).

the productivity of ecosystems. Eugene Odum also published a very popular textbook, *Fundamentals of Ecology* (1953, 3rd edn. 1971) that publicized ecosystem concepts. His ecology school at the University of Georgia studied the ecosystem within the vast US Atomic Energy Commission's Savannah River Installation Area. H. T. Odum pioneered ecosystem modeling, and today modeling is fully integrated into ecology and applied ecology due to important contributions from Denmark, the Netherlands, Sweden, Switzerland, and the US. Recent integrated ecosystem theory is indebted to H. T. Odum (maximum power and energy), R. Ulanowicz (ascendency), B. C. Patten (network theory), and thermodynamics (S. E. Jørgensen). R. O'Neill and Tim Allen developed hierarchy theory.

Evelyn Christine Pielou (1924–2016) (Fig. 42) pioneered mathematical ecology, with methods, indices, and hypothesis tests and applied her methods to organisms and ecosystems from boreal forests to intertidal algae. She linked mathematical ecology, biogeography, and paleoecology. Her awards included George Lawson Medal (Canadian Botanical Association, 1984), Eminent

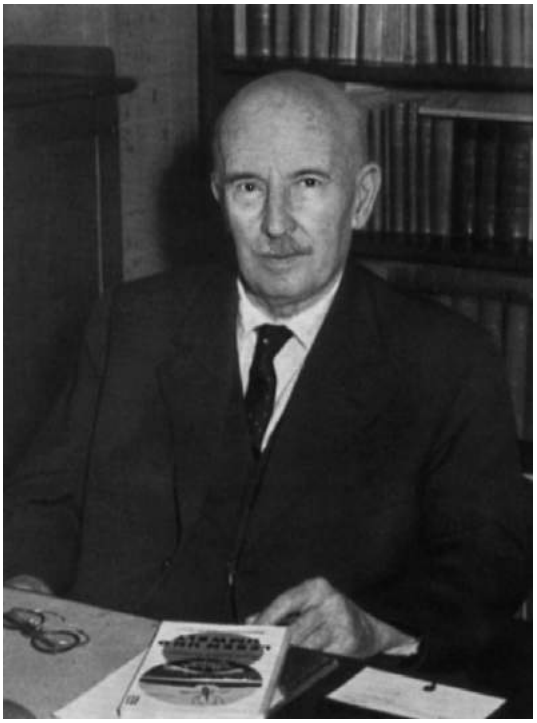

Fig. 33 August Friedrich Thienemann (1882–1960).

Ecologist Award (Ecological Society of America, 1986), and Distinguished Statistical Ecologist (International Congress of Ecology, 1990). The books she published e.g. Introduction to Mathematical Ecology (1969), Population and community ecology: principles and methods (1974), Ecological diversity (1975) served as a basis for learning mathematical ecology for generations of ecology researchers.

Fig. 34 Emmaline Moore (1872–1963).

Fig. 35 Victor Ernest Shelford (1877–1968).

Population studies focused primarily on causes of fluctuations in abundance and on developing accurate mathematical models to describe and predict these fluctuations. The studies were mainly on mammals, birds, fish, and insects. Charles Elton led members of his Bureau of Animal Population (1932–67) into field work and theoretical debate at Oxford University. He discredited the notion of a balance of nature and replaced it with the idea of constant change. Aspects of ethology, the study of

animal behavior, are relevant to animal ecology. The three founders of ethology in the 1930s (Konrad Lorenz, Niko Tinbergen, and Karl von Frisch) received a Nobel Prize in 1973.

The Russian geochemist Vladímir Ivanovich Vernadsky (Fig. 43) studied organisms as the source of atmospheric gases and founded the science of biogeochemistry, explained in *La biosphère* (Russian 1926, French 1929, English 1997). Biogeochemistry has remained a dominant aspect of Soviet/Russian ecology. A similar (but more radical) idea to Vernadsky's is James Lovelock's Gaia theory (1972), which postulates that the Earth is a superorganism that regulates its life forms to maintain an environment that supports life. Gaia theory has attracted popular support and continues to intrigue some Earth scientists, as seen in *Scientists Debate Gaia* (2004).

Fig. 42 Evelyn Christine Pielou (1924–2016).

Ramon Margalef became the leading ecologist of Spain and the Spanish-speaking world with his 950-page *Ecologia* (1974, 4th edn. 1986), though he also published papers and *Perspectives in Ecological Theory* (1968) in English. Michael H. Graham, Paul K. Dayton, and Robert T. Paine have debated in *Ecology* (June 2002) whether ecological concepts are advanced according to a Popperian or Kuhnian model of science or by evolution of a paradigm—showing that a definitive answer probably requires a book-length study.

In coastal ecology, Deborah Rabinowitz (1947–87) (**Fig. 44**) focused her research in mangrove vegetation. Her experiments challenged a previous paradigm that mangrove swamps were zoned according to different tolerances of species for physical conditions. She made important findings on coexistence, species rarity, and the role of dispersal in maintaining species coexistence. She earned her PhD at the University of Chicago (1975) and became assistant professor in the Department of Ecology and Evolutionary Biology, University of Michigan. In 1982 she became a tenured associate professor at Cornell University, until she died of cancer at the age of 40.

Fig. 44 Deborah Rabinowitz (1947–87).

Societies and Journals

The founding of societies and journals is an important indicator of scientific progress. The International Council for the Exploration of the Sea, founded in 1902 with headquarters in Copenhagen, pioneered in relating oceanography to fisheries. Its publications were *Journal du Conseil* and *Rapports et Procés Verbaux*. The first ecological society arose in Britain. Tansley and William Smith had formed the British Vegetation Committee in 1904, which was very active but had difficulty finding funds to publish its memoirs and maps. They decided that an ecological society would be more successful in attracting funds. The British Ecological Society held its first meeting on 12 April 1913, and the first issue of its *Journal of Ecology* was printed for that meeting. Tansley edited it, beginning from 1916. British animal ecology developed more slowly, and only in 1932 did the British Ecological Society begin publishing its *Journal of Animal Ecology*, edited by Elton. The Ecological Society of America (encompassing United States and Canada) was founded in 1915; in 1917, it began publishing its *Bulletin* and in 1920 its main journal, *Ecology*.

In 1922, Thienemann and Einar Naumann, a phytoplankton specialist at the University of Lund, founded the Internationale Vereinigung für Limnologie (later called Societas Internationalis Limnologiae), which meets biannually and publishes its proceedings. In 1936, Americans and Canadians founded the Limnological Society of America, which in 1948 became the American Society of Limnology and Oceanography.

It began publishing *Limnology and Oceanography* in 1956. Since ecological papers were published in botanical, zoological, and general science journals, not all countries formed ecological societies, and some countries did so only later. Germany's Gesellschaft für Okologie was founded in 1970 and Italy's Società Italiana di Ecologia in 1976. More than a dozen specialized ecological journals in English have begun since 1960.

The development of ecosystem models by H. T. Odum and his associates encouraged Sven Erik Jørgensen to lay the foundation for the journal *Ecological Modeling* in 1975. Volume 1 had 320 pages; current volumes contain some 4000 pages per year. This increase is illustrative of the explosion in all aspects of applied ecology since the last decades of the 1900s. Subjects initially published in *Ecological Modeling* soon acquired even more specialized journals: *Ecological Economics* (1988), *Ecological Engineering* (1992), *Ecosystem Health* (2001), *Ecological Complexity* (2004), *Ecological Informatics* (2006), and others.

Institutions

Ecology has flourished in both research institutions and university departments. The *World Directory of Hydrobiological and Fisheries Institutions* which Robert W. Hiatt compiled in 1963 provides information on hundreds of institutions, and their numbers have increased considerably since then. Recent lists of aquatic and terrestrial institutions are in Europa Publications' annuals, entitled *The World of Learning*. Here are just two American examples: the Marine Biological Association of San Diego established its laboratory in 1903, and it became the Scripps Institution of Oceanography in 1925; the Carnegie Institution of Washington in 1903 established the Carnegie Desert Botanical Laboratory outside Tucson; its funding declined during the Depression and in 1940 it was given to the US Forest Service, which sold it in 1960 to the University of Arizona. There are histories of several ecological schools: the plant ecology schools at the Universities of Nebraska and Chicago (Tobey); the Chicago animal ecology school (Mitman); each of the three schools at Oxford University: Tansley's plant ecology school (Anker), Elton's Population Bureau (Crowcroft), and Tinbergen's ethology school (Kruuk, Thorpe); the schools of plant ecology (Fraelish et al.) and limnology (Becker and Egerton) at the University of Wisconsin-Madison; and Eugene Odum's ecosystem school at the University of Georgia (Barrett and Barrett; Craige).

Conservation and Environmentalism

The role of natural history museums for conservation and understanding of ecosystems has been preponderant throughout time.

Maria Corinta Ferreira (1922–2003) (**Fig. 45**) was an entomologist and simultaneously the head of a museum. After graduating in Lisbon (1945), she moved to Mozambique in 1949. In Africa she proceeded her research on entomology, which included field work for the collection of specimens, targeting the enrichment and diversification of the museum's insect collections and increasing the knowledge on the entomological fauna of Mozambique. As the full responsible of Museum of Natural History of Mozambique (MAC) she introduced the dual organizational criteria, which combined an exhibition for the general public (public exhibition), with one aimed at a specialized audience (reserve collection). Until 1974, she also planned and implemented a network of individual and institutional contacts, which allowed to disseminated collections throughout international museums, particularly, in South Africa and Europe. She published more than 120 published papers in English and Portuguese, monographies on Coleoptera, catalogues of new species, among other types of scientific and outreach documents. She was also a brilliant scientific illustrator with over 3000 morphological drawings.

Fig. 45 Maria Corinta Ferreira (1922–2003).

The botanist Ada Hayden (1884–1950) (Fig. 46) specialized in prairies and especially in anatomical adaptions and diversity of prairie plants. She used her research to engage in actions for prairie conservation. Her teaching was remarkable. She was first an Instructor (1910–18), and then Assistant Professor (1919–50) of Botany. She was deeply involved with the Iowa State College Herbarium, from the 1930s until her death. She added to its collection more than 40,000 specimens. She also worked to establish criteria for choosing which prairies should be preserved. From more than 100 tracts, she identified 32 as potential preserves. The College Herbarium and a prairie preserve in Howard County, Iowa, were named in her honor.

Ruth Myrtle Patrick (1907–2013) (Fig. 47) was an aquatic biologist and educator widely regarded as one of the early pioneers of the science of limnology. She was a pioneer on translating her knowledge of river biotic communities into a diagnostic tool for detecting river pollution and on deploying multidisciplinary teams of researchers to assess and monitor aquatic systems. She joined the National Academy of Sciences in 1970 and in 1973 she became chairman of the board at the Academy in Philadelphia. In 1975 she won the John and Ann Tyler Ecology Award, which, at $150,000, was the most generous award in science.

After World War II, both conservationists and ecologists became concerned with negative aspects of the rapid human transformation of the environment. This was an opportunity for ecologists to advise on how to minimize environmental damage and preserve natural areas. This opportunity was first realized in the United Kingdom with the establishment of the Nature Conservancy in 1949. It both preserves natural areas and provides for ecological research in them. In the United States, the triple threats of atomic radiation, phosphate detergents, and dichlorodiphenyltrichloroethane (DDT) insecticide transformed pre-war conservationists into post-war environmentalists. Barry Commoner led the fight against atomic radiation and phosphate detergents, and Rachel Carson (1907–64) (Fig. 48) led the fight against DDT. The outcome was passage of the National Environmental Policy Act (NEPA, 1969), requiring environmental impact assessments before major projects modify natural areas, and presidential establishment of the US Environmental Protection Agency (EPA, 1970), which monitors compliance with environmental laws. Both of these require expert advice from ecologists. Other countries have more or less followed the British and American examples.

Dian Fossey (1932–85) (Fig. 49) earned a B.A. degree (1954) in occupational therapy at San José State University. In 1963, she spent 7 weeks in Africa, where she met Louis and Mary Leakey, who introduced her to the first contact with wild gorillas. Back in USA, she wrote three articles on her trip. Later, she showed her articles to Louis Leakey who lectured in Louisville. He suggested she come to Africa, with his assistance and study gorillas. She did, and began by visiting Jane Goodall at Gombe and observed her studies on chimpanzees. She founded Karisoke Research Center, a remote rainforest camp for studying mountain gorillas. She became the world authority on their physiology and behavior. In doing so, she imitated their behavior and drew pictures of their "noseprints" for identification. She traveled to Cambridge University, UK, and earned a PhD in 1980, and lectured at Cornell University in 1981–83. She achieved considerable fame with her book, Gorillas in the Mist (1983). She not only studied gorillas but also worked to protect them, which may have led to her murder in her camp on December 26, 1985.

Fig. 46 Ada Hayden (1884–1950).

Fig. 48 Rachel Louise Carson (1907–64).

Disease Control

Ecology research is crucial to understand the biological vectors associated with infectious diseases and, thus, crucial for disease and plague control.

Ann Bishop (1899–1990) (Fig. 50) was a pioneer in malaria research. She specialized in protozoology and parasitology and studied Plasmodium, the malaria parasite and its vector, the mosquito *Aedes aegypti*. She tested various anti-malarial chemicals, then studied drug resistance in both parasites and vectors. In 1932 she earned D.Sc. from Manchester University for research on

Fig. 49 Dian Fossey (1932–85).

Fig. 50 Ann Bishop (1899–1990).

blackhead parasites. She was elected to membership in the Royal Society in 1959 and later joined the Malaria Committee of the World Health Organization. In 1992, the British Society for Parasitology created Ann Bishop Traveling Award, to aid young parasitologists to study parasites where they were endemic.

IBP

The success of research conducted during the International Geophysical year (1957–58) inspired three prominent scientists in 1959 to begin planning the International Biological Program, organized by the International Union of Biological Sciences. Barton Worthington (Fig. 51), head of Britain's Nature Conservancy, became its scientific head. Nationally supported IBP research lasted from 1964 to 1974, and some projects continued beyond 1974. The projects were mainly ecological. In the United States, significant new funding enabled ecology to evolve into "big science." George M. Van Dyne and others used a method of monitoring ecosystems with computers called "systems ecology." Without new funds, the USSR contributed about as much IBP research and publications as did the USA. Worldwide, IBP held over 200 meetings, and its research cost over $40 million annually. The resulting publications were numerous and generally of high caliber.

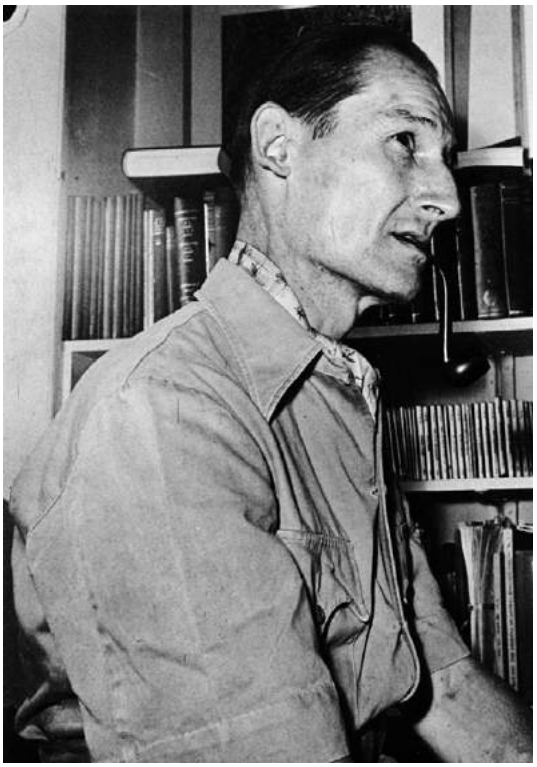

Fig. 51 Edgar Barton Worthington (1905–2001).

Conclusion

Ecology began with natural history observations and a balance of nature concept. It expanded cumulatively through the ages until Linnaeus and Buffon began to expand the theoretical aspects of natural history in mid-1700s. During 1800s ecological disciplines began to emerge, beginning with Humboldt's plant geography. Natural history was revolutionized by Darwin's theory on the origin of species, leading to Haeckel's coining of the word *oecologie* in 1866 and a gradual elaboration of limnology, marine biology, plant ecology, and animal ecology by the early 1900s. During the 1900s, additional specializations emerged (including population ecology and ecosystem ecology), ecological organizations and journals were founded, and ecological professorships were added by universities. A sophisticated science developed well before 2000. Ecology now has the broadest scope of all the sciences, and applied ecology specialties flourish.

Homeotherms

P Frappell and K Cummings, La Trobe University, Melbourne, VIC, Australia

Introduction

Living organisms experience daily, seasonal, and long-term climatic variations in temperature. Many animals respond to changes in body temperature (T_b) with behavioral adjustments, migration, or changes in metabolism (e.g., torpor). However, for some animals and almost all plants such responses are impossible. Animals that effectively regulate their T_b to a thermal set-point despite larger variations in ambient temperature are referred to as homeotherms (in Greek *homoios* means `same, identical', and *therm* means `heat'). Stenotherms (in Greek *Stenos* means `narrow', and *therm* means `heat') are animals that live in a thermally stable environment and can tolerate only narrow temperature changes. Excellent examples of stenotherms are the Antarctic marine notothenioid fishes and invertebrates that have evolved in waters having an annual temperature variation of less than 2 °C. However, despite the narrow range in T_b of stenotherms, they are not homeotherms as they do not actively regulate T_b. The regulation of a T_b in homeotherms, independent of ambient temperature, is determined by the rates of heat gain and/or loss through a combination of physical and physiological means and, in some cases, by heat production.

Although not necessary for homeothermy, many homeotherms regulate T_b through the retention of metabolically generated heat, that is, endothermy (in Greek *endo* means `within' and *therm* means `heat'). Examples of endothermy have arisen in some plants, insects, fishes, and reptiles, and in all mammals and birds (**Fig. 1**). Many endotherms (e.g., hummingbirds, echidnas, billfishes) show substantial daily or seasonal variation in T_b, which in many cases is associated with variation in the thermal set-point. Among ectotherms (in Greek *ecto* means `outside' and *therm* means `heat') there are examples where homeothermy is achieved through heat gained from the environment and where behavioral thermoregulation coupled with improved heat retention enables thermal stability. What then are the benefits and costs of homeothermy? To appreciate the importance of homeothermy in deciding the metabolic niche space of an animal one needs to consider how metabolic rate and other physical factors such as temperature and body size determine an animal's T_b and subsequent life functions.

Temperature

Temperature is an important environmental factor. It influences the biology of an animal through changes in the rates of biochemical and physiological processes and in the stability of biomolecules. An animal's T_b is the result of thermal balance between the rates of heat gain and loss.

Fourier Equation for Heat Balance

Heat balance of an animal is determined by the net exchange of heat. Heat balance is decided through avenues of heat gain or loss and metabolic heat production. The general equation describing heat balance is

$$H_{prod} = \pm H_{cond} \pm H_{conv} \pm H_{rad} \pm E_{vap} \pm H_{store}$$

H_{prod} is metabolic heat production, H_{cond} is heat transfer by conduction through physical contact, H_{conv} is heat transfer across the fluid boundary layer at the surface of the animal, and H_{rad} is radiative heat transfer between the animal and its surrounds; all depend on temperature gradients, either between the animal's body or surface temperature and the ambient temperature or the temperature of the surrounding objects. E_{vap} is the heat that is lost during evaporation (or heat gained during condensation) and depends on the difference in vapor pressure between the animal and the surrounding air, assuming the air at the animal's surface is saturated. H_{store} is the heat that is gained or lost by a change in T_b, and must equal zero for an organism to be in heat balance and thus maintain a constant T_b.

All avenues of heat transfer depend on the surface area of the animal, being greater the larger the surface area. Therefore, by reducing surface area, thermal conductivity, or the coefficient of radiation, an animal can reduce heat transfer to the environment. For a homeotherm to maintain constant T_b the equilibrium between heat loss and gain or production must be maintained at all ambient temperatures (**Fig. 2**). For an ectotherm at a given T_b, if the properties of heat transfer remain unaltered, there can only be a single ambient temperature at which the rates of heat loss and gain with the environment are in equilibrium. An endotherm, without altering the heat transfer properties, at the same ambient temperature, would have a higher T_b; the exact T_b would be determined when equilibrium is established between the rates of heat production and transfer. Under these conditions, T_b will remain constant over time. At ambient temperatures lower than the point of equilibrium the animal must increase heat gain or production to match heat loss, reduce heat loss or a combination of the two to prevent a decline in T_b. At warmer temperatures, the animal must increase heat loss and reduce heat gain or production to maintain T_b. Many endothermic homeotherms extend the single ambient temperature at which equilibrium between heat production and loss occurs into a zone, the thermoneutral

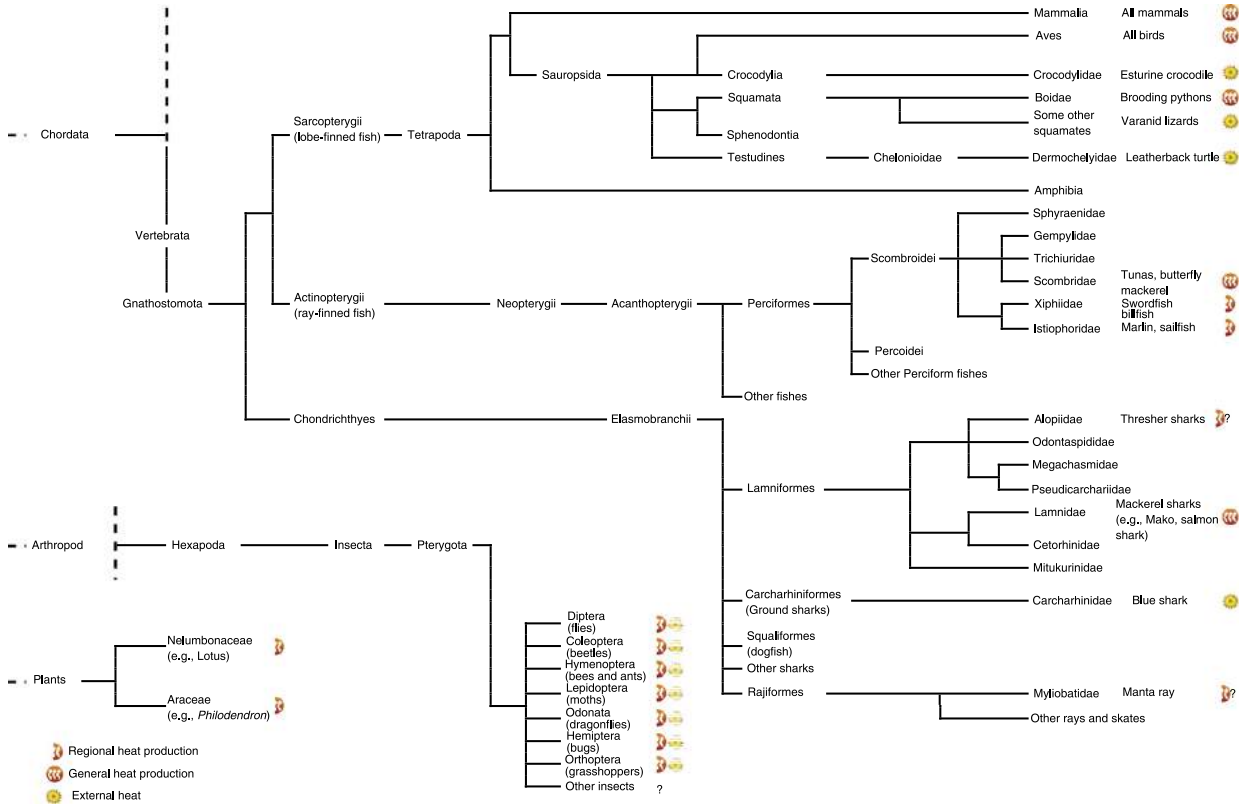

Fig. 1 Cladograms showing proposed phylogenetic relationships among homeothermic organisms. Homeothermy may be achieved in organisms that rely predominantly on external heat obtained from the environment (ectotherms) or in organisms in which the majority of heat is metabolically generated (endotherms). The metabolically generated heat can be either confined to specific areas of the body (e.g., thorax in insects, cranial regions in fish) or more generally distributed and may be purposely generated for thermoregulation (thermogenesis) or as a by-product of other activities.

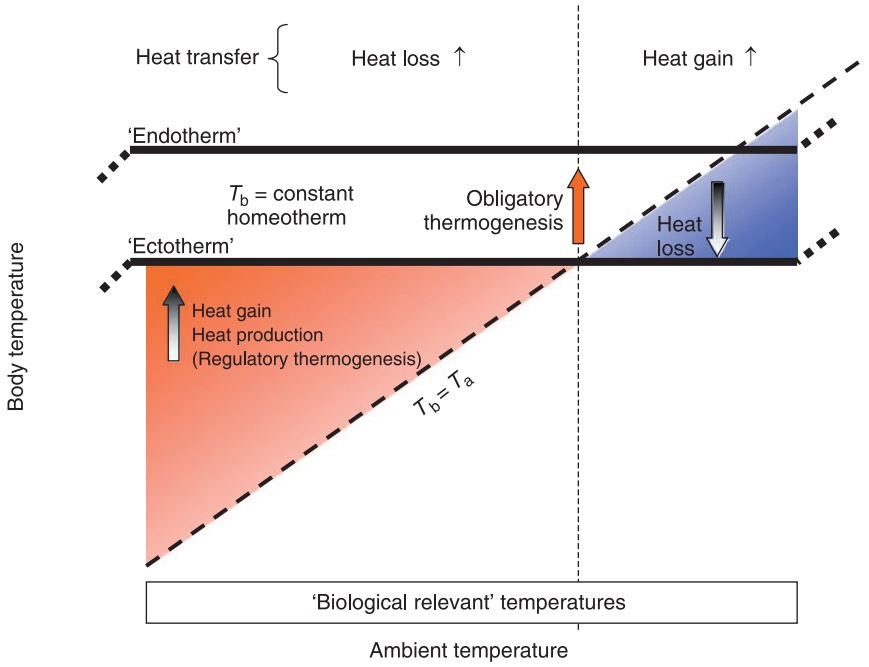

Fig. 2 Body temperature is established as a balance between heat input and heat loss. Heat input occurs through heat transfer or from obligatory or regulatory thermogenesis. Heat transfer, either loss or gain, between the animal and its environment can occur via conduction, convection, radiation, or evaporation/condensation. The rate of heat transfer for each mode is proportional to the surface area and, except for evaporation/conduction, is proportional to the temperature gradient between the animal and the environment. For an `ectotherm' at an established body temperature (T_b) in equilibrium with a given ambient temperature (T_a) heat gain equals heat loss (intersection with $T_b = T_a$). At temperatures on either side of this single T_a, for T_b to remain constant changes in heat transfer need to occur; at lower T_a heat loss will increase and heat needs to be added (or heat loss reduced) and for higher T_a heat gain will increase and heat loss needs to increase (and/or heat input reduced). The increase in cellular metabolism associated with leakier membranes in `endotherms' is coupled with increased heat production (obligatory thermogenesis). The production of heat will result in an increase in T_b to a temperature where heat loss from the increasing T_b–T_a gradient will reestablish equilibrium at the single T_a in which equilibrium was originally established in the `ectotherm'. To maintain $T_b$ with changing $T_a$ again requires adjustments in heat transfer. In the case of an `endotherm', a decrease in T_a is initially met over a narrow temperature range through changes in heat transfer to offset the increasing heat loss (known as the `thermal neutral zone', TNZ), after which further decline in T_a is countered with increased heat production (regulatory thermogenesis).

zone, without activating regulatory heat production. This is achieved by altering heat transfer (e.g., conductance through changes in surface area achieved through posture or peripheral adjustments to the circulation) or by utilizing heat from obligatory heat-generating processes (activity, postprandial metabolism).

Sources of Heat

External heat. Generally, metabolic heat production by ectotherms is negligible. If T_b equals ambient temperature (T_a) then the animal must thermoconform. However, T_b can be elevated above ambient temperature through behavioral adjustments (e.g., basking). In addition, T_b can be elevated by increasing radiative heat gain (e.g., black bodies absorb more radiant heat than white) and/or conductive heat gain (e.g., ventral contact with solar-heated substrate) and can be maintained upon removal of the heat source by minimizing conductive heat loss (e.g., reduced peripheral circulation, addition of insulative fat layers).

Internal heat. Obvious examples of endotherms are mammals and birds but other examples can be found among the reptiles, fish, insects, and plants. In all these examples sufficient heat can be metabolically produced to elevate tissue temperatures above that of the ambient temperature. In many of these organisms the increase in temperature is reflected as a general increase in overall T_b (mammals, birds, tuna, brooding pythons), whereas in others the temperature increase is regional (lamnid sharks, swordfish, many insects, the flowers of some plants). Heat generated from the activity of exercising aerobic skeletal muscle can be retained; this can be an important source of heat in small endotherms and in some endothermic fish. In tuna and lamnid sharks the red muscle is located in a more medial and anterior body position and the perfusion of this muscle enables countercurrent heat entrapment of metabolic heat that accompanies continual locomotion and the maintenance of a stable T_b despite excursions by these fish into cold water (**Fig. 3a**). In lamnid sharks (e.g., Salmon shark) that inhabit cold waters the red muscle has specialized to function within an elevated temperature range (20–30 °C).

In other cases, the skeletal muscles can be activated for nonlocomotory isometric high-speed contractions, that is, shivering, to generate heat. An example is provided by the sphinx moth that requires a thoracic temperature higher than 35 °C for flight,

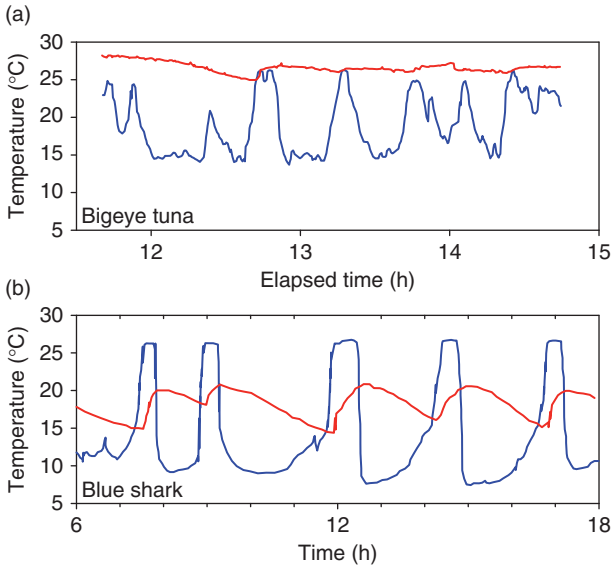

Fig. 3 Body (red line) and water (blue line) temperatures as a function of time in (a) an endothermic fish, the bigeye tuna and (b) a large ectothermic shark. Being an endotherm the tuna has the capacity to elevate T_b above that of the environment, whereas the ectothermic shark adopts a temperature closer to the average water temperature that it is exposed to while diving through the water column. In the case of the shark regulation is dependent on the diving behavior to contain T_b within limits. In the tuna T_b is largely independent of the temperatures encountered. (a) Redrawn from Holland KN and Sibert JR (1994) Physiological thermoregulation in bigeye tuna, *Thunnus obesus*. *Environmental Biology of Fishes*. 40: 319–327. (b) Redrawn from Carey EG and Scharold JV (1990) Movements of blue sharks (*Prionace glauca*) in depth and course. *Marine Biology* 106: 329–342.

achieved by shivering of wing muscles prior to flight. During flight, heat is produced as a by-product of flight metabolism and is independent of ambient temperature across the range of 15–35 °C, yet thoracic temperature is held reasonably constant by adjusting blood flow and hence heat transfer from the pubescent abdomen. At warm temperatures a similar situation occurs in the dragonfly. At cooler T_a the dragonfly and orchid bee, which are both poorly insulated, appear to modulate heat production. In the orchid bee this is achieved by beating their wings at elevated frequencies, reducing flight muscle efficiency, and producing more heat. Either strategy achieves the goal of regulating T_b, particularly the thorax, throughout the flight (**Fig. 4**).

Another mechanism for generating heat is nonshivering thermogenesis (NST). Only two animal tissues are specialized for NST: brown adipose tissue in small eutherian mammals and cranial heater tissue in billfishes and the butterfly mackerel. Brown adipose tissue contains uncoupling protein 1 (UCP 1) that permits futile cycling of the mitochondrial electron transport chain to produce heat without ATP synthesis and degradation. Fish cranial heater tissue have lost their myofibrillar contractile apparatus and participate in futile cycling of Ca^{2+} between the cytoplasm and the sarcoplasmic reticulum which is mediated in the ryanodine receptor by Ca^{2+}-ATPase. In birds it would appear that NST also occurs via Ca^{2+} release uncoupled from ATP synthesis. However, this occurs in the skeletal muscle and is owing to isoforms of the sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase not associated with muscle fiber contraction. Interestingly, UCPs have also been identified in plants. However, in these cases most of the heat is generated via an alternative, cyanide-insensitive oxidase pathway that reduces the electrochemical proton gradient across the mitochondrial membrane. These later cases are examples of regulatory thermogenesis.

A further source of obligatory heat can arise from postprandial metabolism following ingestion of a meal (often referred to as specific dynamic action). The mechanical processing of food contributes little, whereas the high energetic cost associated with the synthesis of macromolecules (e.g., proteins) can be a substantial contributor owing to its high energetic cost. The resulting heat can warm both the viscera and the body core (e.g., albacore tuna).

Thermal Set-Point, Load Error, and Temporal Variation

Body temperature is regulated through multiple temperature sensors (core and periphery) that fall into two groups, one responding with increasing activity to rising temperature and the other responding with increasing activity to falling temperature (**Fig. 5**). Centrally, the coordinated control of T_b takes place mainly in the pre-optic/anterior hypothalamus. The load error is the minimal deviation of T_b from the thermal set-point that is tolerated by the system. Deviation from the thermal set-point triggers a response from multiple effectors, adjusting heat gain or loss, as appropriate, to restore equilibrium. When the signal rates from the warm- and cold-responding sensors balance each other, T_b is at its thermal set-point and load error is zero. Load error is determined in part by the delay of the temperature sensors and the gain of the response by the various effectors. Any regulatory change in heat gain or loss is proportional to the load error and is generated by comparing the signals from both groups of sensors.

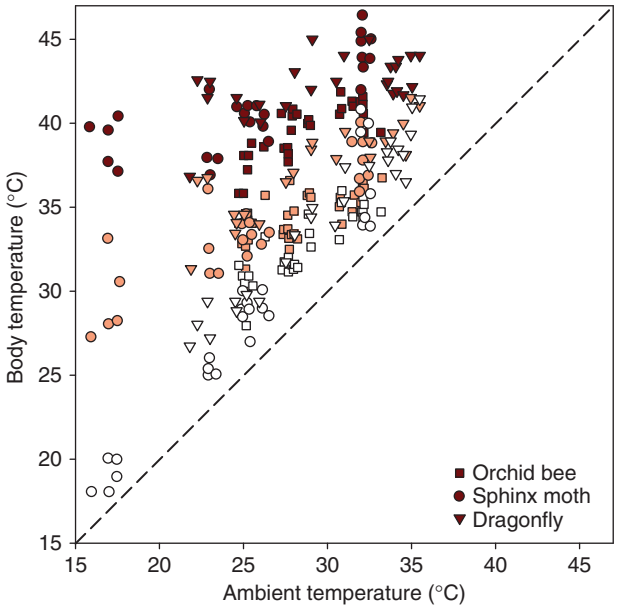

Fig. 4 Body temperatures as a function of ambient temperature during flight in three representative insects. Note that the temperature of the thorax (dark symbols) and, to a lesser extent, the head (light shading) are relatively independent of ambient temperature while that of the abdomen (open symbols) is not. Dashed line $T_b = T_a$. Drawn from data taken from May ML (1995) Simultaneous control of head and thoracic temperature by the green darner dragonfly *Anax Junius* (Odonata: Aeshnidae). *The Journal of Experimental Biology* 198: 2373–2384; Borrell BJ and Medeiros MJ (2004) Thermal stability and muscle efficiency in hovering orchid bees (Apidae: Euglossini). *Journal of Experimental Biology* 207: 2925–2933; and Hegel JR and Casey TM (1982) Thermoregulation and control of head temperature in the sphinx moth, *Manduca Sexta*. *Journal of Experimental Biology* 101: 1–15.

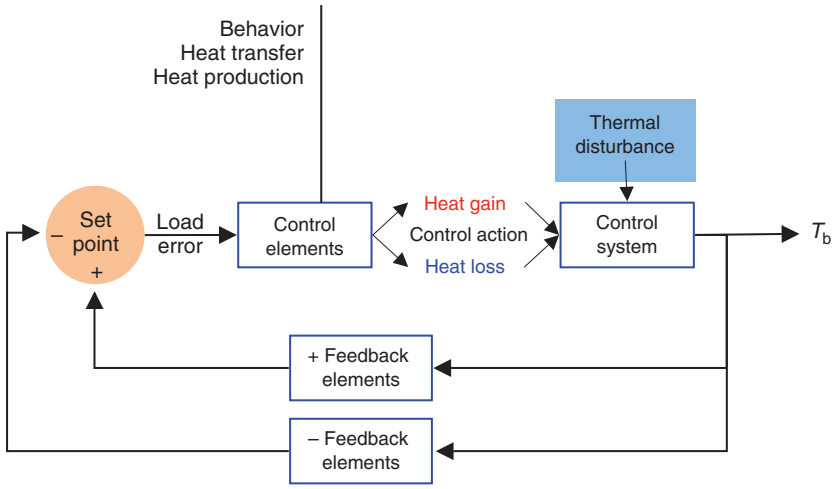

Fig. 5 Dual controller model for the regulation of body temperature with a thermal set-point. One group of feedback elements (sensors) responds with increased activity to rising temperature while the other group responds with increased activity to falling temperature. By comparing the activity of both groups of sensors the load error is generated (the difference between set-point and T_b) and the control elements are activated in proportion to the load error. An increase in T_b results in dominance of warm sensor activity and the control elements (e.g., changes in behavior, heat transfer properties, or heat production) restore equilibrium by increasing heat loss. When the activity from warm and cold sensors equals each other the load error is zero and T_b is at its set-point. For T_b to be regulated the system requires T_b to be displaced from set-point. How far the system can be displaced from equilibrium establishes the load error that is tolerated for the system.

In endothermic homeotherms the load error is generally small; deviations in T_b of a fraction of a degree elicit responses to return T_b toward set-point. Ectothermic homeotherms, on the other hand, often tolerate much larger variations but are still capable of good regulatory control of T_b. For example, varanid lizards, a highly active group of reptiles, are able to behaviorally regulate their T_b between 30 and 36 °C on cold days when provided with an appropriate radiant source of heat (**Fig. 6**).

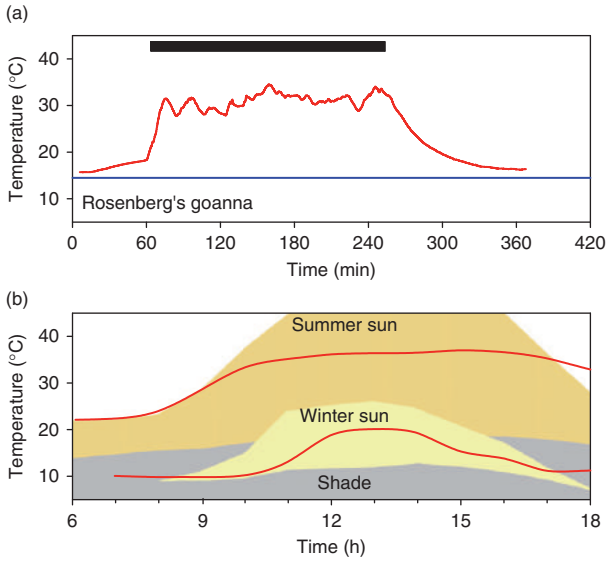

Fig. 6 Body temperature (red line) in relation to sources of heat input as a function of time in the varanid lizard, Rosenberg's goanna. In (a) under constant cool conditions (T_a = blue line) but the animal was free to shuttle in and out from underneath a radiant heat source (black bar) and in (b) under natural conditions that occur in summer and winter. When provided with an appropriate radiant source of heat from the sun Rosenberg's goanna can quickly elevate T_b above T_a in the shade, achieved through dark skin coloration and adjustments in peripheral circulation that favor heat gain. Once the desired (set-point) temperature is achieved the lizard can regulate T_b through behavioral adjustments that affect heat transfer. (a) From Clark TD, Butler PJ, and Frappell PB (2006) Factors influencing the prediction of metabolic rate in a reptile. *Functional Ecology* 20: 105–113. (b) Drawn from data obtained and modified from Christian KA and Weavers BW (1996) Thermoregulation of monitor lizards in Australia – An evaluation of methods in thermal biology. *Ecological Monographs* 66: 139–157.

Some ectothermic homeotherms have a smaller range in T_b. For example, ectothermic fish are not usually considered homeothermic, but many species spend 75% of their time within $\pm 2\,^{\circ}C$ of their preferred temperature. It has also been demonstrated that ectothermic sharks possess thermoreceptors that are capable of temperature resolution to $0.001\,^{\circ}C$ and can occupy narrow thermal niches.

Load error should not be confused with temporal adjustments that may occur in thermal set-point. Even in endotherms, T_b oscillates by as much as several degrees over nycthemeral and circadian cycles (**Fig. 7**). The circadian rhythm of activity can accentuate the daily oscillations of T_b (**Fig. 8**), though elevation of T_b by activity or exercise is not always indicative of a change in set-point. The thermal set-point is also known to change in accord with other cycles. During the human ovarian cycle, for example, the thermal set-point is about $0.5\,^{\circ}C$ higher in the luteal phase. In circannual cycles (e.g., seasons) the set-point is lowered and some animals display a marked reduction in metabolic rate and an associated regulated decline in T_b (e.g., torpor, **Fig. 8**). Finally, stressful situations such as infection result in an increase in thermal set-point (fever), whereas injury, hypoxia, starvation, and other situations can result in a decrease in the thermal set-point (anapyrexia).

Why Elevate and Regulate T_b above Ambient Temperature?

Catalytic or enzymatic rates are temperature dependent according to the Boltzmann's constant (Q_{10} is used to describe the effects of a $10\,^{\circ}C$ temperature difference on reaction rate). A constant T_b allows enzymes to always be at their optimal temperature for catalysis and overcomes the need for having isoenzymes adapted to operate at different temperatures. Interestingly, across the taxa, homeotherms have tended toward T_b's of 30–40 °C. This may be an attempt to minimize the effects of temperature on enthalpy and entropy required for activation energy for biochemical reactions.

A warm constant T_b means that rate processes such as metabolism, digestion, neural function, muscle force, and speed of contraction, growth, and other processes dependent on temperature can be maximized and maintained independent of ambient temperature. In turn, greater and more sustainable levels of activity and various processes enable expansion of both the temporal niche (i.e., animals can forage for longer) and thermal niche (i.e., animals are freed from fluctuations in ambient temperature).

Warm Is Not Always Better

In endothermic homeotherms the major downside to maintaining a warm T_b in the cold is the high energy expenditure for thermogenesis. Obviously, energetic savings can be made through a reduction in thermal set-point and the associated hypometabolism. For all animals a disadvantage of a higher T_b is that the Q_{10} effect will increase demand for energy. Some animals optimize the costs of a

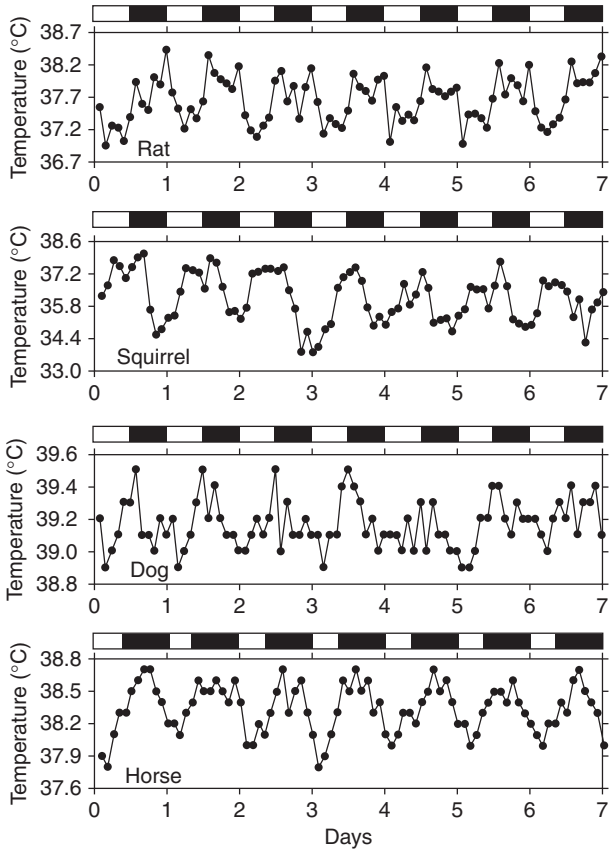

Fig. 7 Daily variation in body temperature in four mammalian species reveals a range of average T_b and variation about the mean. The acrophase (time of peak) for the nocturnal rat was much later than that for the diurnal species. Light and dark phases are indicated. Reproduced from Refinetti R and Piccione G (2005) Intra- and inter-individual variability in the circadian rhythm of body temperature of rats, squirrels, dogs, and horses. *Journal of Thermal Biology* 30: 139–146.

higher set-point through behavioral adjustments. In the case of the dogfish, a squaliform shark, it forages in warm water but lowers energy costs by resting and digesting in cooler water, thereby increasing bioenergetic efficiency and growth rate.

Body Size

The influence of environmental factors is size dependent. Small animals have relatively more surface area and relatively less metabolically active tissue with which to generate heat. Therefore, we would expect a small animal, when challenged with cold, to lose heat more rapidly than a larger animal. If such an animal attempted to generate heat to offset the heat loss and maintain T_b, it would require a relatively higher rate of energy utilization. Small endothermic homeotherms, by virtue of their higher metabolic requirements, are therefore dependent on a reliable supply of energy-yielding foods. Exposure to extreme cold and/or a food shortage would place a small endothermic homeotherm under profound metabolic stress. Obvious energetic savings are to be made under such conditions by lowering the thermal set-point for T_b regulation and depressing metabolism (i.e., torpor, **Fig. 8**). Examples of torpor are found in all three infraclasses of mammals and some groups of birds.

On the other hand, large animals have relatively small surface areas and cool slowly if placed in a cold environment. Once warmed larger insects take longer to cool than small organisms of equivalent taxa. Subsequently, they can successfully forage in a cool microhabitat provided that the foraging bout was less than the equilibration time. Large body size and the resulting thermal inertia together with improved ability for heat retention (insulative layers of fat, counter-current heat exchangers, or physiological adjustments to the circulation that limit peripheral heat loss) and behavioral thermoregulation (basking) enable the largest reptiles, the leatherback turtle and estuarine crocodile (both up to 1000 kg), to achieve a high degree of thermal stability (**Fig. 9**). Large estuarine crocodiles, whose large size is also associated with an increased T_b, actually risk overheating from solar radiation during the day. To minimize this risk they spend much of the day in the water and at night are frequently observed on land. Leatherback turtles also have elevated T_b's, from a few degrees above the warm oceanic waters at low latitudes, to as much as 18 °C above environmental temperatures when diving into high-latitude subsurface waters as cold as 0.4 °C. In the case of leatherback turtles it would appear that metabolic rate is higher than predicted and, in association with relatively warm surface waters and improved ability for heat retention, this is sufficient to maintain warm and fairly stable T_b's when

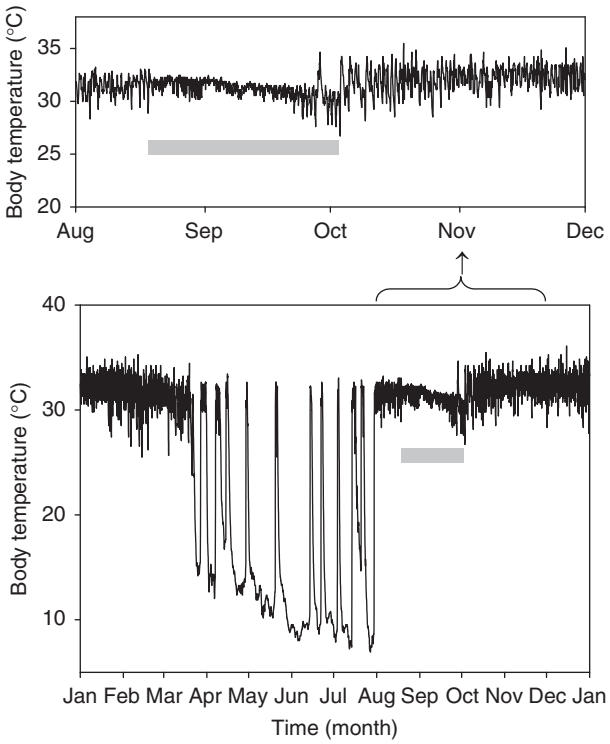

Fig. 8 Body temperature in a monotreme, the echidna, collected over 1 year in Tasmania. During the winter months (April–August) the animal enters torpor, characterized by a lowering of the thermal set-point and subsequent marked decline in T_b together with characteristic test arousals. The characteristic large circadian variation in T_b of echidnas (more easily seen in the upper panel) is a function of the activity cycle. Departures from this daily T_b cycle are associated with a decrease in the activity pattern as a result of the animal spending time in the burrow following egg laying (indicated by shaded bar). Data provided by SC Nicol and modified from Nicol SC and Andersen NA (2006) Body temperature as an indicator of egg-laying in the echidna, *Tachyglossus aculeatus*. *Journal of Thermal Biology* 31: 483–490.

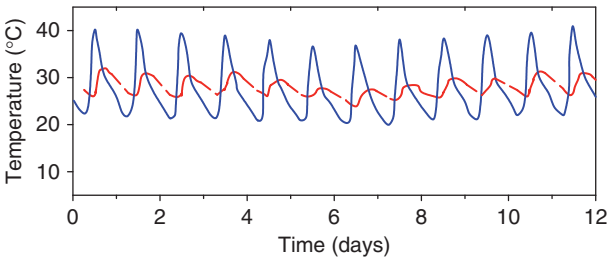

Fig. 9 Body temperature (red line) and operative temperature (blue line, temperature calculated at the body surface and based on heat inputs) for a 520 kg estuarine crocodile. The large body size of the crocodile together with behavioral adjustments permits a high degree of thermal stability in comparison with daily changes in operative temperature. Modified from Grigg GC, Seebacher F, Beard LA, and Morris D (1998) Thermal relations of very large crocodiles, *Crocodylus porosus*, free-ranging in a naturalistic situation. *Proceedings of the Royal Society of London B* 265: 1793–1799.

foraging in cold waters. Interestingly, it appears that muscle tissue metabolism is independent of temperature in leatherback turtles, thereby freeing muscle activity somewhat from thermal constraints in the environment.

In large, non-lamnid sharks, such as the blue shark, a thermal hysteresis permits warming more quickly than cooling. Coupled with regular, vertical excursions in the water column that return the fish to warmer surface water, this enables these sharks to maintain their T_b within a reasonably narrow range (14–21 °C) while diving through water from 26 to 7 °C (**Fig. 3b**).

Homeothermy and Thermal Niche Expansion

Many species encounter wide ambient temperature ranges, the result of moving through their milieu, migrating or changing climatic conditions that occur over various temporal timescales (days, seasons, or evolutionary). Homeothermy permits

exploitation of a range of thermal environs by freeing T_b from ambient temperature. In turn, thermal niche expansion, coupled with elevated T_b which improves temperature sensitive processes (e.g., locomotory performance, digestion, neural function, and metabolic rate) and the advantages of an improved metabolic rate provide the potential to optimize foraging, growth, and reproduction.

The thermal niche of pelagic tuna, billfish, lamnid, and large sharks has expanded because of homeothermy associated with elevated T_b. Improved temporal resolution resulting from retinal warming and temperature stability in endothermic fish such as the swordfish provides benefits over their prey which will have eyes equilibrated with the temperature of the water in which they swim and thus lower temporal resolution, diminishing the ability to avoid predation. Leatherback turtles by their enormity are homeothermic and consequently, like the warm pelagic fish, can travel vast distances across ocean basins to forage in high latitudes or dive to depths in cold waters. At the other extreme, small insects are capable of homeothermy and elevated T_b in order to enable flight for foraging, defense of territory, and mate selection during cool periods. Many insects, together with a host of reptiles rely on behavioral approaches to improve heat transfer between themselves and their thermal environment in an attempt to regulate T_b.

Decreasing T_a is associated with the increased metabolic costs of thermogenesis in endothermic homeotherms. Continual increases in metabolic rate in response to cold can become unsustainable, particularly if resources are limiting. In response to extrinsic constraints many endotherms respond by lowering their thermal set-point and entering a regulated hypometabolic state (e.g., torpor). Others choose thermally buffered microenvironments (e.g., burrows) or behaviors such as huddling or communal roosting to reduce heat loss, conserve energy, and preserve T_b. A worthy example of the latter approach is found in the red squirrel that remains active during winter ($T_a = -26\ ^\circ C$). The red squirrel minimizes energy expenditure during winter by ensuring easy access to a food hoard and a well-insulated nest in which it remains inactive for most of the time, venturing outside only for short periods on the warmest winter days.

Summary

Homeothermy associated with a T_b elevated above ambient temperature has enabled expansion of thermal niches through exploitation of colder habitats and improved rates of biological activity. On the other hand, an organism's metabolism is influenced by ecological determinants such as temperature and the resources available to it. Adaptation to change in environmental temperature across short-term and evolutionary timescales is largely dependent on an organism's ability for adjustments in a multitude of temperature-dependent processes. Homeotherms are able to minimize these changes by stabilizing body temperature.

Hunting☆

M Nils Peterson, North Carolina State University, Raleigh, NC, United States

Introduction

Hunting is the practice of pursuing, capturing, or killing wildlife. This broad definition can be divided into subsistence, commercial, and recreational hunting. Subsistence hunting provided the primary source of protein for most humans prior to widespread domestication of animals and evolution of agricultural societies (2,500,000–10,000 BCE). When agriculture and animal husbandry emerged (10,000 BCE), hunting began moving from a subsistence practice to a cultural practice. This transition is largely complete in developed nations where hunting is an insignificant source of protein. Subsistence hunting, however, still persists in economically depressed areas (e.g., much of rural Africa), and in relatively isolated cultural groups (e.g., Arctic Inuit).

In areas where survival was not the primary objective of hunting, the practice evolved into extermination, commercial, and recreational varieties. Extermination hunting involves attempts to eliminate wildlife which prey on or compete with domestic livestock or crops or threaten human safety. Commercial hunting for meat, hides, plumage, or other tissues (e.g., tusks, antlers, horns, claws, and skulls) often involves special training and utilizes efficient, rather than traditional or stylized, weapons. Recreational hunting evolved as a luxury sport of higher social classes in early agricultural societies (e.g., ancient Egypt and Mesopotamia). In Europe, sport hunting remained in the realm of royalty or aristocracy through the colonial period, and that tradition spread to some colonies (e.g., India). Social and ecological contexts in colonial North America, however, led to a modern hunting culture without strong ties to social class. While modern recreational hunting is often associated with sport hunting (e.g., trophy hunting), many hunters participate primarily to experience the outdoors and associate with other hunters. This hunting culture plays a major role in advertising, economics, and social practices in many rural areas throughout the world. Formal "cultural hunting" regulations also recognize the central role of hunting for some tribal groups.

In the United States, self-sufficient and conservation-minded sportsmen hunters embodied by Theodore Roosevelt represented a shared view of hunting prior to the 1960s. The civil and women's rights movements, Vietnam War and the peace movement, and environmental movement, however, led to a more critical public in late 1960s and early 1970s. Since then, animal welfare and animal rights groups have successfully lobbied against several forms of sport hunting (e.g., "canned" hunts of penned wildlife, hound hunting of fox and bear) and commercial whaling. These successes combined with steady decline in hunter recruitment, retention, and numbers during the same period suggest future changes in hunting culture and practice.

Ecological Effects of Hunting

The ecological effects of hunting are no less diverse than its history. While hunters act as apex predators in ecological terms, human hunters rarely conform to the assumptions of the Lotka–Volterra equations (predator–prey equations). Human hunters can and often have operated as keystone predators, exerting a disproportionate effect on prey populations relative to human numbers. The ecological effects of modern hunting, however, are mediated by governmental regulations. Throughout much of the twentieth century, the maximum sustainable yield paradigm guided hunting regulations. During the latter half of the 20th century fixed harvest quotas based on maximum sustainable yield decimated many global fisheries and whale populations. This failure led to regulation of hunting effort (season timing and length, bag limits, means/methods (archery vs. firearms)). Such regulations control harvest indirectly by altering hunting effort and hunter efficiency. Because hunter effort required to bag an animal increases as prey abundance declines, effort-based harvest regulations are less risky than quota-based systems should initial prey populations be overestimated. This allows regulators time to adaptively implement changes designed to decrease take should this be required.

Idealized narratives of indigenous cultures suggest early humans evolved sustainable hunting systems in a delicate balance with local ecosystems. While some indigenous cultures clearly exhibit sustainable hunting practices (e.g., the Amazonian Korubo, Artic Inuit, South African Bushmen), the apparent stability may reflect historic extinctions of most species vulnerable to indigenous hunting techniques. Many indigenous hunters actively manipulated ecosystems to facilitate hunting. Early hunters in every continent transformed ecosystems by setting fires to drive animals into traps, facilitate tracking animals, and create favorable habitat for prey species. The landscapes greeting European colonists in North America and Australia reflected the fires aboriginals used to create habitat for hunted species.

The overkill hypothesis for the Pleistocene megafauna extinction event represents the paradigm case of unsustainable hunting (Fig. 1). Radiation of hunting cultures into North and South America around 10,000 BCE coincided with extinction

of 33 of 45 and 46 of 58 large mammal genera in each continent, respectively. Since 1600, hunting caused 23% of all known animal extinctions. The list of species driven to extinction (e.g., passenger pigeon (*Ectopistes migratorius*), heath hen (*Tympanuchus cupido cupido*)), extirpated from most of their range (e.g., bison (*Bos bison*)), or threatened (e.g., most whale species) by commercial hunting is staggering. Such changes wrought by hunting often have ripple effects throughout ecosystems. For instance, as domestic livestock replaced extirpated bison, brown-headed cowbirds (*Molothrus ater*) adopted the sedentary lifestyle of their domestic symbionts and became North America's most notorious avian brood parasite. Recreational hunting has had more mixed ecological impacts. In some contexts (e.g., Medieval and Colonial Europe), hunting motivated preservation of forest ecosystems as game preserves. Aristocratic sport hunting, however, nearly led to extinction of the Bengal tiger (*Panthera tigris tigris*).

Hunting became an almost universally positive ecological force during the conservation movement of the late 1800s and early 1900s (to which prominent hunters including Theodore Roosevelt contributed heavily). In the United States, federal excise taxes on hunter purchases ($>$\$200 million annually) support most state-level wildlife management programs in the United States, and the mandatory purchase of Federal Duck Stamps by migratory waterfowl hunters since 1934 helped purchase more than 20,000 km^2 of wildlife habitat in the National Wildlife Refuge System. Recreational hunters also contributed to restoration of North America's decimated game species including white-tailed deer (*Odocoileus virginianus*), pronghorn (*Antilocapra americana*), black bear (*Ursus americanus*), wild turkey (*Meleagris gallopavo*), and wood duck (*Aix sponsa*). Hunters also contributed to establishment of wildlife reserves and conservation-hunting programs throughout the world. The conservation–hunting programs epitomized by Zimbabwe's Communal Areas Management Programme for Indigenous Resources (CAMPFIRE) provide locals in developing nations a sustainable supply of money and meat and preserve local wildlife species. Finally, in areas dominated by private land ownership, hunting provides economic incentives for protecting natural and agricultural lands from suburban or commercial developments.

Some ecologically questionable practices, however, have evolved to capitalize on the growing economic value of hunted species, including high fencing, supplemental feeding, and landscape manipulation to support economically valuable species. While these practices may render keeping private lands in a somewhat natural state more economically viable, they are ecologically problematic. High fences effectively fragment landscapes for many species, supplemental feeding increases the risk of disease transmission, and landscape manipulation intended to help commercially valuable wildlife can threaten other species.

Modern hunting also provides an important tool for managing overabundant wildlife species. Hunting allows natural resource managers to control populations of species before they exceed carrying capacity of their habitat, damage vegetation, threaten other species, or threaten human health and safety. Managers also can use hunting to control a wildlife population's density in efforts to minimize risks associated with wildlife-related diseases (e.g., Lyme disease, bovine brucellosis). In 2005, hunting became a major tool to fight degradation of saltwater marshes caused by growing populations of lesser snow geese (*Chen caerulescens caerulescens*) along the Hudson Bay. Some groups assert reintroducing predators would achieve the same benefits as hunting. Such reintroductions, however, prove politically problematic. Further, considerable evidence suggests prey species typically control predator abundance rather than vice versa.

Ecological Effects on Hunting

Because successful hunting requires a clear understanding of the relationship between the prey species and its biotic and abiotic environment, hunters were probably the first ecologists. In early human history, hunting made most people ecologists by necessity. Now millions of recreational ecologists study the relationships between wildlife and their environments with hopes of increasing the likelihood of successful hunts. Because hunters were among the first ecologists, and continue to study relationships among game species, other organisms, and the abiotic environment, ecosystems shaped and shape the practice of hunting. Hunting generally occurs in areas where prey species predictably occur. Like nonhuman predators, hunters have always focused their efforts in areas and at times where prey species meet critical needs (e.g., food, cover, rest, reproduction). In arctic areas hunters target seals at breathing holes in ice, in arid areas hunters wait near watering holes, and salt and other mineral deposits (natural and artificial) provide a common hunting location throughout the world. Deer hunters often position themselves between cover and foraging areas during dawn and dusk when deer predictably move between these areas. Waterfowl hunters position themselves on or near small water bodies where waterfowl rest along migration routes during fall migrations.

Biodiversity also influenced the persistence of subsistence hunting. In areas lacking domesticatable species, hunting remained essential to human survival until domestic plants and animals were imported from other areas. Changing landscape patterns have also influenced hunting. As agriculture and urban sprawl created a fragmented landscape in many areas, popular game species—including white-tailed deer and Canada geese (*Branta canadensis*)—became nuisances in suburban areas. In many such cases, hunting in nearby areas became an important tool for controlling those nuisance species.

While technology (e.g., firearms, motor vehicles) has allowed modern hunting to develop independent of ecological relationships in some ways, ecosystems have shaped the social nature of hunting. In relatively open landscapes, persistence hunting (using teamwork to run down prey) evolved. In densely forested areas, hunting evolved to be less of a group activity. Attributes of prey also influenced the social nature of hunting. Large prey species required larger groups of hunters, processors, and eaters. Even with modern technology, however, ecosystems influence the social dynamics of hunting. Emerging zoonotic diseases are shaping perceptions of hunting risk and influencing hunting participation. When chronic wasting disease (CWD) was discovered in Wisconsin (USA) deer herds in 2002, hunter numbers began declining and more than 50% of deer hunters using firearms that hunted in 2001, but not 2002, cited CWD as their reason for not hunting.

The Intermediate Disturbance Hypothesis☆

RW Osman, Smithsonian Environmental Research Center, Edgewater, MD, USA

Introduction

The intermediate disturbance hypothesis (Connell, 1978; Grime, 1973a,b) postulates that for any ecological system the diversity of species will be highest when or where disturbance is at some intermediate level. The hypothesis simply overlays environmental disturbances, which negatively impact one or more species, onto the temporal process of community development or succession. Starting with a new, unoccupied patch of habitat the number of species in it will increase as it is colonized. As population densities and species diversity continue to increase resources will eventually become limiting and the species will compete for these resources. With increased competition, inferior competitors will be displaced and eventually lost. At some point species losses should be greater than gains and the number of species will decline and, in the extreme, end with a single dominant species remaining. Thus, the temporal pattern of diversity can be represented by a unimodal curve in which diversity initially increases and then declines over time (**Fig. 1**). Any disruption or disturbance of this process will likely reset the community to some earlier state. High rates of disturbance will keep the community in an early stage with few species and low rates of disturbance will allow competitive exclusion to reduce diversity. Therefore, some rate or magnitude of disturbance should exist that forestalls competitive exclusion (Connell, 1978; Grime, 1973a,b) and maintains the community in an intermediate developmental state of highest diversity.

At its core the hypothesis makes four principal assumptions: (1) that populations and the communities that they form are constantly changing, (2) that these changes can result in the gain or loss of species, (3) that the process of community change can be disturbed or disrupted by any number of physical and biological events that remove individuals, populations, species, or the whole community, and (4) the change in the number or diversity of species is nonlinear as a consequence of the interaction between species recruitment and the limits placed on continued increases by finite available resources. The first three of the assumptions are straightforward. First, normal processes of individual birth, growth, and mortality will produce change. These changes may be limited to replacement of individuals in stable populations with little measurable change at the community level. It is more likely that populations will fluctuate in size and produce changes in species' relative abundances including complete loss of some species. Secondly, for any community, there is always some probability of new species immigrating or existing species emigrating or going extinct locally. Thirdly, disturbances that produce losses certainly can occur in any system, but their effects will vary based on their magnitude, frequency, and spatial extent. The fourth assumption is probably the most contested. The increase in species as a habitat is colonized clearly must occur and the rate of increase will decline as both available resources and the pool of available new species decrease with the addition of each new species. Thus the critical aspect is whether after some period of time competition for limiting resources or some other process results in sufficient species losses to cause a decline in diversity.

Although the intermediate disturbance hypothesis is most often tied to changes in species associated with succession, it is not really dependent on any particular process of community development. Whether one perceives the species composition of a community changing as a fairly systematic successional sequence of species or as a process of random immigrations and extinctions, the process can be interrupted or perturbed by weather, fire, flood, drought, herbivores, predators, disease, tree falls, waves, etc. These disturbances can affect any or all species, randomly or selectively. If diversity increases and then decreases as the community develops through time, then some level of disturbance is likely to maintain the community at a state of maximum diversity.

Because of its apparent generality the intermediate disturbance hypothesis has been studied and tested in a vast array of empirical studies of most types of natural communities and habitats, in experimental communities in small laboratory chambers, and in larger ecosystems and landscapes that can include multiple habitats and communities. There have also been a substantial number of theoretical and modeling studies that have tried to develop and test constraints on the hypothesis and its applicability. As a consequence, there is a diversity of opinions about when, where, and to what systems the hypothesis should be applied. Before limiting the hypothesis to one extreme of catastrophic disturbances that remove all species in fragments or patches within a landscape or to the other of non-catastrophic disturbances across homogeneous habitat that maintain high diversity by reducing populations to non-competitive levels, it is important to examine the historical context of the hypothesis and how it has evolved.

Hypothesis History and Range

The idea that an intermediate level of disturbance can lead to the highest diversity within a system has been proposed independently by numerous ecologists based on their observations of a variety of communities. Although observations of the

☆*Change History:* December 2014. RW Osman has made the following changes: References were added to the text and were updated to include studies up to 2014. Some minor modification of the text was made to incorporate the references. Additional discussion of both recent criticisms of the intermediate disturbance hypothesis and responses to these criticisms. Discussion of some alternatives was modified to accommodate the discussion of criticism. A short section on the links to the intermediate productivity hypothesis and the dynamic equilibrium model of Huston (1979) was included.

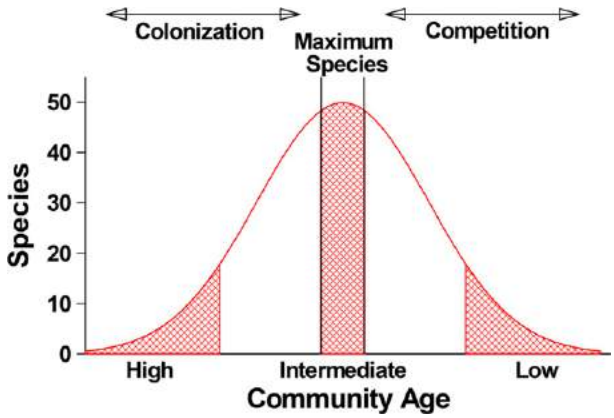

Fig. 1 General concept of the intermediate disturbance hypothesis which overlays disturbance at different times on the diversity changes as a community develops from early stages of colonization with few species to maximum diversity prior to the reduction in diversity through competition after resources become limiting.

phenomenon can be found in studies from the early to mid-1900s (e.g. Gleason, 1917; Hutchinson, 1951, 1953), the link between intermediate levels of disturbance and high diversity was more fully explored in the 1970s (e.g. Connell, 1978; Grime, 1973a,b; Horn, 1974; Huston, 1979; Osman, 1977; Osman and Whitlatch, 1978; Sousa, 1979). Connell (1978) is usually credited with giving the first formal definition and description of this idea as the intermediate disturbance hypothesis. Connell (1978) found the intermediate disturbance hypothesis to be the best of six explanations for the high diversity of species found in the tropical coral reefs and rain forests that he was studying. Alternate explanations included: 'equal chance' in which all species are equal and diversity is a function of the environment and species available in a region, 'gradual change' in which environmental changes prevent competitive exclusion, 'niche diversification' or the finer division of resources among competing species, 'circular networks' in which competition is not hierarchical, and 'compensatory mortality' in which noncompetitive mortality is greatest for dominant species. Connell (1978) was careful to limit the scope of the intermediate disturbance hypothesis to the main structural species of two tropical systems, corals and trees. He saw them as representative of communities of sessile, often long-lived, species with dispersal largely limited to the larval and seed life-stages produced through reproduction. He specifically excluded more motile species which have the potential to avoid or quickly adjust to the impacts of disturbance.

In this context, Connell (1978) described these diverse systems as dynamic, non-equilibrium communities that did not approach maximal diversity by the coexistence of species which have divided available resources on finer and finer scales. Rather than a balance or equilibrium among coexisting species each with their unique way of using some portion of the available resources, species contested limiting resources with those superior competitors ultimately pushing out the inferior. Competitive exclusion and the ability of disturbances to forestall the loss of inferior competitors are critical elements of the hypothesis. Within long-lived coral reef and forest communities competitive exclusion is not instantaneous and may take decades to centuries. In these long time periods any number of events can disrupt the competitive process, remove or reduce the abundance of dominants, and make resources more available. Although one can imagine how disturbances such as disease, wind, or waves might exclusively or disproportionately affect large dominant coral or tree species, such types of disturbance are not necessary for disturbance to contribute to higher diversity. Disturbances that randomly remove individuals or parts of the habitat will create areas available for colonization with available resources and reduced competitor abundance. New or previously lost species have the opportunity to colonize these areas with the potential of increasing local diversity.

At its core the intermediate disturbance hypothesis is recognition that environmental change can alter ecological processes and patterns, particularly when the change is of sufficient magnitude, frequency, or spatial extent to cause mortality and the local loss of populations, species, or whole communities. How disturbance disrupts processes, the nature of the processes being disrupted, and ultimately, the consequences for diversity have had their own diversity of interpretations. The most dominant view has been that of physical processes operating at variable frequencies causing interruptions (e.g. tree falls, rock turnovers) of a successional sequence that progresses from good colonizers to competitive dominants. Even with these constraints intermediate disturbance can be viewed differently. At one end of the spectrum intermediate disturbance can be seen as some frequency of catastrophic or complete removal of the community in patches within a fragmented landscape (e.g. Cushman and McGarigal, 2003; McGuinness, 1984; Osman and Whitlatch, 1978; Paine and Levin, 1981; Roxburgh *et al.*, 2004; Turner, 1989). If this produces patches of different ages, disturbed at different times then some intermediate frequency of disturbance will maximize the cumulative diversity of all patches (**Fig. 2**). At the other end of the spectrum intermediate disturbance can be seen as part of secondary succession in which non-catastrophic disturbances operating in a homogeneous system keep abundances sufficiently low and resources sufficiently available to prevent competitive exclusion from occurring (Horn, 1974). In this context intermediate disturbances provide the environmental variability and temporal diversity in resource availability that can produce opportunities for a greater diversity of species life-histories or adaptations.

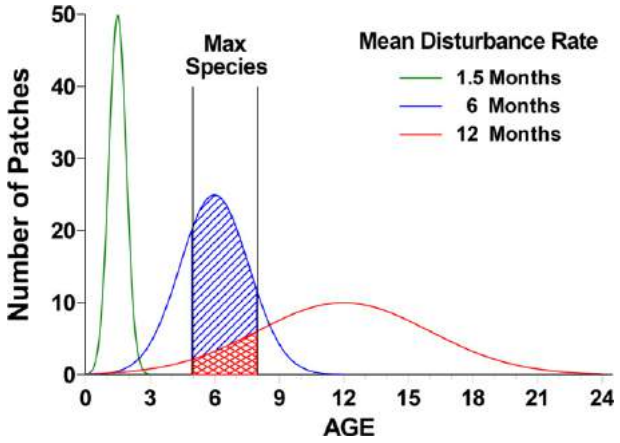

Fig. 2 Distributions of patch ages at different frequencies of disturbance showing the proportion of patches at maximum diversity assuming this is attained in communities 5–8 months old.

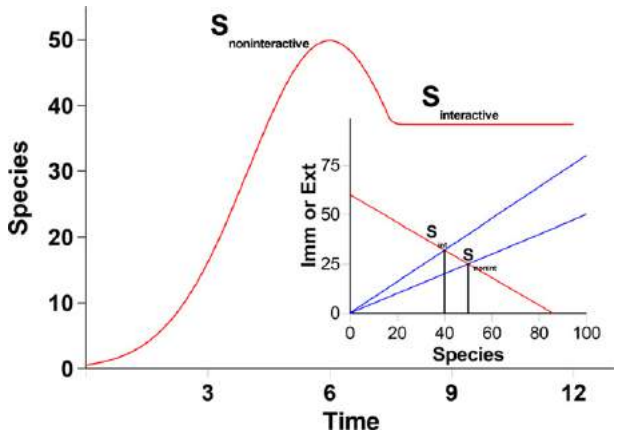

Fig. 3 Diversity (S) changes during colonization as a function of species gains and losses (immigration and extinction) (based on island biogeographic theory). Inset: When species interact or compete for resources the extinction rate increases resulting in a lower number of species. Thus, disturbance at intermediate frequencies can result in highest diversity.

Alternately, the link between high diversity and intermediate levels of disturbance can be maintained independent of any of the specific interspecific relationships that are part of succession. For example, island biogeographic theory (MacArthur and Wilson, 1963, 1967) presents an alternate scenario for the colonization of an island or patch of habitat that is neutral to species identities. The number of species present will be a function of the number of species immigrating minus the number of species lost or going extinct locally. Immigration rate will be a declining function of the number of species present, reaching zero when all species in the available pool of species are present. With all species having some probability of being lost, the cumulative extinction rate will increase as the number of species present increases. Therefore, some balance or equilibrium in species number should exist when immigration and extinction rates are equal. Species extinction rates should also be higher when they begin interacting or when population sizes are limited by available resources. Thus there should be a higher non-interactive equilibrium species number that might be expected to precede a lower interactive equilibrium species number (**Fig. 3**). In patchy environments, the catastrophic random disturbance of individual patches will produce a distribution of patches with a mean age equal to the mean disturbance rate. At some intermediate rate of disturbance, the majority of patches will be at an age when they are at or near the non-interactive equilibrium number of species creating the overall highest diversity for the system (**Fig. 2**). Likewise, non-catastrophic disturbance can lower extinction rate by opening resources and keep individual patches at the highest diversity. This approach is not limited to specific types of species, makes no assumptions about competitive dominance or the relative strengths or directions of any interactions. It relies only on the system reaching some dynamic balance between species losses and gains that will change once resources become limiting. Regardless of whether the probabilities of both immigration and extinction are equal or variable among species, some intermediate level of disturbance should produce the highest number of species.

There have been a number of studies that have questioned the applicability or validity of the hypothesis. These have been either metaanalyses of published papers evaluating the empirical evidence (Hughes *et al.*, 2007; Mackey and Currie, 2001) or studies that have criticized the hypothesis on various theoretical grounds (Chesson and Huntly, 1997; Fox, 2013; Shea *et al.*, 2004). These

criticisms have been addressed (Huston, 2014; Sheil and Burslem, 2013) with Huston (2014) providing a broader context in terms of his dynamic equilibrium model (Huston, 1979) that includes a similar relationship of highest diversity at intermediate levels of productivity (Grime, 1973a,b). The lack of support in many empirical studies points to the importance of defining disturbances in terms of the life-histories of the organisms being studied (see below) as well as the multiple mechanisms contributing to diversity patterns (Sheil and Burslem, 2013). For example, Huston (2014) in linking productivity and diversity found that the level of disturbance necessary for highest diversity can vary with productivity. As Huston (2014) has shown, much of the theoretical criticism has resulted from refuting the ability of intermediate levels of disturbance to maintain stable communities of highest diversity. However, the intermediate disturbance hypothesis is defined in terms of a dynamic process of community development and changing diversity and makes no claims for maintaining diversity at a stable level (Connell, 1978; Huston, 1979, 2014). This can be seen more clearly by examining the elements of the hypothesis.

Elements of the Hypothesis

There are two principal elements of the intermediate disturbance hypothesis, a temporal sequence of community development or change and a set of one or more environmental changes that are seen as disrupting the temporal sequence.

The Developmental Process

A nonlinear change in the number of species in a community or any other ecological system is a necessary component of the intermediate disturbance hypothesis. This change is usually seen as unimodal with a peak in diversity at some intermediate point in time. This is in contrast with two other potential patterns, a continuous increase in species number over time and an asymptotic increase with species number reaching and stabilizing at some maximum (**Fig. 4**). Assuming that there is some finite pool of available species, then stabilization at this number of species represents the upper limit to diversity. It follows that if over time diversity increases or increases to an asymptote without any decrease, then no frequency or magnitude of disturbance can result in higher diversity and the intermediate disturbance hypothesis would be rejected.

Beyond a pattern of increasing and then decreasing diversity over time, the process by which a community develops is unimportant. If development proceeds in an orderly successional sequence of species or through random colonization, the aspect critical to the intermediate disturbance hypothesis is that diversity peaks at some intermediate stage of the process. On the other hand, the characteristics of the system, especially the taxa or species included, the variability in their life-histories, and their trophic relationships, have important consequences to the application and testing of the hypothesis.

Connell (1978) was careful to restrict the intermediate disturbance hypothesis to particular types of species when he applied it to the structural tree and coral species in forest and reef systems. It is logical to assume that within these taxa there will be a limited range of life-histories such that high to low rates of disturbance can be defined. However, if we included all species from bacteria to vertebrates that might be considered to be part of tropical reef or forest systems, then imposing a single meaningful scale of disturbance is difficult. Disturbance is relative to the taxa being examined and their life-histories or generation time (Shea *et al.*, 2004). An intermediate rate of disturbance for a bacterial community may be on the order of hours to days while it may be decades or more for corals or trees. Even for communities of taxa with similar generation times, the intermediate disturbance frequency can also vary with the size of the habitat given that in smaller patches resources will become limiting faster (e.g. Miller, 1982). The size of a disturbance will also vary among taxa with different generation times. Large disturbances to a bacterial community will be too small to be disturbances to trees. In such complex systems it may be necessary to classify disturbances in

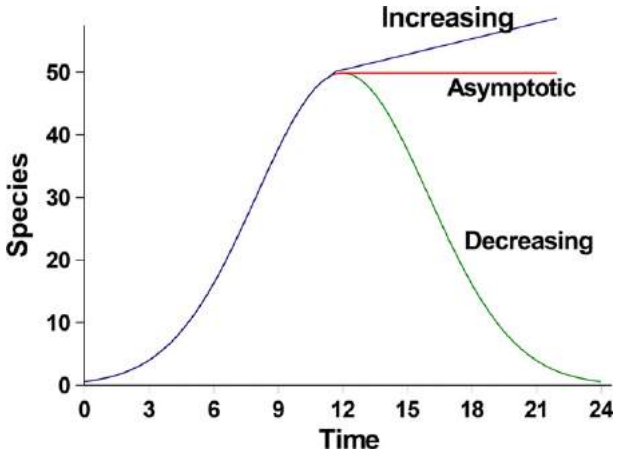

Fig. 4 Alternate patterns of temporal changes in diversity. If diversity is asymptotic or increasing intermediate disturbance would not maximize diversity.

terms of frequency, magnitude, and spatial extent simultaneously and identify a combination that maximizes overall diversity. For example, if an intermediate disturbance frequency for trees is on the order of decades, smaller magnitude daily intermediate disturbances for bacteria will occur multiple times within the period of highest tree diversity. This would produce a set of multiple intermediate disturbances of specific frequencies and magnitudes that result in several diversity maxima.

Including multiple trophic levels within the system being considered produces a similar set of problems (e.g. Gallet *et al.*, 2007; Jeppesen *et al.*, 2000; Wootton, 1998). Modeling has demonstrated that the degree to which disturbances affect each trophic level can influence the overall impact on diversity (Wootton, 1998). If a disturbance affects all levels equally then an intermediate level producing the highest diversity will exist. Alternatively, if the impact of a disturbance is disproportional there may not be an intermediate level producing the highest diversity. For example, if a disturbance principally causes mortality in a lower trophic level this would open resources at this level and some intermediate disturbance rate should lead to higher diversity at this trophic level. At the same time herbivores or predators in the next trophic level would experience reduced resources because of the lowered overall abundances of prey. This should lead to greater competition, lower diversity in the higher trophic level, and an unknown change in overall diversity. If species at higher trophic levels are more selective in their prey then the changes in their resources with disturbance and the effect on overall diversity are even more difficult to predict.

In a similar manner, the degree or number of positive symbiotic interactions within any system may affect directly the relationship between disturbance and diversity (Brooker *et al.*, 2008; Hacker and Gaines, 1997). At its core the intermediate disturbance hypothesis depends on resources becoming limiting and resulting negative effects on abundances and the survival of species. If a significant number of interspecific interactions within a system are positive, then disturbances may actually reduce available resources or the ability of species to utilize them. For such a system no level of disturbance may increase diversity.

Types of Disturbances

Within the context of the intermediate disturbance hypothesis, disturbances are any events or processes that produce mortality. Disturbances will vary in frequency, magnitude, and spatial extent (e.g. Huston, 1979, 2014; Miller *et al.*, 2011; Shea *et al.*, 2004) and they are usually viewed as unpredictable. Frequency is the most common attribute associated with intermediate disturbances (Gaedeke and Sommer, 1986; Lenz *et al.*, 2004; Sousa, 1979; Svensson *et al*, 2007) and the effects of changes in disturbance frequency are, perhaps, those most easily seen. In part, this results because the rate at which disturbances occur can be imposed directly onto the temporal change in a system's diversity. Disturbance rate translates directly into a mean age of the community and its diversity.

The magnitude of a disturbance (Armesto and Pickett, 1985; Bertocci *et al.*, 2005; Biswas and Mallik, 2011) is measured in terms of the mortality it causes which can vary between catastrophic with complete loss of all individuals of all species and non-catastrophic with the loss of only a few individuals and possibly no loss of species. Secondary succession is often seen as resulting from disturbances of low to intermediate magnitude (Horn, 1974). Disturbances of intermediate magnitude and frequency may reduce abundances without causing the loss of any species. The lowered abundances of some or all of the species can free resources, reduce or eliminate competition, and allow coexistence and high diversity.

Finally, disturbances can vary in spatial extent (Altman and Whitlatch, 2007; Angelini and Silliman, 2012; Cadotte, 2007; Grau, 2002; Roxburgh *et al.*, 2004), affecting all or only certain parts of a system. Because species are usually not distributed evenly, the spatial extent and location of a disturbance can result in the complete loss of some species regardless of the magnitude or frequency of the disturbance. Spatial extent of disturbances is particularly important in patchy environments. In a patchy system, the community within each patch may develop independently and the age and diversity of communities can differ among patches as a function of their disturbance histories. Within such systems there may be two or more disturbance levels that promote the highest diversity, one for each patch which may vary with size and a mean disturbance rate for the whole system that maximizes the differences in species composition among patches and thus overall diversity. The degree to which the patches are in phase or disturbed at the same time and to the same degree will affect the impact of patchiness on intermediate disturbance (Abugov, 1982).

Disturbances can result from physical or biological processes and the source of a disturbance will determine its impact on diversity. Physical disturbances are the most common ones associated with intermediate disturbance. A long list of physical phenomena including wind, flooding, waves, fire, exposure to extreme heat or cold, increased UV radiation, low dissolved oxygen or anoxia, drought, extreme pH, etc. can cause various degrees of mortality and disturbance. Although the probability of any of these occurring may vary predictably with location or season, we usually see physical disturbances as unpredictable in the degree to which they affect populations and as being fairly unselective in terms of which species are affected. Species will differ in their tolerances to any of these and other physical phenomena, but these disturbances do not target particular species. Biological disturbances most commonly result from disease, herbivory, or predation all of which may target particular species and result in selective disturbance. If the targeted species are dominants then an intermediate level of disturbance is likely to produce higher diversities by making resources available to other species. If biological disturbances cause a disproportionate loss of rare or competitively inferior species, diversity could be lowered by exacerbating the rate at which dominants monopolize resources. This is not to say that biological disturbances are all selective. For example, a grazing limpet might remove all species from all or part of rock, regardless of whether they are food items. This disturbance would not differ from a similar removal through physical scraping.

The Effect of Intermediate Disturbance on Different Communities

Marine communities dominated by attached or sessile species have been seen as systems in which intermediate levels of disturbance facilitate increases in overall diversity. These communities include not only the coral reefs that led Connell (1978) to hypothesize the effects of intermediate disturbance, but also rocky intertidal invertebrate and algal communities subject to disturbances by waves, predators and herbivores, ice, and desiccation (Sousa, 1979; Svensson *et al.*, 2007), communities on subtidal cobbles and boulders that are turned over by waves or covered by sediment (Osman, 1977), salt marshes with differences in stress associated with tidal zone, sessile communities experimentally disturbed (Lenz *et al.*, 2004) or disturbed by territorial fish (Hixon and Brostoff, 1983), disturbed sandflat communities (Lee *et al.*, 2011), and phytoplankton communities (Gaedeke and Sommer, 1986; Grover and Chrzanowski, 2004). Although most systems have been found to conform to the predictions of the hypothesis, mixed results were found for at least one rocky intertidal habitat subjected to multiple types of disturbances including rock turnover by waves and sand burial, and gradients of temperature and desiccation stress as well as predation. In this habitat rock turnover had little effect on the diversity of algal community on top of rocks but intermediate disturbance by sand burial did increase the diversity of the fauna attached to the undersides of rocks (McGuinness, 1984). Intermediate disturbance has also been found to have mixed effects on the diversity of many infaunal invertebrate communities found in sedimentary environments (Lee *et al.*, 2011; Schratzberger and Warwick, 1999; Villnäs *et al.*, 2012; Zajac *et al.*, 2013). In these complex habitats with multiple resources, competition among infaunal species may be weak with no clear dominants. If resources are not limiting and competition is weak, then disturbance may have little effect on resource availability and, therefore, on diversity.

The effect of intermediate disturbance has been studied on a variety of scales within terrestrial plant communities. Examples include disturbances from storms to tree falls creating light gaps in tropical, temperate, and boreal forests (Molino and Sabatier, 2001; Woods, 2004), fire disturbance and herbivory in grasslands and prairies (Collins *et al.*, 1995; Seastedt and Knapp, 1993), disturbance from flooding, waves, and ice on riparian vegetation (Naiman and Decamps, 1997; Pollock *et al.*, 1998), agricultural disturbance and recovery of old fields (Armesto and Pickett, 1985), and bryophyte communities disturbed by tree falls (Jonsson and Esseen, 1990). In most of these communities patterns predicted by the intermediate disturbance hypothesis have been observed, but there have also been inconsistencies leading to alternative interpretations. In many ways the inconsistencies result from applying a deceptively simple yet somewhat vague hypothesis to very complex communities. For example, tree fall disturbances in tropical forest that create light gaps have been used as a prime example of diversity being maintained by intermediate disturbance (Denslow, 1987; Grau, 2002). The recolonization of these disturbed areas can be viewed as a lottery with all species having an equal chance of recruiting and vying for the newly-released resources and competition eventually causing the loss of some species. This view ignores differences in species not only in their competitive ability but in their ability to recruit. Species differ in their proximity to the disturbed area or their production of seeds that will cause differences in their probabilities of recruiting. Seed banks and degrees of seed dependence on disturbance for germination can also alter recruitment probabilities and herbivory as well as competition can determine survival. Recruitment limitation in which some species have little probability of recruiting into a particular gap can reduce the ability of disturbance to act as a mechanism for maintaining diversity (Hubbell *et al.*, 1999). That is, if recruitment is limited to only those species in mature communities surrounding the gap then increasing diversity by disturbance opening resources for early succession species will not occur. Nevertheless, it remains that the inclusion of early succession species or poor competitors as part of the forest increases overall diversity and resources must be renewed for them by disturbance or some other process. Alternatives such as the clustering of tree fall gaps that create larger gaps that increase the distance of central areas of the gap from the surrounding community may increase the recruitment probability of more distant or early succession species. Although it is clear that adaptations, differences in natural history of species, and chance patterns of distribution will influence the degree to which intermediate disturbance plays a role in maintaining diversity, the frequency, magnitude, and spatial pattern of disturbances must all be considered when evaluating its overall effect. Small tree fall gaps may simply be too small, while other disturbances may happen too frequently to contribute to the maintenance of diversity.

Similar mixed results have also been seen for grasslands and prairies as well as riparian vegetation (Pollock *et al.*, 1998). In prairies the variability among species in their adaptations and tolerances to fire as well as resources that may shift on different time scales can create differential, non-random responses to fire disturbance (Seastedt and Knapp, 1993). The heterogeneity or diversity of these systems appears dependent on the sizes of disturbed areas relative to the size of the whole system. In some experiments, lower diversities were generated at frequencies of one and four years with highest diversity seen after10 years (Collins *et al.*, 1995). This suggests that disturbance frequencies of 10 years or more could maintain the highest diversity in this system. For riparian systems there appear to be multiple sources of disturbance including flooding, erosion from waves, and ice damage and these vary with stream or river size, making it difficult to define an intermediate level of disturbance (Naiman and Decamps, 1997). Nevertheless, when a system is largely affected by one source such as flooding, diversity patterns largely agree with those predicted by the intermediate disturbance hypothesis (Pollock *et al.*, 1998).

As originally proposed by Connell, the intermediate disturbance hypothesis is less likely to be applicable to more motile species and there have been few investigations of its applicability to terrestrial animal communities. When examined, the effects of productivity and multiple trophic levels have been seen limiting the influence of intermediate disturbance in maintaining higher diversity. In some systems with rodent herbivores and carnivore predators, rodent diversity can be linked to variability in productivity with higher diversities at intermediate levels of productivity while carnivore diversity is greater at higher productivity levels (Owen, 1988). Unfortunately, productivity is related to rainfall and its variability can also be seen as a disturbance regime affecting the resources for rodents. The absence of a similar peak in carnivore diversity as seen with the rodents may be less a

refutation of the application of the intermediate disturbance hypothesis than identifying the level of rodent abundance that is necessary for maintaining the highest carnivore diversity (Owen, 1988). This may not coincide with highest rodent diversity. Investigations of less motile animals such as spiders indicate their diversity is greatest at intermediate levels of physical disturbance (Spiller and Schoener, 1988). On the other hand overlaying an additional disturbance from lizard predation has no effect; possibly because spider densities are already held below levels at which competitive exclusion would reduce diversity.

Aquatic systems exhibit mixed responses to intermediate disturbance. The invertebrate fauna of streams and rivers is highly motile, habitats are subject to a high degree of disturbance, the importance of competition in structuring these systems is not clear, and intermediate levels of disturbance are difficult to define. Nevertheless some studies have found patterns consistent with the intermediate disturbance hypothesis (Butler, 1989; Death and Winterbourn, 1995). Disturbance resulting from dragonfly predation produces highest species richness at intermediate levels and fish diversity in some, but not all rivers investigated is highest where disturbance is intermediate (Thorp and Cothran, 1984). Sessile stream species such as bryophyte communities that can be disturbed by both boulder turnover and ice also conform (Virtanen *et al.*, 2001). Dynamics in lakes in which fish predation is the source of disturbance seem to conform to the predictions of the hypothesis. In shallow areas with high predation and deep areas with few predators invertebrate prey diversity remains low, but with different species dominating the two extremes (Butler, 1989). In between these two zones predation and diversity are intermediate. Studies of plankton communities also have exhibited mixed results with diversity in some lakes being highest at intermediate levels of disturbance while in others diversity is most closely linked to the availability of resources (Grover and Chrzanowski, 2004).

The intermediate disturbance hypothesis has also been tested in laboratory mesocosm studies using experimental communities of microorganisms or bacteria. A number of experiments in these systems have produced evidence refuting the intermediate disturbance hypothesis (Huston, 2014). Although the communities used in these types of studies are usually limited to a fairly small number of species, the combinations of species as well as the disturbance regime can be manipulated. Some studies have simultaneously manipulated both frequency and magnitude of disturbance and have found that these characteristics of disturbance can interact such that frequent low magnitude and infrequent high magnitude disturbances both result in low diversity, but for different reasons (Polishchuk, 1999). Frequent low magnitude disturbances do little to disrupt the community or make resources available for new species. Infrequent high magnitude disturbances do free up resources but the long time period between disturbances allow competitively superior species to dominate and lower diversity. In a study of bacterial communities it was found that without strong competition disturbance regime had little effect on diversity (Wohl *et al.*, 2004).

Gradients and Landscapes

The intermediate disturbance hypothesis has been applied and tested in larger systems, in particular to spatial patterns of diversity along gradients and within landscapes. Gradients and zonation patterns often have communities dominated by different species at opposite ends and a mixture of both at intermediate locations, often with higher diversity. The diversity pattern is consistent with the effects of intermediate disturbance, but other factors can contribute to this pattern. Gradients can result not only from unidirectional variations in disturbance but from variations in one or more environmental variables. Gradients in factors such as temperature, light, pH, nutrients, soil type, rainfall, or salinity can result in different communities at the extremes based on species tolerances with the potential for a mixture of species or an ecotone between the two. Diversity will likely be higher at intermediate sites, producing a pattern consistent with the intermediate disturbance hypothesis but not resulting from an actual gradient in disturbance. Gradients in diversity with high intermediate values are not by themselves proof of the intermediate disturbance hypothesis.

Ecological landscapes represent complex spatial variation in habitats or communities and disturbance can be an element in producing these patterns. The relationship of landscape pattern to disturbance is clearest when disturbance acts to fragment a mature homogenous system into a terrain of patches of different ages or states of recovery from disturbances of different magnitudes (Paine and Levin, 1981; Roxburgh *et al.*, 2004). Some intermediate level of disturbance should produce a landscape of greatest diversity (Osman and Whitlatch, 1978). Given the potentially large spatial extent of landscapes, they can be a mixture of habitat types in which overall diversity results from habitat diversity and not disturbance or the landscape can be influenced by multiple types of disturbances that affect only some subset of habitats or fragments (Turner, 1989). If the landscape consists of habitable fragments or patches imbedded within an unsuitable matrix, such as ecological reserves within an urban area, then the intermediate disturbance hypothesis may not apply (Cushman and McGarigal, 2003).

Variations and Alternatives

The attractiveness of the intermediate disturbance hypothesis is its deceptive simplicity of applying some form of disruption to the observable process of community development. Clearly as a barren patch of habitat is colonized species richness should increase regardless of whether one envisions the community developing as a defined succession or as a random accumulation of species. Eventually resources should become scarce with competition causing some decline in diversity. It follows that if this process of change can be halted at the right time diversity will be maintained at the highest level. Reality, however, is not so tractable. Even within a homogeneous habitat, community development will vary as a consequence of random recruitment as well as differences

in competitive ability or susceptibility to predators. Recruitment, itself, may vary with season, distance from source, interspecific differences in productivity, etc. and not be random. Together these can result in delaying any competition for resources and a decline in diversity. Likewise, the simultaneous variability in the magnitude, frequency, and spatial scale of disturbances, whether they operate catastrophically or non-catastrophically, whether they are seen as operating within or among patches, or whether one or more types occur, all create a complexity that makes testing the hypothesis difficult.

This has resulted in both empirical and theoretical challenges to the hypothesis (Fox, 2013; Hughes *et al.*, 2007; Huston, 1979; Mackey and Currie, 2001). In two metaanalyses of published studies (Hughes *et al.*, 2007; Mackey and Currie, 2001) support for the intermediate disturbance hypothesis was found to be weak with less than 50% of the studies supporting the hypothesis. However, Sheil and Burslem (2013) and Huston (2014) have argued that other factors affecting diversity such as variation in productivity (Huston, 2014), the difficulty in sampling the complete temporal sequence of community development, the degree to which the level of disturbance examined was matched to the life histories of the organisms studied, and the specific exclusion of some types of communities (e.g. motile organisms; Connell, 1978) contribute to the expected patterns not being observed.

Fox (2013) presented a set of criticisms based on theory. He refuted the ability of intermediate levels of disturbance to increase diversity by (1) keeping species' densities low and reducing competitive exclusion, (2) interrupting competitive exclusion and preventing the system from reaching an equilibrium, and (3) creating variability in dominance. As Huston (2014) demonstrated, these arguments are focused on the ability of intermediate disturbance to maintain continually high diversity in a community at equilibrium, which is not part of the hypothesis as originally developed by Connell (1978). The hypothesis recognizes the dynamic nature of communities and how they develop and identifies a time during this development at which diversity may be higher before reductions from competitive exclusion. This point is neither stable or in equilibrium, but disturbance can keep the community more in this state than earlier or later states of lower diversity. Other theoretical and modeling studies have led to variations and modifications of the intermediate disturbance hypothesis, including variations in the community or ecological system, variations in disturbance characteristics, inclusion of positive interactions, and linking or contrasting other environmental parameters with disturbance (Cadotte, 2007; Gallet *et al.*, 2007; Hacker and Gaines, 1997; Sugden *et al.*, 2008). For example, when the complexity of the community is increased by the inclusion of multiple trophic levels or groups of species with very different life-histories, intermediate disturbance becomes harder to define (Jeppesen *et al.*, 2000; Lee *et al.*, 2011; Wootton, 1998). A single frequency or magnitude of disturbance is unlikely to affect species of vastly different sizes and generation times in the same way or necessarily be intermediate for all. Likewise, disturbances that maintain higher diversity and presumably lower population levels of prey may have the opposite effect on predators. Characteristics of disturbance such as how the timing or phasing of disturbances among patches can also modify the overall effect of disturbance (Abugov, 1982). Even at the same magnitude and frequency, whether a disturbance affects one or all patches at the same or different times will determine its impact and what level of disturbance produces the highest diversity. Other parameters such as recruitment (Hubbell *et al.*, 1999) or productivity (Grime, 1973a,b; Huston, 1979, 2014; Waide *et al.*, 1999) can also have a nonlinear impact on diversity and change the effect of disturbance. Low and high levels of recruitment may minimize the effects of disturbance. At low recruitment resources may not be limiting and disturbance would have little effect while at high recruitment levels any effect of disturbance would be quickly overwhelmed. Only at intermediate levels would differences in disturbance affect diversity.

There is a strong link between the intermediate disturbance hypothesis and productivity. Huston (1979, 2014) developed a more general, dynamic equilibrium model of diversity that incorporated specific links between the intermediate disturbance hypothesis and a similar intermediate productivity hypothesis that he traces back to Grime (1973a,b). Both hypotheses project a unimodal distribution of diversity with a peak at either an intermediate level of disturbance or productivity. Huston (2014) argued for much stronger empirical support for the intermediate productivity hypothesis and further suggested that intermediate levels of disturbance maximized diversity only at intermediate levels productivity. He suggested that a low levels of productivity; growth and reproductive rates would also be low, making it difficult for communities to take advantage of any resources made available after a disturbance. Likewise, at high levels of productivity high growth and reproductive rates would quickly limit any resources opened by disturbance. However, it could be argued that the effective rate or magnitude of a disturbance would shift with productivity making the 'ideal' intermediate rate a direct function of productivity.

In summary, the intermediate disturbance hypothesis remains a compelling concept that provides a non-equilibrium view of how communities can gain or maintain a richness in species without an intricacy of adaptations. Strong and weak competitors, good and poor colonizers, can all coexist in a system where some process such as disturbance prevents the monopolization of resources at different times and places. Intermediate disturbance remains an hypothesis that is far from proven or universally applicable to all communities. It needs to be tested in each community or habitat with an open mind as to what constitutes a community, a disturbance, and an intermediate frequency, magnitude, or spatial scale of the latter.

Keystone Species and Keystoneness

Simone Libralato, Istituto Nazionale di Oceanografia e di Geofisica Sperimentale—OGS, Trieste, Italy

Glossary

Ecological network analysis Is a methodology to analyze a system of interactions to identify general properties.
Food web model A conceptual or quantitative representation of trophic interactions in an ecosystem.
Interaction strength Is a quantification of the magnitude of effect of one species on another.
Species functional role Main activity characterizing a species or groups of species as a contribution to the dynamics of the system.
Trophic level The position of an organism or species in the food chain.

Keystone Species

Keystones are species whose modifications in abundance cause large effects on the ecological communities they are part (Paine, 1969). These effects are disproportionate with respect to their biomass proportion in the system (Power *et al.*, 1996).

History of the Keystone Species Concept

In the 1960s, Professor Robert T. Paine, while conducting experiments on manipulation of rocky shore communities, noticed that removing the sea star predator *Pisaster ochraceus* resulted in overgrowth of the mussel *Mytilus californicus* (Paine, 1966). The experiment was conducted in the field on rocky shores of the west coast of United States, by manually removing *P. ochraceus* from areas and then protect with metallic cages the plots from sea star predation activity on species in the rocky shores. Under the absence of predator, the mussel become dominant in abundance with consequent reduction of biodiversity. In his later seminal work, Paine defined the sea star as a keystone species (Paine, 1969), that is, a consumer whose intense predation keep at low density potentially dominant species and thus it maintains high the biodiversity. Such work put the attention to the fact that not all predators' alteration result in large community changes, that is, species have not the same functional role. Some species are called keystones because removing them or altering their density result in large perturbations of the communities around them (Paine, 1969).

The large influences of keystones on the communities were connected with the presence of a set of trophic interactions between the keystone species and other surrounding species, not necessarily strong but critical for the prey itself to keep it under control. This original keystone species concept was mainly focused around the approach based on food webs but the introduction of the interaction strength concept and quantification of direct and indirect measurement of interactions introduced new avenues for identification of keystones. These approaches for determining the keystone species resulted in a flourishing of new meanings on the concepts of keystones species (Mills *et al.*, 1993) creating confusion with other ecologically relevant species (see Piraino *et al.*, 2002).

The need to clarify the keystone species concept and avoid confusion resulted in new practical definition that include the accounting of effects per unit of biomass (Power *et al.*, 1996). The peculiarities of keystone species, to distinguish them from dominant species, are that they exert influences on communities through intense predation, thus their direct and indirect effects on other species are disproportionally large compared to their biomass in the system (Power *et al.*, 1996; see **Fig. 1**). Further additional characteristics to determine keystone species included the prevalence of top–down effects and dominance within a functional group (Davic, 2003).

Examples of Keystone Species

Species that exert important impact on many others are routinely observed through trophic cascades analyses from both controlled manipulations and natural experiments evaluated ex-post (Estes *et al.*, 1978; Myers *et al.*, 2007). For example large shark species in the Atlantic Ocean, which includes requiem (Family Carcharhinidae) and hammerhead sharks (Family Sphyrnidae), are ecologically important because they consume mesopredators, which in turn consume estuarine shellfish, such as scallops (*Argopecten irradians*) and hard clams (*Mercenaria mercenaria*). Long-term exploitation resulted in strong reduction of sharks populations which resulted beneficial for rays, and eventually lead to the collapse of estuarine shellfish populations in Core Sound, North Carolina, United States (Myers *et al.*, 2007).

The reduction in the number of sea otter (*Enhydra lutris*) on Alaskan coasts, also revealed it to be a keystone. In normal conditions, sea otter keep low the abundance of the sea urchin through intensive predation, but as the number of sea otters decline

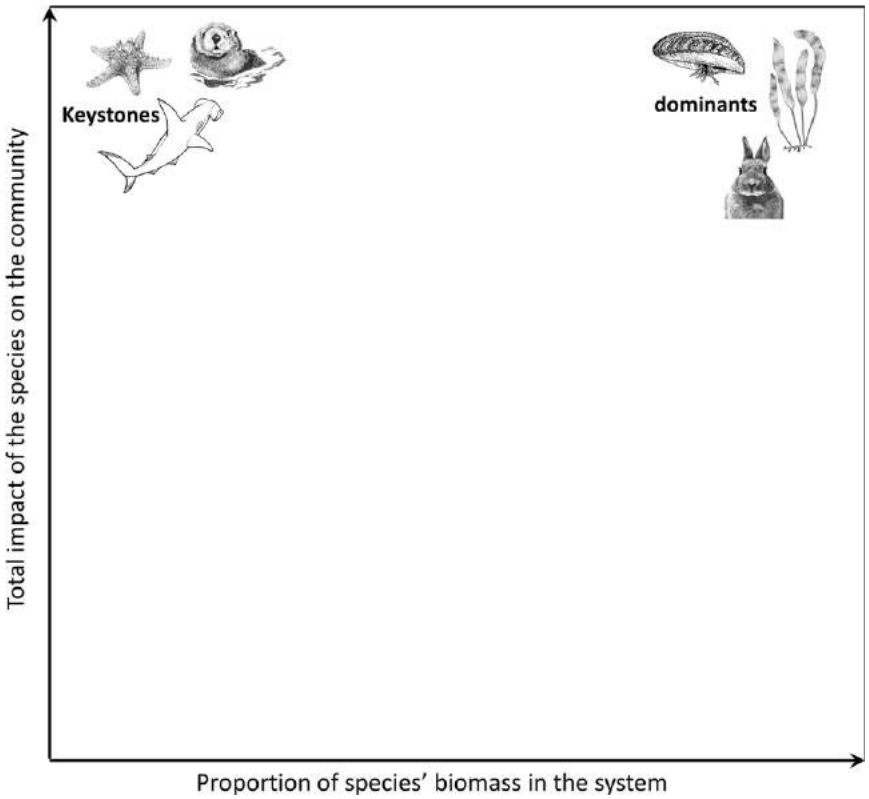

Fig. 1 The schematic representation of the species role on the basis of definition provided by Power *et al.*, 1996. In that essay both keystone and dominants species are considered having high impacts on the community, but they are distinguished in terms of biomass proportion in the system. Redrawn from Power, M.E., Tilman, D., Estes, J.A., Menge, B.A., Bond, W.J., Mills, L.S., Daily, G., Castilla, J.C., Lubchenco, J., Paine, R. T., 1996. Challenges in the quest for keystones. Bioscience 46, 609–620.

the flourishing on sea urchin population result in great reduction of kelp forest (*Laminaria* spp) with relevant consequences and changes for the whole community (Estes *et al.*, 1978).

On terrestrial ecosystem, for example, the Iberian lynx was defined as keystone, as its predation keep rabbit number under control otherwise overgrowing and changing completely the community.

Importance for Conservation and Management

Since the first introduction of the concept, the large interest for the keystone was related to the possibility to identify target priority species for protection and maximize effects of conservation (Paine, 1969; Mills *et al.*, 1993). Although likelihood of extinction is a good reason often used for guiding conservation efforts, rare species are not necessarily the most important species ecologically. Conversely, the ecological role that species play in the ecosystem may be a better measure of the species' need for protection and the keystone species concept allows to place attention on priority species defined on the basis of the role in the ecosystem. Conserving keystone species, in fact, would preserve ecosystem functioning and ecosystem services that are at the very basis of biodiversity maintenance but would also have a large impact on many other species of the food web, including the more rare ones (Chapin *et al.*, 1997). Therefore, keystone concept facilitate meaningful prioritization of conservation interventions and their ecological efficacy. Preserving keystone species, moreover, would allow maintaining high the biodiversity and thanks to control of high competitive species, would allow preserving also rare species and favor ecological redundancy in ecosystems. Overall the keystone species would support maintenance of ecosystem resilience an attribute fundamental for contrasting effects of perturbations, such as those induced by climate change.

Difficulties in Determining Keystone Species

Empirical determination of keystone species is, however, difficult. Experimental manipulation has been the most fundamental method for identify species role and their contribution to ecosystem functioning. It consists in imposing controlled changes on species density to detect community effects: it is a very relevant approach to determine local effects, but empirical determination has relevant limitations. Experiments limited to microscopic communities, in fact, can be successfully carried out in laboratory but direct field experiments on larger invertebrates or vertebrates are not always possible. Field experiments, in fact, are usually

restricted to species with no or limited movement ability such as plants and macrobenthic species, mainly sessile or bottom-moving species and can be carried out on very small plots, where it is very difficult to document a population level response and to describe the space-temporal heterogeneity of physical conditions and biological densities of natural systems. Moreover, direct and indirect effects of biological and anthropic activities can propagate along the components of the ecosystem reaching species not directly impacted, and produce important changes on the ecosystem functioning. These "cascade effects" are usually identified on the basis of observations on few taxa, while models can represent them in their completeness (Libralato *et al.*, 2006).

Experimental approach, moreover, need to be conceived to last in proportion of the life span of the species involved: in case of "natural experiments," therefore, medium term observations are often required, thus increasing their cost, a factor which considerable limit the application of experimental methods. Moreover, since the environment is characterized by stochastic variability and fluctuations, one further limitation is related to the need of distinguishing the results of ecosystem interactions from those of environmental noise: excluding the influence of all other possible factors other than those imposed is not easy and it is not always practicable. Mathematical models allow one to overcome some of the limits outlined for the experimental approach, and represent a valuable shortcut and a priori analysis for subsequent ad hoc experimental measurements (Jordán, 2009).

Keystoneness

Determining Keystone Species From Food Web Models

Several metrics applied to ecological network models such as regular equivalence and other topological measures demonstrated to be useful to quantify the trophic importance of the species and the identification of keystone species (Jordán *et al.*, 2008). The effects of removal in terms of secondary extinctions also revealed useful for the identification of important species. Food web and ecosystem model perturbation, moreover, can also help predicting the ecosystem effects of removal and thus were used to determine keystones. However, the keystoneness derived on the basis of mixed trophic impact analysis on quantitative food web networks demonstrated to be a simple, efficient and useful concept to determine keystone species from a wide range of models. Keystoneness is conceived as a characteristic of any species, and can be used to rank the species or group of species. Only species ranking high in keystoneness would be classified as keystone, but all can have a degree of keystoneness.

This continuous property allows accounting for the fact that species have a potential for explicit their keystone role that also vary from local conditions and can change in space and in time.

Keystoneness is determined for all nodes of an ecological network on the basis of the mixed trophic impact analysis. The approach allows determining not only the total effects of a taxa on the food web, but also to distinguish them into top–down and bottom–up effects. The mixed trophic analysis allows for quantify both keystoneness and top–down contribution of each node of a food web.

Mixed Trophic Impact to Quantify Effects of a Species on the Food Web

The mixed trophic impact analysis results from the application of input output analysis on quantitative weighted network of trophic interactions and permits to account for the direct and indirect impacts that any single node have on any other node of the network. For each couple of nodes (i and j) of network with n nodes it is possible to calculate the net direct impact q_{ij} as the difference between the direct positive impact that a prey flow has for the predator (g_{ij}) and the direct negative impact that a predator has on the prey (f_{ji}). These direct impacts are calculated on the basis of the flux of predation from prey i to predator j, T_{ij} (Ulanowicz and Puccia, 1990). The positive direct impact g_{ij} is calculated as the proportion of the flow T_{ij} with respect to the total consumptions of the predator:

$$g_{ij} = \frac{T_{ij}}{\sum_{k}^{n} T_{kj}}$$

And the negative direct impact as the proportion of the weighted link T_{ij} over all possible consumptions on prey i:

$$f_{ij} = \frac{T_{ij}}{\sum_{k}^{n} T_{ik}}$$

The net direct impact is thus calculated as:

$$q_{ij} = g_{ij} - f_{ji}$$

The matrix of direct net impacts Q includes all the q_{ij} elements for the network of n nodes. It can be demonstrated that the propagation of each net direct impact to the food web can be calculated by multiplying q_{ij} elements of any distinct pathway in the food web. Multiplying Q by itself (Q at the power of 2) allows looking for second order impacts; multiplying Q three times (Q at the power of 3) effects of third order, etc.

Mathematically the complete set of direct and indirect impacts can be obtained by the sum of all integer powers of the matrix Q resulting in a matrix of mixed trophic impacts M. The mixed trophic impact matrix of a network with n nodes, is a squared matrix

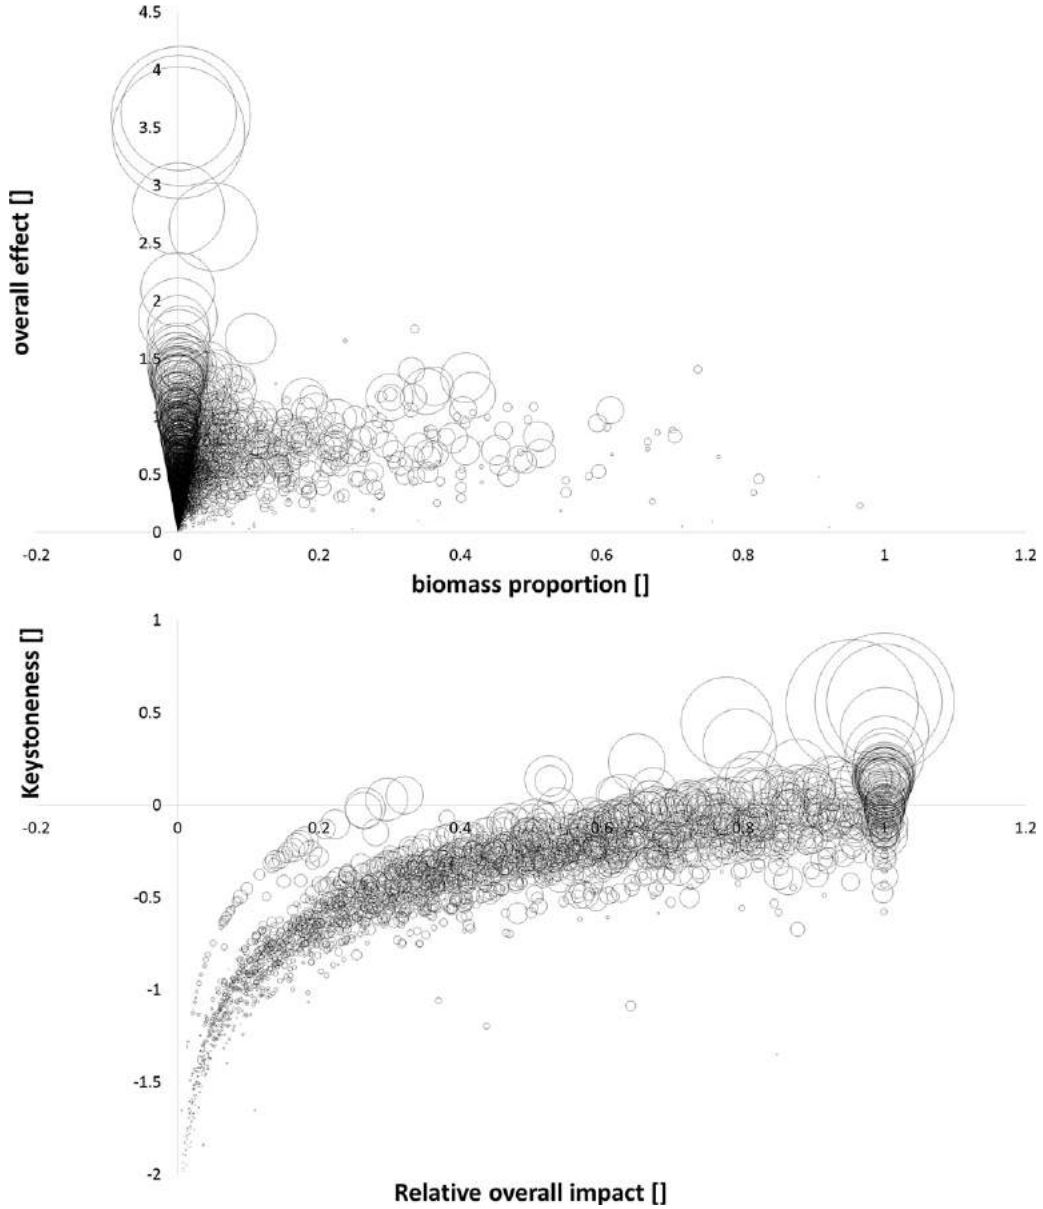

Fig. 2 Overall effect, biomass proportion and keystoneness for the 2635 functional groups of the 107 food webs of marine ecosystems. Area of the bubbles is proportional to the top–down impact measured as the sum of negative MTI elements. Upper panel is built in conformity with **Fig. 1**. Lower panel represent the keystoneness in a common graphics, showing keystones as the groups with keystoneness close to 0 or above.

with $n \times n$ elements, m_{ij}. Each element of the matrix can be positive or negative and represent the impact of the node i on the node j of the network through all possible direct and indirect pathways propagating through the food web (Ulanowicz and Puccia, 1990).

It has been demonstrated that the elements m_{ij} of the matrix M are corresponding to the sensitivity of the node j to perturbations of the node i at the equilibrium. This equivalence was demonstrated on the basis of results from a set of simulations obtained by changing density, biomass or productivity of the group i and evaluating the long term biomass changes on the other groups of the web (Libralato *et al.*, 2006). This equivalence set the basis for defining overall effects (direct and indirect) of a group on all the others of the web, on the basis of the matrix M. It was thus proposed to consider all possible direct and indirect effects produced by a species, as the sum of absolute values of perturbation induced in the food web by a change in one node. Namely, the overall effect $\mathscr{E}_i$ of the node i is calculated as the of all the effects of i over the whole food web. In order to avoid that positive and negative factors eliding each other, for accounting the total overall effect the squared elements of m_{ij} are summed by row as in the following:

$$\mathscr{E}_i = \sqrt{\sum_{j=1}^{n} m_{ij}^2 - m_{jj}^2}$$

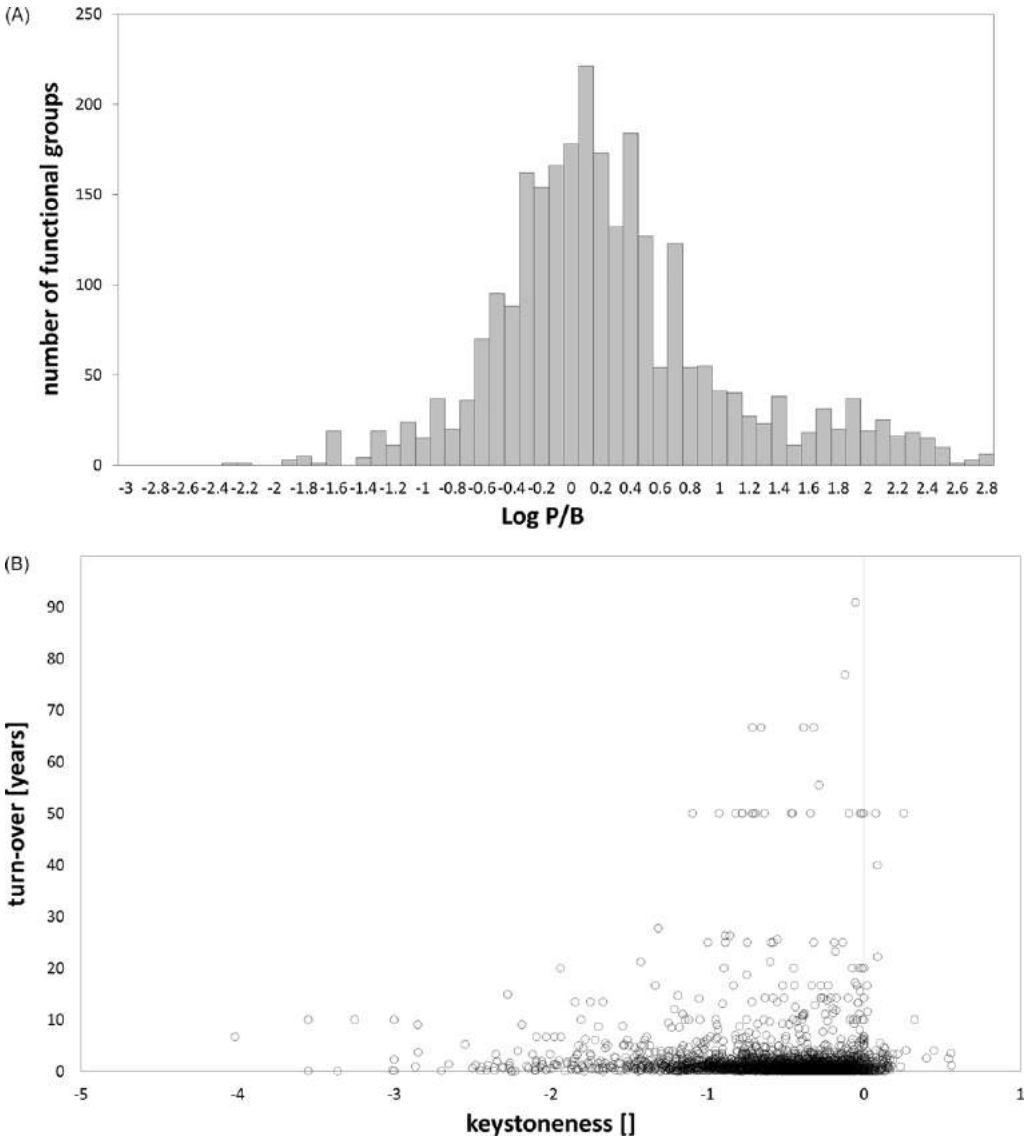

Fig. 3 (A) Turn-over (in years) expressing average longevity of the population as a characteristics of species for the 2635 functional groups of the 107 food webs. Data showed to be normally distributed. (B) Results in terms of keystoneness for the 2635 functional groups with respect to turn-over as a measure of longevity. Results highlight a tendency for high keystoneness to be related with high turnover, that is, to species characterized by high longevity.

where the self-effects are not considered. The overall effect $\mathscr{E}_i$ is thus a synthetic measure of the impact that a species has on all the others and can be considered for evaluating species role.

Notably, it is also possible to consider the contribution of positive and negative m_{ij} elements on the overall effect. Considering that negative m_{ij} indicates a species with direct and indirect negative effects on another, negative m_{ij} is indicative of a top–down effect (Libralato *et al.*, 2006). Exception to this is represented by the beneficial predator (Ulanowicz and Puccia, 1990): a species whose positive indirect effects on the prey are larger than negative impact on a prey due to predation removal (negative impact). Since beneficial predation is quite exceptional feature, considering negative m_{ij} as top–down effects is quite robust (Libralato *et al.*, 2006). Conversely positive m_{ij} is more related to bottom–up effects.

Keystoneness as a Combination of Overall Effect and Biomass Proportion

In line with per capita interaction strength as a measure of keystone role, the impact of a species ($\mathscr{E}_i$) contrasted with its biomass proportion in the system (p_i) was used as a way to distinguish keystone species from dominants (Power *et al.*, 1996). Using the same approach it is possible to contrast overall effect determined from ecological networks on the basis of mixed trophic impact

analysis and the biomass proportion (Libralato *et al.*, 2006). Using these considerations several measures of species importance were evaluated and the keystoneness was chosen as:

$$KS_i = \log\left[\mathcal{E}_i \bullet (1 - p_i)\right]$$

Each node of an ecological network is thus characterized by a keystoneness KS_i which can assume any value in the range from 1 to negative infinity (**Fig. 2**). The keystoneness allows to rank species by keystone role played and by convention species or functional groups with *KS* close or above 0 are to be considered with high keystoneness and thus keystone species (Libralato *et al.*, 2006). Other ways of combining overall effects and biomass proportion in the system have been formally tested highlighting that new possible weighting and/or ranking could be used (Valls *et al.*, 2015), but confirming the potential of these two factors determined from food web models as a basis for determining keystone species.

Applications of Keystoneness

Broad meta-analyses of *KS* application on several marine food webs highlighted that species with high *KS* have also high contribution of negative mixed trophic impacts (**Fig. 2**), i.e., a large proportion of their large impacts are due to top–down effects (Heymans *et al.*, 2014). Among the 2635 functional groups analyzed from a set of 107 ecological networks representing marine ecosystem all over the world highlighted the presence of several high trophic level species having high keystoneness. Therefore keystone species identified included in particular top predators such as large pelagics and sharks (Libralato *et al.*, 2006; Heymans *et al.*, 2014).

Although in the 107 food web models there are many groups long living, such as seals, sharks, whales, turtles, the majority of taxa represented have short generation time and the average turn-over is 2.5 years (**Fig. 3**A) . Species or groups of species with high keystoneness (high impact on the food web) were long living taxa (**Fig. 3**B). This implies that we need longer time series to help our models (and modelers) to be more accurate in their ecosystem predictions.

Leaf Area Index

NJJ Bréda, National Institute for Agricultural Research (INRA), Champenoux, France

Introduction

The plant canopy is a site of physical and biochemical processes associated with the terrestrial biosphere. The functional and structural attributes of plant canopies are dependant on species composition, microclimatic conditions, nutrient dynamics, herbivore activities, and many other activities like management. The amount of foliage in a plant canopy is one of the basic ecological characteristics reflecting the integrated effects of these factors in an ecosystem. In turn, canopy leaf area is the dominant driving force of primary production, water and nutrient use, energy exchange, and other physiological functions of a range of ecosystem processes. Understanding the organization and function of plant canopies is of central importance when conducting many types of comparative ecological studies or when developing biophysical Earth system models involving water and carbon balances. Yet, characterizing plant canopies presents many challenges, largely because of their complex geometry, and because of the difficulties of obtaining meaningful quantitative indices that relate back to fundamental processes such as light interception, transpiration, and photosynthesis. Ecophysiologists, managers (farmers and foresters), ecologists, climate and weather forecast modelers, ecosystem modelers, and atmosphere–ecosystem interaction modelers, request information about canopy leaf area index (LAI), one of the most widely used descriptors of the canopy.

LAI is a measure of canopy foliage content commonly used in studies of vegetation and ecosystems. LAI is the total area of one side of the leaf tissue per unit area of ground surface. According to this definition, LAI is a dimensionless quantity characterizing the canopy of an ecosystem. One unit of LAI is equivalent to 10 000 m^2 of leaves per hectare. LAI has been recognized as the most important attribute of vegetation structure for characterizing canopies from the stand to large areas at broad spatial scales. In defining ecology as the study of the structure and function of ecosystems, LAI is one of the core parameters in ecology, as it links canopy structure and ecosystem function.

Magnitude of LAI across the World

Biomes are major biogeographic regions consisting of distinctive plant life forms (e.g., forest, grasslands, desert, etc.). LAI ranges from 1.3 $\pm$ 0.9 for deserts to 8.7 $\pm$ 4.3 for tree plantations, and up to 20 depending on the biome. Temperate evergreen forest (needle leaf and broadleaf) displays the highest average LAI (5.1–6.7) out of the natural terrestrial vegetation classes (Fig. 1). Biomes with the highest LAI values are tree plantations, temperate evergreen forests, and wetlands. Exceptionally high values have been reported for hybrid poplars grown under intensive culture which could develop LAI values of 16–45, depending on the tree spacing. Those with the lowest LAI values are deserts, grasslands, and tundra.

Environmental Controls of LAI

As climate (especially the mean and variations in annual precipitation and temperature) is the primary force shaping the major biomes of the world, much of the observed pattern of LAI distribution is initially driven by similar climatic factors. Second, biome distribution is controlled by edaphic conditions (water supply and soil fertility), which also control LAI. According to the resources optimization theory, LAI may adjust to climate and site potential. Reviews of plant science literature have computed the response of LAI to variations in soil moisture, soil fertility, and atmospheric CO_2. LAI is probably co-limited by a number of resources, including water, nitrogen, and light. A linear response of LAI to N was reported for some crops or coniferous species, but is not uniform for all plant species, soil nutrients, or fertilization rates. Fertilization (nitrogen, phosphorus, or potassium) strongly increases LAI but the response could be a short-term one, after which an acclimatization of the canopy occurs. A new steady state is adjusted in the following growing seasons, especially in terms of leaf area versus root ratio. LAI sensitivity decreases (i.e., LAI saturates) indicating that something other than soil fertility is a limiting factor for canopy development. In many cases, water supply acts as a strong limitation resulting from LAI increase and related water uptake needs. The response to increasing soil water content is close to that of soil fertility. Increasing soil water availability in soils suffering from severe drought causes a significant increase in LAI. Interestingly, the response to increases in atmospheric CO_2 is nonlinear. LAI curves for crops and plant communities indicate a strong response of LAI to increases in atmospheric CO_2 up to the current ambient content. Afterward, the impact is more limited. At some resource thresholds, the addition of fertilizers or water will have no further influence on LAI. The saturation of LAI is likely to be indicative of light limitation, due to self-shading of leaves and negative carbon balances in low canopy layers. A large proportion of natural ecosystems lies below a threshold of optimal resource availability. LAI saturation is a threshold beyond which any further increase in LAI is compensated for by a negative carbon balance in shaded lower canopy leaves.

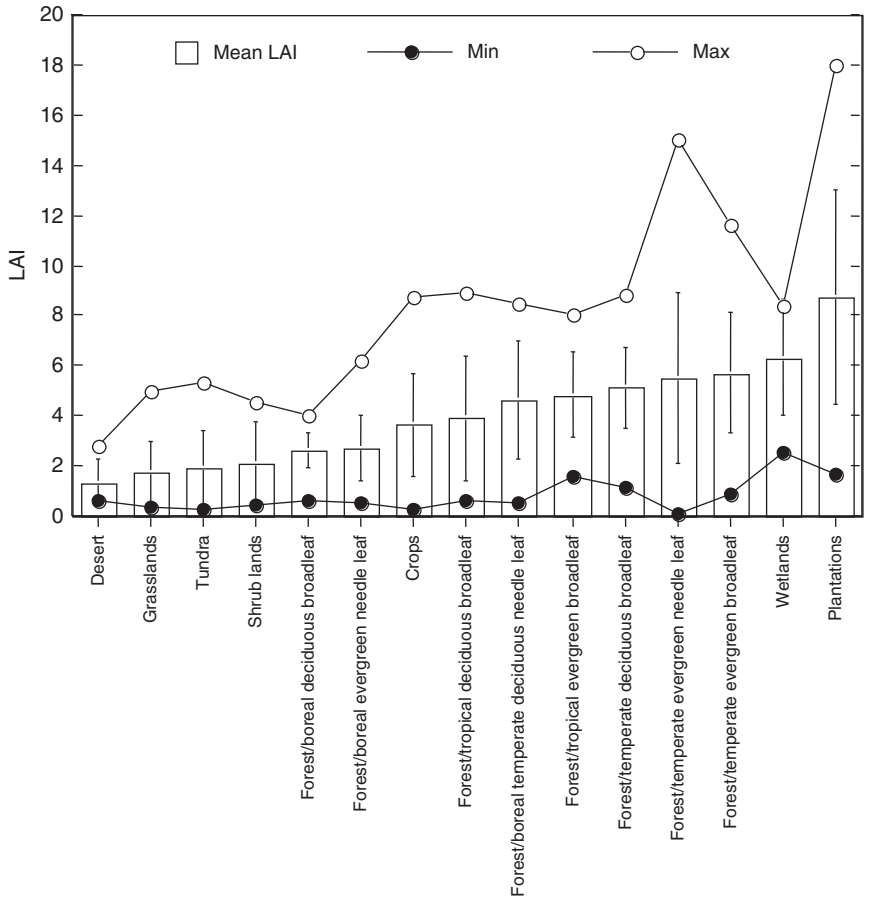

Fig. 1 Mean LAI (+/− standard deviation) of biomes and cover types. Data from Scurlock, J.M.O., Asner, G.P., Gower, S.T., 2001. Worldwide Historical Estimates and Bibliography of Leaf Area Index, 1932–2000. ORNL Technical Memorandum TM-2001/268. Oak Ridge, TN: Oak Ridge National Laboratory. Global Leaf Area Index Data from Field Measurements, 1932–2000. Data set available online (http://daac.ornl.gov) from the Oak Ridge National Laboratory Distributed Active Archive Center, Oak Ridge, Tennessee, USA.

Natural Temporal Variation in LAI

Both seasonal and interannual dynamics of LAI are characteristic of ecosystems, and seasonal dynamics of LAI is one of the aspects of phenology and life form. Evergreen versus broadleaved forests exhibit contrasting seasonal progression of LAI, with seasonal variation of less than 10% of LAI for evergreen. LAI expansion in deciduous species occurs within 1 month from budburst to maximum LAI which remains quite constant over the growing season and then decreases at leaf fall.

On an interannual time basis, adjusting LAI is a response of the ecosystem to cope with drought. Over a large range of climates, changes in LAI have been studied at both the individual and ecosystem scales along gradients from higher to lower rainfall amounts or from moister to drier habitats in broad- or needle-leaved tree or shrub communities. The control of LAI and morphology is often the most powerful means that a mesophytic plant has to influence its fate when subjected to long-term water stress in the field. The main response of the shrubs to different precipitation regimes in the chaparral range is to change LAI, and not physiological parameters like stomatal regulation. This adjustment is largely species dependent and both leaf size and number are affected. For example, mature eucalyptus trees are tall and produce large leaves at moist sites, whereas at drier sites, trees are shorter and tend to produce smaller leaves.

Aging of forest stands also leads to temporal changes in LAI. LAI firstly increases to a maximum at ages ranging from 16 to 50 (depending on species and site index) and subsequently stabilises or declines slightly, up to 20% lower than peak value. Interestingly, aboveground net primary production follows a similar trend with aging.

Natural canopy disturbances like fire or windstorm also induce abrupt changes in LAI. The severity of disturbance determines the regeneration options (by growth of suppressed seedlings and saplings or from the seed bank), as well as the time for stand LAI recovery. Biotic attacks by herbivores and leaf-eating insects, combined with drought, severe early spring freeze–thaw events, and fungal pathogens cause substantial reduction in LAI and hence in productivity. The loss of foliage due to insect defoliation could result in spectacular changes to LAI. Such LAI reduction could be large enough to be detected by indirect measurements, in a quantified way as compared to visual assessment of the severity of defoliation. Monitoring of LAI decrease in this way may be of

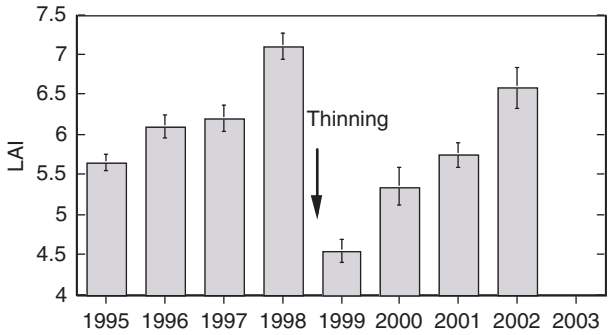

Fig. 2 Stand LAI recovery after thinning in a beech stand (RENECOFOR Network, Plot HET88). LAI was measured using a plant canopy analyzer (LAI 2000, Li-Cor, Nebraska, USA). Data from N. Bréda.

importance in mapping the spatial extension of the attack, may help to predict stand dieback and eventually plant mortality in the following years. Whatever the kind of natural disturbance or extreme event, the time needed to recover pre-event LAI could be used as an index of ecosystem resilience.

Management of LAI

Except in natural ecosystems, the canopy is periodically managed by farmers, foresters, grazing animals, and agriculturists. All management operations including cutting, grazing pasture, thinning, fertilization, liming, mowing, pruning, species sawing, and high herbage use, affect LAI. As stocking rate increases in grazed pasture, the total consumption per hectare goes up, while the net primary productivity decreases. The LAI is usually 2–3 with lower stocking densities and 1–2 at higher densities. In both crops and young forests, fertilizer effects on LAI are significant, and should increase LAI up to 3 units. An example of LAI management in forests is thinning, which reduces stand basal area, density, and LAI. In some cases, especially in even-aged mono-species stands like coniferous plantations, the LAI reduction is proportional to the basal area removed. Nevertheless, in most cases, the percentage of basal area removed is not proportional to those of LAI. Thinning improves water balance, radiation penetration within the canopy of the remaining trees, soil biology, and organic matter mineralization as a result of microclimatic changes. Canopy recovery occurs over several years depending on the intensity of the thinning, tree age, and site fertility (**Fig. 2**).

Managers control LAI to control productivity and water uptake, but in fact agricultural and forest managers should be interested in using estimates of LAI to gauge the vigor of cultures or plantations (crop or forest decline, pathogen attacks), to adjust management practices and thus produce optimum LAI (**Fig. 3**).

LAI as a Descriptor of Canopy Structure

Canopy structure means: (1) the whole of the vegetation community including species, number, leaf area, and leaf history; (2) its spatial organization, horizontal and vertical arrangement; and (3) its time progression (season, year, decade, and more). Then geometric complexities of different canopies are reduced to a simple quantification of the sum of all leaf layers as LAI.

The vertical distribution of LAI in mixed canopies reflects the functional abilities of species or leaves (shade, air humidity, and temperature tolerance). LAI controls both within- and below-canopy microclimate, determines and controls rainfall, snow and deposition interception, radiation extinction, wind velocity slackening, light quality and quantity below the canopy, and hence influences the living conditions of fungi, plants, insects, macro- and micro-fauna communities.

LAI as the Driving Force of Canopy Exchanges

LAI describes a fundamental property of the plant canopy in its interaction with the atmosphere, especially concerning radiation, energy, momentum, and gas exchange. Stand function includes: (1) the rate of biological energy flux through the ecosystem, that is, rates of production and respiration; (2) the rate of material and nutrient cycling, that is, the biogeochemical cycles; and (3) biological and ecological regulation, including prevention of soil erosion and regulation of water uptake, or radiation interception and conversion. LAI is the favored canopy variable because it is required for estimating many process rates, from canopy gas exchange to nutrient return in litterfall, including understorey microclimate control and competition for light, water, and mineral nutrients.

LAI acts as the canopy–atmosphere interface where water and carbon gas exchange occurs and is, therefore, a core parameter of biogeochemical cycles in ecosystems. Any change in canopy LAI, as a result of frost, storm, defoliation, grazing, drought, or management practice, is accompanied by modifications in stand productivity. Process-based ecosystem simulations require LAI as

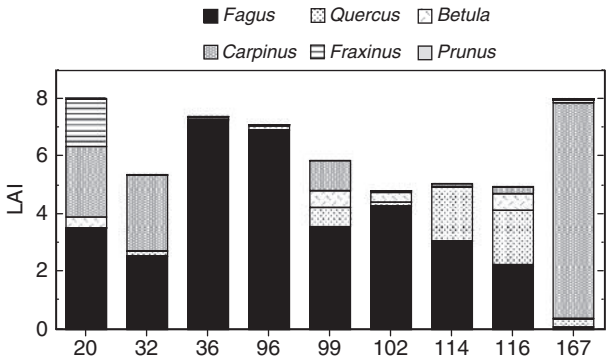

Fig. 3 Spatial variability of LAI in 60 ha of a managed beech forest (Hesse, France). Ground-based LAI measurements were distributed according to a systematic network (50 m x 50 m) using two cross-calibrated plant canopy analysers (LAI 2000, Li-Cor, Nebraska, USA). The scale ranges from 2 to 6, i.e., a similar range to that of the biomes presented in Bouriaud, O., Soudani, K., Bréda, N., 2003. Leaf area index from litter collection: Impact of specific leaf area variability within a beech stand. Canadian Journal of Remote Sensing 29, 371–380.

a key input parameter to produce quantitative analyses of productivity. When LAI of a community is low (<4), which is usually in arid environments or during the establishment of a crop, the transpiration rate (T/PET) is linearly related to LAI. Beyond this point, transpiration rate increases more slowly due to: (1) the saturation of canopy radiation interception and (2) soil water availability limitation (Fig. 4). Growth rates are also dependent on LAI, but as LAI increases, the growth rate reaches a maximum value. Thereafter, it may decline. The existence of an optimum LAI was first observed for herbaceous plants. At the slope inflexion, called critical LAI, an increase in LAI and its associated CO_2 uptake will not counterbalance the reduction of CO_2 uptake in the existing leaf area because of self-shading. The community might still continue to gain in biomass, but at a lower rate. Plant growth and life form strongly affects optimum LAI depending on leaf angle, clustering, and vertical distribution of leaves resulting in differences in the self-shading and greater or lesser depths of penetration of light into the canopy.

Assessment of LAI

Despite its functional importance, the measurement of LAI is not easy, due to its spatial (horizontal and vertical) and temporal heterogeneity. A plethora of ground-based optical, allometric, or litter collection methods and remote sensing approaches to estimate LAI are available.

Direct or Semidirect Methods

These involve a leaf area measurement. The main advantage of direct methods is that they are the only ones giving real LAI without any other plant organs. For that reason, they are considered as reference methods for indirect and remote sensing calibration. However, these direct methods are tedious, time consuming, and some of them are destructive.

Harvesting

The harvest method is one of the oldest methods, used for various vegetation types from crops to forests. A sample to be treated destructively has to be collected 4–5 times during the crop life cycle (i.e., sampling is done at 10–15 day intervals from seedling emergence) or relative to some of the developmental stages of the crop (emergence, flowering, physiological maturity). At each collection date, leaves are separated from the other parts and subsamples are selected for leaf area measurements. Then leaf area models have to be calibrated as: leaf area = (leaf length $\times$ leaf breadth) $\times k$, where k is a species specific coefficient depending on leaf shape and indentation ($k=0.5$ for triangle, 0.75 for grasses such as sorghum and maize, near 2/3 for many dicots). Leaves of the subsample are dried, weighed, and the dry leaf weight ratio is computed. Finally, LAI is computed as the dry weight of leaves $\times$ dry leaf weight ratio.

Litter collection

Using traps, in nets, or sampled on the ground is useful for LAI calculation of broadleaved plants. Species composition in the canopy is not distinguished when using canopy LAI. By sorting leaves from different species in mixed broadleaved forest, the contribution of each species from the community may be quantified (Fig. 5). Few data exist on leaf biomass of temperate deciduous forest communities which include undergrowth. If biomass is nearly negligible as compared to total stand biomass, the contribution of leaf area of undergrowth has been demonstrated to be a significant part (from 15% to 60%) of LAI of the whole community (tree or shrub layer + ground vegetation) within a narrow range of 7. Finally, the measured leaf properties (individual leaf area, specific leaf area, number of leaves, etc.) are of key importance for a comprehensive analysis of LAI changes between stands, species, or dates. Indeed, differences in LAI for a given stand during certain years could be the result of any change in number of plants, number of leaves, or individual leaf area.

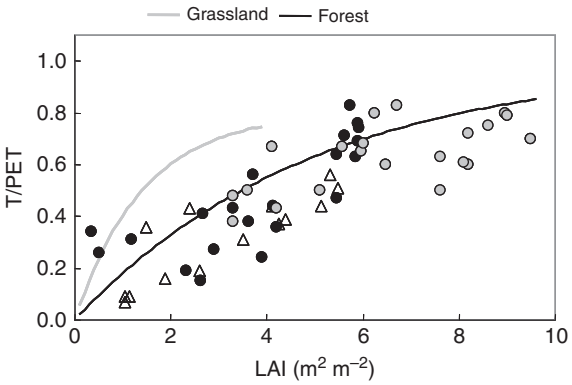

Fig. 4 Transpiration ratio (T/PET) as a function of LAI for forest and grasslands. For forest, symbols are for phenological periods: triangles: LAI increase during leaf expansion; black circles: LAI decrease during autumn; gray circles: maximum LAI for contrasting stands. Data from Granier, A., Bréda, N., Biron, P., Villette, S., 1999. A lumped water balance model to evaluate duration and intensity of drought constraints in forest stands. Ecological Modelling 116, 269–283 and Saugier, B., 1996. Evapotranspiration des prairies et des cultures. Comptes-rendus de l'Académie d'Agriculture de France 82, 133–153, for forests and grasslands, respectively.

Allometry

A relationship exists between sapwood or tree basal area and leaf area. This destructive approach is site-, species-, age-, and management dependent. Allometric relationships give the state at a given date.

Indirect Methods

These use the consequences of LAI on radiation interception or reflectance and are nondestructive. As any measure of radiation, these methods are sensitive to sky condition (direct vs. diffuse radiation or a clear and stable sky).

Ground-based approaches using optical instruments

At plot or stand level, the most common method of estimating LAI and its seasonal variation is from measurements of the fraction of light transmitted through the canopy to the ground. Nondestructive optical methods have been developed to estimate LAI periodically. The simplest approach, using Beer's law inversion with an extinction coefficient depending on the crop or tree properties, is useful and efficient for crops and broadleaved forests. However, for many evergreen species, the procedure requires some corrections to take the clumping of needles and branches into account. In any case, accurate equipment and methods for ground estimates of LAI are now available. Optical methods of estimating LAI use the inversion of gap fraction data. One fruitful approach involves measurement of the gap fraction, the proportion of unobscured sky in a set of sky directions as seen from beneath a plant canopy. Recent advances in the theory make it possible to calculate a useful array of canopy properties from gap fraction measurements, including light extinction coefficients, LAI, and leaf angle distribution. A variety of techniques can be employed to obtain gap fraction measurements, such as linear arrays of light sensors (SunSCAN, Delta-T Devices Ltd., Cambridge, UK and AccuPAR, Decagon Devices, Pullman, USA). Two other devices measure gap fraction for different zenith angles. The LAI-2000 (Li-Cor, Lincoln, Nebraska, USA) measures 5 zenith angles simultaneously, through a fisheye light sensor, while the DEMON instrument (CSIRO, Canberra, Australia) measures direct beam radiation from the Sun through a directional narrow angle of view (0.302 sr). Measurements with the DEMON instrument have to be repeated several times from early morning until noon to collect data over a range of zenith angles. Hemispherical photography and imaging hemispherical sensors (e.g., the CI-100 Canopy Analyzer, CID, Vancouver, USA) are also widely used but these frequently underestimate LAI.

Remote-sensed approaches

As opposed to ground-based methods, remote sensing deciphers the reflected, instead of the transmitted radiation. The plant communities are full of chlorophylls, a set of pigments which absorb part of the solar radiation for photosynthesis. As a result, reflectance of radiation in different spectral bands, especially the two widely used infrared and red ones, is changed proportionally to the amount of green vegetation. Since large-area maps of LAI are needed for global land-surface modeling, plenty of empirical relationships (i.e., statistical correlations) have been proposed between satellite or airborne image reflectance and ground-based (*in situ*) estimations of LAI. There are many vegetation indices developed from radiances in a wide range of channels corresponding to spectral bands. LAI estimation from satellite data requires ground data for validation and testing for bias. Satellite data must be corrected for atmospheric effects, thus requiring additional information on the state of the atmosphere (especially water vapor, aerosols, and ozone). Nondestructive (optical) measurements are the preferred approach for obtaining ground measurements. Classical values of LAI derivation from remote sensed vegetation indices (like Normalized Difference Vegetation Index, NDVI) range from 0 to 4–5, fitting an empirical exponential function with a plateau indicating a saturated signal for higher LAI. Such a relationship was first established for wheat and maize, at various states of growth. Unfortunately, LAI often reaches values above 5 and up to 15 in temperate mixed broadleaved forests or coniferous plantations. Then

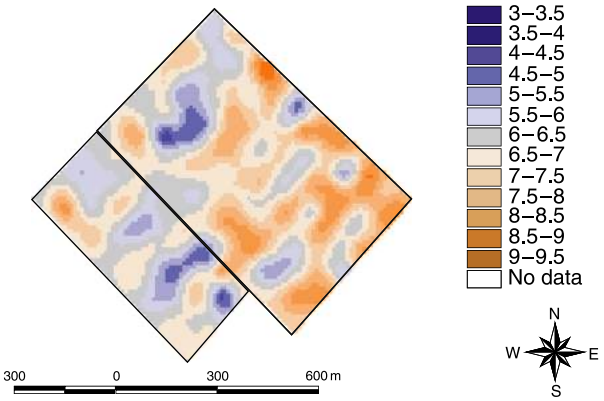

Fig. 5 Species contribution to total stand LAI in beech-dominated forest as estimated by litter collection and species sorting. Each plot number is related to spatial variability within the stand. For further details, see Bouriaud, O., Soudani, K., Bréda, N., 2003. Leaf area index from litter collection: Impact of specific leaf area variability within a beech stand. Canadian Journal of Remote Sensing 29, 371–380.

remote LAI derivation is not well adapted for such kinds of vegetation. New algorithms using the intrapixel variability of signals have been proposed but remain to be tested using ground-based data sets of forest LAI differing from the calibration data set.

Worldwide Maps of LAI and Controversies About Scaling in Global Modeling

Because LAI is a dimensionless quantity and an extensive surface parameter, it can be measured, analyzed, and modeled across a range of spatial scales, from individual tree crowns to whole regions or continents. Estimation of LAI across a landscape is needed for regional ecosystem analysis or modeling, but recent meta-analysis of worldwide LAI measurements highlights weaknesses in the ecological and geographical coverage of LAI measurements on a global basis. LAI is a canopy parameter in several models of growth or net primary production, but also in interactive models of land surface and atmospheric processes. Across wide landscapes, remote sensing is used to derive LAI maps to initiate regional or global modeling and automatic mapping of LAI at 8 km spatial resolution (NASA MODIS satellite data) offers global coverage of the biosphere. The reason for such a broad global ecological research interest in LAI is due to its emergent properties but it is still the subject of controversy in terms of scaling.

Metabolic Theories in Ecology: The Dynamic Energy Budget Theory and the Metabolic Theory of Ecology

Jaap van der Meer, NIOZ Royal Institute for Sea Research, Texel, The Netherlands; Utrecht University, Utrecht, The Netherlands; and VU University Amsterdam, Amsterdam, The Netherlands

Introduction

Animal metabolism is the processing of material that individual animals take up from the environment. Some fraction of this material is unusable and leaves the body as feces. This fraction is sometimes called the non-metabolic waste and not considered as part of metabolism, because it does not pass the gut wall and therefore not really enters the animals body. The remaining usable fraction of the food uptake is converted into other chemical forms and subsequently used for various life processes such as body maintenance, somatic growth and reproduction. Part of the usable material is thus stored in the body, maybe only temporarily as reproductive output, but a substantial amount of material also leaves the body as metabolic waste, in the form of gas such as carbon dioxide, liquid such as water or urine, or even as solid waste in the form of hairs, feathers, scales and skin. If the focus is on energy, a similar division can be made. The free chemical energy of the food is partly transformed into other forms of chemical energy, while a fraction is used for all kinds of internal work and finally dissipates as heat. Metabolic rate is usually defined as the heat production of an animal. So despite the term, metabolic rate is not sufficient to describe metabolism.

A complete description should also include food intake rate and defecation rate (or at least assimilation rate, which is here defined as the difference between these two rates), somatic growth rate, reproductive rate and the rate at which metabolic waste is produced. The description of these rates can be in terms of power measured as Watt, or in terms of material flows measured for example by C-moles per unit of time.

Ecology is the study of organisms in relation to their environment, and because organisms, as we have seen above, can be considered as processors of material, it is obvious that metabolism and how it is affected by the environment should play a pivotal role in ecology. Influential scholars as Lotka, Elton, Von Bertalanffy, Hutchinson, and Lindeman already long ago emphasized the transfer of material and energy from one component of the ecosystem to another. Despite the important work done by these early scientists, by the end of the previous century the focus in ecology had shifted away from energy and material flows and the subject of metabolism was receiving little attention. But two decades ago, papers by James Brown and colleagues put metabolism again strongly on the research agenda of ecology. Brown was, as many others before him, puzzled by Kleiber's observation that metabolic rate of adult animals of different species is proportional to their mass raised to the 3/4 power. Many scientists tried to find laws that could explain this regularity, but none had convinced the scientific community as a whole. The zoologist Brown and plant biologist Enquist joined forces with the physicist West, and they worked out the idea that whole-organism metabolic rate is limited by the internal delivery of resources to cells. Resources have to be distributed through branching networks, and the fractal-like design of these networks cause the supply rate and therefore the metabolic rate, to scale as a 3/4 power of body volume (West *et al.*, 1997). In later publications they worked out this idea and included other aspects of metabolism, e.g. somatic growth (West *et al.*, 2001; Hou *et al.*, 2008), reproduction (West *et al.*, 2001) and feeding (Hou *et al.*, 2011). The same research group was also interested in the effect of temperature on metabolic rate and claimed that it could be understood from basic cellular processes. Combining the two ideas led to the famous, but much questioned core equation of what has become known as the metabolic theory of ecology (MTE). The equation relates the metabolic rate B measured in Watt, to body mass m measured in kg and temperature T measured in K, and is given by

$$B = B_0 m^{3/4} e^{-E_a/(kT)} \tag{1}$$

where the parameter B_0 in W $kg^{-3/4}$ is a normalization parameter, E_a in eV is supposed to be the "average activation energy of metabolism" which should be about 0.6 eV, and k is the Boltzmann constant which equals 8.617×10^{-5} eV K^{-1}. Of course, very similar equations were already in use for a long time, but the claim for novelty was that a mechanistic explanation was offered.

More than a decade earlier the Dutch theoretical biologist Kooijman laid the basis of what has become known as the dynamic energy budget (DEB) theory in two papers, which were hardly recognized in those days (Kooijman, 1986a,b). Kooijman, like Brown, was interested in general patterns in biology, not only Kleiber's law but also the observation that the growth of most heterotrophic organisms, in size differing between a yeast cell and an elephant, follows Von Bertalanffy's equation quite accurately. Many more patterns had his interest, and a complete list will follow below. But Kooijman proceeded in a different way than Brown and colleagues. He realized that metabolic rate is related to many fundamental life processes, such as somatic maintenance, growth and reproduction, which each have their overhead costs, and feeding. In his view a description of these fundamental processes should form the core of a metabolic theory, and metabolic rate will follow automatically from the overall energy balance. He further made the assumption that most of these fundamental processes are simply dependent on either surface area or body volume. He also realized that many of the patterns that he was interested in could not be explained by using a one-compartment model animal. At least two compartments are needed, and they were labeled structural body and reserve, where the main

difference is that structure has maintenance costs, but reserve has not. DEB theory claims that it provides the simplest model that is able to explain all the patterns Kooijman had in mind. Simpler alternatives just do not exist. These early 1986 papers already explained a whole series of empirical scaling relationships, and many more predictions would follow during the development of the theory which led to several monographs (Kooijman, 2010).

Below I discuss and compare the two theories, DEB and MTE, in more detail. A theory in science should be based on assumptions that are in accordance with broadly accepted and more fundamental theories. If measurable quantities are involved in these assumptions, they should be in line with empirical observations. So I will list and discuss where needed the assumptions of the two theories. A theory should further be internally consistent. This will also be discussed. Predictions should be in line with empirical data and finally the theory should not be needlessly complicated. I will comment on the apparent complexity of the two theories. For reasons of convenience I restrict the overview to animals, although both MTE and DEB have something to say about other forms of life.

DEB, Development and Criticisms

The simplest DEB model, which is the standard DEB model, aims to predict a series of empirical patterns observed in living animals. A list of these patterns, which are all related to feeding, assimilation, respiration, growth, development, reproduction and changes in the chemical composition of animals, is provided in **Table 1**. Subsequently DEB theory provides a set of model assumptions that completely define the mathematical formulation of the standard DEB model. The underlying idea is that this set is as limited and as simple as possible, but the model that follows from it is capable of reproducing the observed patterns. A summary of the model assumptions is provided in **Table 2**. A graphical representation of the energy fluxes in the standard DEB model is provided in **Fig. 1**. The model was initially developed by Kooijman (1986a,b), but has been modified in details since then, which basically means that the list of assumptions has been refined, see for example Sousa *et al.* (2008). These assumptions automatically lead to the mathematical description of the model, in terms of a set of coupled differential equations, one for each of the three state variables. State variables and environmental factors are explained in **Table 3**, and the primary parameters of the model in **Table 4**. For completeness the differential equation will be given. For reserve density it is

$$\frac{\mathrm{d}[E]}{\mathrm{d}t} = V^{-1/3}(\{\dot{p}_{Am}\}f - \dot{v}[E]) \tag{2}$$

where f refers to the dimensionless scaled functional response, which is a function of food density X, and can vary between 0 and 1. The scaled functional response relation is basically Holling type II, and is given by $f = X/(X_K + X)$, where X_K is the half-saturation coefficient. This coefficient is directly related to various primary parameters of the DEB model (see **Table 4**) and to μ_X, which is the chemical potential of the food. It is given by $X_K = \{\dot{p}_{Am}\}/(\mu_X \kappa_X \{\dot{F}_m\})$. The differential equation for structural volume is

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \frac{(\kappa\dot{v}[E] - \{\dot{p}_T\})\ V^{2/3} - [\dot{p}_M]V}{\kappa[E] + [E_G]} \tag{3}$$

which reduces to the well-known Bertalanffy equation when the reserve density is in equilibrium. This happens at constant food density. Finally, the equation for maturity is

$$\frac{\mathrm{d}E_H}{\mathrm{d}t} = (1-\kappa)\dot{p}_C - \dot{k}_J E_H \tag{4}$$

for $E_H < E_H^p$. Else, that is when the animals have become mature and $E_H = E_H^p$, maturity does not change anymore and $\mathrm{d}E_H/\mathrm{d}t = 0$.

Table 1 Empirical patterns on feeding, respiration, growth and reproduction that DEB theory aims to explain

Process	*Pattern*
Feeding	During starvation, organisms are able to survive for some time, to reproduce and to grow
	At abundant food feeding rate is at some maximum
Growth	Growth of animals at abundant food is well described by the von Bertalanffy growth curve
	Many animals do not stop growing after reproduction has started, i.e. they exhibit indeterminate growth
	Fetuses increase in weight proportional to cubed time
	The inverse of the von Bertalanffy growth rate of the same species at different food availabilities corrected for a common body temperature decreases linearly with ultimate length
	The logarithm of the von Bertalanffy growth rate of different species corrected for a common body temperature decreases almost linearly with the logarithm of the species maximum size
Respiration	Freshly laid eggs do not use oxygen in significant amounts
	The use of oxygen increases with decreasing mass in embryos, but increases with mass in juveniles and adults
	The use of oxygen scales with body mass raised to a power close to 0.75
Stoichiometry	Well-fed animals have a different body chemical composition than poorly-fed organisms
	Animals growing with constant food density converge to a constant chemical composition
Reproduction	Reproduction increases with size intra-specifically, but decreases with size inter-specifically

Table 2 The basic assumptions of the standard DEB model

1. An organism is characterized by a structural body, reserves, and maturity. The chemical composition of both structural body and reserves is constant, which is called the assumption of strong homeostasis. Maturity indicates the level of development and represents information, but has no energy or mass capacity
2. Each organism starts its life as an embryo (which does not feed and does not reproduce). When the embryo has reached a certain level of maturity, it changes into a juvenile (which feeds, but does not reproduce). Similarly, a juvenile changes into an adult (which feeds and reproduces) when it has reached the maximum maturity value
3. Ingestion depends upon food density by Holling's disc equation (but recall that embryos do not feed). Both the searching rate and the maximum ingestion rate, the latter similar to the inverse of the handling time, are proportional to the surface area of the organism
4. A fixed fraction of the ingested food is assimilated and enters the reserves
5. Reserve density, which is the amount of reserves per amount of structural body, reaches an equilibrium under constant food conditions. This assumption is called the weak homeostasis assumption. The use of reserves only depends upon the amount of reserves itself and on body volume, which in combination with the weak homeostasis assumption implies that the mobilization of the reserves occurs at a rate proportional to the reserve density
6. A fixed fraction κ of the mobilized reserves goes to somatic maintenance and growth of the structural body, with a priority for maintenance. The rest goes to maturity maintenance and either to maturity (for embryos and juveniles) or to reproduction (for adults)
7. Somatic maintenance rate is basically proportional to structural volume, but in specific cases part of the maintenance costs is proportional to surface area of the organism (e.g. heating rate in endotherms). Maturity maintenance costs are proportional to maturity
8. Energetic costs of growth are proportional to body volume and energetic costs per egg are such that the newborn juvenile has the same energy density as its mother

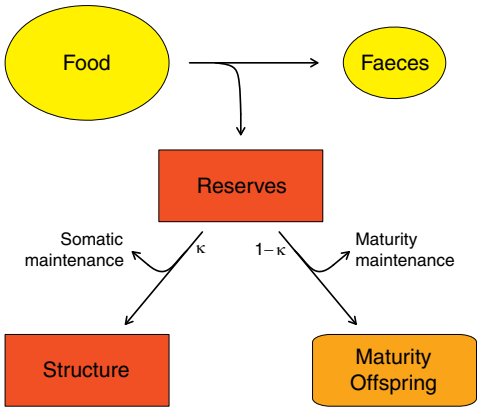

Fig. 1 Conceptual scheme of the main energy fluxes in the standard DEB model.

Table 3 State variables of the standard DEB model and environmental variables

Symbol	*Dimension*	*Interpretation*
V	L^3	Structural body volume
$[E]$	eL^{-3}	Reserve density
E_H	e	Maturity
T	T	Temperature
X	$\#l^{-2}$ or $\#l^{-3}$	Food density in the environment

L stands for the dimension length of the structural body, e for energy, # for mass measured in terms of C-moles, and l for the dimension length of the environment.

For adults the energy flow is channeled to reproduction and the rate of cumulative reproduction is given by

$$\frac{\mathrm{d}R}{\mathrm{d}t} = \frac{\kappa_R}{E_0}\left((1-\kappa)\dot{p}_C - \dot{k}_J E_H^p\right) \tag{5}$$

where κ_R is the reproduction efficiency and E_0 the energy content of an egg. The term $\dot{p}_C$ is the rate at which the reserves are mobilized. This rate is given by

$$\dot{p}_C = \frac{[E]}{\kappa[E] + [E_G]}\left((\dot{v}[E_G] + \{\dot{p}_T\})\ V^{2/3} + [\dot{p}_M]V\right) \tag{6}$$

Table 4 Primary parameters of the standard DEB model

Symbol	*Dimension*	*Interpretation*	*Process*
$\{\dot{p}_{Am}\}$	$eL^{-2}t^{-1}$	Surface-area-specific maximum assimilation rate	Assimilation
$\left\{\dot{F}_m\right\}$	$l^*L^{-2}t^{-1}$	Surface-area-specific searching rate	Feeding
κ_X	–	Digestion efficiency	Digestion
$\dot{v}$	Lt^{-1}	Energy conductance	Mobilization
κ	–	Fraction of mobilization rate spent on maintenance plus growth	Allocation
$[\dot{p}_M]$	$eL^{-3}t^{-1}$	Volume-specific maintenance rate	Turnover/activity
$\{\dot{p}_T\}$	$eL^{-2}t^{-1}$	Surface-area-specific maintenance rate	Heating/osmosis
$[E_G]$	eL^{-3}	Volume-specific costs of growth	Growth
$\dot{k}_J$	–	Specific maturity maintenance	Regulation/defense
κ_R	–	Reproduction efficiency	Egg formation
E_H^b	e	Maturity at birth	Life history
E_H^p	e	Maturity at puberty	Life history

Source: The "wild card" * stands for two when food density is expressed per area or three when expressed per volume, t stands for time. See further **Table 3**.

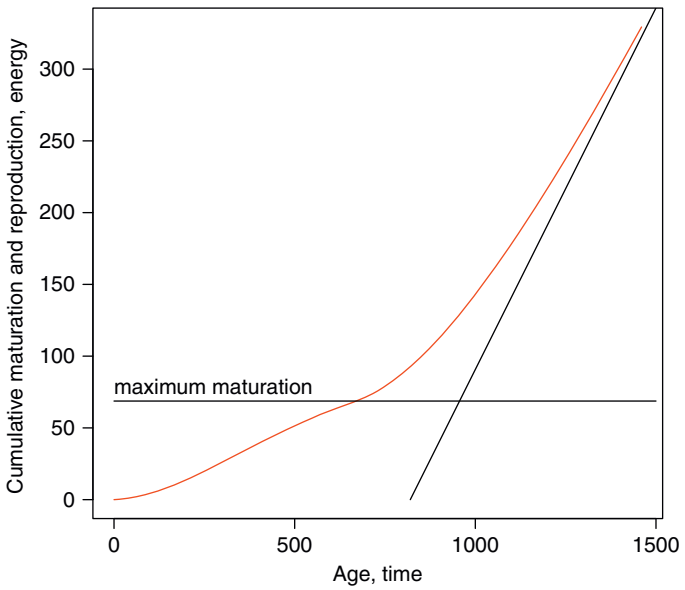

Fig. 2 Cumulative maturation and reproduction as a function of age. Scaled functional response f is 1. When the total investment in maturation has reached its maximum, reproduction starts and the cumulative reproduction steadily approaches a diagonal asymptote.

Combining Eqs. **6** and **5** will give an explicit expression for the reproduction rate as a function of size and reserves (**Fig. 2**).

DEB theory has been mainly criticized for its perceived complexity (Brown *et al.*, 2004; Zuo *et al.*, 2009; Marquet *et al.*, 2014). Brown *et al.* (2004) state that DEB models are complex, using many variables and functions. They argue that how much complexity in a model is desirable is partly a matter of the purpose for which the model is used, and that there is room for a complementary and even more general approach than DEB, something that MTE offers. Zuo *et al.* (2009) consider DEB as a very detailed model and they (erroneously) state that the model requires the measurement of 17 variables and 18 parameters. Marquet *et al.* (2014) even call DEB theory an inefficient theory as it contains too many species specific parameters, which hinders the generation of general predictions.

MTE, Development and Criticisms

The development of the MTE started with a rather technical paper by West *et al.* (1997), using principles of fluid dynamics to show that optimal transport networks yield a supply rate to the cells that scales with the 3/4 power of body mass. The network design, which could for example represent the cardiovascular network of a mammal, was based on certain specific assumptions, such as that the capillaries have to reach all cells. Optimal was defined as having minimal energy loss through dissipation and wave reflections. The approach was applauded by many, but also heavily criticized, both by what I for the sake of simplicity will call

biologists and physicists. The biologists questioned the relevance of the assumed network for animal life. A first problem is that closed branching networks are rarely found in animals. Apart for vertebrates and a few invertebrate groups, such as cephalopods, they do not exist in the animal kingdom. A second problem is that cardiovascular networks are probably designed for peak exercise during short periods, and it seems rather unlikely that the much lower resting metabolic rate that Kleiber was talking about, or even the average or field metabolic rate, has the same proportion to the maximum rate for all animal species. The biologists further thought that the predictions on the type of network that resulted from the optimization procedure were far away from reality. The predicted area preservation of the network implies that the flow rate in the capillaries is as large as that in the aorta. If that would be the case for you and me, we would almost immediately die if we would cut ourselves in one of our fingers. But most criticisms pointed to the fact that there is actually no need at all for predicting a 3/4 relationship, because such universal relation simply does not exist in nature. The physicists merely disagreed on the reliability of some more detailed assumptions on the network itself, e.g. it was originally assumed that the network is infinitely large, and they questioned how critical such assumption is for the outcome. They came to the conclusion that more realistic assumptions on the size of the network would have led to a non-allometric relationship that can be approximated by an allometric one with a scaling coefficient of 0.81. Others had major problems with the optimization procedure that had been used. So Price *et al.* (2012) had to point out in a recent review that "the community at large has not reached a consensus as to whether the theory is or is not logically consistent." This community at large is in fact rather small, as most biologists are not well equipped to follow the detailed arguments of the physicists in this part of the debate.

The development of MTE went on with the paper by West *et al.* (2001), later followed by Hou *et al.* (2008). West and co-workers presented the so-called ontogenetic growth model (OGM). The OGM assumed that organism growth rate is proportional to the difference between the supply rate at which resources are delivered to the cells, which was set equivalent to the average resting metabolic rate B, and the maintenance rate B_{maint}, defined as the power needed to sustain the organism in all its activities. The fractal-like design of the network through which the resources are supplied to the cells causes the supply rate to scale as the 3/4 power of body mass, as earlier proposed by West *et al.* (1997). The maintenance rate was thought to be proportional to body mass $B_{maint} = B_m m$. Hence, the model can be expressed as

$$\frac{dm}{dt} = \frac{B_0 m^{3/4} - B_m m}{E_m} \tag{7}$$

where m is total body mass, t is time, and E_m is the energy required to create a unit of mass of new tissue. Though the OGM was highly influential and widely cited, it was also severely criticized (Makarieva *et al.*, 2004; Van der Meer, 2006). Criticisms pointed among other things to lack of consistency and incompleteness. The criticism that the OGM lacked consistency referred to the ambiguous definition of metabolic rate. The term was both used for the supply rate of energy and for the maintenance rate. At the same time the difference between these two rates was supposed to be used for the build-up of new body tissue. The proportionality parameter E_m which converts energy into biomass, and which thus converts the difference between the supply and maintenance rate into the rate of biosynthesis, was derived from the empirical combustion energy per unit mass of mammalian tissue, for which a value of 7 kJ/g was used. The use of such parameter is in accordance to the idea that the difference between supply and maintenance is entirely stored into new tissue, but the fact that thus a part of the supply rate is not dissipated causes a problem, as you cannot, almost literally, have your cake and eat it. The problem could only be resolved if not the supply rate, but the maintenance rate would be equated to the resting metabolic rate (Van der Meer, 2006). Holding on to the notion that the resting metabolic rate equals the supply rate would violate the energy conservation law (Makarieva *et al.*, 2004). The logic consequence of equating resting metabolic rate to maintenance rate is that the intraspecific scaling power of resting metabolic rate equals 1 (Van der Meer, 2006). Ironically, this disputes the strong claim that the MTE explains Kleiber's law of a scaling power of 3/4, at least as far as intraspecific comparisons are concerned. The supposed incompleteness of the OGM referred to the fact that the metabolic rate of active animals can be much higher than the resting metabolic rate and to the ignorance of all overhead costs of growth (Makarieva *et al.*, 2004; Van der Meer, 2006).

A new model by Hou *et al.* (2008), called the extended ontogenetic growth model (EOGM) and mainly meant to be applied to birds and mammals, aimed to repair these flaws. The EOGM distinguishes between total metabolic rate B_{tot} and resting metabolic rate B_{rest}. The difference between these rates is used for activity. Total metabolic rate is assumed to be proportional to resting metabolic rate, $B_{tot} = fB_{rest}$. Following West *et al.* (1997) total metabolic rate and thus also resting metabolic rate scale as the 3/4 power of body mass. The new model also takes the overhead costs of growth into account and distinguishes between the energy content stored in newly synthesized biomass and the energy expended in synthesizing this biomass from the constituent materials. The difference between resting metabolic rate and maintenance rate is now entirely used for the overhead costs of growth. This implies that the resting metabolic rate is completely dissipated to heat. The new growth model still looks like the old OGM, but the parameter E_m is now interpreted as the overhead costs of growth. So the problems of violating the energy conservation law or contrasting Kleiber's law were solved. One new problem arose and that is, how are the building materials that need to be stored in newly synthesized biomass transported to the cells? Hou *et al.* added the rate S at which the energy content of new biomass accumulates, on top of the total metabolic rate B_{tot} in order to arrive at the assimilation rate of food $A = B_{tot} + S$. They further supposed a fixed ratio between the supply of building materials and the overhead costs of growth (both in terms of power): $S = \gamma(B_{rest} - B_{maint})$. This implies that the assimilation rate equals $A = (f + \gamma)B_0 m^{3/4} - \gamma B_m m$. But Hou *et al.* did not tell how these assimilated products are delivered to the cells and what kind of network is required to do so. The core of MTE is that within organisms the supply rate to the cells is constrained by some specific fractal-like design of branching networks. Consequently, the supply rate scales as the 3/4 power of body mass. Now two options with respect to the design of the network are possible. The

Table 5 Empirical patterns on feeding, respiration, growth and reproduction that MTE theory aims to explain

Process	*Pattern*
Growth	Growth of animals is well described by a von Bertalanffy type growth curve
Respiration	The use of oxygen scales with body mass raised to a power close to 0.75

Table 6 The basic assumptions of the metabolic theory of ecology, and more specifically of the extended ontogenetic growth model (EOGM)

1. An organism is characterized by its body mass
2. Nine detailed assumptions on the design of the distribution network (not spelled out here, but see assumptions A1–A9 in Price *et al.* (2012)) result in the prediction that the delivery of oxygen to the cells is proportional to body mass raised to the power 3/4
3. The oxygen delivered to the cells is used for maintenance, overhead costs of growth, and locomotion and other activities
4. Oxygen delivery needed for maintenance is proportional to body mass
5. Oxygen delivery needed for locomotion and other activities is proportional to the oxygen needed for maintenance and overhead costs of growth
6. The material needed as building blocks for new body tissue is proportional to overhead costs of growth. The delivery of this material to the cells is not restricted by the capacity of the distribution network

Source: Interpreted from West *et al.* (1997) and Hou *et al.* (2008). See text for further explanation.

network is either designed such that its capacity is just sufficient to transport the matter that is dissipated to heat. This means that the supply rate through the network equals the total metabolic rate $fB_0m^{3/4}$. This option thus implies that the EOGM requires additional and unknown ways of transport to deliver the building materials for biosynthesis to the cells. The other option is that the network is able to transport the building materials as well. It can easily be shown that the network should be designed such that the capacity equals $(f + \gamma)B_0m^{3/4}$. Smaller 3/4 scaling networks cannot transport the assimilated matter when the animals are small. In this case the supply rate is no longer constrained by the network when the animal gets larger. For larger animals the network has a huge overcapacity and it remains unclear by what mechanism the total metabolic rate is constrained. In a personal communication the authors stated that the first option is basically the right one, but that "it is primarily the uptake and delivery of oxygen that has selected for the fractal-like design of the vascular system, the matching design of the respiratory system and the 3/4 power scaling of metabolic rate." The processing of food is not constrained by the network as food "can be stored in the body and utilized for metabolism on widely varying time scales." This is an important and essential addition to the original contribution, as it for example suggests that reproduction, which requires very little overhead costs, will hardly be limited by the supply network. Apparently, the transport of food is not hampering the transport of oxygen.

To simplify a comparison with the DEB approach discussed earlier, I also list the type of patterns MTE aims to explain on feeding, respiration, growth and reproduction (**Table 5**). West *et al.* (2001) made a small remark on reproduction, but this was further ignored in the EOGM. Feeding is more recently discussed by Hou *et al.* (2011), but this paper contains some serious problems, about which a discussion is beyond the scope of the present overview. Hence, a single pattern for respiration and one for growth remain. A list of the underlying assumptions of MTE (**Table 6**) also illustrates the more limited scope compared to that of DEB (**Table 2**).

Predicting Scaling Relationships

For aerobic animals metabolic rate, which is the rate at which chemical energy is transformed into heat, is usually indirectly measured by the rate of oxygen consumption. DEB theory is clear about the intraspecific scaling relationship of metabolic rate. Maintenance costs are proportional to structural body volume, but there are other processes contributing to the oxygen consumption. For example, only part of the energy that is allocated to growth is fixed in new body tissue, the rest is dissipated as overhead costs. These overhead costs are proportional to the difference between a surface area-related term and a volume-related term. For endotherms, the heating costs, which scale with surface area, also contribute to the total oxygen use. Taking all these other processes into account, DEB theory predicts that the total metabolic rate will scale (if individuals of different size within the same species are compared) with body volume with a power somewhere between 2/3 and 1. The EOGM assumes that the supply rate of oxygen to the cells sets the rate at which chemical energy is transformed into heat. As the supply rate scales with 3/4 power of body mass, so does the metabolic rate. But, only when animals of different size of the same species are compared.

But what about Kleiber's law of the 3/4 power scaling of metabolic rate, which was not based on an intraspecific but on an interspecific comparison? Assuming that such a comparison concerns full-grown adult organisms, implies that growth has ceased. According to MTE all supplied energy is then used for maintenance. This can be seen from setting the growth Eq. **7** equal to zero. It follows that the ultimate size M_∞ equals $(B_0/B_m)^4$. So it seems logical either to assume that the supply parameter B_0 scales with the double square root of ultimate body mass, that is $B_0 = m_\infty^{1/4}$, or to assume that the maintenance parameter scales inversely with

m_∞, i.e. $B_m = m_\infty{}^{-1/4}$. MTE makes the second assumption, that is cellular maintenance costs scale interspecifically with a power of $-1/4$. The maintenance costs of a lizard are thus much higher than those of a baby crocodile of the same size. It is this assumption, which comes without any mechanistic biological reasoning, that in fact reveals Kleiber's law. So despite several claims, MTE's main idea of transport of resources to the cells through a fractal-like hierarchy of branching vessels does not suffice to predict Kleiber's law.

DEB theory predicts (for convenience restricted here to well-fed ectotherms) a maximum volume that equals $(\kappa\{\dot{p}_{Am}\}/[\dot{p}_M])^3$. Maximum volumetric length (the cubic root of the structural body volume) is thus proportional to the ratio between the maximum area-specific assimilation parameter $\{\dot{p}_{Am}\}$ and the volume specific maintenance parameter $[\dot{p}_M]$. Contrary to MTE, DEB assumes that animals that reach a large ultimate size do not differ in their volume specific maintenance rate from animals that remain small. Animals grow larger because they have higher assimilation capacities. This implies that metabolic rate at ultimate size is proportional to ultimate structural body volume, which seems to contradict Kleiber's law. However, DEB also predicts that species with a large ultimate structural volume have a higher maximum energy density than species that remain small. And because the body mass that is measured in practice is the sum of the structural body mass and the reserve mass, metabolic rate is not proportional to measured body mass. In fact, DEB predicts a non-allometric relationship between metabolic rate and measured body mass, which can be approximated by an allometric relationship with a scaling power very close to 3/4. For endotherms, heating costs, which are related to surface area, have to be added when animals are outside the thermoneutral zone and the approximate scaling power will then be somewhat lower.

DEB distinguishes between parameters that depend upon the local biochemical environment and those that depend upon physical design. The latter parameters are related to the ultimate size of the organism, the first group of parameters do not depend upon size. The maximum area-specific assimilation parameter is one of the few parameters that belong to the second group. Others are the E_H^b and E_H^p, the maturity at birth and at puberty. A variety of body size scaling relationships follow directly from this parameter classification. One example is the Bertalanffy growth rate, whose relation with ultimate body size can be approximated by a scaling relation with a co-efficient of -1. One of the first DEB papers already came up with predicted scaling relations for about 20 physiological variables, as diverse as maximum starvation time or minimum incubation time (Kooijman, 1986b).

Complexity

The standard DEB model contains three state variables (**Table 3**) and 12 primary parameters (**Table 4**). The extended ontogenetic growth model (EOGM) only considers one state variable and has four parameters. So at first sight DEB seems more complex than MTE. One should, however, realize that DEB is able to make predictions about many more processes than MTE, e.g. embryonic growth in eggs and wombs, hatching, maturation, reproduction, food depression, interspecific scaling etc. MTE has nothing to say about these issues. Of course, this difference comes at a cost. But DEB theory allows a reduction of the standard DEB model under certain restrictions. If food conditions are constant, reserve density is also constant after hatching, and growth can simply be described by a Von Bertalanffy growth equation with only three parameters and one state variable. Note that although the equation is the same, it is based on a different biological rationale than Von Bertalanffy had in mind. He did not apply the energy conservation law to the overall organism, but defined growth as the difference between anabolism (synthesis) and catabolism (breakdown).

Beyond the Organismic Level: Populations and Ecosystems

The standard DEB model provides a detailed description of the flows of energy in and out of the individual organism, including reproduction. It is therefore usable as a building block in either physiologically-structured populations models or agent-based models. Several applications are available, e.g. Martin *et al.* (2013). Ecosystem models have also been (partly) based on DEB theory (Saraiva *et al.*, 2017). MTE is less suited for these goals, as it neither incorporates feeding (but see Hou *et al.*, 2011) nor reproduction. Predictions of MTE at for example the population level are restricted to applying the so-called energy-equivalence rule, which says that every population of animals receives the same amount of energy as food. Linking MTE and this rule predict that population abundance scales with body mass with a scaling coefficient of minus $-1/4$. One should however notice that this prediction entirely relies on the 3/4-scaling relationship of metabolic rate, which is not just a result of MTE but also of DEB. In fact, any other explanation of Kleiber's law could have been used. Marquet *et al.* (2014) define an efficient theory as one that generates many predictions. It is a bit ironic that MTE sensu stricto, that is the idea of a fractal-like distribution network, has not generated any further hypothesis above the level of the individual. All predictions could have been made as a consequence of Kleiber's law. And several of the few detailed predictions at the level of the individual, such as that of an area-preserving network, are clearly flawed. One therefore could argue that Marquet *et al.* should have categorized the MTE theory as inefficient.

Temperature Effects

Temperature is, apart from food availability, another important environmental variable that affects metabolism. Both DEB and MTE use the Van't Hoff–Arrhenius equation to describe the dependency of physiological rates on temperature. This equation has

its origin in statistical thermodynamics, where the behavior of a system containing a very large number of a single type of molecules is predicted from statistical considerations of the behavior of individual molecules. In its basic form the Van't Hoff–Arrhenius equation looks like

$$\dot{k}(T) = \dot{k}_\infty e^{E_a/(kT)} \tag{8}$$

where $\dot{k}(T)$ is a reaction rate that depends upon the absolute temperature T (in Kelvin), $\dot{k}_\infty$ is a (theoretical) maximum reaction rate, which is the reaction rate when all molecules would react. The term $\exp(E_a/(kT))$ is the Boltzmann factor, which gives the fraction of the molecules that obtain the critical activation energy E_a (in joules per molecule) to react. This fraction increases with increasing temperature. The constant k (not to be confused with the reaction rate $\dot{k}$) is the Boltzmann constant and equals 1.38×10^{23} J/K. The Van't Hoff–Arrhenius equation can also be re-written in the form

$$\dot{k}(T) = \dot{k}_1 \qquad \exp\left(\frac{T_A}{T_1} - \frac{T_A}{T}\right) \tag{9}$$

where $\dot{k}_1$ is the reaction rate at a reference temperature T_1, and T_A the so-called Arrhenius temperature (which equals E_a/k). The Van't Hoff–Arrhenius equation is approximate for bi-molecular reactions in the gas phase, and Kooijman (2010) emphasizes the enormous step from a single reaction between two types of particles in the gas phase to physiological rates where many compounds are involved and gas kinetics do not apply. He therefore regards the application of the Van't Hoff–Arrhenius relation to physiological rates as an approximation only, for which the parameters have to be determined empirically. For this reason, Kooijman prefers the use of an Arrhenius temperature instead of the use of an activation energy, which would give a false impression of mechanistic understanding. Initially, MTE expressed the more candid view that the Van't Hoff–Arrhenius equation must be applied because it links whole-organism metabolism directly to the kinetics of the underlying biochemical reactions (Gillooly *et al.*, 2001). They furthermore stated that for all aerobic species a single parameter value for E_a can be used, because such species have the same biochemistry. This point of view has been criticized by, among many others, e.g. Glazier (2015). Similar to Kooijman, they stress that the Van't Hoff–Arrhenius equation is just a statistical generalization, and they too conclude that at present we still lack a clear understanding of the relationship between temperature and metabolism at the organismal scale. Glazier also pointed to the huge variation in estimates of the Arrhenius parameter. Indeed the claim of mechanistic understanding has never been substantiated.

Within MTE E_a and k are expressed in eV instead of joules and for E_a usually a value of 0.6 or 0.65 eV is used. Dividing by the Boltzmann coefficient gives an Arrhenius temperature of about 7000 or 7500 K, which is not far from the value of 8000 K used as the default value in DEB theory (Kooijman, 2010). But, as mentioned earlier, in DEB theory the Arrhenius parameter is considered as an estimable parameter, and estimates vary in practice mostly between 6000 and 10,000 K, which is, expressed in eV, equivalent to the range 0.52–0.86. Glazier (2015) mentions even an observed range of 0.2–1.2 eV for various metabolic processes.

Summary

Metabolic ecology describes the uptake of energy and matter by individual organisms and the subsequent allocation to various life processes such as body maintenance, somatic growth and reproduction. The ecological role that organisms play is strongly related to their metabolism and understanding the determinants of metabolism is essential to understanding this ecological role. Two alternative and influential theories on metabolic ecology, the dynamic energy budget theory (DEB) and the metabolic theory of ecology (MTE) are described in detail, with a focus on the underlying assumptions and predictive power. Core of the DEB theory concerns the assimilation of food, limited by the surface area of the organism, the transfer into reserves and the allocation of mobilized reserves, also limited by the reserve-structural body interface, to the various life processes. Metabolic rate, i.e. heat production, follows consequentially from making the energy balance. MTE, on the other hand, considers the supply rate of oxygen, limited by a branching fractal network, as setting the pace of life. Fuel will automatically be available. The theories are further compared in terms of complexity and internal consistency. At first sight, DEB seems to be the more complex theory, but if the scope and predictive power are also considered, it appears that DEB cannot be considered as more complex than MTE. The limited scope of MTE, exemplified for example by the ignorance of reproduction and the possibility of variable food intake rate, the lack of internal consistency and the low predictive power, makes it the least efficient theory of the two.

Further Reading

A contrasting view is expressed by Glazier (2015), who believes that in both DEB theory and MTE the importance of informational control, as mediated by various genetic, cellular, and neuro-endocrine regulatory systems, is underestimated (but see Kooijman, 2010, pp. 15–16).

Recently, several papers suggested ways to test the DEB and MTE theories against each other (Kearney and White, 2012; Maino *et al.*, 2014). Kearney and White (2012) came up with a list of 10 possible tests for which DEB predictions and MTE predictions differed. One example is a test on limb regeneration, in for example lizards. DEB predicts a regeneration rate up to threefold faster than ontogenetic growth rate, whereas these rates should be equal according to MTE. Maino *et al.* (2014) point to the relationship between inter- and intraspecific scaling of biological rates (see also discussion above) that should point to tests that could lead to a further refinement of the current metabolic theories.

Microclimate

KAS Mislan and B Helmuth, University of South Carolina, Columbia, SC, USA

Introduction

The microclimatological conditions surrounding an organism (the local conditions of climate as determined by aspects of the organism's microhabitat) control the exchange of factors such as heat, water, and nutrients between each organism and the surrounding environment. As a result, microclimates drive many aspects of organismal physiology and ecology. In this article, we first describe the physical characteristics of microclimates and the mechanisms by which organisms interact with microclimates through their behavior and morphology. We then discuss the physiological and ecological implications of microclimates over a range of temporal and spatial scales. Using these principles, we conclude with a discussion of mathematical modeling approaches that can be used to quantitatively predict organism distributions using microclimate characteristics.

Physical Characteristics

The ecological concept of microclimate depends largely on the question being addressed. To a landscape ecologist, a microclimate may comprise the side of a mountain, or a section of desert tens or perhaps even hundreds of kilometers in extent. To a reproductive ecologist interested in the life history of a mosquito breeding in a pitcher plant, the term microclimate refers to the inside of a plant only a few centimeters in diameter. Thus, from an ecological viewpoint, microclimate is very much defined by the organism or community in question. As a result, cohabitating species may have different responses to heterogeneity in their local microhabitat, and what constitutes ecologically and physiologically important variability for one species may comprise environmental noise for another. This complex interaction between each organism and its local environment is one of the foundations of population and community dynamics.

The dimensions of any particular microclimate are highly dependent on the mobility and dispersal capabilities of the organism in question. To an organism with limited movement and dispersal capabilities, the world may be restricted to a very small space; to an organism capable of foraging over large areas, such microclimates may appear as mere noise as it shuttles from place to place in search of food and shelter. Consider, for example, the section of rocky shore shown in **Fig. 1**. To a mussel tightly adhered to the substratum, living on the north versus south face of a rock may make an enormous difference in terms of the amount of solar radiation that the animal receives, and thus the maximum body temperature that the animal experiences. Differences in body temperature of 10 °C or more are not uncommon between sessile animals separated by a few centimeters due to differences in solar radiation created by substratum angle. In contrast, a gull foraging in the same intertidal zone may not be able to distinguish this small-scale thermal variability from the larger microclimate of the entire intertidal area. Furthermore, if microclimate conditions become intolerable in the intertidal area, the gull can spread its wings and fly to a more favorable location, perhaps a ledge on a nearby cliff. Measuring an organism's microclimatic conditions thus mandates that we first have an understanding of how far the organism is likely to `sample' its local environment.

The ecological consequences of microclimate heterogeneity are directly dependent on the relative differences in scale between predators (e.g., gulls, crabs, seastars) and prey (mussels, barnacles), and between competitors. Moreover, this scale determines the scale that scientists must measure or model microclimatic parameters. Equally important, however, is the fact that organisms themselves affect the flux of materials between themselves and their local environments. In the next section, we discuss the role of organism morphology and size in driving the transfer of heat to and from the organism's body, and how this affects the means by which we measure microclimates in the field.

Organism–Microclimate Interactions

All organisms exchange heat, water, and nutrients with their surrounding environment, and microclimate can have a significant influence on these rates of exchange. While the exchange of each of these factors is equally important, throughout the rest of this article, heat exchange will be used to explain the intricate relationship between organisms and their local microclimates.

In general, heat flux between an individual organism and the environment is divided into six categories: short-wave (visible) solar radiation, long-wave (infrared, IR) radiation to and from the sky and from the organism's surroundings, conduction to and from the ground, heat convected between the animal and the air, heat lost through the evaporation of water, and (for endotherms) heat generated through metabolism. Environmental variables such as habitat type, substrate orientation, as well as characteristics of the organism itself such as mass, morphology, and color, also drive rates of heat exchange. For example, organisms that have large proportions of their total surface area in contact with the underlying substratum (e.g., barnacles, lichens) may have body

 doi:10.1016/B978-0-444-63768-0.00520-5

Fig. 1 Rocky intertidal zone at Tatoosh Island, Washington State. The importance of microhabitat variability, and thus the concept of microhabitat, varies with movement and dispersal capability of the organism.

temperatures that are tightly coupled with ground temperature. In addition, some organisms use behavioral mechanisms to moderate the amount of heat flux. Snakes bask on hot rocks during the day and take refuge underneath rocks at night when surface conditions are too cold for them to survive. Due to the many variables involved in heat exchange, microclimate (air or surface) temperature and organism temperature are often dissimilar. Moreover, two organisms, even ones of the same species, can experience markedly different rates of heat transfer when exposed to identical microclimates, and can thus experience very different body temperatures.

Endotherms are able to maintain a relatively constant body temperature (i.e., are homeothermic) through the production of metabolic heat (during periods of increased heat loss) and cooling. However, the ability to produce heat is energetically costly for endothermic organisms, particularly when they are in microclimates with temperatures above or below their ideal environmental range. On cold winter nights, elk can reduce loss of radiant heat, and thus save metabolic energy that may be used for breeding in the spring, by seeking refuge beneath trees with needles. The elk can further reduce heat loss by laying down, but a prone position may make them easier prey for wolf predators. For an endotherm, finding the ideal physiological microclimates may be a trade-off between ecological costs such as avoiding predators and the physiological benefits such as gestating young.

In contrast, ectotherms, with negligible metabolic heat production, have body temperatures that change with the rate of heat transfer in and out of their bodies (i.e., are poikilothermic). As a result, most ectotherms have body temperatures that change rapidly as microclimatic conditions change; in some cases, these fluctuations can be rapid and quite large.

Therefore, when making measurements of microclimatic factors such as air temperature, wind speed, and surface temperature, it is important to consider how these factors are translated into factors such as body temperature, as well as to consider both the direct and indirect effects of body temperature on organismal physiology and ecology.

In most cases, the temperature of plants and animals does not track any single microclimatic parameter (such as air temperature; Fig. 2). Moreover, because organisms respond to the same environmental parameters in different ways because of their size and morphology, patterns in the same environmental parameter may not translate into the same pattern of organism stress. Importantly, it is the relative impacts of microclimate on different species that determine the importance of microclimate on ecological interactions.

Physiological Impacts

Weather extremes can cause the conditions of a microclimate to quickly exceed normal limits; these extremes can have catastrophic effects on organisms, particularly ectotherms. A heat wave is an example of a weather extreme that can cause harmful increases in microclimate temperature. In order to quantify the catastrophic effects of extremes on organisms, a physiological index, lethal temperature 50 (LT50), which describes the conditions when 50% of a population dies, has been used. However, the LT50 only provides a way of quantifying lethality at the population level, and there are more subtle effects that may precede these threshold events. Therefore, recent studies have emphasized the importance of quantifying the sublethal effects of weather extremes on organisms.

One of the new ways for quantifying damage from heat stress is to make measurements at the subcellular level. Extreme high temperatures can cause proteins to denature (unfold), but this damage can be prevented by the activity of heat shock proteins (HSPs), which prevent inappropriate interactions between the ends of damaged proteins that have begun to unfold. By measuring levels of HSPs, scientists can determine the relative heat stress an organism experiences. If organisms are responding to acute heat

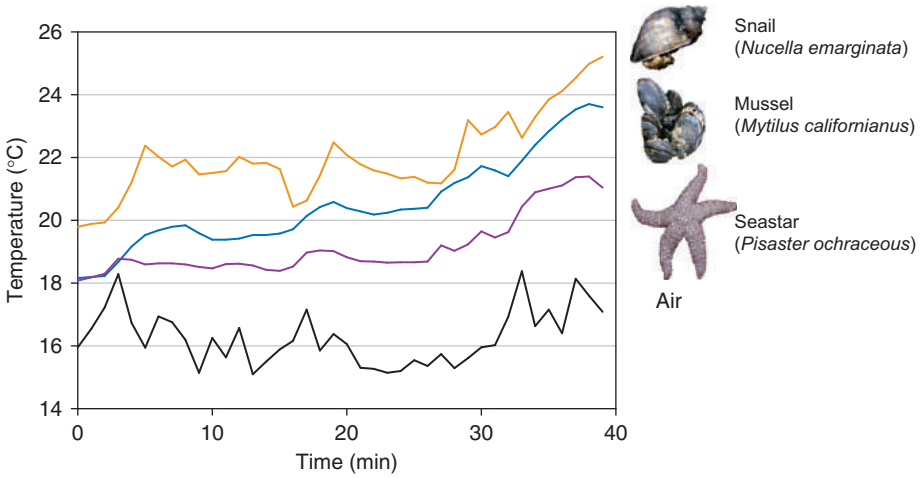

Fig. 2 Comparison between air temperature and body temperatures. Note that body temperatures do not track air temperature and vary for different organisms located in the same microhabitat. Data collected at Strawberry Hill, OR, USA, on 15 July 2006 by L. Yamane and L. VanThiel.

stress at the subcellular level, it is likely that there are other sublethal effects on the physiology of an organism. Making links between extreme temperatures, sublethal effects, and the ability of an organism to grow, survive, and reproduce is an area of active research.

Biogeographic Impacts

Climate plays an important role in determining the limits of species ranges. A species range is usually viewed as a north-to-south continuum with population densities slowly decreasing toward each end. However, variability in microclimate over a range of scales may cause breaks within this continuum, so that the abundance of organisms and levels of physiological stress wax and wane along each species distribution. Therefore, identifying the scale over which climate drives patterns of species distributions is the key to predicting the effects of climate change on ecological communities.

Climates are dynamic and warming and cooling trends occur both slowly, over the course of millennia, and more quickly over a period of years (e.g., El Niño Southern Oscillation and related La Niña events). Microclimates are ultimately derived from the overall climate of an area, so significant changes at the large-scale level will usually be reflected at the small-scale level. However, microclimates include multiple factors, and it can be difficult to predict the long-term direction of change. By observing the changes in particular microhabitats more vulnerable to climate change, it may be possible to make better predictions. For example, a community living on the south face of a mountain in the Northern Hemisphere may exhibit responses to climatic change earlier than a community on a nearby north face. Conditions observed in these vulnerable areas can be used in mathematical models to explore the possible changes in species distributions.

Mathematical Models

Recent approaches have used mathematical models to quantify heat flux between organisms and the environment using microclimate and climate data. These models play an increasingly vital role in improving our understanding of the biogeography and life history of many organisms, from plants to snails to elk. Climate data that must be collected for the models include air temperature, wind speed, solar radiation, cloud cover, and humidity in the vicinity of the organism in question.

The accuracy of the output from these models can be within 1–2 °C when compared to body temperature data collected at the same time from actual organisms. Because collecting data at the scale of the organism is often not practical, new ways have been developed to take factors such as substratum angle into account so that large-scale models of climate may be scaled to microclimatic levels.

There are many applications for mathematical models and an even greater number of ecological questions that can be explored. Some of the applications include: (1) generate and test hypothesis about where and when organism distributions are limited by aspects of their microhabitat (vs. the presence of predators or competitors); (2) hindcast past environmental conditions using historical climate data and make comparisons against historical changes in species distributions; (3) make short-term body temperature and microclimate forecasts to predict where physiological stress is most likely to occur; and (4) explore future climate conditions under a context of global climate change to determine the possible impacts on the physiological state and biogeography of different species.

Summary

Ecologists have long realized the crucial role of climate in determining the distribution and abundance of organisms and have benefited from recent technological innovations improving their ability to study microclimates. Clearly, scale is the most important element when considering microclimates, and it must be considered in the context of the organism of interest. Once the organism and microclimate scale are identified, it is possible to account for sources of heat, water, and nutrient flux and processes that mediate them. Microclimates have pervasive effects from the subcellular level to the biogeographic level making mathematical models, which integrate microclimate with environmental factors and organism physiology, the best way to further test ecological concepts.

Migration and Movement

Lars-Anders Hansson, Lund University, Lund, Sweden

Glossary

Dispersal Individuals or populations (or parts of populations) that move to reach new areas, but do not return.
Invertebrate Animal that has no backbone.
Migration Individuals or populations (or parts of populations) that move between two well-defined habitats on a temporally predictable basis.
Movement Individuals or populations (or parts of populations) that change position at any temporal or spatial scale. Movement includes all other ways of displacement.
Partial migration When some, but not all, individuals of a population migrate.

The Overall Question: To Move or Not to Move, and Why?

Movement is a fundamental process of life for most animals, and the ability to move fast and for a long time is often important both for escaping threats and for catching food. Although movement and migration are impressive phenomena, with continent-wide bird migrations and enormous biomasses of large animals walking long distances on African savannas, movement and migration are by no means the rule in nature. Instead, a stationary lifestyle seems to be as successful as costly movements. For example, any tree you see has been there for decades; it has been on the same spot, during bad as well as good times, irrespective of whether the place the seed once fell on was good or bad. On the other hand, the little bird searching for insects in the tree has chosen a completely different lifestyle by spending all day endlessly searching for the best food patch, the best life companion, the best protection against predators; it is always moving and when times get worse, it migrates to another continent. Hence, the moving animal searches for patches providing well-being, may it be food, a partner, or simply protection, and in places resembling paradise it stays longer, whereas it quickly leaves places of less quality (Brown, 1988). Hence the animal, be it a bird or a snail or a wolf, instantly judges the environment in order to optimize its well-being, which, in simple terms can be said to be the overall driving force of movements and migrations. This driving force towards well-being can be divided into measurable entities; the most common ones are summarized in **Fig. 1** and include components such as food, partner, temperature, predation, and infection risk.

Based on the composition of such drivers in the local environment, each taxon, or individual, may adopt a "movement strategy" aiming at optimizing its fitness (Bastille-Rousseau *et al.*, 2017). Such strategies may include dispersal, that is, leaving the area for potentially better conditions, migration to other places during rough times, such as during winter, but returning when conditions improve, or simply to stay in the same area year around (Mueller and Fagan, 2008). To stay always in the same area requires that moving has higher costs than benefits, whereas the decision to migrate or disperse is based on the benefits exceeding the costs of movement. Such strategies may, of course, change if conditions in the home area change. For example, locusts (e.g., *Locusta migratoria*) are driven to perform mass movements when food becomes scarce and then they become pests, eating anything that comes in their way. Similarly, many rodents, such as lemmings (*Lemmus lemmus*) are often relatively stationary, but perform mass movements (dispersals) away from barren habitats towards some distant paradise, although few of them reach it. However, the ones who happen to disperse to a suitable spot can successfully start exploiting and reproducing.

Partial Migration

In some species, for example, many insect-eating birds, all individuals are always taking the decision to migrate, whereas in other species, none migrates; they all stay in the same area year-round. However, in many species some individuals, but not all, decide to migrate. Such partial migration is actually more the rule than the exception and in most species there are often some individuals that migrate and others that stay, or at least perform only short migrations (Chapman *et al.*, 2011). This suggests that there is an individual dimension involved in the decision to migrate or stay. A possible logic behind this is that if all others migrate, then an individual staying year-round, and surviving, will benefit from low competition and an excess of food. Similarly, if all stay, the one who migrates and survives will have the advantages of less competition and lots of food during the migration period. This means that the advantages depend on which decisions the other individuals in the population are taking (Sinclair, 1983). Hence individuals in a population may take decisions based on expected costs and benefits, for example, they weigh the risk of predation against possibilities for food, and thereby growth.

An example of this dilemma is the partial migration in the fish roach (*Rutilus rutilus*) from the lake where predation is high and food level low in winter, to surrounding streams and wetlands where food is even lower, but where predators, such as pike (*Esox esox*) rarely follow them (Brönmark *et al.*, 2008). Hence a large portion (up to 60%) of the population may leave the lake during

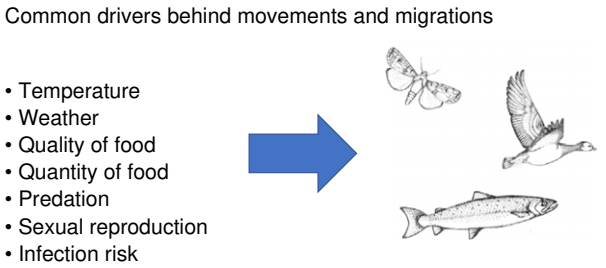

Fig. 1 Common drivers for organisms to undertake movements, dispersal, or migrations.

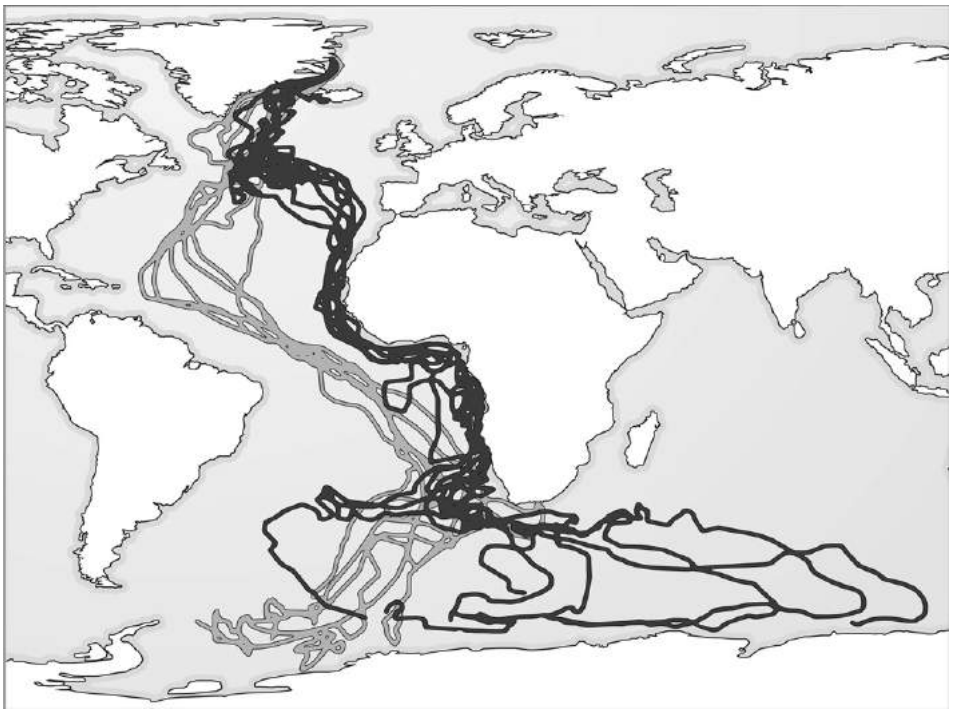

Fig. 2 Yearly migratory journey of Arctic terns (*Sterna paradisaea*) between Arctic regions and Antarctica. The tracks show the route of terns from breeding grounds in fall (*black lines*) and the return in spring (*gray lines*). Redrawn from Egevang, C., Stenhouse, I. J., Phillips, R. A., Petersen, A., Fox, J. W. and Silk, J. R. D. (2010). Tracking of arctic terns Sterna paradisaea reveals longest animal migration. *Proceedings of the National Academy of Sciences of the United States of America* **107,** 2078-20781.

winter, reducing the ratio between predation risk and growth (food), which may be a way to endure, at least for the strongest individuals. Interestingly, less fit individuals are more prone to stay in the lake despite the predation risk, whereas individuals that are more well fed are, to a higher extent, taking on the winter migration to the predator refuge in streams and wetlands (Brodersen *et al.*, 2008). In spring the migratory part of the population returns to the lake and joins the residents. Thus, the decision to migrate or stay is context-dependent; that is, it differs from year to year according to the ratio between risk and benefit. It may, as suggested by the roach migrations, also be condition-dependent; that is, each individual asks themselves the question: "Am I fat enough to endure the whole winter in the stream?"

Generalist or Specialist?

The movements of organisms are a profound phenomenon in nature which has received considerable attention in science as well as in media. For example, the mass migration of large herds of ungulates on the African savannah (Bartlam-Brooks *et al.*, 2013), the migration of birds following similar routes every year, and, of course, all the extreme movements, such as the non-stop flying by wader birds (Gill *et al.*, 2009), the global-scale migrations in Arctic terns (*Sterna paradisaea*) (Egevang *et al.*, 2010) (**Fig. 2**), and the apparently almost endless duration of flight in swifts (Hedenström *et al.*, 2016). It is often the extremes that catch our attention.

To manage extreme journeys, an organism has to specialize and become the best flyer, runner, or swimmer. However, this has high costs and requires investments in organs and skeletons that leads to translocation of energy from other skills. This is why no organism on Earth is the champion in all locomotion modes: running, swimming, and flying. Instead the ones that are specialists in fast running are generally bad swimmers and do not fly at all, and the same is true for excellent flyers, which generally do badly as runners or swimmers; similarly, fast swimmers can generally not walk or fly. Since a normal life often requires that an organism has at least some skills in mastering more than one medium, most animals are more generalists; they are reasonably good at both walking and swimming, for instance, but would never win a competition against a champion. Actually, and maybe somewhat surprisingly, an organism that handles all movement skills reasonably well, that is, is a perfect generalist, may be something like a duck, which can fly, may reach impressive speed when running, and is also a good swimmer. Hence, although a generalist may not be the champion in either running, flying, or swimming, it manages all those locomotion modes pretty well. However, the generalist, such as the duck, could never take up a fight successfully with a specialist in swimming, running, or flying, and below we shall look more closely at some record-winning specialists.

Records in Moving

From an energy point of view, it is cheapest to move in water and most expensive to fly, whereas running on land is in between (Schmidt-Nielsen, 1972). Generally, the more muscle an organism has, the faster it can move, be it in water, air, or on land. However, this is true only up to a certain weight, and when an organism is too heavy—for example, an elephant—it becomes limited in its ability to provide quick energy to the muscles (Hirt *et al.*, 2017). Thus it is medium-sized animals, and not the largest with most muscles, that are generally among the fastest, such as the cheetah (*Acinonyx jubatus*) on land, the tuna fish (*Thunnus thynnus*) in water, and the peregrine falcon (*Falco peregrinus*) in air. In addition to high speed, endurance is also important and some organisms are very good at moving over long distances and for a long time. One of the champions is the wader bird godwit (*Limosa lapponica baueri*), which each year travels non-stop over the Pacific Ocean from breeding grounds in Alaska to New Zealand and Australia. This is a distance of about 10,000 km and the godwit manages it in only 5–9 days (Gill *et al.*, 2009). Since there is no place to rest or eat along the flight, this is an extraordinary extreme of avian flight performance.

Another extreme is the common swift (*Apus apus*). To investigate their position, speed, and altitude, researchers equipped some swifts with micro data loggers and accelerometers. The birds were then recaptured when returning back to their nests 10 months later with their data loggers, which showed that the swifts had been flying for 10 months without touching the ground (Hedenström *et al.*, 2016). This means that they eat, mate, and sleep airborne, and thus live the majority of their life in the air. These are just a few examples of fascinating record stories among moving animals, and we switch now to an even more fascinating question: how are organisms finding their way?

Finding Their Way

In addition to being able to move, an organism has to find its way; this skill is performed using many different senses and cues. The most obvious is to recognize and remember landmarks, such as rivers, lakes, or mountains. More advanced cues include the sun and the stars, despite them appearing to change position in the sky over time. This requires more advanced senses including a time-compensated sun compass (Schmidtkoenig, 1990; Åkesson *et al.*, 2014). Such a "biological compass" compares the position of the sun with the organism's internal clock, allowing them to determine their movement direction. Although the understanding of how such biological compasses function is still not complete, it has been shown to be used by many insects, such as honey bees, ants, and butterflies, as well as by birds, but it is likely that many more moving animals are able to use it (Åkesson *et al.*, 2014). In addition to the sun and stars, the Earth's magnetic field is also used by many organisms to find their way, and this is a very reliable cue especially when the weather is cloudy and the sun, stars, and landmarks cannot be used (Åkesson *et al.*, 2014; Muheim *et al.*, 2014). Many organisms also utilize smell to find their way, including migratory salmon (e.g., *Salmo salar*) which find their way from the ocean and back to the river where they were born by using smell (Stabell, 2012). Interestingly, most organisms utilize a combination of several of these cues and senses to find their way.

Skewed Knowledge on Animal Movements and Migration

Much of the fascination about animal movement and migration lies in the fact that we can see and track their movements, which has led to that the majority of studies performed, and thereby our understanding, is thus focused on larger animals, such as some large insects, birds, and mammals. However, there are probably about 7.7 million eukaryotic animals on Earth (Mora *et al.*, 2011) and most of those are smaller than 10 mm. As a thought experiment, we may combine the approximate number of animals in different size classes with the number of studies performed on their movements and migrations (**Fig. 3**). This thought-provoking analysis provides an interesting illustration of our skewed understanding of animal movements, especially when examining the knowledge per size class of existing species on Earth. This clearly shows that we know a lot about a few large organisms, whereas the movements and migrations of smaller organisms are still a black box (**Fig. 3**). However, this thought experiment may also

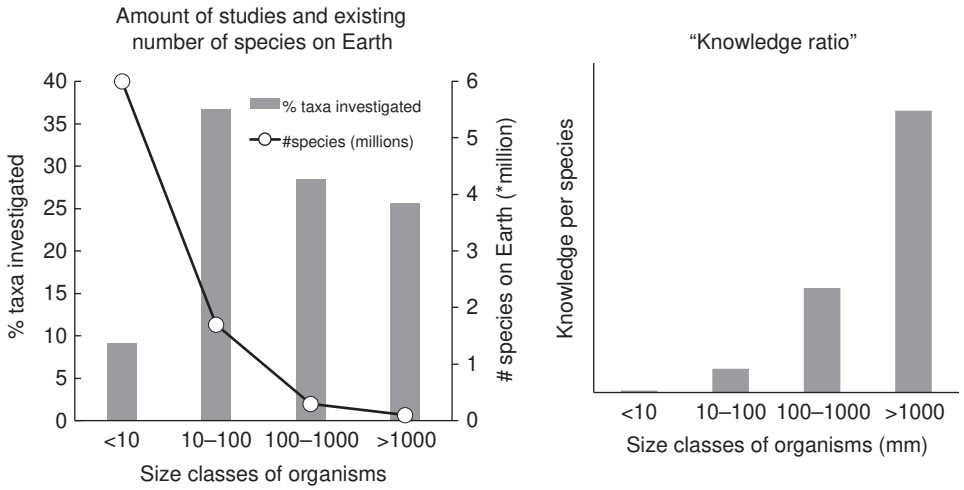

Fig. 3 Analysis of our knowledge of movements and migration of different-sized classes of animals, estimated as number of references (*left panel*; bars) in recent books (Hansson and Åkesson, 2014; Milner-Gulland *et al.*, 2011; Cheshire and Uberti, 2016). The line (*left panel*) shows the estimated number of eukaryotic species on Earth (Mora *et al.*, 2011). In the right panel this data is expressed as a ratio between amount of studies and number of species, showing that our knowledge is highly skewed towards organisms larger than 100 mm, whereas our knowledge on the movement and migration on smaller organisms is indeed scarce.

provide an incitement for researchers not only to study the movement of larger animals, but also to explore the fascinating variety of movement strategies adopted by smaller creatures. A major problem, and reason for the skewed knowledge, for studying small organisms is that they are unable to carry traditional tracking equipment, such as tags, radio, or GPS transmitters. A considerable technical development is therefore required, and below we shall look at a few examples on how such technical advancements can open up the study of the fascinating movements and migrations of small animals: a field where our knowledge is negligible in comparison to that of larger organisms.

Examples of Small Movers

Enormous amounts of insects are moving high up in the atmosphere and specialized radar techniques are required to study these high-flying insect migrants, as they are too small to carry transmitters or to be observed by any other means (Hu *et al.*, 2016). Because many migrant insects are extremely abundant, seasonal migration transfers enormous amounts of energy, nutrients, propagules, pathogens, and parasites between regions. For example, it has been estimated that such "bioflows" contain ~3.5 trillion insects (3200 tons of biomass) passing over the southern United Kingdom every year (Hu *et al.*, 2016). Although some of these insects perform proper migrations, most of them do not return. Instead they disperse, reproduce, and then the offspring makes the return flight. Below we shall look more deeply at some fascinating trans-generational migrations of insects, but also at the diel vertical migrations of tiny animals under the water surface, constituting enormous amounts of biomass migrating up and down through oceans and lakes.

Trans-generational migration: The monarch butterfly

Short-lived organisms, such as insects, do not live long enough to perform long-distance migrations. However, some, such as many lepidopterans, have solved this by spreading out the journey over several generations. An iconic example of such transgenerational migrations is the Monarch butterfly (*Danaus plexippus*), which during fall migrates southwards from the northern United States and Canada to Mexico, where it spends the winter. In spring, these butterflies fly north and lay eggs in the southern United States. The new generation then continues northwards to the northern United States and Canada and thereby closes the transgenerational migratory cycle (Reppert *et al.*, 2010). In all parts of this cycle the individual animal is naïve to the route—that is, it has never flown the route before. Therefore, it is puzzling how they manage to find their way, but it seems as though the Monarch butterflies are using several types of compasses, including both sun- and magnetic compasses (Guerra *et al.*, 2014).

The Bogong moth's nocturnal travels

Another transgenerational migrant is the Australian Bogong moth (*Agrotis infusa*), which make yearly migrations of more than 1000 km between the inland of the Australian continent and the south-eastern coast (Warrant *et al.*, 2016). In high altitude caves (up to 1800 m above sea level) the moths hibernate for several months and then migrate back to warmer regions, where they lay eggs and die. The next generation performs the same long journey without having any experience of how to find their way to the alpine caves. Since they are flying during night-time, they cannot use the sun to navigate, and although the moon and stars are possible cues when finding their way, these are less reliable. Instead a likely cue is the Earth's magnetic field (Åkesson *et al.*, 2014, Muheim *et al.*, 2014), although the successful navigation of Bogong moths is still an open question (Warrant *et al.*, 2016).

Aquatic zooplankton move away from predators and ultraviolet radiation

One of the largest migrations on Earth is the enormous numbers of mm-sized crustacean zooplankton moving downwards from sunlit surface waters of oceans and lakes during day and returning to surface waters every night to feed (Hays *et al.*, 1995). The drivers of this diel (or diurnal) vertical mass-migration (DVM) seem to be a combination of avoiding predation from visually hunting predators (fish), but also to escape from harmful solar ultraviolet radiation (UVR) (Hansson and Hylander, 2009a; Williamson *et al.*, 2011). Hence, zooplankton respond to each of these threats separately, but more strongly to a combination of the threats (Hansson and Hylander, 2009b). Although the DVM phenomenon has been known for decades, little is known about the individual dimension of the migration, mainly due to lack of suitable techniques. Recent developments in nanotechnology, however, have provided opportunities to utilize tiny "nano-lamps," that is, fluorescent particles that can be attached to the animal, allowing cameras to see and track their migrations and movements (Ekvall *et al.*, 2013) (**Fig. 4**). A short movie showing how two individuals of *Daphnia* move from harmful ultraviolet radiation down to a depth refuge is shown here: https://youtu.be/aqOGNziAf-0.

The technological development within nanotechnology has advanced our understanding of how, when, and why zooplankton move. For example, despite their small size and simple neurological systems, it seems that individuals of the zooplankter genus *Daphnia* may have some kind of "personality"; that is, different individuals show repeatability in their behavior, for example, some show a strong and some a weak response when exposed to a threat (Heuschele *et al.*, 2017). Although this is a very weak expression of personality, the study shows that the evolution of personality, and thereby individual decisions regarding, for example, migration, may not be restricted to more complex organisms, but may actually have evolved also in invertebrates. Such individual decisions may also partly explain why DVM is not performed by all individuals in a population, that is, it is a partial migration.

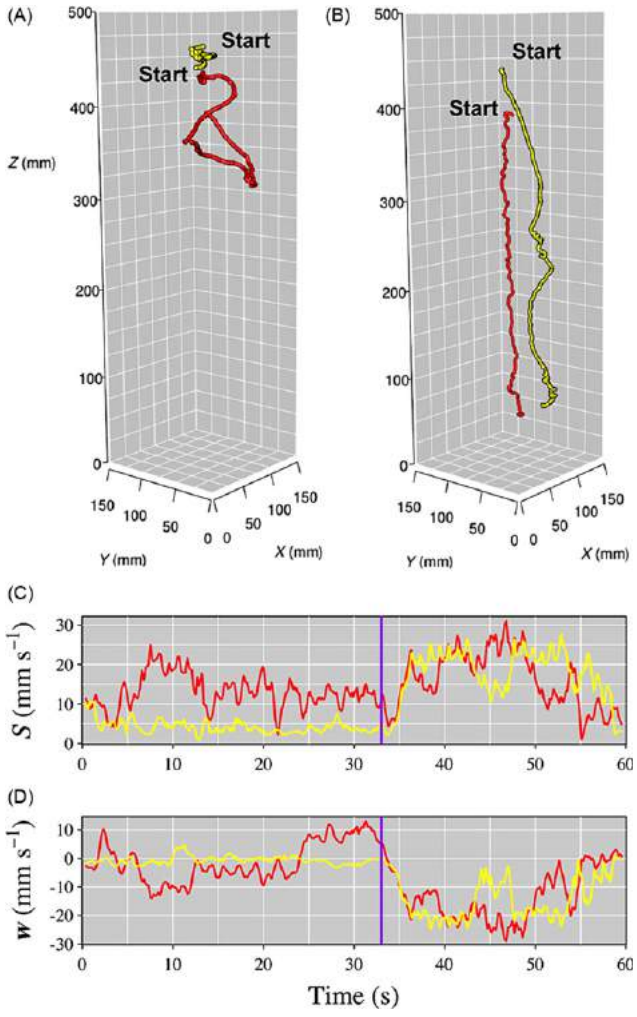

Fig. 4 Tracking of the position, speed, and vertical displacement of two *Daphnia magna* individuals in the absence (A) and presence (B) of UV radiation. The animals were marked with yellow and red nanoparticles (quantum dots), and monitored simultaneously to obtain 3D trajectories. Swimming speed (*S*) for both animals is shown in (C) and vertical speed (*w*) in (D). From Ekvall, T. M., Bianco, G., Linse, S., Linke, H., Bäckman, J. and Hansson, L.-A. (2013). Parasites on the Move

It is likely that all moving animals are hosts to one or several parasites and pathogens, such as viruses and bacteria, which will hitch-hike on the host migrator to wherever it flies, walks, or swims. Hence, in addition to being forced to have an immune-defense against parasites and pathogens in its resident place, a migrant also has to handle the menagerie of parasites at the site to which it is migrating (Westerdahl *et al.*, 2005). Moreover, the diversity and abundance of parasites and pathogens are greater at lower (tropical) latitudes than at higher (temperate and polar regions) ones (Guernier *et al.*, 2004). Many birds migrate from temperate/polar regions, where they reproduce and raise their offspring, and the tropics, where they stay during winter when the temperature is low and food is scarce at higher latitudes. A logical question here is why do they not stay in the tropics all year round and reproduce where temperatures are high and food is in excess? It is probable that one of the drivers here is the high diversity of pathogens in the tropics, which has proven more beneficial to performing long migrations and raising offspring where the infection risk is lower, than to staying in the tropics year-round (Westerdahl *et al.*, 2014). This means that breeding at high latitudes may provide not only long days and a lot of food for the offspring, but also a pause for the immune system, suggesting that pathogens and parasites may actually be an important piece in the jigsaw puzzle of the evolution of migratory strategies in many organisms.

Migration and Climate Change

The climate is constantly changing, but during recent decades the change has been much faster and more pronounced in many regions, and since temperature is a major driver of movement, considerable changes in the migratory systems of organisms are also to be expected. There are already examples of how timing in migration has changed due to higher temperatures, and many songbirds have advanced their arrival by more than 2 weeks during the latest 50 years (Stervander *et al.*, 2005). Similar observations have been made on the migration of pink salmon (*Oncorhynchus gorbuscha*) up through the Alaskan rivers (Taylor, 2008). Climate-induced changes in migratory patterns may not have any major effects given that other variables, such as food availability, change in a similar way. However, different organisms respond differently to altered temperature, which has led to mismatches between return migration times of, for example, pied flycatchers (*Ficedula hypoleuca*) and their insect prey in the breeding areas in Europe. In the Netherlands, for example, spring, and thereby the burst of insect larvae, occurs earlier, whereas the arrival of migrating flycatchers has not changed much. This has meant that the flycatcher nestlings miss the period when insect larvae peak in abundance, that is, a climate-induced mismatch between predator and prey (Both *et al.*, 2006).

Human Movements

It is not only animals that are moving; humans have also moved and migrated throughout history. It is currently believed that man's first movement is likely to have started in eastern Africa, and that our ancestors then dispersed to other continents. Ever since, humans have moved on and conquered new land. However, pure migrations have also occurred, for example, when whole populations of Stone Age people went north to the edge of the ice-shelf to hunt in spring, and then migrated back south to warmer regions in fall. Similarly, many nomad tribes, for example, in North Africa, migrate back and forth depending on temporal differences in opportunities. Moreover, only 150 years ago a considerable part of the North European population left the prospect of starvation in Scandinavia, for example, and moved westward to settle in North America. Some of them returned to Europe, that is, they were migrants; others dispersed and stayed on the new continent and are now assimilated in the North American population. The main reason for this large-scale movement was lack of food (**Fig. 1**), and rumors of the "promised land" on the other side of the ocean, where food and land were available, which made millions of starving farmers take on the risky journey westwards. Similar movements have been common on all continents throughout the history of man, leading to permanent human settlings on all continents except Antarctica. Sadly, the reasons for human movements nowadays are still shortage of food or disasters, such as war. Hence, we may finally conclude that the drivers of movement, dispersal, and migration (**Fig. 1**) of humans are by no means different from similar phenomena among other animals.

Monocultures Versus Polycultures[☆]

Matthew ES Bracken, Northeastern University, Boston, MA, United States

Introduction

In evaluating the interactions between organisms, ecologists are often interested in whether the performance of an individual species by itself (in a monoculture) is different from the performance of that species when other species are present (in a polyculture). Experiments comparing the growth, fecundity, or physiological rates of species in monocultures versus polycultures are used to assess competitive versus facilitative interactions between species and to evaluate the degree to which species are partitioning limiting resources.

These approaches have their origins in studies conducted to understand and improve the yield of agricultural crops, but they have recently been applied to more basic ecological questions, including evaluations of resource use, competition, and complementarity among species. Comparisons of monoculture versus polyculture performance have been especially useful in understanding the mechanistic links between the number of organisms and the rates of ecosystem-level processes in a given area.

Below, we briefly present the agricultural roots and history of experiments evaluating monocultures versus polycultures, describe some of the statistical methodology used in these comparisions, and illustrate how they have been used to evaluate both competitive interactions and the relationship between biodiversity and ecosystem functioning.

Agricultural Origins

The use of polycultures in agriculture, usually referred to as intercropping, is based on the traditional knowledge that carefully selected mixtures of crops are characterized by higher overall yields. This occurs because of more thorough use of limiting resources (complementarity), lower fertilizer requirements, greater resistance to herbivorous pests, and greater soil stability in polycultures when compared to monocultures. Additionally, growing multiple crops in a field provides farmers with a form of insurance: there is still something to harvest if one crop fails.

Because of these benefits, intercropping was the primary method of agriculture worldwide throughout most of history. Intercropping remains widespread in developing countries, though it has been largely abandoned in developed countries (e.g., the United States and in Europe) in the latter half of the 20th century due to the industrialization of agriculture. More recently, interest in organic farming techniques and sustainable agriculture has prompted First World farmers to return to this time-tested technique for increasing crop yield without applying chemical fertilizers and pesticides. Because of this agricultural legacy, many of the earliest experimental comparisons of monocultures and polycultures were conducted to evaluate the effects of mixed cropping on crop yields and to understand mechanisms of competition and coexistence between different agricultural species.

Competition and Coexistence

As ecologists began to experimentally evaluate the mechanisms underlying competitive interactions between species, it became clear that insights into these interactions could be obtained by comparing the performance of individuals in monocultures versus polycultures. For example, in Georgyi Gause's classic experiments on competition, he tested simple theoretical models of competition by measuring the relative population densities of two species of *Paramecium* (microscopic heterotrophs) competing for bacteria in experimental microcosms. Gause specifically compared the abundances of the two species in monoculture and in polyculture and found that both species perform well in monoculture, but when both species are cultured together, one of them (*Paramecium aurelia*) outcompetes the other (*Paramecium caudatum*), driving it locally extinct. Similarly, in another classic ecological experiment, Thomas Park evaluated competition between two species of *Tribolium* flour beetles by comparing their performance separately versus together and found that one species always competitively displaces the other. In the case of *Tribolium*, one of the species (*T. castaneum*) is susceptible to infection by a parasite. When the parasite is present, *T. castaneum* is outcompeted, whereas when the parasite is absent, *T. castaneum* outcompetes its congener.

[☆]*Change History:* February 2018. I. Martins made minor changes to the references.

However, the diversity of coexisting organisms on Earth suggests that competitive exclusion is not the rule. For example, 200–300 species of trees can coexist in a 100 × 100 m region of tropical rainforest, despite the fact that all of those species have similar basic requirements for potentially limiting resources such as light, nutrients, and water. How does this occur? Theory suggests that species coexist by carving out unique niches in resource space, so that they minimize their competition for resources.

What evidence is there for this phenomenon of resource complementarity? Again, comparisons of monocultures and polycultures have been used to quantify the degree to which species compete versus coexist. For example, plant assemblages are often composed of monocots, which are characterized by tall, erect shoots and shallow, laterally spreading roots, and dicots, which occupy lower aboveground strata and have deeper, less lateral rooting systems. When both monocots and dicots are mixed together in a polyculture, the yield (harvested dry mass) is higher than when either monocots or dicots are grown alone. This suggests that intraguild competition (monocots vs. monocots or dicots vs. dicots) is more intense than interguild competition (monocots vs. dicots), because the plants use different spatial niches. Mixtures of shallow- and deep-rooted species are characterized by more efficient use of limiting nutrients (e.g., nitrogen), resulting in higher rates of total nitrogen use, and leading to higher productivity in polycultures.

Several techniques have been used to statistically evaluate the relative importance of intra- versus interspecific competition in structuring assemblages of organisms. One of the most widely used metrics is the "relative yield total" (RYT, which is similar to the land equivalent ratio often used in agricultural intercropping studies). The relative yield of a species in a polyculture is defined as

$$\mathrm{RY}_i = \frac{P_i}{M_i} \tag{1}$$

where P_i is the observed yield of species i in polyculture and M_i is its yield in monoculture. Summing these values across all species gives the RYT:

$$\mathrm{RYT} = \sum \mathrm{RY}_i \tag{2}$$

This metric allows researchers to test the null hypothesis that observed yields are associated with proportional changes in the contributions of each component species (RYT = 1). When RYT = 1, the component species achieve their "expected yield." There is either no evidence of interactions between species, or the intensities of intra- and interspecific competitive interactions are equivalent. Deviations from RYT = 1 can provide some information on the interactions between the component species. For example, when RYT < 1, the component species may be competing for limiting resources, whereas when RYT > 1, the species may be complementary in their use of those resources.

It is important to realize, however, that the RYT simply reflects the combined interactions of the species in the mixture, which may include dominance, complementarity, competition, and facilitation. The mathematical properties of the RYT can also make it somewhat misleading as a summary of competitive versus complementary interactions. Consider, for example, a case where two species are grown in monoculture and in mixture. When the most productive species in monoculture has a lower than expected yield in polyculture, but the other species performs equally well in monoculture and in mixture, RYT can be >1, despite the fact that the polyculture yield is lower than that predicted by a weighted average of the component species' yields.

A conceptually simpler way to evaluate resource use by an assemblage of species is to compare the expected performance of a polyculture with the performances of its component species. When a polyculture performs better than predicted based on a weighted average of the performance of its component monocultures, it is said to overyield, which is evidence for either facilitation or resource-use complementarity. Overyielding can take two forms, nontransgressive overyielding, which occurs when a mixture performs better than the weighted average of its component monocultures, but does not perform better than the best-performing monoculture, and transgressive overyielding, which occurs when a mixture performs better than the best-performing monoculture

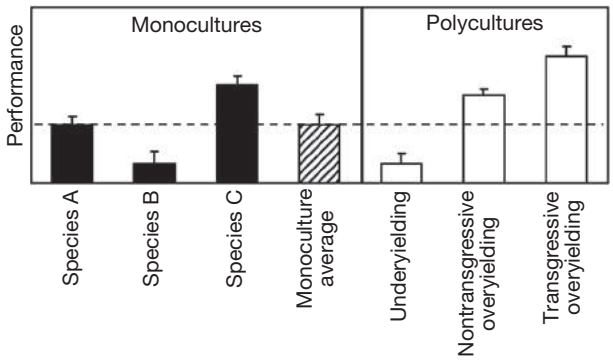

Fig. 1 Performance of monocultures and polycultures. On the left side of the figure the performances (e.g., yield, fecundity, or physiological rates) of three species grown in monoculture (*solid filled bars*) and the average performance of those three monocultures (*hatched bar* and *dashed horizontal line*) are illustrated. On the right side of the figure are three possible outcomes of an experiment containing all three species in mixture: underyielding, when the mixture does not perform as well as the monoculture average; nontransgressive overyielding, when the mixture performs better than the monoculture average but not better than the best-performing monoculture; and transgressive overyielding, when the polyculture outperforms the best-performing monoculture.

(Fig. 1). Distinguishing between mechanisms responsible for overyielding (i.e., facilitation vs. complementarity) requires a solid knowledge of the natural history of the system being investigated.

This method of comparing monoculture and polyculture performance is summarized by the $D_{\max}$ metric, which quantifies the degree of transgressive overyielding:

$$D_{max} = \frac{\sum P_i - \text{Max}\,(M_i)}{\text{Max}\,(M_i)} \tag{3}$$

where $\sum P_i$ is the total performance of the mixture (the sum of the yields of each component species in polyculture) and $\text{Max}(M_i)$ is the performance of the best-performing monoculture. When $D_{\max} > 0$, either complementarity or facilitation must be occurring.

Biodiversity and Ecosystem Functioning

More recently, these metrics have been formalized by researchers seeking to evaluate the effects of declining biodiversity on the transformation and flux of energy and matter in ecosystems. In the mid-1990s, scientists began to realize that more diverse assemblages were characterized by higher rates of productivity, growth, and resource utilization. However, this early work was criticized because researchers had not explicitly differentiated between two possible mechanisms for enhanced ecosystem functioning in more diverse assemblages: the "sampling effect," which occurs because a more diverse assemblage is more likely to contain one or more species with a dominant effect on the process being measured, and "complementarity," which occurs when organisms successfully partition limiting resources, reducing competitive overlap between them and leading to higher rates of collective resource use. Statistical comparisons of monocultures and polycultures were invoked as effective methods of differentiating between these possible mechanisms which link diversity and ecosystem functioning.

In particular, when the performance of a diverse assemblage is greater than predicted, it is possible to partition this positive influence of diversity into the portion attributable to complementarity (or facilitation) and the portion associated with the sampling effect. The sampling effect occurs when the best-performing species dominate the multispecies assemblages, and it is mathematically calculated as the covariance between the species yields in monoculture and their yields in the mixture. The net biodiversity effect is expressed as

$$\Delta Y = \sum \Delta \text{RY}_i M_i = N\overline{\Delta \text{RY} M} + N \,\text{cov}\,(\Delta \text{RY}, M) \tag{4}$$

where ΔY is the deviation of the polyculture from the yield predicted by its component monocultures, ΔRY_i is the deviation of species i from its expected relative yield, M_i is the yield of species i in monoculture, N is the number of species in the polyculture, and $\overline{\Delta \text{RY}}$ and $\bar{M}$ are the average deviation of the N species from their expected yields and the average yield of the N species in monoculture, respectively. The net biodiversity effect (ΔY) can then be separated into the complementarity effect $N\overline{\Delta \text{RY} M}$ and the sampling effect (N cov $(\Delta \text{RY}, M)$).

One real benefit of using these comparisons of monoculture and polyculture performance in evaluating the relationship between diversity and ecosystem functioning is the fact that important insights into the relationship can be gained using a relatively small number of experimental units. For example, imagine a (rather small) local pool of ten species. In order to generate a diversity gradient containing all combinations of those species, with richness levels of 1, 2, 3, ..., 10 species, a researcher would need to assemble over 1000 different experimental treatments. Replicating each of those treatments multiple times would create an incredibly unwieldy (though statistically powerful) array of experimental units. In contrast, a researcher could compare monocultures of each individual species with a polyculture of all ten species using only 11 unique treatments, allowing sufficient replication with a manageable sample size.

Approaches using the metrics and comparisons described above have advanced our knowledge of the relationship between biodiversity and ecosystem functioning in many different systems, including grasslands, soils, benthic marine habitats, streams, and estuaries. Other experiments using these techniques to evaluate the consequences of changing biodiversity have included comparisons of the invasibility of plots containing monocultures versus polycultures and evaluations of the effects of genetic (intraspecies) diversity on the recovery of species following disturbance events. Comparisons of monocultures and polycultures, originally used to evaluate crop yields and competitive interactions, have proven to be robust techniques for evaluating the effects of biodiversity on many different community and ecosystem functions, including both long-term processes (e.g., recruitment and/or growth of organisms over time) and physiological rates (e.g., uptake of nitrogen or utilization of carbon).

Numerical Ecology

Pierre Legendre, Université de Montréal, Montréal, QC, Canada

Introduction

Numerical ecology is the field of quantitative ecology devoted to the numerical analysis of [mostly multivariate, but also time series] ecological data, with emphasis on community composition data. Community ecologists, whose data are multivariate by nature (many species, several environmental variables), are the primary users of these methods. Hence, population dynamics, single-species distribution models or the analysis of single species spatial patterns, which are powerful applications of mathematical ecology, are not considered parts of numerical ecology sensu stricto.

Numerical ecology is a sub-discipline of ecology, not of statistics or other mathematical discipline. In numerical ecology, the analysis starts with consideration of an ecological question and the data available to answer it. Numerical analysis methods are chosen to answer the question at hand and test ecological hypotheses about the data. When tests of statistical significance are in order, ecologists use permutation tests in most cases. These tests are applicable to non-normal univariate or multivariate data, in particular multivariate community composition data.

Many of the methods used in numerical ecology have been developed by ecologists, specialists of classification methods, geneticists and other researchers who were facing questions about multivariate data in their fields of study. Their training often combined statistics and some field of ecology or biology, in different proportions. So, historically, it is the people who needed to analyze intricate data sets to address high-level scientific questions in their fields of research, and had statistical or numerical training, who often developed statistical or numerical methods of data analysis. The first statisticians, people like Galton, Pearson and Spearman, who created the bases of modern-day statistics, had not been trained as statisticians either: that field did not exist before their work.

The field was reviewed and synthesized by Legendre and Legendre in five editions of a book published in French ("*Écologie numérique*") and in English ("*Numerical Ecology*") from 1979 to 2012. Because of the successive editions of this successful book over more than three decades, people often associate the field to the names of these authors. This short article will show how these books were part of a trend in the ecological literature that started before the 1960s and involved many researchers.

When Legendre and Legendre published the first editions of their book, they called it "*Écologie numérique*" and "*Numerical Ecology*" to emphasize the lineage with the field of *numerical taxonomy*, founded in 1963 by microbiologist Peter H. A. Sneath and population geneticist Robert R. Sokal. Numerical taxonomy aimed at testing hypotheses about biological systematics, population biology, and phenetic, phyletic and phylogenetic relationships, using multivariate data analysis. The approach included explicit steps to create dendrograms and cladograms using numerical methods, instead of the subjective syntheses of data that were generally favored until then. Likewise, numerical ecology includes steps to test ecological hypotheses using data and explicit methods of numerical analysis.

A Brief History

Pioneer Researchers

Numerical ecology developed thanks to the work of a numerous researchers. Until about 1970, community ecology had been mostly a descriptive science, although some ecologists had ventured into mathematical analyses. Pioneer researchers who developed key concepts and numerical methods of great importance for multivariate data analysis include the following well-known scientists:

- Vegetation scientist Paul Jaccard, working in the Alps, developed the first similarity coefficient used to analyze vegetation survey data (Jaccard, 1900). His coefficient is still in wide use nowadays in all fields where scientists analyze multivariate presence-absence observational data.
- In 1954, the vegetation ecologist David Goodall was the first to use factor analysis in community ecology. Goodall proposed the term "ordination" to designate this type of analysis, a term now widely used in textbooks and publications in community ecology and many other fields (Goodall, 1954). At that before-computer time, several other ecologists had experimented with numerical methods to address ecological questions.
- Robert R. Sokal (State University of New York, Stony Brook, United States) developed *numerical taxonomy* with Peter H. A. Sneath (University of Leicester, England; their foundation textbooks were published in 1963 and 1973; see Further Reading) and promoted the use of multivariate data analysis in biology and ecology. These two researchers proposed several methodological developments, including similarity coefficients and clustering methods, and experimented with the use of computers.
- John C. Gower spent his career (1955 to present) developing numerical methods of analysis for numerical taxonomy, numerical ecology and agricultural experimentation. He was also a pioneer in the use of computers at the Rothamsted

Experimental Station in England. The author of this article had the privilege to work with him on the properties of dissimilarity coefficients (Gower and Legendre, 1986).

- Robert H. Whittaker (Cornell University, United States) proposed the five-kingdom taxonomic classification of the world's biota into the Animalia, Plantae, Fungi, Protista, and Monera (Whittaker, 1969) and developed the key ecological concepts of alpha, beta, and gamma diversity (Whittaker, 1972). He hired young collaborators who wrote and distributed important computer software for community ecology.
- Cajo J. F. ter Braak (Wageningen University, The Netherlands) developed canonical correspondence analysis and many other key methods related to canonical ordination. He also wrote the Canoco program (the first version was developed in 1985), which was the first generally available software for community ordination, simple and canonical. Successive versions were released to researchers from 1988 (version 2.1) and in the following years up to now. The history of the Canoco software is recounted in ter Braak (1988) and in Section 1.2, entitled "Canoco for Windows", of the successive versions of the Canoco manual, for example, ter Braak and Šmilauer (2002).

Numerical ecology is the result of many years of collaborative work among many dedicated researchers in the fields of numerical classification and quantitative ecology, too many to be listed here. Many of them are cited in the *References* sections of the "*Numerical Ecology*" and "*Numerical Ecology with R*" books. These collaborations are illustrated in **Fig. 1**.

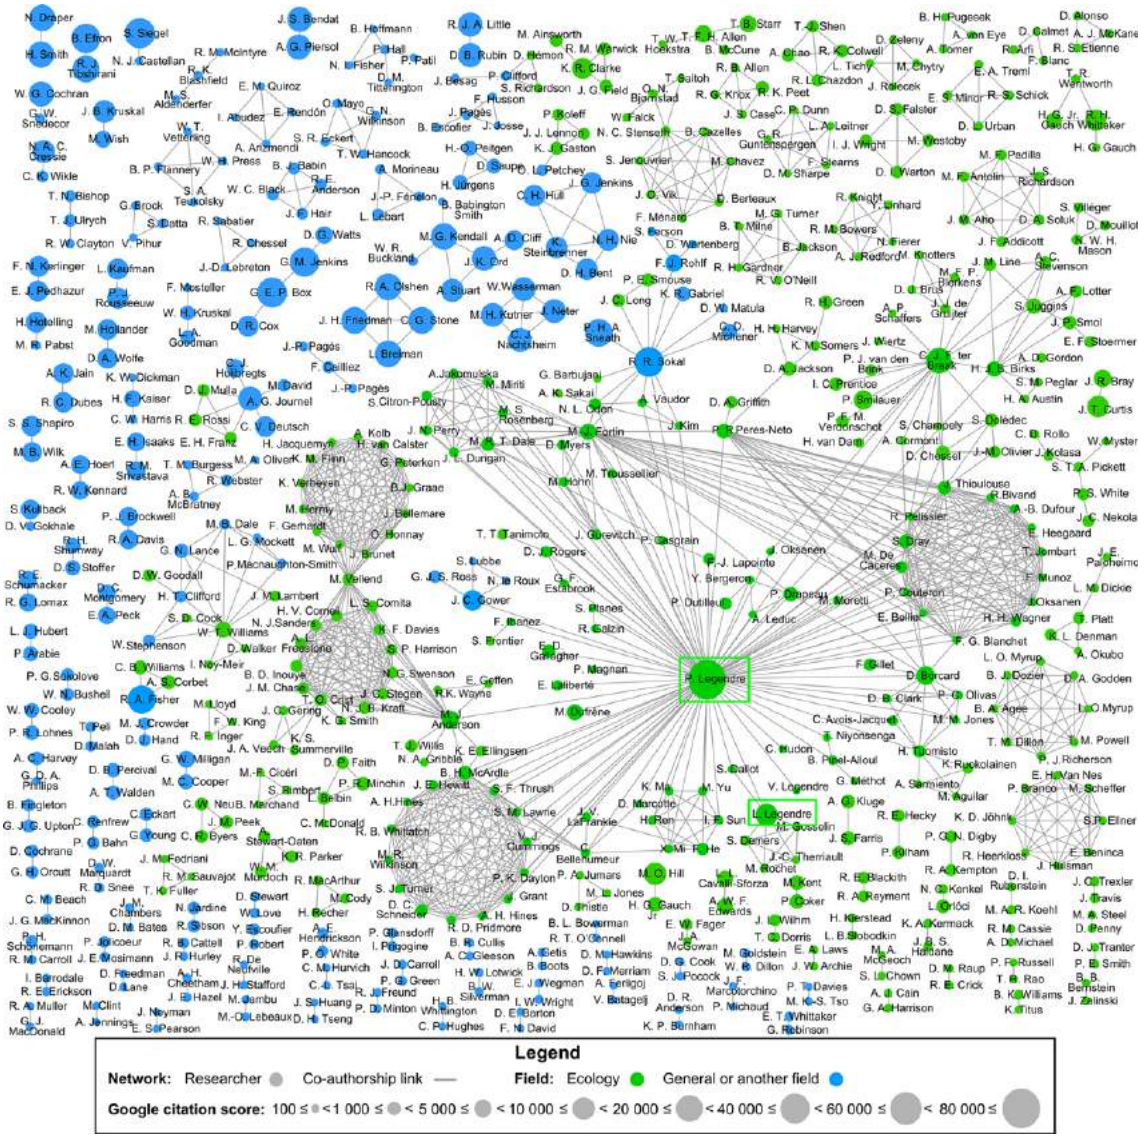

Fig. 1 This figure describes the network of collaborators who produced the references in the 2012 edition of the *Numerical Ecology* book (Legendre and Legendre, 2012). Single-author references were excluded. Network computed and kindly provided for use in this article by Prof. V. Makarenkov, Department of Computer Sciences, Université du Québec à Montréal.

Numerical ecology has been able to make great progress in the computer age thanks to the dedication of many developers of statistical packages, especially in the R language, who wrote software designed to analyze ecological data. Cited here, in alphabetic order, are some of the packages, available on the Comprehensive R Archive Network (CRAN) Web site, that have been developed by and for ecologists: ade4, adespatial, BiodiversityR, cocorresp, codep, ecodist, FactoMineR, FD, labdsv, lmodel2, mvpart, pastecs, picante, princurve, rioja, vegan, vegclust. That list is not exhaustive. Many other packages and functions are available on researchers personal web pages or in appendices of published papers describing statistical methods for ecological analysis.

Textbooks

From 1969 to 1979, the contributions of the previous decades were synthesized in four textbooks that marked the foundation of the field of numerical ecology:

- Statistical ecologist Evelyn Christine Pielou, Professor of mathematical biology at Queens' University (Kingston, Canada), formally introduced the field in 1969 by publishing a textbook entitled "*An Introduction to Mathematical ecology*" (Pielou, 1969). The Preface opened with the following sentences:

  "The fact that ecology is essentially a mathematical subject is becoming ever more widely accepted. Ecologists everywhere are attempting to formulate and solve their problems by mathematical reasoning, using whatever mathematical knowledge they have acquired, usually in undergraduate courses or private study. The purpose of this book is to serve as a text for these students and to demonstrate the wide array of ecological problems that invite continued investigation." (Pielou 1969, p. v.)
- László Orlóci, University of Western Ontario, London, Canada, published in 1975 "*Multivariate Analysis in Vegetation Research*" with a clear orientation towards community ecology (Orlóci, 1975). The main articles described ways of computing resemblance functions as well as methods of ordination and classification.
- Roger Green, who was Orlóci's colleague at the University of Western Ontario, London, Canada, published in 1979 "*Sampling Design and Statistical Methods for Environmental Biologists*" oriented towards animal ecology and sampling designs (Green, 1979). The book is a comprehensive guide to the principles of sampling design and methods of statistical analysis. It reviews the principles of inference, sampling and statistical design, and hypothesis formulation, with reference to ecological data.
- The first French and English editions of the Legendre and Legendre (1979, 1983) numerical ecology textbook provided a differently oriented synthesis of statistical methods aimed at all fields of ecology. The authors presented the mathematical bases of the methods of data analysis, and illustrated these methods with easy-to-compute numerical examples and real-data ecological applications drawn from the published literature.

Contribution of the Legendre Brothers

In May 1975, a dozen or so ecologists, mostly marine, sat during 3 days in a classroom on the second floor of a historical building of the *Station marine de Villefranche-sur-Mer* (Université Paris 6, France), a few meters away from the Mediterranean shore, to discuss developments concerning a new trend in the ecological literature: the statistical analysis of multivariate ecological data. The meeting was called "Séminaire de mathématiques appliquées à l'océanographie biologiques" and had a marine ecology orientation.

Because they had both worked in data analysis, Louis Legendre (oceanographer, Université Laval, Canada) and Pierre Legendre (community ecologist, Université du Québec à Montréal, Canada) had been independently invited to participate in the seminar, where they contributed several presentations. On the evening of the closing day of the meeting, sitting at the terrace of a restaurant with view on the harbor, Louis and Pierre Legendre wrote, on a paper place mat, a list of subjects, which was to become the table of contents of a book about the new subdiscipline of ecology that had been discussed during the seminar. They published the first edition of the book in 1979, in French, under the title "*Écologie numérique*."

History of Publication of the Numerical Ecology Textbook

- The first edition of "*Écologie numérique*" (in French) was published in 1979 by Masson, in Paris, and Presses de l'Université du Québec in Québec City (two volumes, 473 pages in total).
- The work was translated into English, under the supervision of the two authors, and published in 1983 by Elsevier Scientific Co. in Amsterdam under the title "*Numerical Ecology*" (435 pages).
- A second French edition, revised and augmented, was published in 1984 by the two original publishing houses (2 volumes, 618 pages in total) (Legendre and Legendre, 1984a).
- During the 1980s, community ecologists started to study species-environment relationships thanks to the computer package Canoco made available by Cajo ter Braak. During the 1990s, they became aware of the importance of spatial structures to understand the spatial variation of community composition (Levin, 1992; Legendre, 1993). The second English edition of "*Numerical Ecology*" was published in 1998 by Elsevier (868 pages) (Legendre and Legendre, 1998). It mostly focused on modeling the multivariate structure of community composition data. It incorporated a whole chapter on canonical ordination

and one on spatial analysis, and described the partitioning of the variation of community composition data into spatial end environmental components, a method, now very popular, that had been proposed by Borcard *et al.* (1992).

- The years 2000 were marked by the development of multiscale variation partitioning, a development initiated by Borcard and Legendre (2002), and the progress of methods for the analysis of beta diversity. The third English edition of "*Numerical Ecology*," published in 2012 (1006 pages), featured a new chapter on multiscale spatial eigenfunction analysis, as well as substantial additions to most other chapters.

In the meantime, a companion book, "*Numerical Ecology with R*", had been written by Daniel Borcard, François Gillet and Pierre Legendre and published by Springer Science in 2011 in the *Use R!* book series. The book contained detailed accounts of the computation of the numerical ecology methods of analysis using R packages. It was based on the major developments of R packages for ecologists since the year 2000, produced by various groups and their collaborators around the world, including the packages vegan (2001) and ade4 (2002). The list of R packages used in the various articles occupies several pages at the end of the book. A second edition of the R book was published by Springer in 2018. The R book was translated to Chinese by Jiangshan Lai (Institute of Botany, Chinese Academy of Science) and published in 2014 by Higher Education Press (Beijing). The data sets used in the R books (Borcard *et al.*, 2011, 2014, 2018) and the scripts of all analyses are freely available on a Web page cited at the end of this article.

In February 2018, the various editions of the "*Numerical ecology*" textbook had been cited more than 18,000 times in the scientific literature and the "*Numerical Ecology with R*" book more than 1600 times.

Important Papers Across the Years

Users of numerical methods and graduate students often wonder where the basic ideas of the methods we are routinely using come from and how they were developed. Here is a selection of papers that have changed the way ecologists analyze multivariate data during the past 50 years and the teaching of numerical ecology to graduate students in universities. The following list is by no means exhaustive.

The years 1960 and 1970—Development of redundancy analysis (RDA); Rao (1964) called the method "principal components of instrumental variables"; van den Wollenberg (1977) called it "redundancy analysis." Principal coordinate analysis (PCoA): Gower (1966). The concepts of alpha-beta-gamma diversity: Whittaker (1972). Time-constrained clustering: Gordon and Birks (1972, 1974).

1980–89—Spatially-constrained clustering: Lefkovitch (1978); Legendre and Legendre (1984b). Metric and Euclidean properties of dissimilarity coefficients: Gower and Legendre (1986). Canonical correspondence analysis (CCA): ter Braak (1986, 1987a,b). Spatial analysis as a tool for community ecologists: Legendre and Fortin (1989).

1990–99—The method of variation partitioning: Borcard *et al.* (1992). Spatial autocorrelation, a new paradigm for ecology: Levin (1992), Legendre (1993). Co-inertia analysis (CoIA): Dolédec and Chessel (1994). Indicator species analysis: Dufrêne and Legendre (1997). RLQ analysis: Dolédec *et al.* (1996). Fourth-corner analysis: Legendre *et al.* (1997); Dray and Legendre (2008); Dray *et al.* (2014). Distance-based redundancy analysis (dbRDA): Legendre and Anderson (1999).

2000–09—Transformations for community composition data prior to linear ordination, Legendre and Gallagher (2001), leading to transformation-based PCA (tbPCA) and transformation-based RDA (tbRDA). Spatial eigenfunction analysis—Moran's eigenvector maps (MEM): Borcard and Legendre (2002); Dray *et al.* (2006); asymmetric eigenvector maps (AEM): Blanchet *et al.* (2008). Concordance analysis of species associations: Legendre (2005). The rationale for estimation of beta diversity by the variance of the community composition data table, Var(**Y**): Legendre *et al.* (2005). Improving indicator species analysis: De Cáceres and Legendre (2009); De Cáceres *et al.* (2010).

2010 to present—Should the Mantel test be used in spatial analysis? Legendre and Fortin (2010), Legendre *et al.* (2015). Testing the space-time interaction in community surveys: Legendre *et al.* (2010). Test of significance of the canonical axes in RDA: Legendre *et al.* (2011). Partitioning beta diversity: Legendre and De Cáceres (2013), Legendre (2014). Temporal and space-time analysis of beta diversity: Legendre and Gauthier (2014). Study of temporal beta diversity: Legendre and Salvat (2015). Multiscale codependence analysis (MCA), which quantifies the joint spatial distribution of a pair of variables at different spatial scales (Guénard *et al.*, 2010), was generalized to handle multivariate response data (Guénard and Legendre, 2018).

Workshops

On 3–11 June 1986, Pierre and Louis Legendre, assisted by Marie-Josée Fortin (now Professor at University of Toronto), organized a NATO Advanced Study Workshop on Numerical Ecology at the *Station biologique de Roscoff* in France. Methods of data analysis were presented by statisticians and methodologists, followed by discussions of their application to ecological problems by working groups of ecologists. A book of proceedings was published after the workshop (Legendre and Legendre, 1987).

On 26–28 May 2008, a workshop entitled Spatial Ecological Data Analysis with R (SEDAR) was held at *Université Claude Bernard* in Lyon. It had been organized by Stéphane Dray to coordinate efforts among researchers developing the spatial analysis of ecological data and make plans for the future. One of the results of this workshop was a new R package, adespatial, for spatial and time-series analysis of community data. Written under the direction of Stéphane Dray, adespatial appeared on CRAN on 6 June 2016. New functions are still being added to this package.

On 6–7 October 2016, a workshop organized by Pedro Peres-Neto (Concordia University) and Marie-Josée Fortin (University of Toronto) was convened at Concordia University in Montreal. Twenty participants discussed future developments of the field. Following the meeting, one of the participants, Prof. Vladimir Makarenkov, computed a network describing the scientific collaborations that produced the wealth of references to numerical methods included in the 2012 edition of the "*Numerical Ecology*" book. Although the list of references at the end of a textbook is admittedly biased in favor of its authors, this network (**Fig. 1**) illustrates the fact that the development of data analysis methods for ecologists is the result of a broad and fruitful collaboration among many scientists.

Developments in Progress

Community Ecology

One of the primary concerns of community ecology nowadays is to test hypotheses about the processes that generate and maintain biodiversity in ecosystems, in particular beta diversity (i.e., the spatial variation in community composition among sites) in a region, through neutral processes, abiotic environmental species filters and biotic interaction filters. Numerical ecology develops and provides the statistical methods to test such ecological hypotheses.

Methodological developments on which researchers are presently working include the following topics:

- Beta diversity analysis of spatially distributed genetic, molecular and trait data. This work extends the concept of beta diversity, which was originally defined as the spatial variation of community composition data, to other types of biodiversity data.
- Beta diversity analyses across temporal and space-time surveys. Comparison of two and multiple surveys across time. Identification of the processes that cause changes in community composition for species, genetic, molecular, and trait data.
- New advances in spatial modeling by spatial eigenfunction analysis. Translation of landscape resistance networks into spatial eigenfunctions.
- Paleoecological analysis: new advances in time-constrained clustering and other methods for modeling abrupt changes in multi-species paleoecological data series.
- Three-table analysis. The basic methods, called RLQ analysis (Dolédec *et al.*, 1996) and fourth-corner analysis (Legendre *et al.*, 1997), test hypotheses of relationships between species traits and environmental characteristics of the sites mediated by the observed site-by-species data matrix. The two methods were unified by Dray and Legendre (2008) and Dray *et al.* (2014). Future developments, recently published or under discussion, involve other characteristics of the species, for example their phylogeny, and other characteristics of the sites, for example their spatial structure. Examples of such extensions are given in Dray *et al.* (2014). Mathematical extensions of the method are also considered.
- Analysis of multi-species community data using multivariate generalized linear mixed models (GLMM) or a latent variable model (LVM) that combines GLM with Markov Chain Monte Carlo (MCMC) methods (Warton *et al.*, 2015), as in the boral R package (Hui, 2017).
- Analysis of ecological networks.

The methods developed for community ecology can be transferred to other fields where empirical research is also concerned with frequency data, namely: gene frequencies, molecular data (including those used in microbiology nowadays), as well as biological and behavioral trait analysis.

Software Development

In most cases nowadays, new methods of analysis are published accompanied by software. For decades, Fortran, then C dominated the programming environment. An important program, which implemented a variety of simple and canonical ordination methods and allowed researchers to apply them to data, is Canoco; version 2.1 became available in 1988 (ter Braak, 1988).

R is a free software environment for statistical computing and graphics distributed on the CRAN Web site. The first stable version, R 1.0, appeared on CRAN on 29 February 2000. The R language is in fashion at the moment, and it is likely to be around for quite some time, given that the research community has produced thousands of packages, each containing from a few to hundreds of functions for data analysis. More than 12,000 packages are presently distributed on the CRAN site, in addition to the many other packages and functions available on individual researchers' Web pages or found in appendices of methodological papers. R may eventually be replaced by other software development environments, or complemented by other more specialized programming and computing environments. The future will tell, but for sure, ecologists will keep computing.

Conclusion

As pressing new ecological questions emerge in the world, ecologists and methodologists will keep developing methods of data analysis to answer these questions using multivariate data and enrich the methodological framework of numerical ecology.

Acknowledgments

Many thanks to Louis Legendre (Université Paris 6, France) for comments on a first draft of this article, and to Vladimir Makarenkov (Université du Québec à Montréal, Canada) who computed the network of scientific collaborations shown in **Fig. 1**.

Paleoecology☆

H John B Birks, University of Bergen, Bergen, Norway

Glossary

Chronology Obtaining absolute (or relative) dating of events in the archive (such as a fossil or sediment sequence).
Fossil Any preserved remains, impression, or trace of any once-living thing from a past geological age.
Geological time scale A system of chronological dating that relates geological strata to time.
Proxies Parts of an archive that provide the evidence of the biota and the physical environment.
Uniformitarianism An essential assumption and philosophical principle in paleoecology that "the present is the key to the past." That is processes that took place in the geologic past are the same as the ones that are observed today.

Research Approaches

Just as there are many approaches to ecological research (e.g., population, community, landscape, ecosystem, global ecology; descriptive, deductive, experimental ecology), there are several approaches to paleoecological research, resulting in several types of paleoecology. One division is based on the biological scales of study ranging from the paleoecology of individuals (adaptation, evolution) to population, community, landscape, ecosystem, and global paleoecology. Other types of paleoecological research can be taxonomically based or habitat based as individual paleoecologists often study particular organisms (e.g., vertebrates, insects, and diatoms) or work in a particular habitat (e.g., wetlands, lakes, oceans, and deserts). The major division within paleoecology, however, concerns timescales and time periods.

Ecologists are primarily interested in timescales of hours, days, weeks, months, years, or decades (so-called real time as these timescales lie within the realm of direct human experience and observation). In contrast, paleo-ecologists are interested in timescales of hundreds, thousands, or millions of years. The major division within paleoecology is between deep-time paleoecology and Quaternary-time paleoecology.

Deep-time researchers use fossils from preQuaternary sediments to study the distribution, evolution, and dynamics of past biota over timescales from thousands to millions of years. Research emphases are on adaptation, evolution, extinction, and biogeography. Quaternary-time (Q-time) researchers use techniques from paleontology, sediment geology, geochemistry, and isotope analysis to reconstruct past biota and environments and to study biotic responses to environmental change at Quaternary timescales (decades, hundreds, or thousands of years) during the last 2 million years of Earth's history. In practice, much of Q-time paleoecology is centered on the past 50,000 years, the period over which radiocarbon dating can be used to provide a chronology. The Quaternary has witnessed many major climatic oscillations between temperate interglacial and cool glacial stages. It has also witnessed the evolution, cultural diversification, and global spread of humans. The last few hundred years have seen the increasing role of humans in altering Earth's biota and environment, resulting in the so-called Anthropocene in which we live today where there is detectable human impact on the atmospheric composition and climate.

Deep-time biologists are usually called paleontologists or paleobiologists, whereas Quaternary biologists are often called paleoecologists.

A real-time ecologist may ask why study paleoecology and what can paleoecologists contribute to contemporary ecology? There are many reasons for studying paleoecology and integrating paleoecology into ecology. These are given as follows:

1. Present-day ecology benefits from a long-term perspective. Paleoecology provides direct evidence for ecological dynamics over long timescales that supplements ecological observations and tests ecological theories about succession and community dynamics.
2. Paleoecology can provide valuable insights into ecological legacies from human activity and environmental change. Ecological legacies are properties of an ecological system today that can only be explained by events or conditions absent from the system today.
3. Paleoecology provides a long-term context for current ecological phenomena and landscape patterns. Many ecological processes occur over decades to millennia (e.g., succession, migration, and pedogenesis). A long temporal perspective is essential to understand factors that determine the rates and causal mechanisms of these processes.
4. Reconstructing past environments is important to evaluate the extent of natural environmental variability, to place current environmental changes, particularly climate, into a long-term context, and to detect if current changes lie within the range of natural variability.

☆*Change History*: March 2018. H R Pethybridge included glossary, keywords, and updated references.

 doi:10.1016/B978-0-12-409548-9.00884-8

5. Understanding past climatic change and studying the response of organisms to those changes can contribute to predicting biotic changes in the future.

Philosophy of Paleoecology

Paleoecology is primarily a descriptive historical science involving inductive reasoning and research approaches and techniques drawn from the earth and biological sciences. Its language is therefore derived from both sciences. As fossils are central to paleoecology, careful identification, sound taxonomy, and unambiguous nomenclature are essential.

The method of multiple working hypotheses, presented by Thomas Chamberlain in the mid-nineteenth century, is essential in paleoecology as several explanations are often possible for an observed biotic change. The principle of simplicity (Occam's razor), proposed by William of Occam (1280–1349) is also essential. It proposes that given a set of competing explanations, all of which offer an adequate explanation for a given data set, the simplest explanation is preferable.

An essential assumption and philosophical principle in paleoecology is uniformitarianism, namely "the present is the key to the past"." Since James Hutton (Fig. 1) in the late eighteenth century and Charles Lyell (Fig. 1) in the 19th century, earth scientists have debated this assumption. Stephen Jay Gould resolved the debate by emphasizing the fundamental distinction between substantive uniformitarianism where rates of geological processes are thought to be constant in time and methodological uniformitarianism or actualism where the nature of the processes and their underlying laws are assumed to be the same through time but the rates may be very different at different times. Catastrophes (e.g., floods and volcanic eruptions) do occur so the rates of change can vary greatly but they all follow the basic laws of nature because the properties of matter and energy are invariant with time. Methodological uniformitarianism is an untestable methodological assumption common to all sciences. It represents the simplest approach to paleoecology and is thus an application of the principles of simplicity and induction.

Paleoecological Evidence

The geological record for Q-time and deep-time paleoecology can be rich in biological and environmental information.

Biological information comes from fossils preserved in sediments. The most common types of fossils in Quaternary paleoecology have much original material preserved, such as "hard parts" of shells, insect exoskeletons, diatom frustules, leaf cuticles, bones, pollen, seeds, and wood. Other types of fossils include impressions and films, petrifications and replacements, molds and casts, and trace fossils. These can provide valuable biological evidence in deep-time paleoecology.

Preservation of biotic remains usually requires deposition in anaerobic environments such as lake bottoms, ocean floors, or wetlands, or more rarely, freezing or desiccation. Plant microfossils (e.g., pollen) and macrofossils (e.g., seeds, leaves, wood) provide information about past flora and vegetation. Remains of animals (e.g., ostracods, beetles, cladocerans, testate amebae, and vertebrates) give insights into the past fauna.

In Q-time paleoecology, fossils are identified, as far as possible, by comparison with living taxa and are given names of the living taxa that the fossils most closely resemble. In deep-time paleoecology, the fossils are regarded as representing extinct taxa and taxonomies are developed for particular fossil groups based entirely on fossil remains.

Environmental information (e.g., climate, lake levels, and water temperatures) can sometimes be obtained from the sediments in which fossils are preserved. Such information is obtained by physical, inorganic and organic chemical, biogeochemical, and stable-

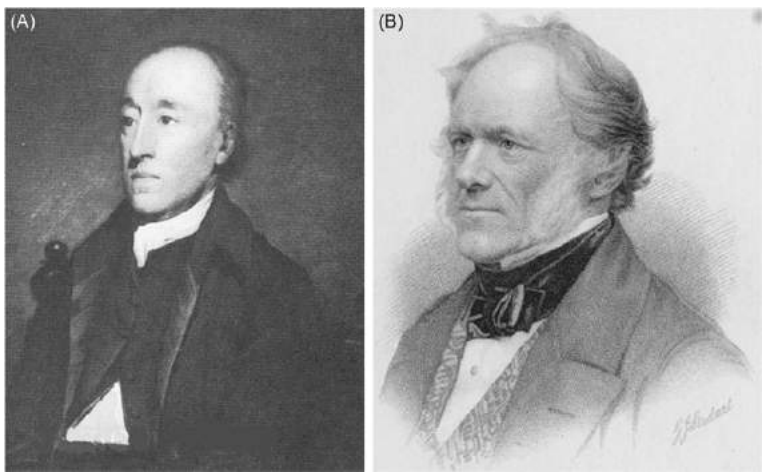

Fig. 1 (A) James Hutton (1726–97) and (B) Charles Lyell (1797–1875), the founders of modern earth science and of the concept of uniformitarianism, "the present is the key to the past," the basic principle of paleoecology. (A) From http://www.science.siu.edu/geology/people/ferre/hutton.html (accessed January 2008). (B) From http://kentsimmons.uwinnipeg.ca/16cm05/1116/16evolut.htm (accessed January 2008).

isotope analyses of sediments. Components of the sediments such as charcoal provide direct evidence for the occurrence of fires. Environmental information is often derived indirectly from biological evidence. For example, changes in lake-water pH can be inferred from changes in the composition of fossil diatom assemblages, under the assumption that the ecological preferences of the modern taxa are the same as they were in the past. Indirect sources of environmental information are called environmental "proxies."

A sound chronology is essential in paleoecological investigations to determine timings of past events, estimate rates of change, and permit correlations. Various dating techniques provide chronologies. In Q-time research, radiocarbon dating and other radiometric techniques (e.g., ^{210}Pb-dating) are the major geochronological tools. Other techniques include tree rings, annually laminated sediments, volcanic-ash layers, and paleomagnetics.

Paleoecological data are frequently quantitative and consist of many variables (e.g., diatom taxa and chemical elements) and many samples. Numerical methods such as principal components analysis are valuable tools in summarizing major patterns of variation in complex, multivariate paleoecological data. Statistical techniques (e.g., regression) are important in testing hypotheses about possible causes for observed changes in the paleo-ecological record.

Selected examples of different types of Quaternary paleoecological evidence are listed in **Table 1**, along with the type of paleoecological inferences possible from such evidence. If the inferences are quantitative, this is indicated along with the applicability of these types of evidence in deep-time research. Evidence types unique to deep-time studies are not given.

The major techniques in Quaternary paleoecology are pollen analysis, paleolimnology (e.g., analyses of diatoms, chironomids, and ostracods), paleoceanography (e.g., analyses of foraminifers, radiolarians, and cocco-lithophorids), tree-ring analysis, paleoentomology, peat stratigraphy, plant–macrofossil analysis, inorganic and organic geochemistry, and geochronological dating. Important reference works discussing many of these techniques are given in **Table 2**.

Table 1 Selected examples of Quaternary paleoecological evidence and their paleoecological inferences

Evidence	D	Q	Inference
1. Individual fossils			
Number and variation in growth rings(e.g., tree rings)	+	+	Age, seasonality, growth rates, growth conditions
Stomatal density in leaves	+	+	Atmospheric CO_2
Body size	+	+	Size, biomass, size frequency distribution
Density	+	+	Biomass, spatial patterns
Geographical location	+	+	Geographical distribution, habitat, dispersal, climate
Tooth wear	+		Diet in mammals
Fossil DNA			Species presence, evolutionary relationships and rates
2. Fossil assemblages			
Taxonomic composition	+	+	Taxa present, environmental conditions
Taxonomic richness, evenness, and diversity	+	+	Taxonomic richness, evenness, diversity
Relative abundance of taxa	+	+	Abundance frequency distribution, dominance, rarity
Geographical location	+	+	Geographical distribution, climate
Presence/absence and relative abundance of plant functional types	+	+	Vegetation structure and ecological properties (e.g., albedo)
3. Geochemical and isotopic composition of fossil hard parts			
Oxygen isotopes	+	+	Temperature, ice volume, salinity, moisture sources
Carbon isotopes	+	+	Food sources, vegetation type, productivity, atmospheric CO_2, moisture, temperature
Nitrogen isotopes	+	+	Food source, trophic level
Hydrogen isotopes	+	+	Temperature, moisture source
Mg/Ca ratios	+	+	Temperature
Sr/Ca ratios	+	+	Temperature range
4. Geochemical evidence from sediments			
Heavy metals and organic toxins		+	Human disturbance, atmospheric contamination
Mn, Fe, Mo, Cr	+	+	Redox conditions
Sulfur isotopes	+	+	Redox conditions, microbial activity
K, Ca, Mg		+	Erosion
5. Biogeochemical evidence from sediments			
Biomarkers and other molecular markers	+		Species presence, trophic structure
Photosynthetic and other pigments	+	+	Productivity, trophic status
N and C isotopes in organic compounds	+	+	Productivity, organic sources
Organic compounds (e.g., alkenones)	+	+	Temperature, organic sources
6. Lithological evidence			
Sediment grain-size	+	+	Sedimentary environment (e.g., glacial, aolian, alluvial)
Peat and coal stratigraphy	+	+	Wetland hydrology, moisture changes
Charcoal	+		Fires

Plus signs in the column labeled D, Deep-time; and Q, quantitative indicate that this evidence is also applicable in Deep-time research and that the paleoecological inferences are quantitative.

Paleoecology can be studied in any deposits containing fossils that provide evidence for past life. In Quaternary paleoecology, especially the last 11,500 years of the Holocene (postglacial) and the recent past (last 100–250 years), lakes and their sediments provide the most diverse records of past biota and environment because lake sediments integrate a range of regional and local biological and environmental signals. Lake sediments consist of material from several sources. The material can be divided into allochthonous (derived from outside the lake from the catchment or atmosphere) and autochthonous (derived from the lake itself) material.

Autochthonous material includes fossils of limnic organisms such as diatoms, chrysophytes, other algae and their pigments, bacteria, aquatic macrophytes, cladocerans, ostracods, chironomids, fish, etc. Input of allochthonous material to a lake has three main sources—groundwater, catchment or watershed, and atmospheric. Groundwater inputs include solutes (e.g., Ca, Mg, Na, K, Cl, SO_4, and HCO_3), nutrients (e.g., P and N), and toxins (e.g., pesticides). Catchment inputs include fossils of terrestrial biota (e.g., seeds, leaves, charcoal, and insects), inorganic material, nutrients, organic detritus, and toxins. Atmospheric inputs include radioactive nuclides (^{210}Pb, ^{137}Cs, ^{241}Am, ^{14}C, etc.), charcoal, spheroidal carbonaceous particles, pollen, trace metals (e.g., Pb, Cu), volcanic ash, toxins (e.g., persistent organic pollutants), sulfates, nitrates, and dust.

Stages in a Paleoecological Study

Although each paleoecological study is unique, depending on the research problems, geographical area of study, site type, expertise of the paleoecologists, age of the sediments, etc., there are several stages that are common to many, if not all, Quaternary paleoecological studies.

1. *Definition of research problem*. Careful definition of the research problem and hypotheses to be tested is important at the outset, as paleoecology is a very labor-intensive and time-consuming activity. A poorly designed project results in a considerable waste of time and effort.
2. *Selection of site to be sampled*. Careful site selection is essential if the research questions are to be answered. Site selection requires not only knowledge of the study area and its geology, topography, and hydrology but also knowledge of the ecology and land use of the possible sites to be selected (**Fig. 2**). Exploratory studies are invaluable.
3. *Selection of coring site*. Once a site has been selected, the next stage is to select where to take a core of the sediments for paleoecological study. In general, the aim is to maximize between-site variability and hence to minimize within-site variability. Experience has shown that the deepest point in a basin is often the place where within-site variations are minimal and is thus the preferred place for sediment coring. Again exploratory studies are invaluable.
4. *Collection of sediment cores*. There are several different types of coring devices. The choice depends on many factors, including water depth, nature of the sediments to be sampled, amount of sediment needed for study (pollen analysis only needs 1 cm^3 of sediment, whereas paleoentomology requires large volumes), temporal resolution required, and remoteness of the study site. Details of suitable coring devices can be found in the works given in **Table 2**. The most common type is illustrated in **Fig. 3**, along with a sediment core.
5. *Sampling and describing sediments*. This involves describing the sediments in terms of physical properties (e.g., color, stratification, and water content), humification (degree of decay), and composition (clay, silt, sand, organic detritus, mud, etc.). The subsampling resolution depends on the research questions and the rate of sediment accumulation. In some arctic lakes where the last 10,000 years may be represented by only 1 m of sediment, sampling at 10 years intervals requires a sampling resolution

Fig. 2 Lille Kjelavatn, a small lake at 1000 m in southern Norway. This is an ideal site for a paleoecological study as the lake is small and relatively deep ensuring that the pollen record is from the catchment (watershed) and the sediments are undisturbed; the surrounding slopes are gentle and there is no sedge-swamp around the lake ensuring that terrestrial plant macrofossils are washed into the lake; and the bedrock is acid, thereby minimizing errors in radiocarbon dating.

Fig. 3 (A) Coring lake sediments using a Livingstone piston corer at Haugtjern, southeast Norway and (B) a 1 m long, 2.5 cm diameter core of lake sediment extruded from a Livingstone piston corer at Mangrove Lake, Bermuda.

of every 1 mm. Such sampling must be done in the laboratory using specially constructed equipment. Time spent on careful sampling is time well spent, because contaminated samples are worthless.

6. *Dating*. An absolute chronology is essential in almost all Quaternary studies. For the last 150 years, radio-metric-dating techniques involving ^{210}Pb, ^{137}Cs, and ^{241}Am are invaluable. For the last 15,000 years, radio'carbon dating is the major chronological tool.
7. *Collecting paleoecological data*. A very wide range of data types can be collected, including physical, chemical, and biological data (see **Table 1**).
8. *Presentation of paleoecological data*. The resulting data may be complex and it is a challenge to present the results of several paleoecological analyses in a clear and effective way. Much thought is required and many critical questions need to be considered—should all variables be presented when there may be 200 diatom taxa present, should the data be presented as relative percentages or "absolute" accumulation rates, should the data be plotted on a sediment age scale or on an estimated age scale? Numerical techniques can be valuable in summarizing the patterns of variation within and between different data sets from the same sediment sequence.

9. *Interpretation*. There are two major approaches to the interpretation of paleoecological data: (1) paleoecological reconstructions, a primarily descriptive approach where the emphasis is on reconstructing past biota, populations, communities, landscapes, and ecosystems; (2) ecological paleoecology, a hypothesis-testing approach where the emphasis is on interpreting the observed changes in terms of underlying causes.

Paleoecological Reconstructions

In this approach, paleoecologists use the available evidence for reconstruction purposes at a range of ecological scales.

1. Past biota—what taxa were present in the past?
2. Past populations—what were the population sizes in the past?
3. Past communities—what communities or "life assemblages" were present in the past?
4. Past landscapes—what was the past landscape and how did it vary in space and time?
5. Past environments—what was the environment (e.g., climate and lake-water pH) at particular times in the past?
6. Past ecosystems—what was the ecosystem at particular times in the past?

Reconstructions can be based on a few "indicator species" or on the fossil assemblage as a whole. The reconstructions may be qualitative or quantitative. An important approach for quantitative environmental reconstructions in Quaternary paleoecology involves modern organism–environment transfer or calibration functions to transform fossil assemblages into estimates of the past environment (Fig. 4).

Transfer functions are mathematical regression-type models that express the relationship between modern assemblages of organisms (e.g., pollen) preserved in surface sediments (Y_m) and the contemporary environment (e.g., mean July temperature—X_m):

$$X_m = \hat{U}_m Y_m$$

where $\hat{U}_m$ is the modern transfer function estimated by U_m inverse regression or calibration.

The transfer function is assumed to be invariant in time and space and is applied to fossil assemblages, Y_f, to derive estimates of the past environment, X_f:

$$X_f = \hat{U}_m Y_f$$

This general approach has been used to estimate sea-surface temperatures from fossil foraminifers, radiolarians, coccolithophorids, diatoms, and dinoflagellate-cyst assemblages, terrestrial climate from fossil pollen, chironomid, cladoceran, diatom, mollusk, and insect assemblages and from tree-rings, lake conditions (e.g., pH, salinity, total P, and anoxia) from fossil diatom, cladoceran, chironomid, chrysophyte, and ostracod assemblages, bog moisture from fossil moss and testate amebae assemblages, and atmospheric CO_2 from stomatal density of fossil leaves.

As all the biotic evidence is generally used for reconstruction purposes, it is not possible to use the reconstruction as a basis for interpreting the observed biotic changes, except in the rare cases where the environmental reconstruction is based on independent sources of evidence such as stable isotopes, sediment geochemistry, or one biological proxy that is used solely for reconstruction purposes.

Ecological Paleoecology

In this approach, paleoecologists are interested in the causal underlying processes or "forcing functions" for the observed stratigraphical patterns. For example, what factors caused the observed changes in pollen stratigraphy at a site over the last 11,000 years? Are the biotic changes responses to changes in climate, soils, biotic interactions, pathogens, disturbance regimes, land-use, etc.? It is essential to interpret paleoecological data in terms of underlying causal factors if the paleoecological record is to be used as a long-term record of ecological dynamics that can help understand present-day systems.

In causal interpretations, there may be two or more competing hypotheses to explain the observed patterns. At least three independent proxies are needed to test two hypotheses. A major development in Quaternary paleoecology has been multiproxy studies where several proxies are studied on the same sediment core. To test competing hypotheses, one or more proxy is used to reconstruct the past environment. These reconstructions and other independent paleoenvironmental variables are then used as predictor variables to test hypotheses about the causes of change in the other proxies when they are considered as response variables. A range of statistical regression-modeling techniques can be used to test different hypotheses about the causes of the observed changes in the response variable in relation to the predictor variables. Statistical significance can be assessed by permutation tests that take into account the numerical properties of time-ordered paleoecological data.

Contributions of Paleoecology to Ecology

Paleoecological research has in the last 30 years made many important contributions to our understanding of present-day ecological systems. Some examples are summarized in Table 3 in terms of the ecological questions considered and the paleoecological techniques employed. Further examples can be found in the "Further reading" section.

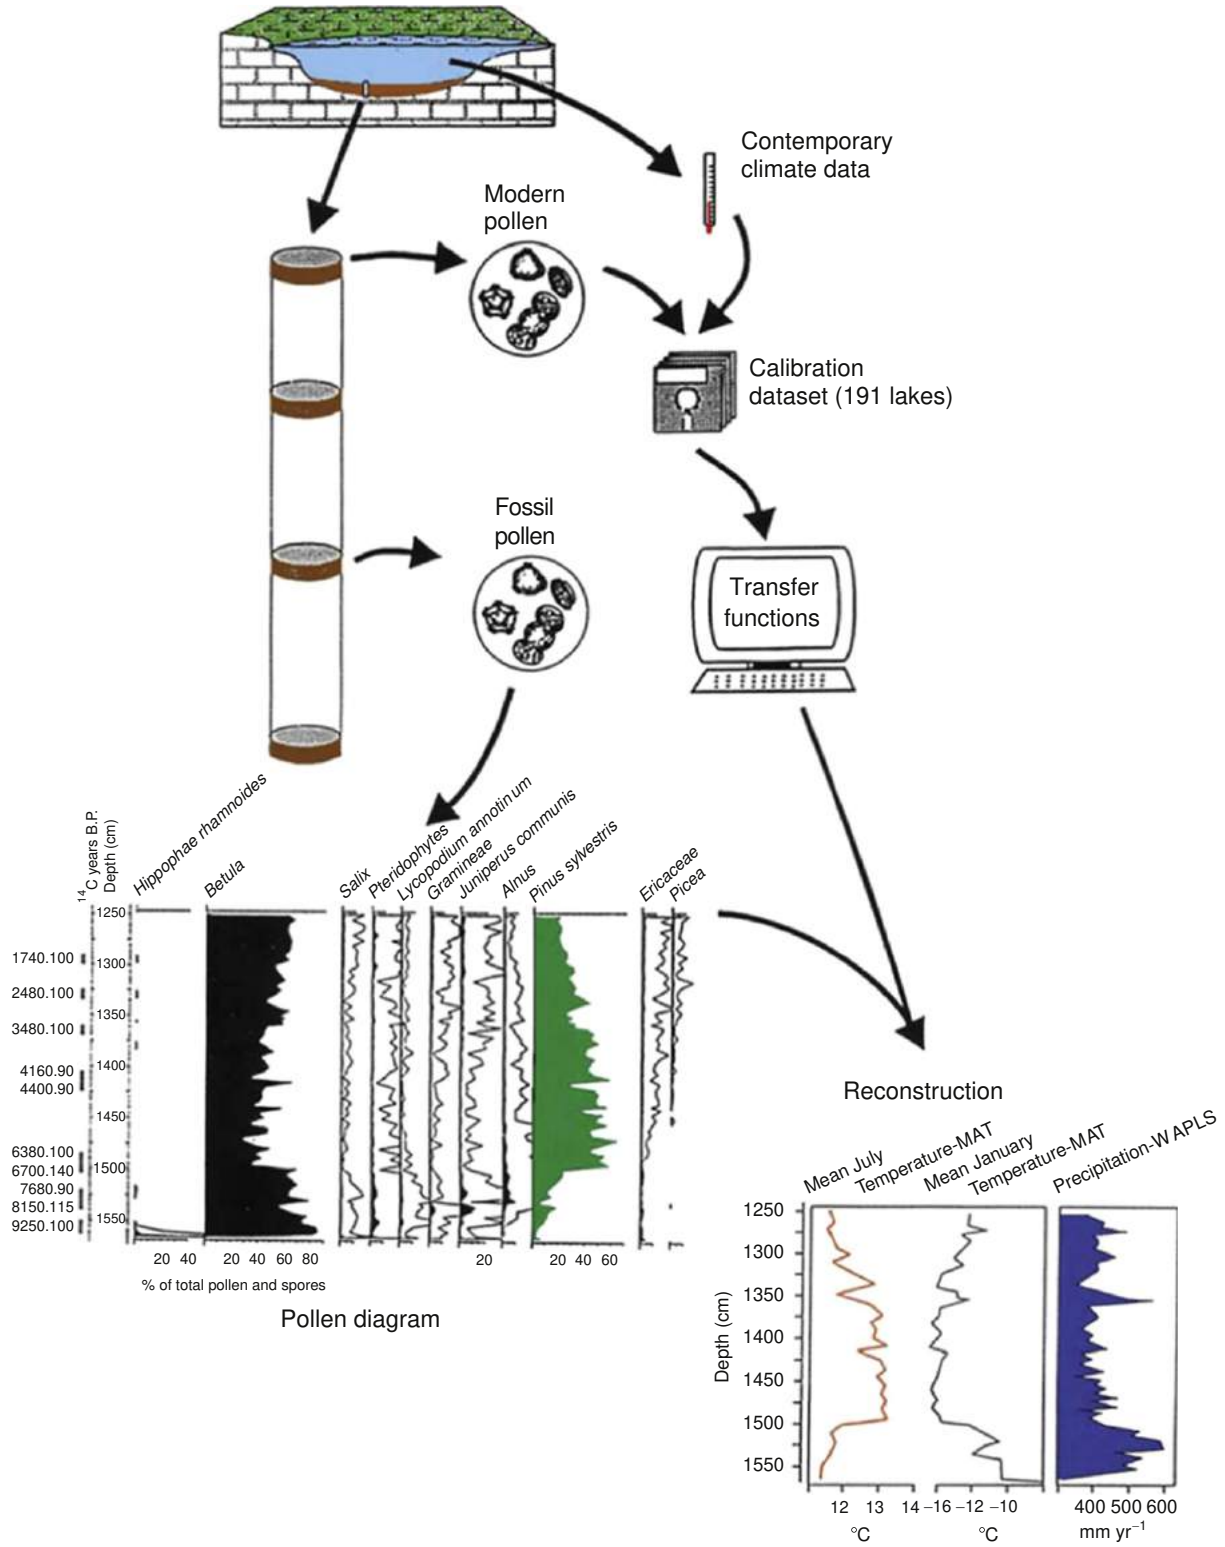

Fig. 4 A schematic representation of the stages involved in deriving a quantitative reconstruction of past environment from pollen-stratigraphical data using a modern calibration training set and transfer or calibration functions. Based on an unpublished diagram by Steve Juggins.

One of the major contributions (Table 3) that paleoecology has made to our understanding of present-day ecosystems concerns the cause of recent surface-water acidification in Europe and North America. Competing hypotheses for recent pH decreases are given as follows:

Table 3 Examples of Quaternary paleoecological studies that have contributed to modern ecological understandings

Ecological question	*Paleoecological techniques used*
What is the cause of recent surface-water acidification?	Paleolimnology (especially diatoms), transfer functions, chronology
What role does a lake's catchment play in lake development?	Paleolimnology, pollen analysis, plant macrofossils, statistics and hypothesis testing, chronology
What is the origin of landscape mosaics (e.g., forest and grassland)?	Pollen analysis of pond sediments, statistics, chronology
What is the role of human activity in landscape change and species extinction?	Vertebrates, pollen analysis, plant macrofossils, sediment geochemistry and magnetism, chronology
What is the role of soil development in long-term vegetation dynamics?	Pollen analysis, sediment inorganic geochemistry, chronology
Is there an orderly and predictable succession of community types in hydroseral successions?	Sediment composition, pollen and macrofossil analysis, chronology
Does the "regeneration complex" hypothesis explain the mechanisms of bog growth and development of pools and hummocks?	Peat composition, plant macrofossils, chronology
Has the frequency and extent of wild-fires changed in time?	Charcoal, pollen, sediment geochemical analyses, statistics, chronology
Have pathogens been important in influencing long-term forest dynamics?	Pollen analysis, statistics, chronology
Have forest trees spread since the last glacial stage as assemblages or individualistically?	Pollen analysis, chronology, mapping

1. the recent changes result from land-use, vegetational, and soil changes (e.g., land dereliction, secondary forest succession, and soil deterioration);
2. the recent changes are the result of natural long-term vegetational and soil acidification that has occurred over the last 10,000–11,000 years; and
3. the recent changes are a result of atmospheric deposition of strong acids following the combustion of fossil fuels, the so-called "acid-rain" hypothesis.

As a result of international research programs in Europe and North America in the 1980s and 1990s, detailed paleoecological studies of lake sediments showed that the recent land-use and natural long-term acidification hypotheses could be falsified, whereas despite several attempts to reject the acid-rain hypothesis it could not be falsified. The paleoecological studies (**Fig. 5**) primarily involved fossil algal (diatom and chrysophyte) assemblages preserved in lake sediments, sediment inorganic geochemistry, counting of spheroidal carbonaceous particles formed by the combustion of fossil fuels, ^{210}Pb-dating, transfer functions linking modern algal assemblages to lake-water pH, and fine-resolution sampling (about every 5–10 years for the last 250 years).

Paleoecology, particularly for the last 100 years, is making major contributions to assessing the "health" of ecosystems in terms of contamination by heavy metals (e.g., Cu, Cd, Zn, Pb, Ni, and As) and persistent organic pollutants (e.g., polycyclic aromatic hydrocarbons), of eutrophication by nutrients (e.g., N and P), and of recovery following decreases in the atmospheric deposition of "acid rain."

A current research activity for many paleoecologists is detecting impacts of recent climate change on biological systems. A synthesis of paleoecological data for Arctic lakes has shown that major changes in biotic composition have occurred in the last 150 years in over 80% of the lakes examined above the Arctic Circle, whereas further south, less than 60% of the lakes showed any major changes. All available evidence suggests that arctic lakes have changed dramatically and directionally within the last 150 years. "Regime-shifts" have occurred rapidly, characterized by changes to taxonomically more diverse and increasingly productive aquatic ecosystems, with more complex community and trophic structures and enhanced plankton development.

A new application of paleoecology, conservation paleoecology, is developing where results of paleoecological studies are used to provide historical perspectives relevant to nature conservation and ecosystem management. These perspectives include insights into biotic responses to environmental change, rates and mechanisms of biological invasions, extent of naturalness in ecological systems, and the frequency of disturbance, especially wild-fires. It is in nature management in relation to fire that conservation paleoecology is making major contributions. It is essential in management to know the natural variability of wild-fires so that this can be used as a reference against which contemporary conditions and future alternatives can be evaluated. Such assessments are often based on short-term records (<50 years) only. Although climate change and human activity are recognized as the major drivers of fire frequency and extent, paleoecological studies show that these relationships are often surprisingly complex. Results from studies involving pollen, plant macrofossils, charcoal, sediment geochemical, and time-series analyses show that warmer/drier conditions do not necessarily result in a high fire frequency. Fires often occur more frequently under wetter conditions, because in moist intervals biomass production and hence fuel loads increase. Fire frequency and extent thus oscillate with climate through time. Paleoecological data suggest that in a given region, there may be several possible ecosystem or "regime" states corresponding to different fire frequencies which, in turn, are a function of climate–fuel relationships. Such insights can be used to define the context of current forest conditions and potential future changes.

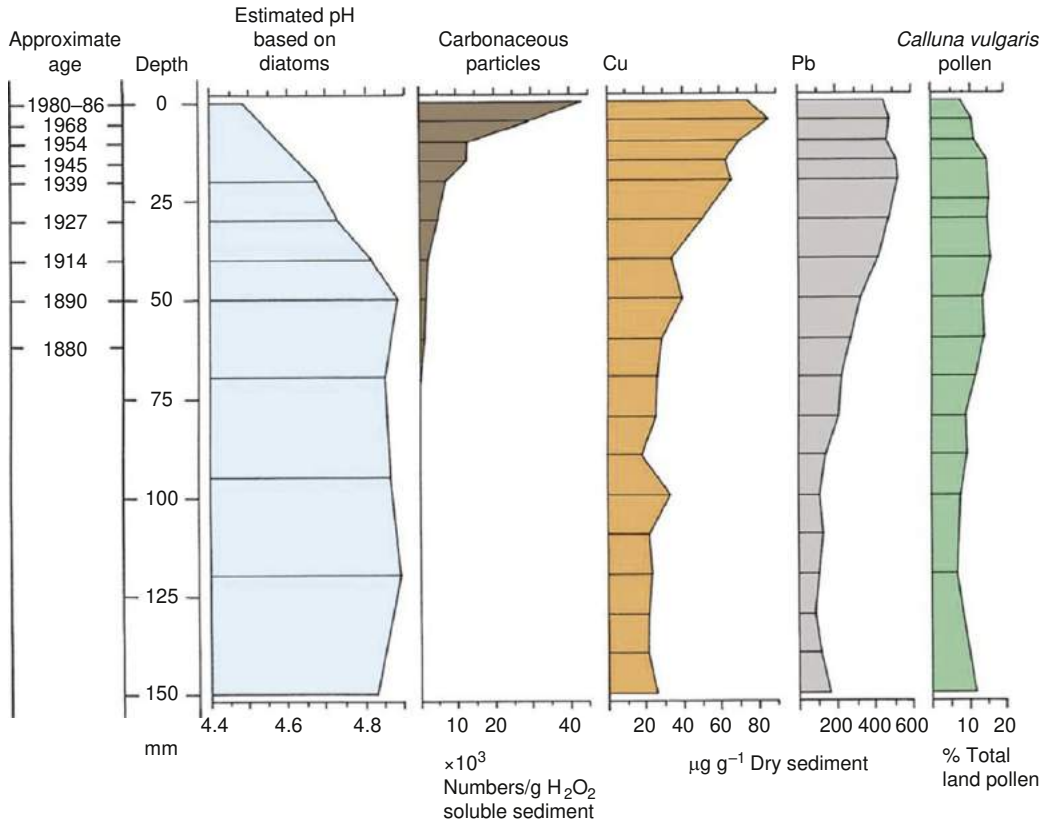

Fig. 5 A stratigraphical diagram from Holetjørn, a small hill-top lake in southwest Norway that covers the last 250–300 years. The diagram shows the decrease in lake-water pH beginning at about 1890. This acidification coincides with the beginning of the deposition of carbonaceous particles formed by the high temperature combustion of fossil fuels. The concentrations of the heavy metals Cu and Pb also increase at about 1914, reflecting atmospheric contamination due to industrialization and the use of lead in petrol. There is a small decline in *Calluna vulgaris* (heather, lyng) pollen since 1939, reflecting the increase in upland grazing in recent years. The age scale is based on ^{210}Pb-dating. Modified from an original diagram by H. J. B. Birks.

Future Directions and Potentialities

There have been major advances in Quaternary paleoecology since the pioneering pollen-analytical studies by Lennart von Post (Fig. 6) in Sweden in the early 20th century. After the sophistication of pollen analysis by Johs Iversen, Knut Faegri (Fig. 7), and others in the 1940s–1970s, important advances in paleoecology have come from the developments of paleoceanography in the 1960s–1980s, paleolimnology in the 1980s–1990s, and a wealth of isotope and geochemical techniques in the last decade.

A major future development in paleoecology will come from recent advances in earth sciences. These involve stable-isotope analysis, organic geochemistry, and detection of molecular markers that will allow past environmental conditions to be inferred independent of biological proxies. To date, there have been few paleo-ecological studies that exploit these developments to explore links between independently derived records of environmental change, particularly climate change, and observed biotic changes. When this is done more fully, it will allow paleoecological research to focus directly on the nature of biotic response to environmental changes over a range of temporal and spatial scales, namely to study the ecology of the past. This will be a major break-through, as the geological record of fossils can then be used as an ecological observatory or laboratory for studying long-term ecological changes over timescales beyond direct ecological observations. As the paleoecological record is a unique record of biotic responses to a wide range of environmental changes, it can help predict biotic responses to future environmental change, a major concern of much ecological and conservation research today.

Ecology, conservation, and nature management are primarily concerned with the present and increasingly with the future. Paleoecology considers the past but can provide a historical perspective to the present. With the ever-increasing quantity and quality of paleoecological data at a fine spatial and/or temporal resolution, there is great potential for close interactions between real-time ecologists and Quaternary paleoecologists, as there is an enormous contribution that paleoecology can make to ecology. The paleoecological record contains many "lessons from the past" about biotic responses to environmental change. With recent developments in paleoecology and earth sciences, it will soon be possible to read this record ecologically and to learn from these "lessons" so as to improve our understanding of ecological dynamics over long timescales and to contribute to nature conservation and management policies for the future.

Parasites

KD Lafferty, University of California, Santa Barbara, CA, USA

Introduction

Parasites Are Everywhere

Parasitism is the most popular lifestyle on Earth. Roughly, half of plants and animal species are parasitic at some stage of their life cycle. Few species, if any, lack any parasites and most species have at least one host-specific parasite species. Even parasites have parasites. We know the most about humans, who host 342 parasite species, not including viruses and bacteria. Many of these only parasitize humans. Parasites tend to be more abundant in places where hosts are abundant and more diverse in places where hosts are diverse. For instance, more parasites species are found in the tropics than at high latitudes. While parasite diversity follows host diversity, parasitism may also select for diversity in host communities.

What Is a Parasite?

Parasite comes from the Greek *parasitos*. Originally, *parasitos* referred to a dinner guest. However, around 400 BC, Greek comedies began featuring a stereotyped character: a hard to get rid of guest whose obnoxious nature becomes tiresome. Hereafter, *parasitos* took on the meaning of a freeloader.

Tapeworms, digenetic trematodes, and acanthocephalans are familiar parasitic taxa. Among the animals, there are nine entirely parasitic phyla and 22 predominantly ($>99\%$) predatory phyla. For the remaining 11 phyla that have a mix of parasitic and free-living species (e.g., Nematoda, Platyhelminthes, and Arthropoda), clades within a phylum are often either entirely parasitic or predatory. Nonetheless, parasitism lacks a single evolutionary origin and is spread among phyla.

The field of parasitology traditionally limits its focus to animal groups that one can see clearly with a microscope. These include protozoans (amebas, flagellates, ciliates, apicomplexans, myxozoans, and mesozoans) and metazoans. Of the metazoans, several parasitic groups are familiar: platyhelminthes (monogenes, trematodes, cestodes), nematodes, acanthocephalans, pentastomids, and arthropods (crustaceans and insects). Some of these groups (particularly the dipterans) are best defined as micropredators. Small and nonanimal parasitic taxa (viruses, bacteria, fungi, and plants) are not included in the field of parasitology. These groups are often termed pathogens. For these reasons, an ecological/evolutionary concept of parasitism does not necessarily conform to the taxa treated by the field of parasitology.

Natural enemies of all taxa take nourishment from a victim (host) or victims (prey) using a variety of trophic strategies. The particular strategy an individual natural enemy uses can vary from one victim to the next. How do parasites differ from predators? At first glance, it appears that relative body size is the key factor. Parasites are generally much smaller than their hosts and predators are larger than their prey. But a wolf is not a parasite of the larger moose and body size is not a particularly useful means of distinguishing among trophic strategies, despite the fact that it appears to be a key correlate and evolutionary driver of trophic strategies.

The durability of the enemy–victim interaction has been argued as a useful distinction between predators and parasites (i.e., parasitic interactions are durable). While parasites are generally intimately associated with their hosts, intimacy is difficult to apply as a dichotomous operational definition. There is no obvious durability criterion that would clearly allow us to distinguish predator from parasite. For instance, a lion may stay for several days feeding on a zebra carcass while the nymph of a tick takes one blood meal from a deer and drops off within a few hours.

If intimacy is difficult to apply as a categorical definition of parasitism, what other criteria are available? Population models provide a possible perspective of trophic strategies. In infectious disease models, a parasite exploits only one host during a particular phase of its ontogeny. In contrast, most population models in ecology incorporate a functional response that considers how predators eat many prey. In other words, population modelers have established a well-accepted dichotomy between parasites and predators based on the number of hosts or prey attacked during a particular life-history stage. Attacking one versus more than one victim is easier to apply as a means to distinguish parasites from predators than durability of an attack, though the two views are not in conflict (exploiting only one victim during a life-history stage is necessarily a durable attack).

Micropredators

Mosquitoes are included in parasitology texts, yet because an individual feeds on more than one victim during the adult life stage, adult mosquitoes fail to meet the criterion for a parasite. Instead, they represent a type of predator that does not reduce the fitness of prey to zero. For this reason, `micropredators', like mosquitoes, have similarities with parasites. Many natural enemies are obligate micropredators, others such as vampire bats, lampreys, cookie-cutter sharks, and many herbivores (e.g., deer) switch between micropredation and predation, depending on the relative size of the predator and its prey.

The Diversity of Parasite Life Histories

Whereas the criterion `Does the enemy attack more than one victim?' separates predators from parasites, criteria that help distinguish among parasitic life-history strategies are (1) does the enemy eliminate victim fitness, (2) does the enemy require a victim's death? and (3) does the enemy cause intensity-dependent pathology? Predators can also be subdivided into useful categories by applying the first and third criteria. The next sections describe common types of parasite life histories.

Parasitoids

Parasitoids are a type of parasite that requires their victim's death, thereby reducing host fitness to zero. Entomologists use the term parasitoid to describe wasps and flies that lay eggs in or on insect hosts. The larvae then consume the host from the inside. When the carcass is consumed, the parasitoid wasps or flies metamorphose into free-living adults. For this reason, parasitoids are relatively large parasites. Other taxonomic groups (turbellarians, nematodes, crustaceans) also use a parasitoid life-history strategy. For instance, an intertidal turbellarian infects young crabs, grows to a large size, and, on adulthood, bursts through the crabs' exoskeleton to become a free-living adult worm. Because a diversity of taxonomic groups must kill their hosts as a normal aspect of their development, the term parasitoid is best used as a description of a parasite life-history strategy instead of a taxonomic category for certain flies and wasps.

Microparasites and Macroparasites

Intensity-dependent pathology is an important criterion for distinguishing among parasites, and parasite body size is somewhat correlated with this criterion. The protozoans, bacteria, and viruses have short generation times, rapid reproduction inside the host, a tendency to induce immunity in surviving hosts, and a short duration of infection. Most parasites and pathogens that fit these assumptions are relatively small. The population dynamics of such parasites are well described by `intensity-independent' (SEIR) models. Because such parasites are small, these models have gained the nickname of microparasite models.

The population dynamics of most parasitic worms are not well described by SEIR models. Because pathology increases with the number of worms in an infection (or intensity), and worms typically aggregate among hosts, pathology varies considerably from host to host. To model such worms more appropriately requires accounting for parasite intensity and aggregation, and more specifically keeping track of the number of individual parasites in the parasite population, the number of hosts, and the number of parasite free-living stages. Intensity-dependent models are better able to accommodate the biology of many species of adult parasitic worms. Because helminths are much larger than are protozoans, bacteria, and viruses, intensity-dependent models are termed macroparasite models.

While the terms macroparasite and microparasite have utility for modeling purposes, they have been inappropriately used as a coarse taxonomy, presumably because the prefixes in the terms focus attention to the body size of the consumer. Protozoa and smaller microbes are `microparasites' and helminths and arthropods are `macroparasites' even though some small parasites may be better modeled as macroparasites and many large parasites may be better modeled as microparasites.

Parasitic Castrators

Parasitic castrators take the bulk of their energy from their host's reproductive tissues, often reducing the host's fitness to zero. While the host is alive, and appears well, it is dead from an evolutionary perspective. This strategy is not commonly recognized in the veterinary and medical fields, because large vertebrates generally lack parasitic castrators. In many other systems, however, parasitic castrators may be common: cestodes can castrate their fish and invertebrate hosts, larval trematodes usually castrate their molluskan first intermediate hosts, and parasitic barnacles castrate their crustacean hosts. Parasitic castrators are large with respect to their hosts, but ironically, they are generally best modeled as microparasites because their effects on the host are intensity independent.

Complex Life Cycles

Within a complex life cycle, a parasite may use more than one life-history strategy, exploiting several host species in succession. Most complex life cycles can be considered predator–prey (e.g., acanthocephalans), vector (e.g., malaria), or free-living stage transmitted (e.g., trematode cercariae). For instance, trematodes most likely began as parasites of mollusks and later added vertebrate definitive hosts, while many parasitic nematodes whose adults live in vertebrate guts later added intermediate hosts. There are a variety of ways parasites can add new hosts. Biting arthropods clearly provided a convenient means for blood and tissue parasites to contact new hosts. In addition, there should be selection for parasites to survive the predation of their hosts by parasitizing their host's predator. The latter case provides a new category of parasite, the trophically transmitted parasite. Such parasites do not kill their intermediate host, but require its death for transmission.

Ecological Effects of Parasites

Parasite ecology is a developing tradition and already has a rich set of its own jargon (Table 1). Parasites are small but their numbers and biomass can add up so that they can have impacts at the level of host individuals, populations, and communities. Parasites also have important evolutionary effects in that they promote the evolution of host defense and sexual reproduction.

Competition

Density-dependent transmission allows parasites to disproportionately affect common species. This helps maintain rarer competitors, thereby promoting coexistence and stability. In addition, when hosts share parasites, parasites can be competitive weapons. For example, two competing species of amphipod may coexist in nature because a trematode reverses their relative population growth rates. Competitive weapons, such as parasites, can also reduce biodiversity if subordinate species are more susceptible. For instance, a larval tapeworm shared by two flour beetle species increases the rate at which the dominant beetle excludes the subordinate.

Parasites could tip the balance in competitive interactions between native and introduced species. Invasive species typically bring only a small fraction of their parasites to invaded regions, and what they pick up from the native community rarely makes up for the difference. Alternatively, an invader has no coevolved history with the few new parasites it acquires, and these could limit the invasion. Parasites can cause two species to interact indirectly even if these species do not compete for resources. Such apparent competition occurs because one host (the more tolerant or resistant) helps maintain the abundance of a natural enemy that then differentially affects the second species.

Predation

Disease can affect top predators. For instance, a Scandinavian outbreak of sarcoptic mange (caused by mites) in the late 1970s through the 1980s reduced the density of red fox. Prey (rodents, rabbits, ground birds, deer) increased as a result and then declined after the epidemic waned and fox populations recovered.

The fate of most parasites is tied to that of their hosts. If their hosts die, this is usually a bad thing for host and parasite alike. In nature, parasites are part of nearly every meal. This puts tremendous evolutionary pressure on parasites to survive the ingestion process, particularly if they can relocate in the predator. Perhaps as a result, many parasitic species have complex life cycles where an intermediate host must be eaten by a final host. In such life cycles, the parasite must wait for the consumption of the intermediate host by an appropriate final host. However, not all parasites are patient. Some parasites manipulate the behavior or appearance of the intermediate host to increase the rate at which a predator host will catch and eat it. For instance, in southern California estuaries, the most common trematode, *Euhaplorchis californiensis*, encysts on the brain of killifish; the worms alter the fish's behavior, making it shimmy and swim to the surface. These fish are 10–30 times more likely to be eaten by birds, the final host of the worm. In this system, the worms essentially dictate which fish live and die. They also provide an easy snack for egrets and herons that otherwise might have to work harder for a living. Some mathematical models indicate that such parasite-increased trophic transmission can reduce prey density; it can also increase predator density so long as the energetic costs of parasitism for the predator are not too severe. Other mathematical models suggest that some predators may depend on parasites to supply them with easy prey.

Parasitism

Parasites can interact with each other. Some parasites have parasites (i.e., hyperparasites), while other parasites compete with each other for host resources. For larval trematodes, competition for resources within the snail is intense and trematodes have special

Table 1 Ecological measures of parasitism

Parasite term	*Definition*
Abundance	Parasites per host (whether infected or not)
Aggregation	A statistical measure of the distribution of parasite abundance among hosts
Colonization	The infection of an uninfected host
Component population	All individuals of a specified life history stage at a particular place and time
Density	Parasites per sampling unit (per host, per gram tissue, etc).
Incidence	Rate at which uninfected hosts become infected
Infrapopulation	All individuals of a species of parasites in a single host
Intensity	Parasites per infected host
Prevalence	Proportion or % of hosts infected by a parasite
Suprapopulation	All developmental phases of a species at a particular place and time

Modified from Bush AO, Lafferty KD, Font JM, and Shostak AW (1997) Parasitology meets ecology: Definitions, clarifications, examples and Margolis *et al.* revisited. *The Journal of Parasitology* 83: 575–583.

morphological and behavioral adaptations for interspecific interactions. For example, adding dominant trematode species to ponds can exclude subordinate trematode species. Parasites can interact with the host, often via the immune system, to displace other parasites or alter their pathogenic effects on the host. Despite all the potential for parasite–parasite interactions, few studies have considered what this means at the community level.

Mutualism/Facilitation

Sometimes, by altering their host, parasites can alter communities dependent on these hosts or their actions. In one case, such manipulations can have dramatic and unexpected consequences for communities. The trematode *Curtuteria australis* reduces the ability of cockles to bury into New Zealand mudflats (perhaps this increases an infected clam's vulnerability to predation by final host birds). The shells of infected clams stick up out of the mud and provide a hard substrate for sessile invertebrates, such as limpets, that otherwise could not persist in the soft sediment. Parasites can affect substrate-forming species as well, shifting communities in the opposite direction. For instance, trematodes reduce populations of a tube-building corophiid amphipod, thereby destabilizing the sediment and altering the faunal composition of a Danish mudflat.

Food Web Topology

Many ecologists acknowledge the potential importance of parasites in food webs and advocate their inclusion. Parasites add links and species to food webs (Fig. 1). Like any consumer, this has the potential to change the chain length, linkage density, or connectance of a food web (which may alter stability). But as mentioned above, parasites differ from predators in several ways, the most notable being their intimate association with their prey and their relatively low individual biomass. Although the individual body size of a parasite is very small, parasite abundance can be high, leading to comparable total biomass of parasites and top predators. Relatively little is known about parasites in food webs, but the studies published to date indicate that parasites are likely to be worth including. They may comprise most links in a food web and, at least for generalist species, be more densely linked in webs than predators. It would seem that no food web is complete without parasites.

Ecological Effects on Parasites

Host Diversity

Parasitism has been posited as a factor that promotes biodiversity, but it is equally logical to expect that high host diversity and abundance should promote parasitism. Hosts serve as both habitat and dispersal agents for parasites and an abundance of hosts should lead to an abundance of parasites. Further, because parasites tend to be host specific, increased species heterogeneity of

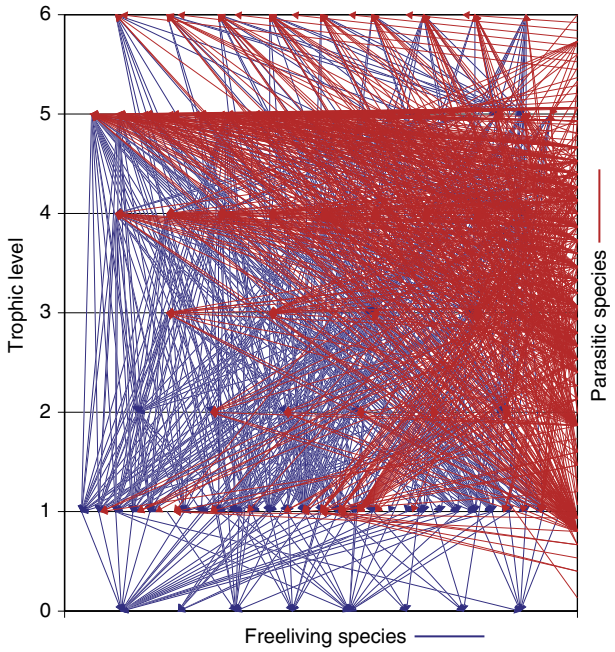

Fig. 1 A food web of Carpinteria Salt Marsh showing predator–prey links in blue and parasite–host links in red.

host communities can facilitate increased species heterogeneity of parasite communities. As a result, a high richness of hosts should contribute to a high richness of parasites. In some cases, parasites may make costeffective bio-indicators of ecosystem health, but here the prediction is counter intuitive – ecosystems with abundant and diverse hosts should support abundant and diverse parasites. There are two exceptions to this prediction. If host abundance decreases because of high diversity, few parasite species may be able to sustain transmission. In addition, if a parasite's vector attacks hosts the parasite cannot develop in, a high diversity of hosts can mean a high probability of contact with non-hosts, thereby diluting transmission.

Environmental Change

Pollutants, malnutrition, and thermal stress due to climate change are all examples of stressors hypothesized to increase individual susceptibility to infectious diseases. This line of thought suggests that parasites should increase in response to environmental stress. For example, intensities or prevalences of ciliates on fish gills increase with oil pollution, pulp mill effluent, industrial effluent, and thermal effluent. This appears to be due to an increase in host susceptibility because toxic conditions impair mucus production which is a fish's main defense against gill parasites.

An opposing prediction generally emerges from considering the population dynamic context of infection. Outside stressors that depress host population density should reduce the chance of an epidemic, or even the ability of a parasite to persist at all, because factors that reduce host density also reduce contact rates between infected and uninfected individuals. Threats to biodiversity, which are generally mediated through reductions in abundance, should indirectly reduce risk to host-specific parasites. By this same reasoning, direct reduction of host density should reduce disease. Culling of seal populations reduces intestinal nematode parasites by reducing host density below transmission thresholds. Fishing can similarly reduce parasites in fish populations and may be responsible for long-term declines in fish parasites in the ocean. For instance, a species of swim bladder nematode was apparently extirpated from native trout in the Great Lakes after a variety of stressors reduced trout populations to very low levels. Alternatively, some stressors may increase parasitism by increasing host density. In particular, the addition of nutrients to aquatic systems increases primary productivity that indirectly increases some grazers and predators. This is probably why the stress most commonly observed to be associated with increased parasitism in fishes and invertebrates is eutrophication.

Stressors may more negatively influence parasites than their hosts. Toxic chemicals and metals have a relatively consistent negative effect across studies of intestinal helminths. Selenium, for example, is more toxic to tapeworms than to their fish hosts. A pollutant may also kill sensitive free-living stages of the parasite. For example, trace metals in sewage-sludge reduce the survival of free-living cercariae and miracidia, leading to a lower trematode prevalence in intermediate-host snails. It is also possible for parasitic infection to make the host more susceptible to toxins. For instance, cadmium is much more toxic to amphipods infected with larval acanthocephalans than uninfected amphipods. While this latter effect decreases the spread of an epidemic through a population, it also increases the impact of disease on infected individuals.

This heterogeneous array of potential effects of stress on infectious disease makes it unclear how a particular stressor should affect the overall course of an epidemic in a host population, or endemic levels of a disease. Although stressed individuals should be more susceptible to infection if exposed, the stressor could simultaneously reduce opportunities for infection because the contact rate between infected and uninfected individuals will decline with the extent that the stressor reduces host density. In addition, populations of some parasites that are directly susceptible to the stressor may not be able to persist at all. It would also appear, *a priori*, that stress can either aggravate or diminish the population-level impact of a host-specific infectious disease organism upon its host.

Philosophy of Ecology: Overview

K deLaplante, Iowa State University, Ames, IA, USA

Introduction

At its most general level, the philosophy of ecology is the philosophical study of (1) ecological phenomena and (2) those disciplines that study ecological phenomena.

This definition has certain virtues, but it lacks content until we specify what we mean by `ecological phenomena' and what sorts of disciplines study such phenomena. The task is complicated by the fact that the term `ecology' is used in different ways in different contexts.

Ecology is of course a science, but ecology is also identified with a broader philosophical and ethical worldview that in various respects predates modern ecological science. In the `romantic ecology' of the nineteenth century associated with writers like Wordsworth, Thoreau, and Emerson, it was associated with a rejection of mechanistic, atomistic, and reductionistic science and philosophy that was believed to be responsible for a variety of human and natural ills. This conception carried over into the `ecology movement' of the 1960s, an environmental movement tied to broader sociocultural movements of that decade (women's liberation, civil rights, and a range of anticonsumerist, anticapitalist, and antimilitarist movements). In recent decades the term has been appropriated by a number of sociopolitical movements and philosophies that seek to diagnose and ameliorate humanity's dysfunctional relationship with nature (deep ecology, social ecology, socialist ecology, ecofeminism, etc.). Do all of these philosophies count as philosophies of ecology? Are they all branches of the philosophy of ecology?

Within academic philosophy, the most common approach to this question tries to draw a distinction between ecological science and the ethical, social, and broader philosophical uses of the term. Proponents of this approach reserve the term `philosophy of ecology' for the philosophical study of ecological science qua science, with a focus on conceptual issues in fields like behavioral ecology, population ecology, community ecology, evolutionary ecology, and ecosystem ecology. On this view, ecology is conceived as a branch of the natural, biological sciences, and the philosophy of ecology as a specialization within the philosophy of science. Though they may occasionally appeal to the ecological sciences for intellectual support for their various philosophical positions, deep ecology, social ecology, and other radical ecophilosophies are regarded as branches of social theory or environmental philosophy, not the philosophy of ecology.

The approach just described has much to recommend it, but the conception of the philosophy of ecology that will be developed in this article takes a somewhat different tack, one that endorses a broader conception of both the domain of ecology and the philosophy of ecology than is commonly found in the literature. This approach views ecology as a discipline that spans both the natural and social/behavioral sciences. Once this broader conception of ecological science is acknowledged, it becomes increasingly difficult to draw sharp lines between philosophical issues raised by ecological science and philosophical issues raised by a broader ecological worldview.

Ecology: The Study of Ecological Phenomena

Ecology is, at its most general level, the study of `ecological phenomena'. This simple definition is more useful than it appears.

First, though it may initially seem vacuous, the definition acquires content when we specify what it is for a phenomenon to be `ecological'. It is a useful exercise because it forces us to consider the `object' of ecological theorizing rather than the specific techniques, theories, or methodologies that characterize particular forms of ecological science. We want to know what it is about a given subject matter that suggests to the investigator that ecological concepts may be appropriately or usefully applied to it in the first place.

Second, the definition allows us to distinguish ecological `science' from other forms of ecological inquiry simply by defining ecological science as `the scientific study of ecological phenomena'. It is important to keep the issue of the scientific status of different forms of ecological inquiry separate from the question of what it is about some phenomenon that motivates an ecological inquiry in the first place.

Third, we can now give a correspondingly straightforward definition of a `philosophy of ecology'. If ecology is the study of ecological phenomena, then a philosophy of ecology is `the ``philosophical'' study of ecological phenomena'. However, this definition fails to capture the second-order character of much philosophical theorizing (thinking about thinking about X); we will also want to talk about the philosophical study `of the study' of ecological phenomena, that is, the philosophical study of `ecology'.

For the remainder of this article we will interpret ecology as ecological science and the philosophy of ecology as the philosophy of ecological science.

 doi:10.1016/B978-0-444-63768-0.00247-X

Two Conceptions of the Domain of Ecology

What Exactly Is the Domain of Ecology?

Among ecologists and philosophers we can distinguish two schools of thought on this question, each motivated by a variety of methodological, institutional, and social factors. There are those who defend a more `restrictive' view of the domain of ecology, and those who endorse a more `expansive' view. The distinction is important as it imposes a corresponding distinction on ways of understanding the philosophy of ecology.

The Restrictive View: Ecology as Natural Biological Science

The more restrictive view of ecological science is the one encountered today in most standard textbooks used to teach ecology, and currently has the status of orthodoxy within academic ecology. This view was strongly influenced by the rise of evolutionary and population ecology in the 1960s and 1970s, which reinforced an organism-centered conception of ecology that focused on demographic properties of populations and communities. It also developed in response to the appropriation of the term `ecology' by the environmental movement during the same period, which pressured ecologists to clarify how ecology differs from a general concern for environmental welfare.

Supporters of the restrictive conception of ecology are inclined to agree with the following claims:

- Ecology is a pluralistic discipline with many subfields, but ultimately it should be understood as a natural (as opposed to social), biological (as opposed to physical) science.
- The ultimate aim of ecology is to explain and predict patterns and changes in the distribution and abundance of organisms. Ecology is, fundamentally, a science of demographic processes. Ecosystem processes acquire their ecological relevance indirectly, in virtue of their impact on demographic properties of ecological systems.
- Ecology focuses on the natural world of plants and animals. Ecology does not study the root causes of human impacts on the environment, or the social ramifications of such impacts. That is the job of the human social sciences and the humanities, and interdisciplinary fields like environmental studies, which should be distinguished from the natural science of ecology.

The Expansive View: Ecology as Synthetic Systems Science

More expansive conceptions of ecology have also been popular, both within and outside academic ecology. Expansive conceptions of ecology flourished during the heyday of ecosystem and systems ecology under the influence of Eugene and Howard Odum (roughly 1950 to late 1970s). Though currently a minority view in mainstream academic ecology, expansionism has seen a resurgence in certain branches of applied ecology (e.g., systems approaches in conservation ecology and ecosystem management), and it has always been a foundational premise of ecological economics and those traditions of human ecology that claim a strong kinship to scientific ecology.

Supporters of a more expansive conception of ecology are likely to agree with the following claims:

- Ecology is a pluralistic discipline with many subfields, and should be understood both as an interdisciplinary science that spans the physical, biological, and social sciences, and as a synthetic science that has as one of its aims to integrate ecologically relevant information from various different spatial and temporal scales and levels of organization, including human social organization.
- The ultimate aim of ecology is to explain and predict properties of living systems (individuals, populations, communities) as functions of their relationships to their various biotic and abiotic environments. These properties include, but are not restricted to, demographic processes concerning abundance and distribution of organisms.
- Human beings are the most ecologically influential species on the planet and human ecology – the study of the ecological dimensions of human nature and human behavior, including the root causes of environmental attitudes and practices – is an important and legitimate branch of ecology.

Though there exists a set of research traditions in sociology that bear the name `human ecology', this expression is better understood as a general umbrella term for a wide range of scientific disciplines that address different aspects of human–environment relations. Human ecology would thus include fields like ecological economics, ecological anthropology, ecological history, and ecological psychology.

The distinction between the restrictive and expansive conceptions of ecology outlined above induces a corresponding distinction between restrictive and expansive conceptions of the philosophy of ecology.

Issues in the Philosophy of Ecology: Restrictive Mode

Philosophy of ecology in its more restrictive mode focuses on philosophical issues in population, community, evolutionary, and ecosystem ecology as these fields are ordinarily represented in the standard textbooks and journals. In this mode, the philosophy

of ecology is generally understood as a specialization within the philosophy of the natural, biological sciences, alongside (and overlapping with) other such specializations, such as the philosophy of evolutionary theory. For the most part, this is how the subject matter of the philosophy of ecology is conceived within the tradition of Anglo-American philosophy of science.

Many of the philosophical issues studied within this mode are better understood by situating them within the context of the broader intellectual debate that has served to structure much of the foundational discourse of ecology in the twentieth century. This is the debate between `holistic' and `reductionistic' research traditions in ecology.

As the story is usually told, holists believe that ecological systems exhibit order, structure, and regularity at population, community, and ecosystem levels of organization, with higher-level properties and regularities both emerging out of and constraining lower-level properties and regularities. Hence, holists believe the search for law-like generalizations governing the behavior of populations, communities, and ecosystems is a reasonable and desirable goal of ecological research, and formal investigations of community and ecosystem structure are a worthwhile – indeed, indispensable – activity. The ecosystem concept has its home within this broadly holistic picture of ecological systems.

Reductionists, on the other hand (as the story goes), believe that ecological systems are nothing more than assemblages of individual species populations whose behavior is determined largely by response to local environmental conditions (both biotic and abiotic). There are no such things as `communities' or `ecosystems' with emergent causal properties of their own; any properties they have are, at best, epiphenomenal statistical properties of the collection of species populations that compose them. The ecological properties of species populations are best understood in evolutionary terms, as products of natural selection and other evolutionary mechanisms. Consequently, reductionists eschew the search for general laws governing large classes of ecological systems, for it is assumed there are none to discover; rather, their focus is on local, historically contingent, site-specific investigations of population behaviors and environmental conditions.

This dualistic narrative, or some variant of it, has provided the motivating context for most of the writings on foundational issues in ecology, from the early decades of the twentieth century through to the present (e.g., the Clements–Gleason debate over the nature of communities and ecological succession). In this context, to engage in the philosophy of ecology is to take up and defend a position on foundational issues that place one somewhere along the spectrum between extreme holism and extreme reductionism.

One can characterize the core issues in the philosophy of ecology in terms of a set of metaphysical and epistemological questions on a handful of key topics:

The metaphysical status of ecological entities. What is a population, a community, an ecosystem? Do ecological entities have emergent properties that play a causal role in determining how ecological systems change over time? Is the concept of a community or an ecosystem even operationally meaningful?

Law-like regularity versus historical contingency. Does ecology have general laws? If so, what are the causal properties of ecological systems that ground these regularities? Is the existence of such laws consistent with neo-Darwinian selection theory operating at the level of individual organisms? At what levels of organization should we expect to see such laws?

The epistemology of modeling. What is the proper role of theoretical models and model-building in ecological science? If models can only give approximate descriptions of real-world ecological systems, how should their predictions be tested and assessed? Should we interpret theoretical models realistically or as mere tools for organizing, explaining, and predicting observable patterns in ecological data?

Model-driven versus data-driven research traditions. Should ecological research focus on empirical case studies of particular ecological systems rather than general model-building? How should we compare the results of controlled ecological experiments with the results of comparative field studies of natural systems? What are the weaknesses and advantages of each approach?

Evolution and ecology. Is natural selection acting at the level of individual organisms sufficient to explain the organization and structure of communities? Do ecosystems coevolve with their component species populations? How, in general, do evolutionary and ecological mechanisms interact?

This list is incomplete, but the majority of philosophers of science who specialize in the philosophy of ecology have research programs that bear directly on some subset of these questions.

Have any consensus views emerged with respect to any of these questions? As with any branch of philosophy it would be overly optimistic to expect consensus on foundational questions. One can, however, identify historical and recent trends in how ecologists and philosophers have viewed these issues. One can say, for example, that the 1950s and 1960s were dominated by holistic approaches in ecology, and there was a high degree of optimism about the prospect of a mature ecological science that could compare favorably with law-governed fields like physics. Opinion swung the other way in the 1970s and 1980s with the rise to dominance of evolutionary and population approaches in ecology, during which period greater emphasis was placed on historically contingent, site-specific features of ecological systems, along with an attending skepticism about laws in ecology and criticism of holistic approaches in ecology generally. Professional philosophers of science have really only started looking at these questions within the last 15 years, but recent work indicates that the pendulum is swinging back to a more intermediate position between the holistic optimism of the 1950s and the reductionistic pessimism of the 1980s.

Issues in the Philosophy of Ecology: Expansive Mode

Those who endorse a more expansive conception of ecological science believe that ecological concepts and theories may be usefully applied to a broader range of phenomena than do defenders of the more restrictive conception. In this section we review two sources of motivation for the expansive conception, and introduce a set of issues for the philosophy of ecology pertaining to each source.

Systems Ecology

One of the sources of motivation for the expansive conception of ecology is reflection on the domain of systems ecology. Systems ecologists use a variety of formal techniques – network theory, information theory, dynamical systems theory, etc. – to describe the structural and dynamical properties of whole ecosystems. But why should systems ecology be associated with the expansive conception of ecology? Is systems ecology not commonly viewed as a branch of traditional ecosystem ecology?

To answer this question it may be useful to distinguish three related types of ecological properties or phenomena:

1. properties of `biological entities' that depend on or make essential reference to relations to environments;
2. properties of `environments' that depend on or make essential reference to relations to biological entities; and
3. properties of the `relations' that obtain `between' biological entities and their environments.

Different research traditions in ecology can be distinguished in part by which of these three categories of ecological phenomena are the main focus of study. Population and community ecology, for example, are organism-centered branches of ecological science that focus on phenomena of type (1). The magnitude and rate of change of properties like population size and density and community composition all depend in various ways on the relationships that the component populations have to their biotic and abiotic environments.

Empirically oriented forms of ecosystem ecology (i.e., biogeochemistry and ecological stoichiometry) tend to focus on phenomena of type (2) involving stocks and flows of biologically relevant elements, nutrients, and minerals. For example, the standing stock of phosphorus in a lake ecosystem is a property of the environment of the lake's biotic community, but its properties depend in part on the biotic activities of this community.

Systems ecology, by contrast, focuses on phenomena of type (3). The nodes of an abstractly defined ecological network are meant to correspond to functionally defined ecological types (predators, filter feeders, deposited detritus, microbiota, etc.), but for the most part the phenomena of interest to systems ecologists are the `network' or `organizational' properties of such systems (e.g., connectance, cycling indices, throughputs, and other measures of network structure and function). Systems ecologists are perhaps better described as `complex systems' ecologists; they seek to describe and explain macro-level patterns in the structure and behavior of ecosystems – patterns, for example, associated with self-organizing processes – that may be characteristic of certain generic classes of complex systems.

A striking feature of such complex systems patterns is that they can often be realized in systems of different kinds (physical, chemical, biological, ecological, etc.). To give just two examples: (1) the same critical point phenomena observed in phase transitions in gases and fluids can be observed in the transition from ferromagnetic to paramagnetic state in magnetic materials; and (2) the same `period-doubling route' to chaotic dynamics has been observed in systems as diverse as fluids, chemical clocks, electrical circuits, lasers, and acoustic systems. These and other complex systems behaviors have the following generic features:

1. The details of the system (those details that would feature in a complete causal-mechanical explanation of the system's behavior) are largely irrelevant for describing the behavior of interest.
2. Many different systems with completely different `micro' details will exhibit identical behavior.

What do fluids, chemical systems, electrical circuits, lasers, and acoustic systems have in common that would explain their common period-doubling route to chaotic dynamics? Whatever it is, it cannot have much to do with the specific material properties of the components that make up these systems. Any explanation must refer to the relational or structural features that the systems have in common – in short, it must abstract away from the `matter' to identify the underlying `form' that is common to all the systems in question.

Theoretical systems ecology looks to discover properties of this type that describe ecological systems, but due to their formal character, they may equally describe properties of neural networks in the brain or human socioeconomic networks. It should not be surprising, then, that systems ecologists have a tendency to speculate on the implications of their work for phenomena in other branches of natural and social science.

Philosophers of ecology have largely ignored systems ecology, an unfortunate situation given the number of interesting philosophical questions that the field raises. For example,

- What precisely does it mean to say that a real-world ecosystem instantiates or exemplifies the organizational properties of a formal ecosystem model?
- How do we know when a real-world system actually instantiates a particular formal model? How can such claims be tested? What evidence would bear on them?

- How do the formal properties of ecological systems (the properties that might be instantiated in many different kinds of systems) interact with the material properties of ecological systems (the properties that are particular to the material constitution of the system in question), to generate observed structural and behavioral patterns?
- Does the existence of formal properties of ecosystems demand a holistic view of ecosystems, or is it compatible with a reductionistic view whereby the properties of the whole are determined by the properties of the component parts?

Human Ecological Sciences

We have already noted a second motivation for an expansive conception of ecological science, namely, the fact that there already exists a variety of ecological sciences that deal with human–environment relations.

There are subdisciplines within traditional ecology, such as human paleoecology and human paleobiology, that focus on human–environment relations in the evolutionary past. These disciplines are components of human origins research, an interdisciplinary field that draws on expertise in anthropology, archeology, and linguistics as well as traditional ecology and biology. Philosophers have taken great interest in human origins research. The field is foundational for human sociobiology and evolutionary psychology, which in turn are foundational for naturalistic theories of cultural evolution, and for a variety of positions in the philosophy of mind, language, and ethics.

There also exist a variety of ecological disciplines that study human–environment relations in the present, such as ecological economics, ecological psychology, ecological anthropology, and ecological sociology. Those who work in these fields usually have disciplinary affiliations in economics, psychology, anthropology, or sociology, rather than biology or ecology, yet it is typical for workers in these nontraditional ecological disciplines to view their field as continuous with a general ecological science of organism–environment relationships.

Note that acknowledging these disciplines as ecological sciences does not imply that they all employ the same scientific methods nor that they are all equally successful as sciences. It implies only that at some level they are part of a common scientific enterprise.

It should be obvious that a philosophy of ecology that includes all these human ecological sciences within its scope will have a correspondingly broader sweep than its more restrictive counterpart, since it self-consciously includes philosophical issues relating to the ecological dimensions of human cognition, human social organization, and human–environment relations more broadly. In this mode, the philosophy of ecology naturally spans both the natural and social sciences, and reaches deeper into the domain of sociopolitical philosophy and ethics than it does in its more restrictive mode.

Consider, for example, philosophical issues in ecological economics. One goal of ecological economics is to devise methods of economic valuation and organization that promote the goals of long-term ecological and economic sustainability. A fundamental challenge of this goal is to provide a meaningful definition of `sustainable' that applies to ecological and economic systems. Research on this question has shown that the concept of sustainability is inherently value-laden, and that one cannot properly address the issue without considering the ethical and sociopolitical consequences of public policies that would operationalize the concept. Evaluating these consequences is, naturally, a task for ethics and sociopolitical philosophy. But if ecological economics is a branch of ecology, and the foundational issues of ecological economics belong to the philosophy of ecology, then the challenge of evaluating the ethical and sociopolitical dimensions of the concept of sustainability also belongs to the philosophy of ecology. Similar reasoning applies to the foundational problems of all the human ecological sciences noted above.

Ecology-the-Science and Ecology-the-Worldview

In the introduction we noted two senses of the term `ecology', one associated with ecology as a natural biological science and the other associated with ecology as a philosophical worldview concerned with human–environment relations in the broadest sense. The dominant tradition in the philosophy of ecology tries to separate these senses as much as possible, restricting the philosophy of ecology to the investigation of foundational issues in ecological science and relegating the ethical, political, and more speculative metaphysical dimensions of the broader ecological worldview to other branches of philosophy. This approach has its merits; it is consistent with the way most professional ecologists understand ecology and it makes more efficient use of the professional division of labor among philosophers.

We also noted, however, that there has been disagreement among ecologists over how to understand the domain of ecology. Some argue for a more restrictive conception of ecology that identifies it with the traditional ecological disciplines taught in natural science departments. Others argue for a more expansive conception that includes the study of human–environment relations. We saw how this expansive conception of ecology draws support from two sources: first, a consideration of the distinctive character of systems ecology; and second, the existence of a variety of human ecological sciences.

If we accept an expansive conception of ecology, do we lose the sharp distinction between ecology-the-science and ecology-the-worldview that was such an attractive feature of the restrictive conception? Yes and no. On the one hand, the philosophy of ecology in its expansive mode will inevitably include questions that address metaphysical, epistemological, and normative issues that are also addressed in more speculative ecological and environmental philosophies. The domains of the philosophy of ecology and environmental philosophy will necessarily overlap.

On the other hand, in demanding that ecology operates as a science that is beholden to the epistemological standards of the scientific disciplines that it encompasses, and not to the presuppositions of any particular philosophical worldview, then ecological science will retain its autonomy and identity as a science. Though their domains may overlap, the methods of empirical science distinguish ecology-the-science from ecology-the-worldview.

Phytosociology

J Dengler, University of Hamburg, Hamburg, Germany

Introduction

Phytosociology is a subset of vegetation science, in which it stands out by focusing on extant (vs. fossil), taxonomic (vs. physiognomic or functional) plant assemblages at the scale of vegetation stands (vs. landscapes or biomes). Its principal goal is the definition and functional characterization of vegetation types based on the total floristic composition of stands. Phytosociology distinguishes between concrete vegetation stand (phytocoenosis), which can be represented by a plot record (relevÅ), and abstract vegetation type (syntaxon), representing a group of all stands sharing certain attributes. The classification framework (syntaxonomy) is designed in close analogy to plant taxonomy, with association as the basic unit.

The fundamental concepts of phytosociology were developed by Josias Braun-Blanquet in the 1920s. He combined a standardized protocol for plot sampling, sorting of species-by-plot matrices, demarcation of community types, and their hierarchical ordering into a practical and efficient framework for the study of vegetation. In this article, we use the term phytosociology for the Braun-Blanquet approach and its modern extensions.

Phytosociology is the mainstream vegetation classification scheme in Europe, as well as in several countries outside Europe, and has become increasingly popular worldwide from the 1990s onward. Within modern ecology, phytosociology represents the most comprehensive and consistent methodology for vegetation classification. RelevÅs are the most widely used standardized protocol for sampling plant species co-occurrences at the stand scale. Being derived from the vast body of relevÅ data, syntaxonomy provides a comprehensive yet open system of vegetation types, which are indispensable in land-use management and nature conservation. Consisting of abundance data on individual plant species, relevÅs and vegetation types organized in large phytosociological databases are an enormous source of fine-scale biodiversity information. If linked to the growing body of plant trait or indicator value data or environmental information in geographical information systems (GISs), phytosociological data open new avenues for exploring large-scale ecological patterns and processes, and provide spatially explicit information necessary for environmental management.

Phytosociological Data

Data Records

In phytosociology, the data of a single plot are called a relevÅ (French for record, see **Table 1**), which consists of `header' and species data. The `header' comprises plot identification, methodological information, and metric, ordinal, or categorical data on geographic position, environmental conditions, and overall vegetation structure. Some of these data are essential, others optional, depending on the purpose and resources of a project (**Table 2**).

The species data are composed of a list of plant taxa (species and infraspecific taxa; further referred to as `species') and their attributes. A full relevÅ lists all plant species occurring in the plot and growing on soil, including bryophytes, lichens, and macroalgae. Additional recording of species growing on substrata other than soil, such as on living plants (epiphytes), rocks (saxicolous plants), or dead wood (lignicolous plants), is desirable, but not standard in phytosociology. Every species observation is assigned to a vertical stratum (e.g., tree layer, shrub layer, herb layer, and cryptogam layer). Woody species occurring in different layers are recorded separately for each layer. For each species observation in a layer, an importance value is estimated and usually expressed on a simplified scale of abundance (number of individuals/ramets) and/or cover (area of the vertical projection of all aerial parts of a species relative to the total plot area) (**Table 3**). As mixed cover-abundance scales pose problems in data analysis, pure cover scales are preferred when precise quantitative estimates are required, for example, in studies of vegetation change in permanent plots. Sometimes, additional characteristics of the species – such as sociability (degree of clustering of the individuals), vitality, fertility, age class (e.g., seedling or juvenile), and phenological status – are recorded, but these are of little or no importance for standard analyses.

Selection and Size of Plots

Plot sites in the field are positioned in vegetation stands that are relatively homogeneous in terms of structure, species composition, and environment, so that variation is minimized within and maximized between plots.

The traditional sampling strategy in phytosociology, preferential sampling, in which the researcher selects stands that are considered as representative of some vegetation units, has several disadvantages: it is not repeatable by other researchers, tends to neglect some vegetation types and oversample others, and produces a nonrepresentative sample of vegetation diversity in the study area. In spite of these disadvantages, probabilistic sampling strategies, such as random or systematic sampling, have never received

2a	Any	5–12.5	5
2b	Any	12.5–25	6
3	Any	25–50	7
4	Any	50–75	8
5	Any	75–100	9

wider acceptance in phytosociology. While providing reliable estimates of vegetation attributes, probabilistic sampling is less suited to phytosociology's goal of representing maximum variation in vegetation diversity across a study area, as it tends to undersample or even miss rare types. GIS and global positioning system (GPS) technology have made stratified-random sampling schemes increasingly popular in phytosociology. Based on the overlay of digital maps in a GIS, the study area can be stratified into patches with certain combinations of land-cover types and environmental variables that are supposed to correlate with plant distribution. Within each of these strata, plot positions are randomly placed and subsequently found in the field with a GPS receiver. A related sampling strategy is a gradient-oriented transect or gradsect, which establishes plot sites along a landscape transect that runs parallel to an important environmental gradient.

Phytosociological plots are usually squares or rectangles, which, as a rule of thumb, are roughly as large in square meters as the vegetation is high in decimeters (e.g., 200 m^2 for a forest of 20 m height). Despite this rule and other suggestions in textbooks, actual plot sizes used may span more than one order of magnitude within the same vegetation type. Standardization of plot sizes is hindered by the vague and misleading concept of `minimal area', which is thought to be a certain plot size specific for each vegetation type, beyond which any further enlargement has negligible effects on species richness and composition. However, plot size strongly influences estimates of species richness and other vegetation parameters. Joint use of differently sized relevÅs in a single analysis may thus produce artifacts in classification, ordination, and calculation of fidelity of species to vegetation units. To safeguard data compatibility, standard plot sizes have been proposed for use within certain structural formations, for example, 200 m^2 in forest vegetation; 50 m^2 in scrub vegetation; 16 m^2 in grassland, heathland, and other herbaceous vegetation; and 4 m^2 in aquatic and low-growing herbaceous vegetation.

Vegetation Databanks

Phytosociology has a long tradition of publishing, archiving, and re-analyzing relevÅs as its basic primary data. Many phytosociological journals print full tables including all relevant relevÅs, thus making data accessible for future compilation and analysis, which was

traditionally performed as synoptic tables on paper. The limitations of manual data management were overcome by using table editing and databank software, which allows seizing, storing, managing, filtering, and analyzing relevÅ data in multiple ways.

Compilation in a databank requires that all information obeys stringent formal and technical rules laid down in reference lists, meta-data and data models. Databanks of different formats and complexity were established, ranging from simple spreadsheets to relational and object-based data models that allow flexible definitions and comprehensive documentation of meta-data. Simple databanks are able to exchange data freely if the same standards, database formats, definitions, and reference lists are used. The success of phytosociological databanks is so far due to rather simple management software packages such as TURBOVEG, which is currently the most widespread program in Europe and beyond, distributed free of charge or at small cost along with taxonomic reference lists and tools to create, edit, and analyze phytosociological tables.

While early databank development revolved around fixing standards for data types and references for plant taxon concepts and names, modern ecoinformatics provides tools to exchange data of different formats and taxonomic reference and, ultimately, link up databanks of any format in networks. Rather than enforcing standard formats, these systems require that data are recovered and stored with as much original information as possible, including meta-data on sampling design and methods, cover-abundance scales, definition of layers, taxonomic references, and original data sources.

Classification of Vegetation

Aims and Criteria

Vegetation classifications are performed with three fundamental goals: (1) delimiting and naming parts of the vegetation continuum to enable communication about them; (2) predicting a multitude of ecosystem attributes (e.g., species composition, site conditions, and ecological processes) from the assignment of a particular stand to a vegetation unit; and (3) making multi-species co-occurrence patterns representable by verbal descriptions, tables, diagrams, and maps. Floristically defined vegetation types are thus suitable reference entities for ecological research, bioindication, and nature conservation.

Reaching these aims requires of the classification approach:

1. coherence of units with respect to major ecosystem properties;
2. simple and clear discernability of units;
3. completeness of the system (i.e., coverage of all vegetation types of the given area);
4. robustness (i.e., minor changes of the data should not considerably change the classification);
5. tolerance against varying data quality;
6. supra-regional applicability;
7. applicability for a range of different purposes;
8. hierarchical structure, allowing for different degrees of generalization;
9. equivalence of units of the same hierarchical level; and
10. adequate number of units with respect to practical use.

As no single classification can ideally meet all of these criteria at the same time, and their relative importance depends on the purposes, competing classifications of the same objects and data are a reality. Thus, the interpretation of local data will change with scaling up from local to regional and supra-regional context. However, there is also a practical requirement to have a unified supra-regional classification to enable communication among scientists, managers, and authorities between regions.

Braun-Blanquet Approach

The `Braun-Blanquet approach' provides a methodological framework for vegetation classification that seeks an optimal combination of the above criteria and that reconciles conflicting requirements of different scales and purposes. However, it is not an unambiguous and uniform set of recipes, and it has been subject to diverse modifications. Despite the variety of different versions, practitioners agree on certain fundamentals, which distinguish the Braun-Blanquet approach from most other ways of vegetation classification: (1) The classification is based on the (total) species composition of the sample plots (floristic–sociological method), whereas structural or environmental criteria play a subordinate role. (2) The classification units called syntaxa (singular: syntaxon) are arranged into a hierarchical system according to their floristic similarity. The principal ranks of this system are, from bottom up, association, alliance, order, and class. (3) There are generally accepted rules for the scientific naming of syntaxa (see the section entitled `Phytosociological ranks and nomenclature').

Within the Braun-Blanquet approach, the concept of character and differential species is important for the recognition of previously defined syntaxa. Differential species are those that positively differentiate, by their occurrence, the target syntaxon from other syntaxa. Character species are a special case of differential species: they positively differentiate the target syntaxon from all other syntaxa. The differential and character species combined are called diagnostic species. The validity of diagnostic species may be restricted to comparisons within the syntaxon of the next higher rank or within a physiognomic vegetation type. Diagnostic species are based on the concept of fidelity, that is, concentration of their occurrence or abundance within the given syntaxon. Traditionally, arbitrary measures of fidelity were used, such as constancy in the target syntaxon had to be at least twice as high as in

any other syntaxon. Nowadays, statistical fidelity measures are increasingly used (see the section entitled `Numerical approaches'). However, in spite of several attempts at a formal definition of differential and character species, no widely accepted agreement in this respect has been reached so far.

Phytosociology faces difficulties in the classification of vegetation types that lack species of narrow ecological amplitude which could be used as character species of the respective syntaxa. This problem led early practitioners to avoid stands without specialist species as `atypical' and `fragmentary' and oversample those containing presumed character species. Even when sampled and recognized, such poorly characterized vegetation types were often excluded from the syntaxonomic system. Vegetation types poor in diagnostic species may be incorporated into the system in several ways, for example: (1) Deductive classification affiliates such units as so-called basal or derivative communities to higher syntaxa of the system, from which their formal names are derived (e.g., *Elymus repens* [*Artemisietea vulgaris*] derivative community). (2) According to the concept of central syntaxon, there can be one negatively differentiated syntaxon within the next superior syntaxon of the hierarchy; central syntaxa have the same ranks (e.g., association) and nomenclature as normal syntaxa.

This diversity of approaches within the Braun-Blanquet system must be unified where all vegetation types of a large area are to be placed in a single coherent system, such as in modern projects of national vegetation classifications. These projects have usually developed consistent systems of standardized and operational methodology of vegetation classification based on the Braun-Blanquet approach.

Numerical Approaches

Traditional phytosociological work was based on the subjective delimitation of vegetation units, made either already during the field reconnaissance and sampling or in the process of manual sorting of relevÅs and species within tables. The need for more formal, transparent, efficient, and repeatable classification procedures led to the introduction of numerical classification methods in phytosociology since the 1960s. They can be either agglomerative or divisive. Agglomerative methods start with linking individual relevÅs based on the similarity of their species composition, forming relevÅ clusters and subsequently linking these clusters to form a hierarchical classification, usually presented as a dendrogram. Divisive methods start with dividing the set of relevÅs into subsets, which are further divided into subsets on a lower hierarchical level, thus eventually proceeding to the single relevÅs. The most popular divisive method is two-way indicator species analysis (TWINSPAN), which uses the ordination method of correspondence analysis to divide the relevÅs into subsets. Simultaneously with the classification of relevÅs, TWINSPAN classifies species, and produces an ordered species-by-relevÅ table similar to that used in traditional phytosociology (see the section entitled `Phytosociological tables'). The classifications of the same data sets produced by agglomarative clustering and TWINSPAN usually roughly correspond but differ in details. Agglomerative clustering is the method of choice when cluster homogeneity is the principal goal, while TWINSPAN better reflects the main gradients in species composition of the input data set. An important choice in any numerical procedure is the transformation of cover-abundance data, which determines to what degree species cover-abundance will be accounted for in the analysis.

In addition to numerical classification, phytosociology frequently uses various ordination methods, such as correspondence analysis (CA), detrended correspondence analysis (DCA), or principal components analysis (PCA). Sometimes, ordination and classification are perceived as antagonististic approaches, representing the Gleasonian continuum concept and the Clementsian concept of superorganism, respectively. However, phytosociologists never engaged in that ideological debate, and nowadays both approaches seem to be reconciled: classification studies often use ordination to visualize the position of vegetation units along gradients, and ordination patterns are used to propose the delimitation of relevÅ groups for certain purposes.

Applicability of an established classification crucially depends on finding those species that are typical of relevÅ groups (vegetation units) and make them recognizable by simple floristic criteria. Such species may include the most frequent species, dominant species, or diagnostic species. The former two groups of species can be easily defined by setting some threshold of constancy or cover-abundance values that a species must exceed to be considered as frequent (constant) or dominant, respectively. Diagnostic species are determined based on the concept of fidelity, which quantifies the degree of concentration of a species' occurrence or abundance in the relevÅs of the target vegetation unit. If a species occurs mainly in the relevÅs of the target vegetation unit while it is largely absent elsewhere, it is considered as faithful to this vegetation unit. Fidelity can be quantified by various statistical measures. If it is based on species presence/absence, various measures of association between categorical variables can be used, for example, chi-square, G statistic, or phi coefficient of association. Some fidelity measures have also been proposed to deal with cover-abundances, for example, the Dufrêne–Legendre indicator value. The properties of different fidelity measures vary slightly, for example, with respect to the weight given to rare or common species. Statistical significance of fidelity can be either derived directly from the values of some of these measures or determined by a separate procedure such as permutation test. Apart from the selection of the appropriate fidelity measure, fidelity can be measured in two different ways. First, species occurrence in the target group of relevÅs can be compared with all the relevÅs in the data set that do not belong to the target group, irrespective of the divisions of the rest of the data set. Second, species frequency in that group of relevÅs where it is most common is compared with its frequency in the group where this species is the second most common. In both cases, some arbitrary threshold fidelity value is selected and species that exceed this value are considered as diagnostic. The first approach is not affected by the divisions of the data set outside the target vegetation unit, thus yielding a more general result, whereas the latter approach is only valid in the context of a given table or classification, but it provides a clearer separation of vegetation units through diagnostic species within this table or classification. The results of both approaches depend on the geographical extent, sampling design, and delimitation of the available set of relevÅs, the `universe of investigation'.

Integrating the Different Approaches

While having the basic aims in common, the traditional Braun-Blanquet approach and numerical approaches differ in some respects. Indeed, no approach produces an objective or `the correct' classification. In spite of the high degree of formalization involved in numerical classification, the numerous choices concerning the data set composition, cover-abundance transformation, numerical coefficients, classification algorithms, or number of vegetation units to be accepted result in the fact that numerical methods, like the traditional expert-based approaches, may suggest many different partitions of the same data.

Unlike the expert-based classifications, which often use unclear classification criteria, numerical classification methods consistently use explicit information on species occurrence and cover-abundance and apply it consistently across vegetation types. However, while experts often implicitly incorporate in the classification process knowledge of species behavior in a broad geographical and environmental range, numerical methods only use information contained in the particular data set, which often results in rather idiosyncratic classifications. It is therefore difficult to combine different numerical classifications into a single system of syntaxa, which would be valid over large areas and different habitats, without relying on expert judgment.

To avoid these problems, supervised classification methods have gained importance recently. They take traditional syntaxa that are widely recognized by phytosociologists as given and assign new relevÅs to these syntaxa by numerical procedures. Such an approach supports both the stability of the traditional phytosociological system, which has already received wide acceptance, and the application of formal, unequivocal classification procedures. A simple approach is to calculate an index of similarity of species composition between new relevÅs and constancy columns of synoptic tables (see the section entitled `Phytosociological tables') that summarize the traditional classification and subsequent matching of each new relevÅ to the vegetation unit to which it has the highest similarity. More sophisticated methods of supervised classification include quadratic discriminant analysis, multinomial log-linear regression, classification trees, and artificial neural networks. The latter, for example, can establish a classifier based on the previous knowledge of what the relevÅs belonging to a certain vegetation unit look like. When new relevÅs are submitted, the classifier assigns them, with some degree of uncertainty, to the correct vegetation unit.

Another method of supervised classification is COCKTAIL, which was specifically designed to imitate traditional Braun-Blanquet classification. It uses the external information on species behavior, extracted from large phytosociological databases, and forms sociological groups of species with statistical tendency of co-occurrence in the relevÅs of the database. Then, unequivocal definitions of syntaxa are created that involve decision rules, postulating which of the sociological species groups must be present or absent for a particular relevÅ to be assigned to the target syntaxon. COCKTAIL definitions can be created to fit the meaning of the syntaxa of traditional phytosociology. In such a way, traditional syntaxa can be defined formally and applied in the computer expert systems, which automatically assign newly encountered relevÅs to syntaxa.

Phytosociological Tables

In phytosociology, original data and classification results are presented as tables of species by relevÅs or community types. There are two types of phytosociological tables, relevÅ tables (**Table 4(a)**) and synoptic tables (**Table 4(b)**). In both cases, species are listed in the lines and relevÅs (in relevÅ tables) or combined groups of relevÅs (in synoptic tables) in the columns.

Both types of tables are normally presented in a structured manner. Lines and columns are arranged in such a way that `species blocks' (i.e., groups of nonempty table cells) form more or less a diagonal from the top left to the bottom right. Therefore, the diagnostic species corresponding to the syntaxa ordered from left to right are to be found from top downward (except for the negatively differentiated syntaxa). In tables representing multi-layered woody vegetation, plant species of upper layers are normally listed at the top of the table to give an impression of stand structure. At the bottom of the table, those species are listed that have no diagnostic value within the respective table. These may be diagnostic species of superior syntaxa or `companions', that is, species that have no diagnostic value for any syntaxon included in the table. Within blocks, species are sorted by decreasing constancy or decreasing fidelity. Species blocks or individual diagnostic species can be highlighted by frames or shadings in the tables; the criteria for doing so are related to species fidelity to syntaxa and should be clearly defined in particular studies.

In synoptic tables, all relevÅs assigned to the same vegetation unit are represented by a single column with constancy values (i.e., the percentage proportion of relevÅs in which the species is present). Constancy values are often presented as classes indicated by Roman numerals (I: 1–20%; II: 21–40%; …; V: 81–100%), but the use of percentages has several advantages, for example, it does allow the application of modern fidelity concepts and merging of different synoptic tables without loss of accuracy. In addition to the constancy values, medians or ranges of the cover-abundance values or fidelity levels may be indicated. It is important to note (though long-neglected in phytosociology) that the calculation and comparison of constancy values does only make sense for plots of the same or similar size, because constancy values are strongly influenced by plot size.

Phytosociological Ranks and Nomenclature

Abstract vegetation units defined by floristic–sociological criteria are termed syntaxa. They are positioned in a hierarchy of different ranks (**Table 5**), which is meant to make the multitude of units manageable and offers the opportunity to vary the conceptual resolution of analysis, maps, and graphs. The association is considered as the basic unit, comparable to species in taxonomy. Ranks below the association level are often used to express edaphic (subassociations and variants), climatic (altitudinal forms), geographic (vicariants or races), structural (facies of dominant species), and successional variation (phases).

Table 4 (a) Worked example (I): RelevÅ table containing three associations of three alliances and two classes of the subalpine heathland and grassland vegetation of the Czech Republic (see **Table 6** for their position in the syntaxonomic hierarchy). Species of the cryptogam layer are marked with `C', the other species belong to the herb layer. Blocks of diagnostic species are shaded. Within blocks, diagnostic species are ranked by decreasing fidelity to the given syntaxon. Fidelity was measured with the phi coefficient of association and was based on the comparison of species occurrences within the syntaxa of this table only; species with $\phi > 0.25$ were considered as diagnostic. As each association belongs to a different alliance, diagnostic species of the associations can be partly considered as diagnostic of the alliances. Companion species are ranked by decreasing constancy within the entire table. Data were taken from the Czech National Phytosociological Database. Species occurring in a single relevÅ are not shown. (b) Worked example (II): Synoptic table based on the same data as **Table 4a**. The numbers in the table are percentage constancies

      Association: *Carici bigelowii-Nardetum strictae* (Zlatník 1928) Jeník 1961

Like other fields of biological systematics, syntaxonomy is an open-ended process that is carried out by a large community of independent researchers and requires unequivocal rules for naming classification units. Therefore, the Nomenclature Commission of the International Association for Vegetation Science (IAVS) and the FÅderation Internationale de Phytosociologie (FIP) have established the International Code of Phytosociological Nomenclature (ICPN), similar to the nomenclature codes used in botanical and zoological taxonomy.

The ICPN regulates the scientific nomenclature of four principal and four supplementary ranks of syntaxa. Neither synusial nor symphytosociological units (see the section entitled `Symphytosociological approaches'), nor informally named syntaxa (e.g., *Elymus repens* community) fall under the ICPN. The ICPN provides precise instructions for the formation of syntaxon names, their valid publication, and the decision about which of several available names from the earlier literature to apply. According to the ICPN, every syntaxon of a certain circumscription and rank has only one correct name. However, the ICPN only regulates the nomenclature and does not define rules for proper delimitation and classification of syntaxa. Aiming to provide unambiguity and stability of syntaxon names, the ICPN is based on two major principles: (1) among several names for a syntaxon, the oldest valid (published) name is the correct one (priority); (2) each syntaxon name is connected to a nomenclatural type (a single relevÅ for associations, a validly described lower-rank syntaxon for higher syntaxa), which determines the usage of the name when this syntaxon is split off, merged with others, or otherwise changed in its delimitation.

Syntaxon names are formed of the scientific names of one or two (in the case of subassociations, up to three) plant species or infraspecific taxa, which usually are, but need not be, characteristic in the respective vegetation type. The formation of the scientific syntaxon names involves connecting vowels, the declination of the taxon epithets, and addition of terminations indicating syntaxonomic rank (Table 5). An `author citation' (i.e., the author(s) and year of the first valid publication) also forms part of the complete syntaxon name (see Table 6).

Other Levels of Classification

Synusial approaches

While phytosociological classifications are usually based on all plant species occurring in vegetation stands, for some purposes sampling may be restricted to certain taxonomic, functional, or structural parts of these. Abstract types of such partial communities are called synusiae (singular: synusia) in order to differentiate them from normal community types (syntaxa) (Table 7). Synusiae include plant assemblages of horizontally differentiated microhabitats within larger vegetation stands, of vertical vegetation layers, and of seasonally separated phenological phases. Epiphytic cryptogams inhabiting tree bark are a typical example of a synusia, which is recorded in small plots with cover projection estimated perpendicular to the substrate surface. Synusiae should be placed in a separate hierarchical system with ranks of their own and the union as its basic unit. However, many studies of partial

Table 7 Levels of classification from synusial phytosociology to sigmasociology

Concrete object	*Elements recorded in relevés*	*Abstract type*
Partial vegetation stand (e.g., layer)	Species	Synusia
Vegetation stand (phytocoenosis)	Species	Syntaxon
Vegetation stand (phytocoenosis)	Synusiae	Coenotaxon
Vegetation mosaic (tesela)	Syntaxa or coenotaxa	Sigmataxon
Landscape mosaic (catena)	Sigmataxa	Geosigmataxon

communities place their units in the system of syntaxa, leading to the ambiguous situation that the same name can refer to both a synusia and a syntaxon.

Symphytosociological approaches

While plant communities and partial communities are assemblages of plant species and their individuals, symphytosociological units are assembled of synusiae or syntaxa (Table 7) and represent a coarser view of community diversity. Sampling and classification basically follow the phytosociological method, but use synusiae or syntaxa (fine-scale vegetation types) instead of plant species as objects of observation. Two major concepts fall in this category and may be combined: (1) `Integrated synusial phytosociology' of some French authors classifies separate `associations' for tree, shrub, herb, and cryptogam layers, which in the normal terminology would be synusiae. These `associations' are recorded in relevÅs of entire stands, analyzed like species in normal phytosociological tables, and such relevÅs are then classified to form so-called coenotaxa. (2) Sigmasociology records syntaxa (or coenotaxa) in large relevÅs of uniform macrotopography, substrate, and climate (tesela), which are tabulated and classified to form sigmataxa, which at a yet coarser scale (catena) become the elements of landscape units called geosigmataxa.

Applied Phytosociology

Ecological Assessment

The study of species–environment and community–environment relations is the key to the functional interpretation of plant communities and to applications of phytosociology in bioindication and predictive modeling. Since the time of Braun-Blanquet, many relevÅs have been made in conjunction with measurements of soil, topographic, and climate variables. If relevÅ coordinates are known, environmental variables can also be *post hoc* read from maps or modeled from geodata. Environmental data are of multivariate nature, which requires condensing their information content and choosing the most meaningful variables. As in species-by-relevÅ matrices, the dimensions of environmental variation can be reduced by extracting continuous gradients (ecological factors) or by forming clusters (site types). Relationships with the environment can be established for community types or species.

While often restricted to verbal descriptions and simple outlines of schematic correspondences (e.g., vegetation type–soil type) in early phytosociology, vegetation type–environment relationships are nowadays studied based on measured variables. These data enable to establish environmental envelopes, which define the possible occurrence of each vegetation type in ecological space. The overall significance of environmental differentiation between types can be tested, for example, by nonparametric permutation procedures (MRPPs).

There is a long tradition in phytosociology of defining ecological groups of species that exhibit similar behavior along gradients and represent species of similar realized niche (`ecological amplitude') rather than fundamental niche (`physiological amplitude'). Such groups are mainly based on expert knowledge and are only partly calibrated on independent measurements of environmental variables. Also, the derivation of ecological indicator values of plant species strongly relies on phytosociological descriptions of vegetation patterns, from which the principal ecological gradients are extracted. While separate species group systems and indicator value systems have been devised for vegetation of arable fields, grasslands, and forests, Heinz Ellenberg created a general, semi-quantitative system of indicator values for the central European flora, in which most species of vascular plants, bryophytes, and lichens are assigned a value on an ordinal scale, ranging from 1 to 9 and representing the estimated ecological optimum with respect to the principal factors light, temperature, continentality, moisture, soil reaction, nutrient availability, and salinity. Being unique in summarizing the niches of an entire flora, Ellenberg values are widely used for calibrating ecological conditions based on plant communities. The concept of plant indicator values has been recently adapted for use beyond central Europe.

Vegetation Maps

Information on spatial distribution of syntaxa is often summarized in vegetation maps. Maps of actual vegetation show the current distribution of vegetation types in a given area, usually in small areas of particular interest, such as nature reserves. Fine-scale mapping of actual vegetation requires operational definitions of syntaxon boundaries and their differential floristic and structural features, which are laid down in detailed mapping keys.

For mapping larger areas, the concept of potential natural vegetation (PNV) is often used. PNV is hypothetical vegetation that would exist at certain sites under current site conditions and current climate, provided the vegetation is not disturbed by humans

and is allowed to develop into equilibrium with the prevailing site conditions. Being based on the knowledge of the relationship between habitat and natural vegetation, PNV maps implicitly or explicitly rely on models, which can take different forms. Traditional phytosociology establishes the correspondence between actual (e.g., certain meadow or weed communities) and natural vegetation (e.g., certain forest types), and maps PNV units by interpreting actual vegetation. More modern PNV models are calibrated from joint descriptions of vegetation and site conditions of remnant natural stands, and use combinations of site conditions to extrapolate natural vegetation for any point in the landscape. Process-based models predict the outcome of competition between the dominant plant species, but have so far rarely been used to construct PNV maps.

While maps of actual or potential vegetation provide full coverage of a study area and its vegetation units, selective maps show the distribution of certain syntaxa, based on the available relevÅs. They can be presented as dot maps of exact plot positions or as grid maps, indicating presence or absence of the syntaxon in grid cells. As, however, information on distribution of syntaxa is often less comprehensive than on plant species, the potential range of a syntaxon can be modeled by superimposing distribution maps of its diagnostic species. The more the number of these co-occur in a certain area, the higher the probability to find the respective community type there. Models of potential syntaxon ranges can be based on outline or grid maps and on simple or weighted sums of species, but the prediction value is best for high-resolution grid maps where the contribution of diagnostic species to the prediction of a syntaxon is weighted by their fidelity to the latter.

Spatial models of syntaxon distribution can also be based on the knowledge of the relationships between environmental variables (including land use) and syntaxon occurrence. If digital maps of environmental factors and landscape structures relevant to plant distribution are available, the model can be made with the probability of syntaxon occurrence as a response variable and a set of landscape variables as predictors. The relevant environmental maps are then overlaid in a GIS and the probabilities of syntaxon occurrence predicted by the model are mapped.

Monitoring Temporal Change

As spatially and temporally explicit, detailed representations of vegetation, phytosociological relevÅs and maps are appropriate tools for monitoring change in plant species composition and the underlying environmental conditions. Thus, fine-scale monitoring systems in agriculture, forestry, nature conservation, and civil engineering have used repeated phytosociological relevÅs at permanently marked locations over many decades, which allow us to analyze trends in diversity of species and species groups (such as Ellenberg indicators or plant functional types). Besides detecting gradual changes, phytosociology expresses succession as a change of community types. Where many permanent plots conform to the same rules, succession can be generalized into temporal gradients and/or sequences of community types (seres). However, many phytosociological succession models have been based on comparative observation (space-for-time substitution) rather than real time series. Larger groups of old relevÅs without permanent marking are sometimes used to detect succesional trends by making new relevÅs in the supposed old positions (`quasi-permanent plots') and by detecting systematic differences between old and new data.

Repeated mapping may reveal changes in the spatial delimitation of vegetation units and allow representation of succession in a transition matrix. However, its validity crucially depends on fully operational mapping keys that unequivocally define the criteria for drawing boundaries between types.

Nature Conservation

The conservation of species depends on the maintenance of their habitats. Habitat classifications can be founded on structural or abiotic features, but they are often based on syntaxa, conveying a summary of ecosystem properties that are difficult to measure or model. Preserving the diversity of extant plant communities is thought to safeguard the survival of typical species not only of plants, but also of animals, fungi, and microorganisms, and the maintenance of current ecosystem processes.

In Europe, phytosociological units were important in defining habitats (biotopes) in the CORINE and EUNIS systems, which contain a comprehensive classification of European habitats. The CORINE classification provided the basis for inclusion of habitat types under the Habitats Directive of the European Union, the most powerful legislative instrument for nature conservation in Europe. In the Union-wide conservation network Natura 2000, phytosociologically defined habitat types are crucial for the delimitation, inventory, monitoring, and management of protected areas.

In landscape planning and policy making, phytosociological units are used to underpin normative judgments and set conservation priorities by evaluating their naturalness and endangerment. Naturalness, or its reciprocal concept, hemeroby, ranks communities by the strength of human influence and consequent alterations of species composition, structure, and ecological processes. Methodologies range from assigning community types to classes of naturalness to complex evaluation schemes taking detailed account of community features.

Reporting the degree of threat to the habitats of a region, red lists of plant communities are another potentially powerful policy tool in nature conservation. Compilation of red lists presupposes a comprehensive and well-established phytosociological classification for the target region, including detailed knowledge about distribution, commonness, and temporal trends of syntaxa. With the advent of phytosociological databanks and GIS, red list compilation is moving from pure expert judgment to a process driven by relevÅ data and rule-based decisions on the vulnerability and conservation value of plant communities. While vulnerability considers current distribution, quantitative development in the past, and foreseeable threats in the future, conservation

value may be based on the frequency and status of component red-listed plant species, naturalness of the inhabited sites, and responsibility of the target region for the global preservation of a syntaxon. The combination of vulnerability and conservation value may be used to set reasonable priorities for conservation measures.

Introduction

Three fundamental properties differentiate the ecology of plants and animals: resource use, mobility, and patterns of growth. Plants are photoautotrophic (except for parasitic species), gaining energy solely from light, and take up essential nutrients (e.g., nitrogen) mostly in inorganic forms. Plants are sessile, lacking mobility. Finally, plants exhibit indeterminate, modular growth, meaning that they continue to grow their entire life span, and do so via expansion of modules (e.g., roots, stems, leaves) that often operate independent of each other. Individual plant success is dependent upon its arrival as a seed (or some vegetative propagule, such as a rhizome) at a suitable location and upon its ability to occupy that site and tolerate local conditions of the environment. Avoidance of predation (herbivory) by plants is dependent upon mechanical, chemical, and life cycle characteristics. In contrast, animals get their energy from other organisms, move within and between habitats to maintain a suitable habitat and, in addition to mechanical and chemical deterrence, depend upon behavior for predator avoidance as well as for mating. In addition, being sessile means plants must obtain light energy for photosynthesis by producing organs with a large surface area to volume ratio, such as occurs with leaves, to harvest light energy, and extensive root systems with which to withdraw water and nutrients from the soil. In contrast, animals have a relatively small surface area to volume ratio, and internalize their absorptive tissues within their bodies through extensive folding (i.e., intestinal villi, alveoli in lungs), where they are protected against the vicissitudes of the environment, such as desiccation and wind.

Plants have specific environmental requirements. For example, they require light, nutrients, water, carbon dioxide, and oxygen. Each of these is a resource needed for growth, survival (maintenance), and reproduction. Acquisition of resources, along with variation in availability of these resources determine the presence or absence of plants at specific sites. Additionally, tolerance ranges of plants to environmental variables such as temperature, wind, physical soil properties, soil pH, fire, salinity, atmospheric humidity, and the presence or absence of herbivores and dispersers all affect the ability of plants to colonize and utilize the resources at a site. It is often the extremes of these factors, such as record low or high temperatures or early and late frosts, that determine the persistence of a plant in a particular habitat, and not the average or range of values. It may only take one cold snap to extirpate a species from an area, whereas a species might persist for many years even if the optimal level of resources is reduced, but not by enough to cause death. Finally, resources are dispersed over time and space, which provide additional niche dimensions in which plants are found.

This entry will examine the properties of the principal resources of plants, the factors affecting the availability of resources to plants, and the response of plants to these variations. Finally, how these resources influence the interactions of plants to form dynamic biotic communities will be discussed.

Plant Life History Traits and the Principle of Allocation

Virtually all organisms are limited in their access to essential resources, especially energy, regardless of form, and plants are no exception. The principle of allocation states that organisms have limited resources to allocate to three main functions required for success of a species: growth, survival (maintenance), and reproduction. The wide variety of life history patterns among plants (e.g., annuals, biennials, perennials) is the result of evolution selecting for optimal allocation of essential resources. Annual plants (e.g., crabgrass) initially allocate resources to growth, but only long enough to produce flowers and seeds, after which essentially all resources are allocated toward reproduction. In sharp contrast, long-lived perennials (e.g., oak trees) allocate more resources toward maintenance (consider their large woody stem), with allocation toward reproduction confined mostly to growing seasons with high resource availability (Fig. 1).

Light

Light is the energy resource of plants captured through the process of photosynthesis, but it also affects plants in myriad other ways. The light used in photosynthesis is roughly comparable to the visible portion of the spectrum for humans (i.e., from 400 nm, the blue wavelengths, up to 700 nm, the red wavelengths) and is expressed as the *photosynthetic photon flux density* (*PPFD*) in units of μmol photons m^{-2} s^{-1}. PPFD at sea level on a bright summer day is approximately 2000 μmol photons m^{-2} s^{-1}. Alternatively, beneath a forest canopy the PPFD can range from a low of only 5 up to 200 μmol photons m^{-2} s^{-1} (0.3%–10% of full sunlight) although in most forests it tends to be less than 140 μmol photons m^{-2} s^{-1} (7% of full sunlight). Most plants reach their maximum photosynthetic rates at PPFDs between 150 and 600 μmol photons m^{-2} s^{-1} although some plants, especially certain grasses like *Zea mays* (corn) do not saturate even at full sunlight. Shade plants tend to saturate at lower PPFD than do sun plants, which is one factor contributing to their ability to persist in deep shade.

At lower irradiances, light is limiting to photosynthesis and plant growth. Plant species with high irradiance requirements are called *sun plants*, while those with lower light requirements are shade plants. Sun plants photosynthesize at greater rates in high light, but are often unable to maintain themselves under low-light environments. Conversely, *shade plants* do well in low light, but can be

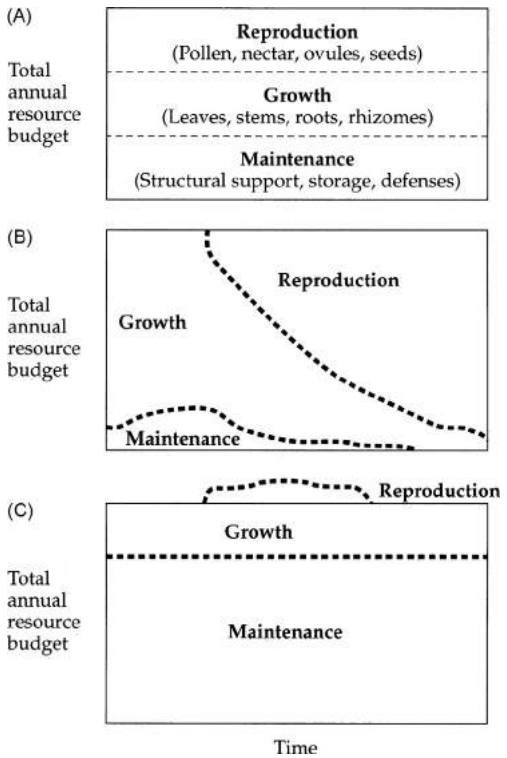

Fig. 1 Three patterns of life history among flowering plants illustrating variation in allocation of resources toward basic plant functions of reproduction, growth, and maintenance. (A) A hypothetical situation wherein allocation is equal to all three; (B) an annual plant with allocation initially toward growth, followed by reproduction; (C) long-lived perennial (i.e., tree) with disproportionate allocation of resources chronically toward maintenance, with allocation toward reproduction confined to periods of high resource availability. Redrawn from Barbour, M.G., Burk, J.H., Pitts, W.D., Gilliam, F.S., and Schwartz, M.S. (1999). *Terrestrial Plant Ecology*, 3rd edn., Menlo Park, CA: Addison Wesley Longman, Inc.

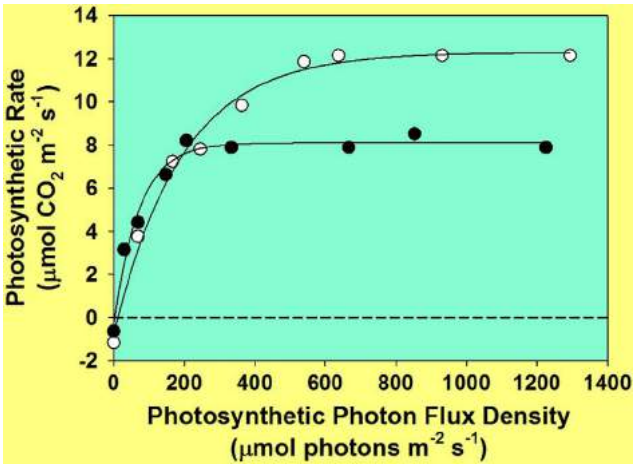

Fig. 2 Curves of net photosynthesis (PS_{net}) as a function of light intensity (PPFD) for a sun plant (*Helianthus annuus*, sunflower, open symbols) and a shade plant (*Oxalis rubra*, wood sorrel, filled symbols). Positive values for PS_{net} indicate uptake of CO_2 into the leaf, whereas negative values indicate release of CO_2 from the leaf, such as would occur if the leaf was only respiring (e.g., in the dark). Net photosynthesis is simply the difference between uptake (gross photosynthesis, PS_{gross}) and respiration (R): $PS_{net} = PS_{gross} - R$. The dashed line at zero photosynthesis indicates when $PS_{gross} = R$. Sun plants have higher maximum rates of PS_{net} in high PPFD, and greater rates of R in the dark than shade plants. However, shade plants often have higher quantum efficiencies at low light as indicated by a steeper slope of the photosynthetic curve below 200 μmol photons m^{-2} s^{-1}. This means that shade plants achieve a greater increase in PS_{net} per photon absorbed than sun plants, which is mainly a function of the fact that shade leaves are thinner and have less self-shading. The light compensation point is the PPFD where $PS_{net} = 0$ (where PS_{net} crosses the dashed line) and is lower in shade plants than sun plants. This, coupled with lower R, may contribute to the ability of shade plants to persist in low light habitats. Conversely, sun plants can achieve higher rates of photosynthesis and outcompete shade plants in full sun habitats. Adapted from data in Figures 3 and 10 in Böhning, R.H. and Burnside, C.A. (1956). The effect of light on rate of apparent photosynthesis in leaves of sun and shade plants. *American Journal of Botany* **43**, 557–561.

inhibited by high light (Fig. 2). Shade plants have thinner, broader leaves which increase the efficiency of light capture, while sun leaves are thicker and often contain an extra layer of cells with which to capture light for photosynthesis (Fig. 3).

On cloudless days, light is largely directional while on overcast days, it is mostly diffuse and appears to come from all directions. Competition for light, and in particular, direct light, is mediated by differences in vertical plant size and angular distribution of leaves. Shade plants frequently display their leaves in ways that minimize overlap (i.e., a mono-layer canopy such as that shown by flowering dogwoods (*Cornus florida*), while sun plants have an architecture composed of multiple leaf layers, which maximizes light interception (e.g., pines, *Pinus* sp., and birch trees, *Betula* sp.). The upper leaves of sun plants are often more vertically oriented while the lower ones are more horizontal. This allows more light to penetrate farther into the crown, maximizing light interception by the plant. These physiological and structural differences restrict shade plants to understory habitats and sun plants to more open habitats.

Not only do plants respond to the quantity of light, but they can also detect the quality of that light. In full sun, for example, the ratio of red to far-red light is approximately 1:1, whereas in the understory, it is substantially reduced, often to as low as 0.1:1. This is because the green leaves of the canopy primarily absorb the red light and allow more of the far-red light to penetrate to the understory. Plants have special pigments, such as *phytochromes* and *cryptochromes*, which respond to the lower ratio of red to far-red light. This can stimulate height growth in shade-intolerant plants and serve as a mechanism to avoid prolonged shading. Some shade-intolerant species, such as black cherry (*Prunus serotina*) have seeds that germinate only when the *red: far-red ratio* is near one, because this indicates an absence of an overstory canopy, and thus conditions more suitable for germination and subsequent survival.

Plants also differ with respect to their tolerance to the periodicity of light. In virtually any canopy environment, some light passes through the canopy relatively unaffected by leaves and branches. This creates a *light fleck* (or *sunfleck*) on the surface below it. These light flecks differ considerably in their duration and energy content. In one study in Great Smoky Mountains National Park, 80% of the sunflecks lasted less than 1 min each, but contributed nearly 80% of the daily PPFD even though their cumulative duration totaled only 6 h. Most sunflecks last less than 120 s, yet the 5% that are longer can contribute up to 75% of the total radiation input to the forest understory. The intensity of light received in these sunflecks is proportional to their size and duration: larger and longer sunflecks have higher PPFDs.

The photosynthetic apparatus of plants requires the prior presence of light to react quickly to a sunfleck, a phenomenon called photosynthetic induction. Understory plants have a low irradiance requirement to remain induced, while sun plants require higher light to maintain induction. Even though sunflecks are present for only a small fraction of the time, they contribute toward a substantial amount of photosynthetic carbon gain by shade plants. In tropical forests, sunflecks may contribute from 30% to 60% of the daily carbon gain, whereas it is a lower percentage (10%–20%) in temperate forests.

Another response to periodicity reflects changes in day length accompanying seasonal changes in temperate regions. For many plants the length of the photoperiod controls flowering. Short-day plants will initiate flowering when day length gets shorter than

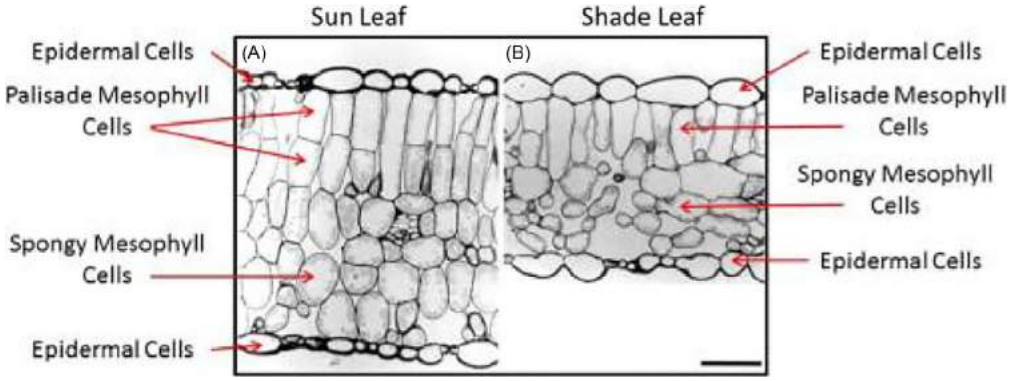

Fig. 3 Light micrographs of cross-sections of (A) sun and (B) shade leaves of *Chenopodium album*. Sun leaves were grown in PPFD of 360 μmol photons m^{-2} s^{-1}, and shade leaves in 60 μmol photons m^{-2} s^{-1}. The bar in the lower right is 50 μm in length. Note the double layer of palisade mesophyll cells in the sun leaves, and the greater thickness of the sun leaf compared to the shade leaf, which has only one layer of palisade mesophyll cells. The *light gray* objects arrayed within and on the periphery of the mesophyll cells are chloroplasts. From: Yano, S. and Terashima, I. (2001). Separate localization of light signal perception for sun or shade type chloroplast and palisade tissue differentiation in *Chenopodium album*. *Plant Cell Physiology* **42**, 1303–1310.

some critical period (or more properly, as the night gets longer, since plants respond more to what happens at night than what occurs during the day). Alternatively, long-day plants (i.e., short-night plants) will flower when day length exceeds a critical period. A new hypothesis suggests photoperiodic control of flowering may be linked to internal circadian rhythms in plants. The ability to properly time flowering enables plants to complete their reproductive cycle before adverse environmental changes limit their activity. In the prairies of North America grasses must initiate flowering early enough to complete their reproductive cycle before the first killing frost. For the same species in the north, flower initiation occurs in June, while in the south flowers are initiated in October. The two populations are ecotypes (genetically different populations of the same species), and the differences in flowering time are maintained when they are grown together in the same environment.

Water

The availability of water controls plant distribution on scales ranging from microhabitats to continents. Precipitation, temperature and nutrient availability are the primary factors that distinguish the various biomes of the world and which exert controlling influences on their annual productivity. Terrestrial *annual net primary productivity* (*ANPP*) is measured as g C produced m^{-2} $year^{-1}$ and ANPP is the difference between *annual gross primary productivity* (*AGPP*), or how much C is assimilated by plants per m^2 $year^{-1}$, and how much is annually respired (R_a) away: ANPP = AGPP − R_a. Annual evapotranspiration (AE) is a measure that integrates precipitation and temperature and is positively correlated with ANPP across terrestrial biomes (Fig. 4).

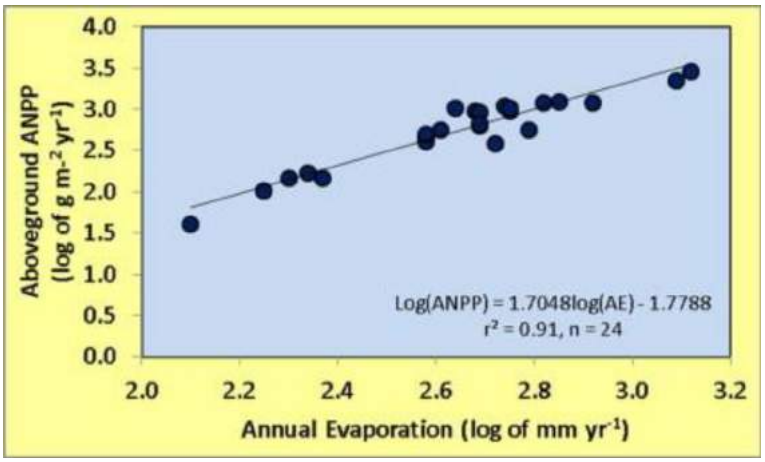

Fig. 4 Relationship between the log of annual evapotranspiration (AE) and annual above ground net primary productivity (ANPP). The original units for ANPP and AE are g biomass m^{-2} $year^{-1}$ and mm H_2O m^{-2} $year^{-1}$, respectively. AE is the amount of water that enters the atmosphere from the combined activities of evaporation from plant and soil surfaces and that which is transpired by plants. AE integrates the availability of both water and solar energy, which is why it is so highly correlated with ANPP. The more available water, when combined with abundant solar energy to drive photosynthesis, leads to greater ANPP in ecosystems. Figure Drawn from data in: Rosenzweig, M.L. (1968). Net primary productivity of terrestrial communities: Prediction from climatological data. *American Naturalist* **102**, 67–74.

Water in plant systems is best described using concepts of thermodynamics as exhibited by the concept of water potential (Ψ_w). This value, derived from the natural gas laws, expresses the energy contained in water in units of pressure (e.g., MegaPascals, MPa; 0.1 MPa = 1 bar = ~0.9869 atmospheres = 750 mmHg = 14.5 psi at sea level). The Ψ_w of pure water is defined as 0 MPa. Numerous physical and chemical factors affect Ψ_w, including solutes (Ψ_s), matric (i.e., surface) attributes (Ψ_m), pressure (Ψ_p), and gravity (Ψ_g). The addition of solutes to water lowers the free energy of water in that system by altering hydrogen bonding between water molecules and by lowering their kinetic energy. Both of these changes result in a lowered capacity for that solution to do work compared to pure water, which is why water containing solutes always has a negative Ψ_s. For example, a 1.0 m solution (g solute/kg water) of a nondissociating solute will create a $\Psi_s = -2.5$ MPa. If this solution is separated from pure water by a semipermeable cell membrane, then a potential energy gradient will exist from the water to the solution.

This energy gradient means that water will move from areas of high potential energy (pure water) to areas of low potential energy (solution) following basic principles of thermodynamics. Since cells contain numerous solutes, water will move down the potential gradient into the cell via osmosis resulting in an increase in cell volume. This increase in volume is quickly constrained by the cell wall, which creates a positive pressure on the water in the cell. The end result is an increase in the Ψ_p of the cell. Ultimately the Ψ_p (which is positive) would partially or totally offset the Ψ_s (which is negative), and the cell would reach an equilibrium Ψ_w of 0 MPa. For example, a plant rooted in a wet, saturated soil, which would have a Ψ_{soil} near zero, would have an equilibrium Ψ_{plant} also near zero. Total plant water potential is simply the sum of all the components of water potential described above: $\Psi_{plant} = \Psi_s + \Psi_p + \Psi_m + \Psi_g$.

Matric potential (Ψ_m) is most important component in determining soil water availability, but is only a minor component of Ψ_{plant}. The surfaces of soil particles (sand, silt, and clay) provide a strong attraction to water and limit the ability of plants to absorb this water. As soils dry down, the Ψ_{soil} begins to decline and becomes more negative due to matric effects that result from the strong adsorption of water (via hydrogen bonds)to the soil particles.

Water usually moves from the soil, then to the root, stem and leaf before eventually evaporating into the atmosphere. It does so by moving passively down a Ψ gradient from soil to atmosphere, which is known as the Soil-Plant-Atmosphere Continuum, or *SPAC*. With few exceptions, this is a one way gradient, which is why water moves primarily from soil to plant to atmosphere. This occurs because the atmosphere has a very negative Ψ (e.g., at 50% relative humidity and 20°C, $\Psi_{air} = -93.6$ MPa) while a dry soil might be only −0.5 MPa. Plants effectively act as giant wicks, moving water from the relatively higher Ψ in the soil, to the very low Ψ in the atmosphere (Fig. 5).

A temperate forest tree, transpiring at its maximum rate of about 10–15 mol H_2O m^{-2} s^{-1} might have a Ψ_{leaf} of −1.5 MPa. In contrast, a creosotebush (*Larrea tridentata*) growing in the dry Chihuahuan Desert, may have a much lower $\Psi_{leaf} \sim -7$ MPa. This shows the great range in Ψ_{plant} possible among species adapted to habitats with different availabilities of water. Friction in the xylem conduits, through which the transpirational water moves, and the inability of the root system to provide water at the same rate at which it is lost from the leaves, leads to this drop in Ψ_{plant} from the much higher Ψ_{soil}. It is this drop in Ψ that induces movement of water from the soil into the roots, while the large gradient from the leaf to the atmosphere insures that water evaporates out of and not into, the leaf.

The upward movement of water in the xylem of plants is widely accepted as occurring by cohesion-tension forces, a theory first proposed in 1895 by the Irish botanist Henry Horatio Dixon and the physicist John Joly. Water lost by evaporation in leaves is replaced by water pulled up by the strong cohesive forces between water molecules. Because more water is lost than can be replaced by root uptake, and because of frictional resistances in the xylem, the water column is placed under tension (negative pressure) and becomes metastable.

Pressure potentials within living cells are typically positive; however, the pressure potential of the water moving up the plant through its xylem is negative, and frequently referred to as xylem potential (Ψ_x). It is easily measured using a pressure chamber and serves as a proxy for plant water status. The potential energy of water in the xylem column is also affected by gravity and Ψ_x decreases with height by 0.01 MPa m^{-1}. Thus a fully hydrated tree, 50 m in height, would have a maximum Ψ_x of −0.5 MPa instead of 0 MPa due to the impact of Ψ_g. Maximum tree height (*c.* 130 m) may even be a function of the decreased Ψ_{plant} with height because this decreases turgor, increases the chances of embolisms, and ultimately reduces photosynthetic carbon gain at the tops of tall tree crowns.

Plants have a physiological limitation for water absorption based upon their ability to lower osmotic potentials of root cells. This limitation is described as the permanent wilting point (PWP), which is an expression of the water content of a soil when a plant is no longer capable of extracting water from it. The Ψ_{plant} at PWP varies with species, but for mesophytic, agricultural plants is approximately −1.5 MPa. At PWP in sandy soil the remaining water may be less than 1% by dry weight, but in clay soil the water content may be nearly 20% by weight. Small clay particles attract water more tightly than larger sand particles making it more difficult for roots to extract.

Water use by individual plants varies considerably depending on plant size, availability of soil water, and atmospheric temperature and humidity. A large tree may transpire as much as 1000 L H_2O day^{-1} whereas a desert cactus may lose less than 1 g day^{-1}. Transpiration ratio (TR) is a measure of water loss to carbon gain by plants, typically expressed as mass of water lost to mass of plant weight gained (mol H_2O/mol CO_2). This value will vary between plants and the photosynthetic pathways they possess (discussed below). Plants with the C3 photosynthetic pathway (most trees, wheat, for example) have a TR of 666–2000 and have the least efficient TR; those with the C4 pathway (maize, sorghum) have an intermediate TR of 500–1000; while those with the CAM pathway (cacti, pineapple) have the most efficient TR of 100–250. If calculated in terms of the demand for water

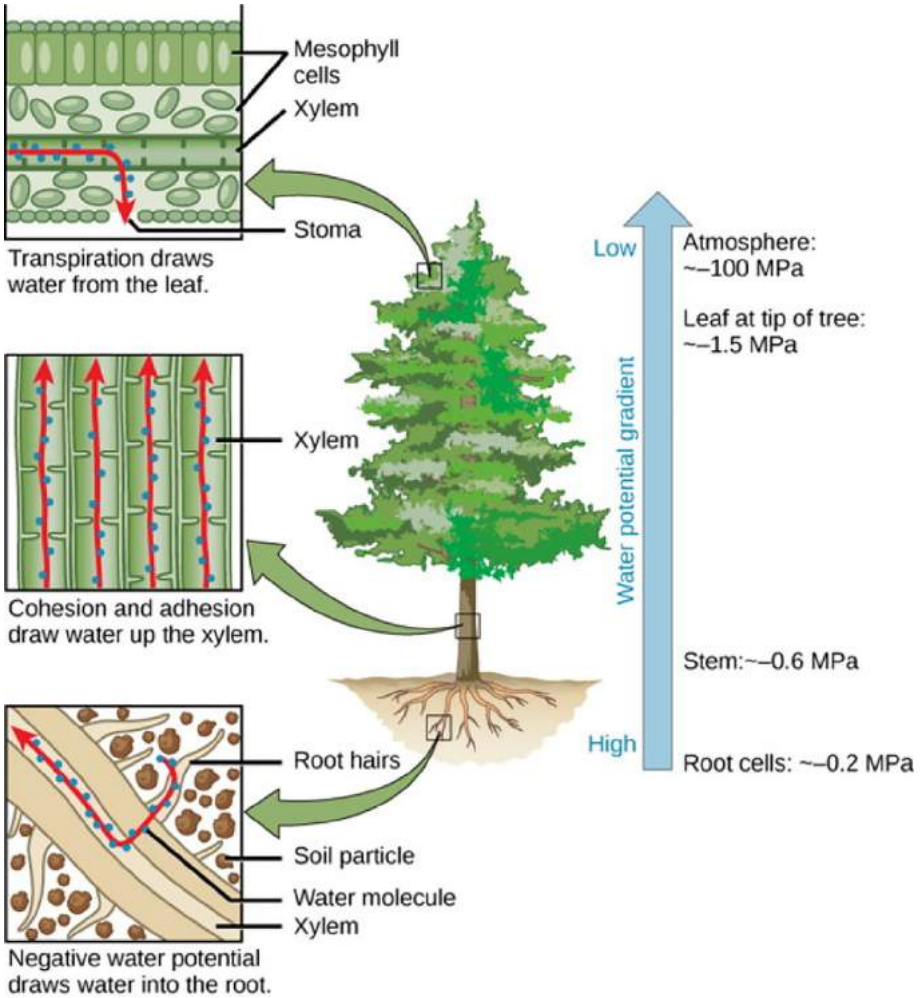

Fig. 5 The Soil–Plant–Atmosphere-Continuum (SPAC). Water moves passively down a free energy gradient (i.e., down the Ψ_w gradient) as it moves from the soil into roots, then stems and leaves, before evaporating into the atmosphere. Because the atmosphere has such a low Ψ_w, the gradient is unidirectional. In essence, plants act as giant wicks, removing water from the soil and transpiring it back to the atmosphere. Frictional resistances in the xylem, and an evaporative demand that exceeds the capacity of the roots to take up water, result in a lowering of the Ψ_w along the pathway through the tree. Figure courtesy of Pearson publishing.

(Mg H_2O ha^{-1} $year^{-1}$), which includes both the fraction taken up by the plant and that evaporated from the soil back to the atmosphere, per unit biomass produced (Mg biomass (tonnes) ha^{-1} $year^{-1}$), the differences in the ratios become quite dramatic. For C3 plants, the ratio ranges from 400 to 1200, for C4 from 286 to 571, while for CAM it is 60–150. These differences account, in part, for the relatively higher proportion of C4 and CAM plants in hot, arid regions where water is frequently limiting to plant growth. The very high water use efficiencies of C4 and especially CAM plants is one reason why scientists are attempting to incorporate these alternative photosynthetic pathways into C3 crop plants, so future agricultural water use can be reduced.

The water status of plants varies both seasonally and diurnally. Stomata usually open early in the morning and close at dusk. Some plants may close their stomata in the afternoon because of drought stress resulting from an inability to match absorption to transpiration rates. This results in a decrease in mid-day photosynthetic capacity, often termed the mid-day depression (Fig. 6). Similarly, on a seasonal basis, when evapotranspiration rates have depleted soil water, low Ψ_{soil} makes water uptake difficult. As a consequence Ψ_{plant} decreases, resulting in stomatal closure during much of the day, and preventing the occurrence of catastrophic drought stress.

The velocity of water movement in *xylem vessels* and *tracheids* is proportional to the fourth power of the radius of the conduits. Thus a simple doubling of conduit diameter can result in a 16-fold increase in flow, which means that larger xylem elements will move most of the water in a plant. The first vascular plants evolved tracheids to conduct water. These relatively primitive xylem cells have end walls and narrow conduits, and for water to move from one cell to another must pass through circular structures known as pits, which have thinner cell walls than the rest of the cell surface. The most recently evolved plants, the angiosperms, or flowering plants, have evolved shorter, but wider xylem cells known as vessel elements. These cells are joined end to end to form a conducting tube, with end walls only occurring occasionally. Because of the lack of end walls, and their much wider diameters, water flows more easily through vessels than tracheids, and angiosperms have a higher hydraulic conductivity than more primitive vascular plants,

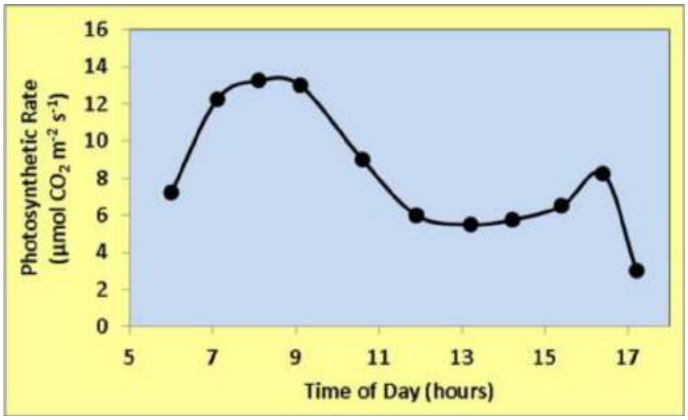

Fig. 6 Mid-day depression in photosynthesis for sun leaves of the understory herb *Arisaema heterophyllum*. The mid-day depression starts just after 10 am and is maximal at about 1 pm (13 h) in the afternoon. The depression is initiated by the closing of the stomata due to excessive transpiration, which in turn reduces the CO_2 concentration inside the leaf. Low internal CO_2 directly leads to lower photosynthetic rates, but it also favors relatively more oxygenation of the RUBISCO molecule and higher rates of photorespiration, further contributing to lower photosynthetic rates. Later in the afternoon, when transpirational demands lessen, stomata open and photosynthetic rates rise temporarily before dropping again, this time due to low light late in the day. Figure redrawn from: Muraoka et al. (2000). Contributions of diffusional limitation, photoinhibition and photorespiration to midday depression of photosynthesis in *Arisaema heterophyllum* in natural high light. *Plant, Cell and Environment* **23**, 235–250.

like gymnosperms, as a result. Hydraulic conductivity is simply the ease with which a plant can move water through its xylem. Tracheid diameters in some conifers, such as redwood trees may only be 20 μm, whereas in angiosperm lianas, such as kiwi (*Actinidia deliciosa*) and grapevine (*Vitis vinifera*), which have very large vessels up to 500 μmin diameter), their hydraulic conductivities are among the highest for any plants.

Because the water in the xylem of a transpiring plant is under tension and metastable, large negative pressures developing within the xylem can result in *cavitation*, which is the formation of air bubbles in the xylem column. Cavitation can lead to *embolisms*, which are breaks in the water column that result in the loss of conduction from that point on in the xylem.

Embolisms form when air is drawn into a xylem element because of a pressure difference across the cell wall (Fig. 7). Xylem under large tension can aspirate an air bubble from outside the cell and pull it through pit pores that separate the xylem cell from a neighboring air space. Once inside the cell, the negative pressure allows the bubble to rapidly expand, resulting in the embolism and cessation of flow. The larger the pit pores, the more easily a bubble can be aspirated (a consequence of surface tension), and susceptibility to embolisms is partially correlated with pit pore sizes.

Freezing can also result in the formation of embolisms due to the release of gases as the temperature of the xylem decreases (note how gas bubbles form in ice cubes as the water freezes). Subsequent thawing under tension results in the expansion of these trapped air bubbles and the formation of an embolism. The larger the xylem conduit, the more susceptible the plant is to such freezing-induced embolisms. As a consequence, lianas, which have the largest diameter vessels, are effectively absent from colder habitats, such as occur at high elevations and latitudes. Instead, they reach their peak abundance in tropical habitats where freezing events are absent. Conversely, the small conduits of tracheids found in gymnosperms afford protection from this type of embolism and may account in part for their prevalence in such habitats. Most angiosperms contain a mixture of large diameter, rapidly conducting vessels, and narrow diameter, slower conducting, tracheids, and vessels. The combination of these xylem elements provides a measure of hydraulic safety for plants.

Nutrients

Plants generally require the same nutrients, although their absolute and relative requirements may vary. While nutrients have traditionally been categorized into two classes (macro- and micronutrients) depending upon their proportion in the plant body, this division has been difficult to justify from a physiological standpoint. A recent proposal divides nutrients into four classes based on their biochemical and physiological functions in the plant. These are nutrients such as (1) N and S, used in organic compounds, (2) P, Si, B, which are used for structural integrity and energy storage, (3) K, Ca, Mg, and others which are used in ionic form and, (4) Fe, Zn, Cu, and other metals, which are involved in redox reactions.

Some nutrients are used in high amounts, and can constitute more than 1% of the weight of plants. These include C, H, O, N, P, S, Ca, Mg, and K. Carbon, H, and O are incorporated into plants through photosynthesis and respiration while the remaining nutrients are absorbed from the soil, although some, such as N, can be absorbed in gaseous form on occasion. Most of the other nutrients make up less than 1% of a plant's weight, such as Fe, Mo, Cu, Zn, Mn, and B. Although plants may contain Na, Cl, Se, Ni, and Si, it is not always clear whether these elements are required. Nonetheless, some of these may contribute to the survival of

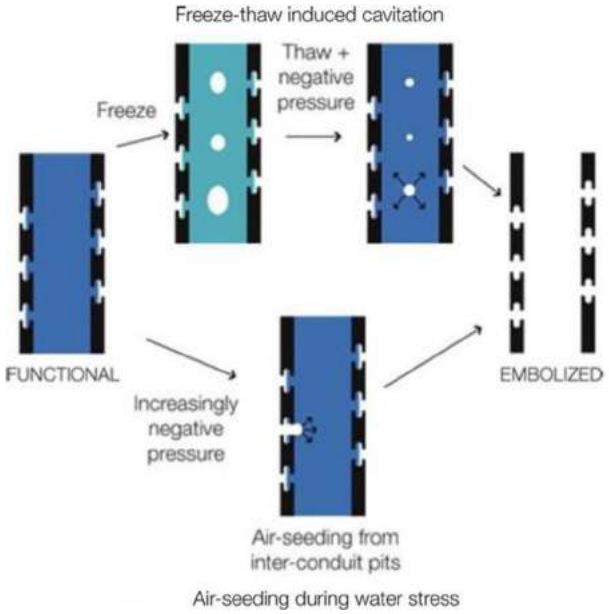

Fig. 7 Cavitations can arise from either air-seeding or freezing in xylem conduits. The functional conduit on the left is a xylem element containing water under tension. The conduit on the right is an embolized xylem element, with no water inside. The upper two xylem elements illustrate freezing-induced cavitation while the bottom one shows cavitation caused by air-seeding. With air seeding, the pressure differential across the xylem cell wall is so great that an air bubble is aspirated from an intercellular airspace outside the xylem, or from an adjacent, embolized xylem element, and pulled into the functional conduit through the pit pores. Pit pores are spaces between the cellulose microfibrils where the secondary cell walls are absent and can facilitate intercellular movement of water. Because functional xylem is under negative pressure (tension), and the airspace outside is at atmospheric pressure, the air bubble is directed inwards toward the functional conduit. If the pressure differential becomes large enough, it overcomes the surface tension of the air bubble, enabling it to be pulled into the conduit. This action constitutes the cavitation event. Once inside the xylem cell, the low xylem pressure allows the bubble to rapidly expand and form an embolism. Once embolized, the xylem conduit can no longer conduct water to the leaves. With freezing-induced embolisms, bubbles form as the sap freezes. When the conduit thaws under tension, the bubbles rapidly expand and embolize the xylem element. Figure taken from: Cain, M.L., Bowman, W.D. and Hacker, S.D. (2011). *Ecology*, 2nd edn, Sunderland, MA: Companion website by Sinauer Associates.

certain plants. Silicon is found in high amounts in grasses and horsetails (*Equisetum* sp.) while other plants accumulate nickel to very high amounts (*hyperaccumulators*), both of which may be strategies to deter herbivores. Sodium is thought to be required for plants that perform C4 photosynthesis.

Soil nutrient availability may be divided into two groups: (1) nutrients whose availability is largely controlled biologically, for example, N, and (2) those whose availability is largely controlled abiotically, for example, P. The nitrogen cycle consists of biological processes involving incorporation of atmospheric nitrogen into ammonia or ammonium nitrogen (fixation), release of organic nitrogen into the soil solution (mineralization), and conversion of ammonia into nitrate (nitrification), which is the form of nitrogen most commonly absorbed by plants. Each of these steps is mediated by soil microbes that control the rate of availability of N to plants. Soil factors such as oxygen content and pH have important effects on the availability of N because of effects on soil microbes and root functioning.

Successional processes (the changes in plant communities through time) can also affect the partitioning between nitrate and ammonium nitrogen. Apparent nitrate uptake decreases during succession while ammonium uptake increases, which are mechanisms by which late successional communities conserve nitrogen and energy. Since nitrate is a negatively charged anion it is repulsed by the negatively charged soil particles and is lost from ecosystems after disturbances. Ammonium, on the other hand, is a positively charged cation and is retained in the soil. Furthermore, less energy is required by plants to build nitrogen containing organic compounds from ammonium than from nitrate.

Phosphorus is most commonly available to plants as phosphate and is ultimately derived from the substrate. The availability of phosphorus is controlled by pH and the abundance of other ions that immobilize it in the soil. Calcium, silicates, and oxides of aluminum and iron bind phosphorus at different soil pH resulting in low soil availability. Phosphorus availability to many plants is enhanced by mutualistic relationships between plants and mycorrhizal fungi. These fungi derive carbon energy from the host plant and have hyphae that extend through the mineral soil and absorb large quantities of phosphorus (as well as other nutrients such as N, also C and even water), which are shared with the host plant. These mutualistic associations arose as soon as plants began colonizing terrestrial habitats, perhaps in response to the extremely limiting amounts of available phosphorus on land before the formation of deep, nutrient rich soils. So, despite the abiotic control of phosphorus availability in the soil, the absorption by plants of phosphorus at low concentrations is often dependent upon an association with mycorrhizal fungi.

Mycorrhizae can even transfer nutrients and carbon among individual trees whose roots are connected by the same hyphae. Suzanne Simard and colleagues used ^{13}C and ^{14}C isotopes to follow the movement of carbon from one tree to another through

interconnected hyphae for individuals of Douglas fir (*Pseudotsuga menziesii*) and across species boundaries to paper birch (*Betula papyrifera*). Trees in full sun served as "donor" trees and provided C to the trees in the shade ("receiver" trees). This illustrates that there are complex biological interactions taking place belowground among plants, fungi and soil fauna that have strong influences on aboveground processes.

Nutrients present in excess amounts in the soil can result in toxicity symptoms in plants. In theory, any element may be present in excess, including nitrogen, but the most common forms of nutrient toxicity arise from salinity and heavy metals. Salinization of soils is a worldwide problem that results from high evaporation rates after irrigation in arid regions. Evaporation concentrates salts in the upper soil layers, where it can reach toxic levels. There also biological processes that concentrate salt. The invasive saltcedar (*Tamarix* spp.) transpires copious amounts of salt-laden water that it absorbs from deep within the soil (Fig. 8). The result is the accumulation of salts in its leaf tissues, which it then exudes from special salt glands. The salt then falls off the tree and accumulates in the upper layers of the soil to the detriment of surrounding plants, since the salt is both toxic and makes water uptake difficult because it decreases ψ_{soil}.

Excess N deposition may cause plant diversity to decrease in various ecosystems. Preindustrial N deposition rates may have been as low as ~2 kg N ha^{-1} $year^{-1}$, whereas today in Europe and the eastern United States, this represents <10% of rates in the eastern United States and <1% of the maximum rates in Europe. Mechanisms for the decline in diversity include altering interspecific competition to favor nitrophilic species over a diverse N-efficient flora, increasing degree of herbivory, decreasing success of mycorrhizal infections, increasing severity of pathogenic fungal infections, and enhancing success of invasive species. Nitrogen deposition may also reduce *carnivory* in pitcher plants by shifting production away from pitchers, which are the leaves that capture prey, to *phyllodes*, which are leaves that only do photosynthesis.

Lastly, acid deposition can cause the leaching of cations from the soil, creating nutrient deficiencies for certain plants. Acid deposition (as either rain, fog, dew or snow) is the result of nitrogen and sulfur compounds being added to the atmosphere through combustion processes such as coal burning, and their transformation to nitric and sulfuric acids. These acids compete for binding sites on soil particles and cause leaching of Ca^{+2}, K^{+}, Mg^{+2}, and other cations. The loss of these ions, and in particular, Ca^{2+}, can result in an inability of some trees, particularly red spruce (*Picea rubens*) to withstand extreme cold periods, and may be a cause of forest decline in northern areas. Soil acidification also increases the solubility of heavy metals, such as Al^{3+}, which is extremely toxic to roots. Acidic deposition may have leached so much Ca^{2+} out of the soils at the Hubbard Brook site in New Hampshire, United States, where nutrient cycling patterns have been studied since the 1960s, that forests there are unable to increase their biomass from year to year.

Adaptive Plant Strategies

One of the goals of any science is to develop predictive theories on which future research can be based. This is how science progresses, which distinguishes it from faith based initiatives, where the conclusions are reached without reference to either data or experimentation. In plant ecology, scientists continue to search for particular adaptive (i.e., evolutionary) plant strategies that may be used conceptually to increase our knowledge about how plants interact to form communities and ecosystems. If a set of

Fig. 8 Salt Cedar (*Tamarix* sp.) is an exotic invasive tree that currently occupies over 1.6 million acres of land in North America alone. It is highly competitive with native species, often displacing them from riverine habitats. It can extrude salt from glands in its leaves and raise the salinity level of soil so much so that native plants are excluded. It also has very high transpiration rates which deplete soil water and further enhance its competitive abilities. Photo courtesy of Dr. Jonathan Horton.

functional traits can be found that have broad predictive capabilities, this would eliminate the necessity of studying each of the ~225,000 species of plants, which would be an essentially impossible task. In this section, various adaptive plant strategies are examined, but it should be kept in mind that this list is by no means complete, and that the very concept of functional traits is still a matter of much discussion among ecologists. Also, the reader should rest assured that in applying the concept of "strategy" to plants, we are not implying that they have either intent or foresight to prepare for the future. Rather, adaptive plant strategies are the means by which plants come to be competitively successful through the exploitation of various physiological and structural attributes, each of which have evolved as the result of natural selection.

Plant Functional Groups—Alternative Photosynthetic Pathways

All higher plants assimilate CO_2 through the process known as C3 photosynthesis, named for the fact that the first stable product is a 3C sugar, 3-phosphoglycerate, or 3-PGA. In addition, however, two alternative photosynthetic pathways have evolved; the C4 pathway, named for the fact that the first stable product of fixation is a 4C organic acid and the crassulacean acid metabolism pathway, or *CAM* as it is known (named after plants in the Crassulaceae family). Both alternative pathways incorporate a new primary fixation event involving another enzyme, phosphoenolpyruvate carboxylase (or PEPc) before shuttling the fixed carbon to the C3 apparatus. These new pathways can be viewed as "add-ons" to the more evolutionarily primitive C3 pathway. The C4 pathway involves a spatial separation, whereas CAM involves a temporal separation, of additions steps.

The evolution of CAM preceded that of C4, and is restricted to vascular plants, whereas C4 has evolved only in the angiosperms. CAM plants make up about 6%–7% of the flora, whereas C4 plants comprise just 3%. Both groups, however, are ecologically important in ways that belie their taxonomic rarity; CAM plants predominate in desert and epiphytic habitats, whereas C4 plants thrive in warm, dry areas, but with notable exceptions in both cases.

During the process of C3 photosynthesis, light energy is used to fix CO_2 in the chloroplasts to create a stable 3C compound, known as a triglyceride, which gives this pathway its name. All plants are derived ultimately from the green algae, which also perform C3 photosynthesis, and it is the evolutionarily most primitive pathway in plants. The fixation process is catalyzed by an enzyme known as *RUBISCO*, which stands for ribulose-1,5-bisphosphate carboxylase oxygenase. Having evolved long before global oxygen levels reached their current levels, it is probably an accident of evolution that it can also fix O_2 in addition to CO_2. Under ambient conditions, about one in four fixation events is an oxygenation instead of a carboxylation, resulting in an efficiency of carboxylation of ~75%. Oxygenation adds no new C to the plant, but instead results in the loss of CO_2 through a process known as photorespiration.

Beginning ~100 MYa, atmospheric CO_2 levels began declining and during Pleistocene glaciations (~2 MYa) may have ranged between 180 and 200 ppm. For comparison, preindustrial concentrations were 270–290 ppm, whereas current levels (2018) now hover around 409 ppm, an increase almost solely due to human activities especially the burning of fossil fuels. These low prehistoric atmospheric CO_2 concentrations would have reduced the gradient for diffusion into the leaf, making photosynthesis difficult for C3 plants. Since CO_2 and O_2 competitively inhibit each other for binding sites on RUBISCO, the low CO_2 levels would have also favored a relative increase in the rate of oxygenation. Beginning around 35 MYa fossil leaves of plants structurally different from typical C3 plants are found, constituting the first evidence for the evolution of a new photosynthetic pathway known as C4 photosynthesis. These plants are categorized by their ability to concentrate intercellular CO_2 around RUBISCO to enhance photosynthesis when atmospheric concentrations are low.

C4 photosynthesis evolved independently at least 66 times in 19 families of angiosperm plants (of which four, Poaceae, Cyperaceae, Chenopodiaceae, and Amaranthaceae account for most lineages). While C4 plants constitute only about 3% of all plant species (~7500 species), they account for nearly 25% of all annual net primary productivity worldwide (mainly in the large grasslands such as the savannas and prairies) making them extremely important ecologically. In addition, some of our most important crops are C4, such as maize (*Zea mays*), sugarcane (*Saccharum officinarum*), and sorghum (*Sorghum bicolor*).

C4 leaves differ structurally from those in C3 plants (Fig. 9). C3 plants have an upper layer of long columnar cells (palisade) and a lower layer of irregularly spaced and shaped cells (spongy) where photosynthesis occurs. Leaves of C4 plants, on the other hand, are divided into mesophyll cells and another set of large cells surrounding the vascular bundles known as bundle sheath cells. This type of leaf anatomy is called *Kranz anatomy* ("Kranz" means "wreath" in German), and was known to plant scientists in the late 19th century. However, the link with C4 photosynthesis was not realized until the mid-20th century.

PEPc is kinetically faster than RUBISCO and insensitive to O_2. It fixes CO_2 onto a 3C pyruvate molecule in the mesophyll cells to form a stable 4C compound, usually oxalic or malic acid. The malic acid is then shuttled to the bundle sheath cells where the recently fixed CO_2 is then removed from the organic acid and subsequently fixed via RUBISCO and the C3 pathway (Fig. 10). To put it simply, C4 is an "add-on" to the C3 pathway. The end result of this process is that it functions to "pump" CO_2 to the bundle sheath cells, where it can build up to concentrations nearly $10\times$ those in ambient air. This shifts the competitive equilibrium between carboxylation and oxygenation on RUBISCO in favor of the former, essentially eliminating photorespiration. As a consequence, rates of photosynthesis can be substantially higher than those found in C3 plants.

Although C4 photosynthesis may have originally evolved as a way to cope with declining atmospheric CO_2 concentrations, any ecological situation that resulted in a substantial loss of carbon from photorespiration probably served as a necessary selection pressure for this photosynthetic pathway. In habitats where high salinity, temperature, or drought would cause stomatal closure and a lowering of the internal CO_2 concentration, there would be more photorespiration and evolution of the C4 syndrome would be favored.

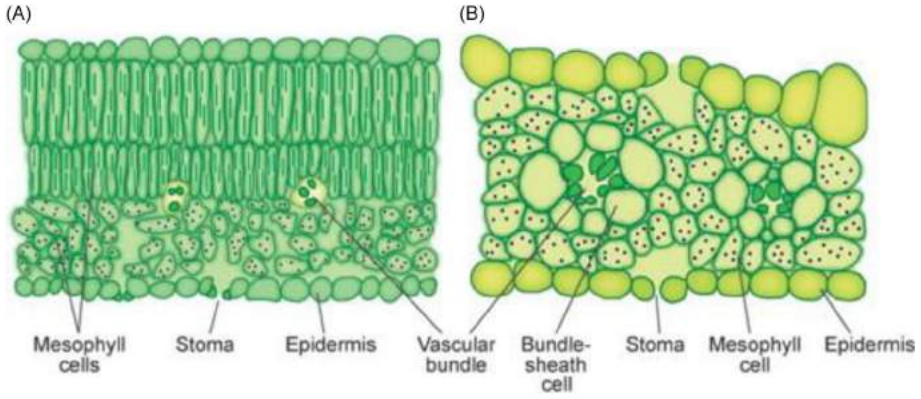

Fig. 9 Idealized cross-sections of (A) C3 and (B) C4 leaves. The enlarged bundle sheath cells surrounding the vascular bundle in C4 leaves give rise to the anatomical formation known as Kranz anatomy. The term "Kranz" refers to the wreath-like arrangement of the cells around the vascular strand. In C3 plants, CO_2 is assimilated in both the palisade and spongy mesophyll cells via the C3 pathway, using the enzyme RUBISCO to perform the fixation reaction. In C4 plants, CO_2 is initially fixed in the mesophyll cells by phospho-enol pyruvate carboxylase (PEPc), and a four carbon organic acid is then transported to the bundle sheath cells, subsequently decarboxylated, and the resultant CO_2 fixed by RUBISCO via the C3 pathway. Any photorespired CO_2 is re-assimilated by the mesophyll cells before it can escape the leaf, which is one reason for the absence of any apparent photorespiration in C4 plants. Figure courtesy of: Tipple, B.J. and Pagani, M. (2007). The early origins of terrestrial C4 photosynthesis. *Annual Review of Earth and Planetary Sciences* **35**, 435–461.

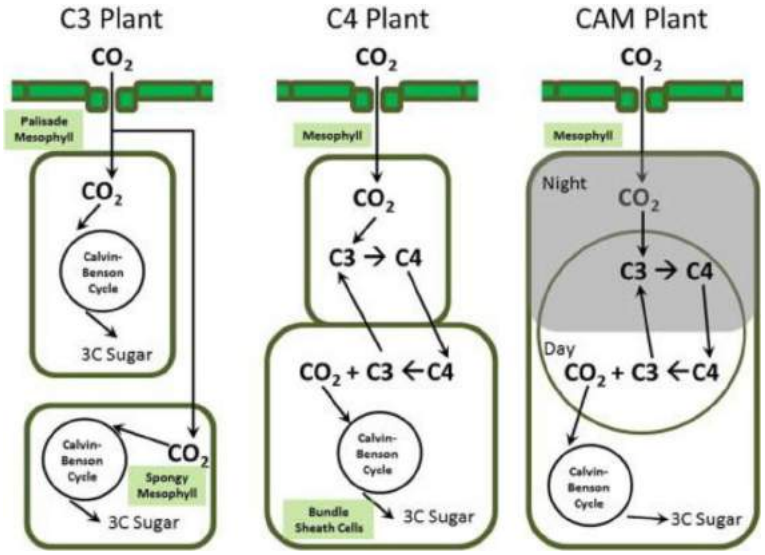

Fig. 10 Schematic comparisons of the three major photosynthetic pathways in plants. C3 plants fix CO_2 onto a 5C sugar (ribulose-1,5-bisphosphate) in both palisade and spongy mesophyll cells using the enzyme RUBISCO. The resultant 6C compound splits into two 3C sugars, which constitute the first stable products of photosynthesis and which give the pathway its name. C4 plants perform an initial fixation of CO_2 onto a 3C compound (phosphoenolpyruvate) by PEPc that is found only in mesophyll cells, to form a 4C organic acid. This acid is then shuttled to the bundle sheath cells where the CO_2 is removed. The 3C pyruvate is recycled back to the mesophyll cells while the CO_2 is fixed by RUBISCO via the C3 pathway, which is localized only to these specific cells. The CAM pathway is very similar to the C4 pathway, but both fixation reactions occur in the same cell, although at different times. The initial fixation by PEPc occurs at night, whereas the decarboxylation and re-fixation by RUBISCO occur during the day using the energy of the sun to power these reactions. By opening their stomata at night, CAM plants achieve the highest water use efficiency of any of the photosynthetic pathways. NOTE: Original artwork by authors.

The lack of photorespiration shifts the temperature optimum for photosynthesis higher for C4 compared to C3 plants. C3 plants reach maximum photosynthesis in a broad plateau centered around 25°C, whereas in C4 plants it is 35°C or higher. The higher photosynthetic rates of C4 plants allow them to assimilate more C per unit of water taken up, which is why their water use efficiencies are so much higher than for C3 plants (see earlier discussion). This is one reason why C4 plants are common in warmer, drier areas. In more mesic habitats they often reach their peak activity during the drier portion of the year. In the prairies of central North America, C3 species dominate in the cool, wet spring, while C4 species become more common in late summer when it is hotter and drier. Biogeographically, the proportion of a flora that is C4 declines with both latitude and altitude to the point that there are no native C4 plants in Alaska, or in most arctic or alpine areas (Fig. 11).

Lastly, C4 plants discriminate less than C3 plants against heavy stable isotopes of carbon, such as ^{13}C (Fig. 12). C4 plants have a discrimination of between −10 and −18 parts per mil, whereas C3 plants range between −23 and −36 parts per mil, with no overlap. This means that stable isotopes analyses can be used to distinguish which plants are C3 or C4. Stable isotope analysis can be used to analyze annual average water use efficiencies of plants, dietary preferences (you are what you eat), agricultural practices, and the relative productivity of C3 and C4 plants worldwide. Scientists have analyzed the stable ^{13}C isotope ratios of human skeletons from South America and used the change in $^{13}C/^{12}C$ ratios to estimate that after 1000 AD maize (a C4 plant) became a prominent staple food in the diet.

A third photosynthetic pathway, first noted in the family Crassulaceae, and now called crassulacean acid metabolism (or CAM) bears strong resemblance to C4 photosynthesis in that it concentrates CO_2 around RUBISCO, but the separation of the two fixation reactions is temporal instead of spatial and occurs in a single cell. These plants include all the cacti, many succulents, and even pineapples (*Ananas comosus*) which grow in the most xeric environments, such as deserts, as well as a variety of epiphytes like Spanish moss (*Tillandsia usneoides*), an iconic CAM plant that grows on trees in the southeastern United States. CAM plants, for reasons discussed below, can, paradoxically, also occur in aquatic habitats.

The unique distinguishing feature of CAM plants is that they open their stomata at night, at which time CO_2 diffuses in and is fixed by PEPc. The resultant malic acid is stored in the large central vacuole overnight. This requires a large volume of water, which is why many CAM plants have thick, succulent leaves. During the day, the malic acid is decarboxylated and the sun's energy is used to fix the CO_2 into triglycerides using RUBISCO and the C3 pathway. By restricting stomatal opening to the cooler night time hours, these plants greatly reduce transpirational water losses, and as a result, have the highest water use efficiencies of any plants, which in turn, enables them to grow in the driest habitats.

CAM plants are also found in aquatic habitats, particularly small pools of water where the CO_2 concentrations during the day are depleted by the photosynthetic activities of other plants and algae. Plant such as *Isoëtes* sp. take up CO_2 at night when respiratory processes have raised the CO_2 concentrations in the water, and then during the day, they decarboxylate the malic acid and fix the CO_2 into 3-PGA via the C3 pathway.

Plant Functional Traits

Currently, 225,000 species of plants are catalogued, but scientists estimate that there may actually be 298,000 species throughout the world. If we are to understand global patterns in functioning, and use these inputs for predicting community successional patterns and ecosystem functioning, we will need to develop proxies for various species traits, such as photosynthesis, reproduction and growth, since it will be impossible to measure these for each and every species. Plant functional groups, such as the alternative photosynthetic pathway traits discussed earlier, or *Raunkiær's lifeform classifications* based on the location of the perennating bud, are

Fig. 11 The percentage of the grass flora that is C4 plants in North America. The percentage decreases with increases in latitude. There are no native C4 grasses in Alaska, although crabgrass (*Digitaria sanguinalis*), which is C4, has been introduced there now. Similar biogeographical patterns hold for C4 forbs (herbaceous plants that are not grasses). Figure adapted from Teeri, J.A. and Stowe, L.G. (1976). Climatic patterns and distribution of C3 and C4 grasses in North America. *Oecologia* **23**, 1–12 as presented on the web by Forseth, I.N. (2010). The Ecology of Photosynthetic Pathways. *Nature Education Knowledge* **3**(10), 4. http://www.nature.com/scitable/knowledge/library/the-ecology-of-photosynthetic-pathways-15785165.

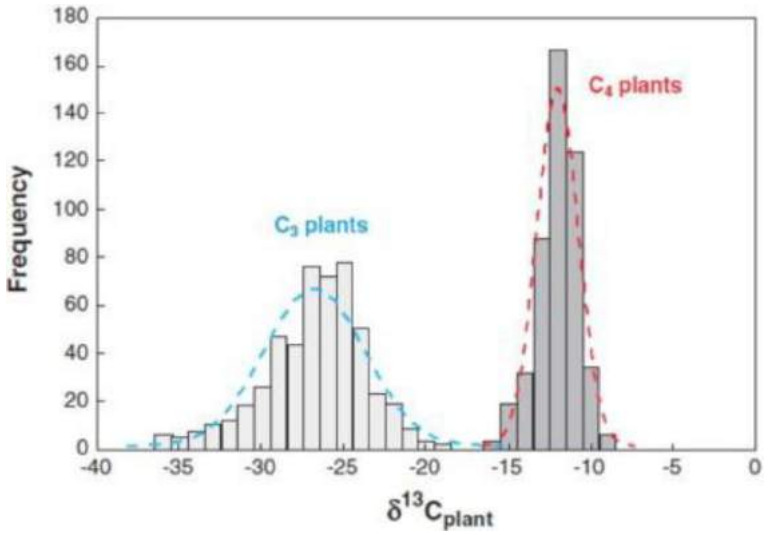

Fig. 12 C3 plants discriminate more against the uptake of ^{13}C than do C4 plants. The *light gray* bars show the discrimination in C3 plants in $\delta^{13}C_{plant}$ units and the *dark gray* bars that by C4 plants. $\delta^{13}C_{plant}$ units are a way of expressing how much less ^{13}C is in a plant relative to a fixed standard, such as Pee Dee belemnite, a clay obtained from South Carolina and which is used to calibrate such measurements. Two things are clear from this graph: (1) C3 plants have a wider range of discrimination than C4 plants and (2) the mean discrimination is much greater in C3 than C4 plants. Also, since there is no known overlap between the two groups of plants, $\delta^{13}C_{plant}$ analysis can be used to distinguish the C3 and C4 photosynthetic pathways of a plant without having to resort to measuring gas exchange or leaf biochemistry. Figure from: Tipple, B.J. and Pagani, M. (2007). The early origins of terrestrial C4 photosynthesis. *Annual Review of Earth and Planetary Sciences* ***35***, 435–461, and the original figure was obtained from data in Cerling, T.E. and Harris, J.M. (1999). Carbon isotope fractionation between diet and bioapatite in ungulate mammals and implications for ecological and paleoecological studies. *Oecologia* **120**, 347–363.

attempts at just such an endeavor. However, these classifications, while useful for distinguishing major plant types across biogeographical distances, ultimately fail when it comes to predicting growth because they contain no physiological mechanisms, and also because structural traits tend to cross over these particular groupings, making the distinctions less useful for modeling purposes. For example, some genera of trees and herbs may have species with thin leaves and high photosynthetic rates, as well as species with thick, evergreen leaves and low photosynthetic rates. Thus, the anatomical classifications are of limited utility for determining those factors constraining physiological functioning, productivity and reproduction.

An alternative strategy is find a suite of traits that is quantitative, continuous, easily measured, and has broad explanatory power without reference to a particular species. Such traits would represent broad-based evolutionary patterns that serve as proxies for how plants respond to environmental selection pressures, and could be incorporated into predictive models, such as, for example, how plants will respond to future global climate change.

A variety of traits have been proposed for just such an effort (Fig. 13). The most successful attempts to date include three major trait dimensions: (1) a leaf economics spectrum, running from cheap (on a carbon basis), short-lived, leaves with high nitrogen content (and consequently high photosynthetic rates), to thicker and denser (i.e., higher mass per unit area), longer-lived leaves with lower nitrogen content; herbs, grasses, and deciduous trees cluster with the former group, while evergreen plants are representative of the latter; (2) reproductive output, whereby species with larger seeds have a lower output per m^2 of canopy, but higher survival rates upon germination and throughout the plant's early life, and (3) final height at maturity, where final height trades off with rapid, early height growth or tolerance to shade.

Newly formed leaves become "profitable" after photosynthesis accrues enough new carbon to pay back the construction costs for that leaf, that is, the carbon that was expended to make new cell walls and membranes, as well as the photosynthetic apparatus. Once these costs are paid back, any additional assimilated carbon can be considered profit, and is exported to other parts of the plant to build new roots, stems, more leaves, and of course, reproductive structures such as flowers and seeds. Thin, less dense leaves require less time to become profitable because of the smaller amount of carbon invested in them, whereas thicker and denser leaves take longer. As a consequence, leaf life spans are shorter where the pay back times are shorter, such as for thin leaves, those with high photosynthetic rates, and those in full sun. Spring vernal herbs, such as trout lily (*Erythronium americanum*) make such leaves. These plants take advantage of a small window of opportunity for photosynthesis that is limited to the period before the overstory canopy leafs out, when most of the carbon assimilation for these plants is accomplished. They have fairly high photosynthetic rates and can assimilate most of their annual carbon in just a few weeks. Once the canopy closes their leaves senesce rapidly and their total lifespan may be only a few weeks. In contrast, evergreen plants, which invest a considerable amount of carbon to make durable leaves, have lifespans that exceed 1 year, and some pines can maintain needles for over a decade. When scientists combine climate parameters with leaf trait variables their models are able to explain nearly 75% of the variation in photosynthetic rates, nitrogen concentrations, respiration rates and specific leaf area ($g\ m^{-2}$ of leaf), all without reference to any one particular species.

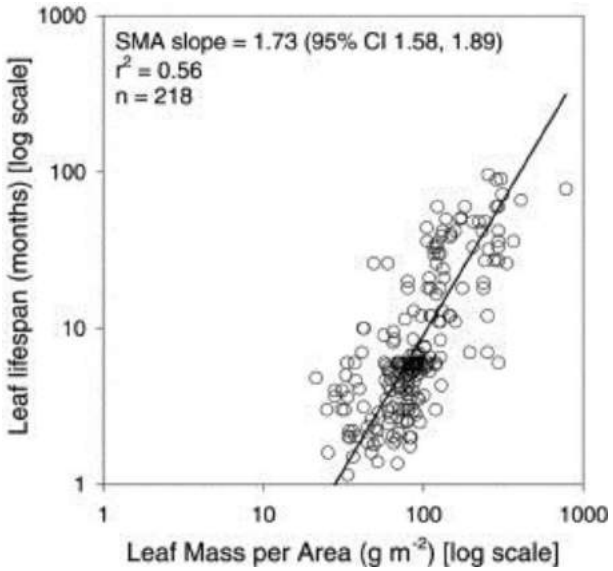

Fig. 13 The lifespan of a leaf is highly correlated with the mass of leaf tissue per unit area of leaf (g m^{-2}). Leaves with a higher mass per area have longer leaf lifespans because they require a longer period of time to pay back their construction costs (i.e., the amount of carbon and nutrients invested in building the new leaf). Once these costs are met, the leaf can then provide a net benefit in terms of carbon to the plant. This is but one of many correlations among various leaf traits that make up what is known as the worldwide leaf economics spectrum. These correlations cross over species and may be useful in developing models of plant functioning without having to make detailed physiological measurements on all known species. Figure from: Westoby, M., Falster, D.S., Moles, A.T., Vesk, P.A. and Wright, I.J. (2002). Plant ecological strategies: Some leading dimensions of variation between species. *Annual Review of Ecology and Systematics* **33**, 125–159; and is redrawn from original data in: Reich, P.B., Walters, M.B., and Ellsworth, D.S. (1997). From tropics to tundra: Global convergence in plant functioning. *Proceedings of the National Academy of Sciences of the United States of America* **94**(13), 13730–13734.

Functional traits other than leaves are also being investigated. They include a worldwide wood economics spectrum, whereby woody plant strategies can be estimated using easily measured traits such as density, which integrates both structural and functional attributes. For example, wood density is an excellent predictor of mid-day water stress and whole tree transpiration rates, independent of any particular species designation. A recent metaanalysis (a metaanalysis is a study of general patterns obtained from a suite of previous independently done studies) showed that the relationship between density and water use was quadratic in form: trees with either low or high wood density had lower transpiration rates than those with an intermediate density. The explanation proposed for this pattern is that trees with low wood density have wider diameter conducting xylem elements that are more susceptible to cavitation. Under stressful conditions these trees close their stomata to restrict water loss, while conversely, trees with high wood density have narrower conduits that limit the maximum rate of water movement up the trunks due to the constraints imposed according to the Hagen–Poiseuille law, where flow is proportional to the fourth power of the radius.

The evolution of potential plant strategies could be restricted by limited genetic variation in particular traits, which would constrain their ability to evolve in the face of strong pressures from natural selection. However, recent analyses of the amount of genetic variation in populations for various functional traits suggests that genetic constraints are less important than natural selection in determining the suite of traits that make up the worldwide leaf and wood economics spectra. The interesting opportunities for future research are to more clearly understand the tradeoffs among adaptive traits that result in the plant forms and functions specific to particular habitats and biomes, and why there is selection against alternative trait syndromes.

Plant Interactions

Interactions between plants are one of the driving forces controlling plant community structure. The nature, importance, and demonstration of these interactions generate considerable discussion among ecologists. Such interactions can result in the elimination of species from communities through the various processes of competition, whereas even very small niche differences may be enough to maintain a high biodiversity of perennial plants, sometimes for several hundreds of years.

Interaction between plants resulting in increased plant growth is called facilitation, which is most frequently viewed as one species making the environment less harsh to which the second species responds favorably. An example of facilitation is hydraulic lift. In arid environments surface soils become too dry to support shallow-rooted species, but deep-rooted species persist. In the cold deserts of North America, big sage (*Artemisia tridentata*) brings water to the surface from deeper layers. Some of this water then diffuses into the soil and supports herbs beneath the shrubs. Another example involves the fixation of atmospheric nitrogen by legumes that colonize young, infertile soils recently exposed by retreating glaciers. The addition of nitrogen to the soils then allows other plants with higher nutrient requirements to establish.

Negative interactions between plants occur when one or both plants grow poorly in the presence of the other. The term "*competition*" is frequently used to describe any negative interaction; however, this use does not fully describe the mechanisms of the interaction. If the interaction is a result of two plants utilizing the same limiting resource such as water, light, or nutrients, then that interaction is called "*resource competition*" or "*scramble competition.*" Typically the species differ in their ability to utilize the resource or to tolerate the result of reduction of the resource. Competition for water was demonstrated in a study of the interaction between the perennial bluebunch wheatgrass (*Agropyron spicatum*) and the introduced annual cheatgrass (*Bromus tectorum*) in the Palouse prairie grasslands of Northwestern United States, where most of the limited precipitation falls as winter snow. Cheatgrass grows in the winter, exhausts the water supply, and survives the summer drought as seed, while the bluebunch wheatgrass grows slowly in winter, experiences low water availability for its summer growth, and dies. This exemplifies the preemptive use of a resource and the tolerance of the result by cheatgrass.

Negative interactions may result if a substance is added to the environment by one plant with a detrimental effect on a second plant. This may be referred to as "*interference competition*" or "*contest competition*." Plants add a wide range of chemicals to the environment that have negative effects and include salts, phenolics, terpenes, alkaloids, mustard oils, and cyanides. If the added material has a negative effect on neighboring plants, then the term "*allelopathy*" is used to describe the interaction. However, such chemicals may also have additional effects in the ecosystem, such as deterring herbivores, altering litter decomposition, and affecting the nitrogen cycle. Chemical interactions among plants is now a vibrant field of study, and may help shed light on such topics as why invasive species often do so much better in their nonnative environment than the one they evolved in.

An early classic study of allelopathy by Cornelius H. Muller in the California chaparral described interaction of an aromatic shrub (*Salvia leucophylla*) with the surrounding annual grassland in which a zone immediately surrounding the shrubs was devoid of grasses, a second zone stretching out an additional 2 m had stunted grasses of a limited number of species, and a third zone was composed of uninhibited grasses, including wild oat (*Avena fatua*) and ripgut brome (*Bromus diandrus*) (Fig. 14). Muller demonstrated that the shrubs produced a variety of volatile terpenes (e.g., cineole and camphor) with the potential to inhibit growth of seedlings. However, later studies showed that the situation was much more complicated and could not be attributed solely to the production of allelochemicals from the *Salvia*. When herbivore exclosures were erected in the bare zones, grasses and other plants began growing there, suggesting that animals were also involved in the maintenance of the bare zones about the shrubs.

More commonly, allelopathic interactions result from water-soluble materials leaching from the canopy or litter or which are actively exuded from roots. In some cases, production of allelochemicals is stimulated by another stress, such as herbivory. When sagebrush is eaten by herbivores, it responds by producing allelochemicals that inhibit the germination of nearby plants. The Novel Weapons Hypothesis was proposed recently to explain biogeographical patterns in the success of the invasive species *Centaurea diffusa*. It states that when species are introduced to a new ecosystem, they may produce novel allelochemicals that inhibit native plants and facilitate their competitive abilities. Despite a long history of research, the demonstration of allelopathy in the field is difficult, since there are so many competing hypotheses to deal with. As such, the phenomenon remains controversial. As stated by Inderjit et al. (2011), "Mere production of chemicals by a plant is not sufficient to ensure their allelopathic potential." To show that a negative interaction is allelopathic, an investigator must demonstrate no other biotic interaction (resource competition or herbivory) is causative, a chemical is produced and released in sufficient quantity and at time to be effective, that the target plant is susceptible to the chemicals, and finally, that microbial transformations in the soil do not modify the allelochemicals in ways that reduce their toxicity.

Fig. 14 Allelopathy purportedly demonstrated in shrubland–grassland interface in Santa Ynez Valley, CA, United States. At left is a stand of purple sage (*Salvia leucophylla*) surrounded by a bare zone with few or no grass species. An inhibition zone of 1–2 m with foxtail fescue (*Festuca megalura* (= *Vulpia myuros*)) and soft chess (*Bromus mollis*) grading into uninhibited grassland of wild oat (*Avena fatua*) and ripgut brome (*B. diandrus*). The aromatic shrubs produce volatile compounds including cineole and camphor, which can be toxic to some of the grasses.

Plant Community Dynamics

Plant communities are assemblages of species co-occurring in a given time and place (see McGill et al., 2006). The organization, development, and repeatability of plant communities in similar habitats and through time entailed considerable discussion and controversy among plant ecologists during the 20th century. Disagreements regarding the structure and functioning of plant communities resulted from attempts to define the composition, stability, and boundaries of communities and as a result, numerous competing theories have been proposed over the years to explain these patterns. The modern synthesis states that the plant community is an assemblage of species' populations aggregated in a region resulting from dispersal mechanisms, physiological tolerances to local site characteristics, and responses to disturbance. Others suggest that new approaches are now necessary to understand the rules governing community structure and how communities may respond to disturbance and climate change.

Plant succession is described as the change in composition of vegetation in one place over time. Succession is viewed as one of two related processes: primary succession or secondary succession. Primary succession is the development of vegetation on substrate previously lacking plants (Fig. 15). Examples include the development of vegetation on sand dunes, glacially exposed substrate, filling in of lakes, etc. The earliest ecological descriptions of primary succession were by H. C. Cowles on the sand dunes of Lake Michigan and by W. S. Cooper on the development of vegetation following retreat of glaciers in Glacier Bay, Alaska. In both, the development of vegetation was viewed as a chronosequence characterized by the predominance of conspicuous plants. Conspicuous early invaders were replaced over time by species that were inconspicuous at the onset or arrived later. An example of such a chronosequence at Glacier Bay is the presence of avens (*Dryas drummondii*), followed by alder (*Alnus tenuifolia*), and subsequently by Sitka spruce (*Picea sitchensis*), a process estimated to take several hundred years.

Secondary succession is the development of vegetation following a disturbance to the original plant community. Disturbances leading to secondary succession include fire, windstorms, and anthropogenic disturbances such as logging and farming (old field succession). These successions occur on substrate that is wholly or partially intact, and consequently they occur more rapidly. The pattern of secondary succession is greatly dependent upon the type of the disturbance. For example, in a study of vegetation development at one location over several hundred years, the outcome was dependent upon whether the disturbance initiating the succession was fire or windstorm. In a classic study of old field succession, Catherine Keever found that the time of year the stand was released from farming affected the sequence of development of early plants. From this arose a body of evidence supporting the view that species' characteristics such as seed dispersal, photosynthetic light requirements, growth rate, and longevity control much of succession. Accordingly, early-successional plants are often rapidly dispersed, require high light, have high photosynthetic rates and growth rates, but are relatively short lived. Species possessing these traits are classified as r-selected. These plants give way in time to species with slower dispersal rates, greater shade tolerance, slower growth rates, but are long lived (K-selected). This concept of tradeoffs among suites of traits between early- and late-successional species frames much of the current discussion of the mechanisms of succession.

A complementary theory of plant strategies was proposed in the mid-1970s by J.P. Grime. He suggested that the dichotomous categorization of plants as early and late successional was too simplistic, and that a third axis, stress tolerance, was necessary to encompass the range of possible adaptive plant strategies (Fig. 16). Grime employed a three axis strategy, often referred to as C–S–R theory: Competitive species (C, comparable to K-selected or late successional species) are found where productivity is high and competition severe; and stress tolerators (S) occur where environmental stress, such as shade or low nutrients, is high and consequently competition is low. Ruderal species (R, comparable to r-selected, or early successional species) inhabit sites with high disturbance rates but where competition is low. The last possible adaptive strategy, which combines all three factors (high disturbance, competition, and stress), was viewed by Grime as an impossible evolutionary outcome, so no plants fell into that portion of the schema.

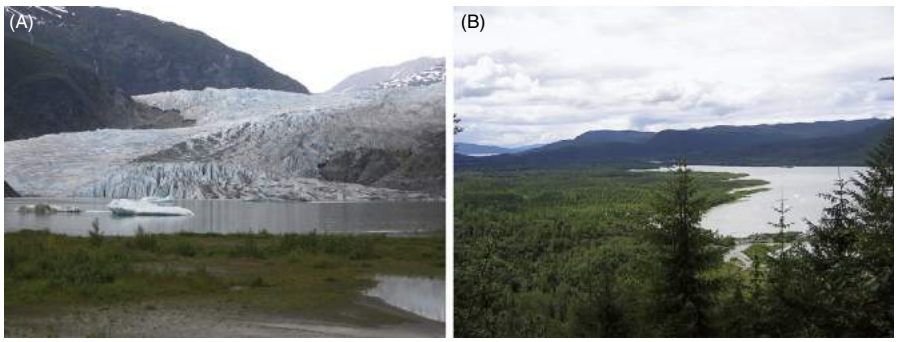

Fig. 15 Primary succession of forest development following retreat of the Mendenhall Glacier, Alaska, United Sytates. (A) Initial stages of vegetation on newly exposed glacial till in the foreground. The site was exposed within the last 20 years, and the vegetation consists of willows (*Salix* sp.), fireweed (*Epilobium* sp.), lupines (*Lupinus* sp.), alders (*Alnus* sp.), scattered Sitka spruces (*Picea sitchensis*), and western hemlocks (*Tsuga heterophyla*). (B) Forest development on glacial till adjacent to Mendenhall Lake. Ice occupied these sites in the mid-1700 s and is currently retreating at a rate of approximately 40 m year^{-1}. The vegetation consists largely of alders, Sitka spruces, and western hemlocks.

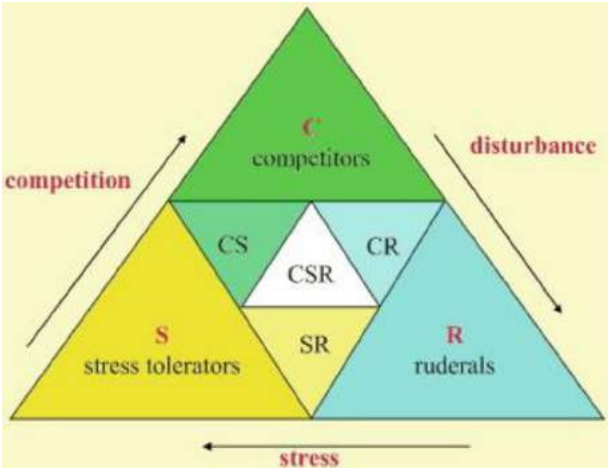

Fig. 16 Philip Grime's C–S–R triangle of plant strategies. Grime proposes that plants must adapt to three major environmental pressures: competition with other plants, habitat disturbance, and stress, caused by either excesses or deficiencies in water, light, nutrients, or herbivory. Early successional plants (often called pioneer or Ruderal plants) would be found primarily in highly disturbed, low stress environments, where competition is low (*right hand corner*). Plants in late successional environments are subject to high amounts of competition but low rates of disturbance (*upper corner*) and are known as competitors. Plants in habitats with high rates of disturbance and stress are most likely subject to low rates of competition, and are termed stress tolerators (*lower left corner*). There are no plants known that are able to withstand high levels of all three pressures, and so there is no fourth plant strategy. Of course, many habitats fall between these extremes, and may contain plants with a mixture of strategies, depending on the relative amounts of each of the three main driving factors (CS, CSR, CR, and SR). Figure from Shiro Tsuyuzaki, Hokkaido University: http://hosho.ees.hokudai.ac.jp/~tsuyu/top/dct/lc.html.

In 1988, David Tilman proposed a competing theory, known as the resource-ratio theory, to address perceived deficiencies in Grime's C–S–R theory. The resource-ratio theory predicts that plants require different ratios of resources, rather than simply different amounts of resources, and it is the ratios that place species into different niche spaces, thus allowing them to co-exist and to not violate the dictum that species with identical niches cannot co-exist indefinitely. However, extensive research over the past 25 years has failed to find much evidence in support of this theory, and it is now no longer considered as viable an explanation of plant strategies. Rather, plants compete and co-exist by modifying their physiological tolerances and their responses to environmental variation in ways that allow them to compete successfully against neighboring plants.

A rigorous review of Grime's C–S–R theory by J. Wilson and W. Lee found that there were many deficiencies in its assumptions: many of its predictions were either impossible to make, or had never been tested. Where they had been tested, the C–S–R theory proved useful in identifying various adaptive strategies of plants in particular habitats. Its main contribution appears to be that it includes the extra dimension of stress tolerance and Wilson and Lee suggest combining it with the Leaf Amortization theory, which says that the more carbon and nutrients invested in a leaf, the longer it takes for the plant to payback those construction costs before the leaf begins yielding a net profit (e.g., C) to the plant. Stress tolerant plants often display a common suite of adaptations, such as long leaf lifespans (i.e., evergreen leaves), tough leaves to withstand harsh winter conditions, low photosynthetic rates and consequently low growth rates coupled with low nitrogen content and demand from the soil.

Historically, communities were thought to progress from early successional states to a self-sustaining endpoint known as the climax community. In the early 20th century, Frederick Clements envisioned such communities as highly repeatable through time (i.e., climax communities were co-evolved sets of species) and implied, but never explicitly, that such communities might even be viewed as super organisms to an extent. This view was sharply challenged in the 1920s by H.A. Gleason, a botanist from the New York Botanical Gardens, who promoted the theory that species segregated individually along environmental gradients according to their own physiological tolerances, an idea known as the individualistic hypothesis. Most ecologists today concur with Gleason's hypothesis and paleoecological studies of community composition changes that occurred as the glaciers receded in North America and other places document the presence of unique communities unlike any we see today.

In the current view a climax community represents an oscillation of community organization around a dynamic equilibrium stage, that is, there are small, mostly random changes in species composition, but with little or no direction (Fig. 17). The difficulty of describing the climax state is one of scale. Vegetation change is observed differently as the size of the measurement unit increases from a single stand of a few individuals to regional scales incorporating hundreds of stands. Small-scale disturbance on the order of loss of single individuals may cause a microsuccessional sequence, if that individual is predictably replaced by another species with other ecological attributes. This may create a patchwork of communities, which on one scale appear to be in different stages of succession while on a larger scale appearing to represent a dynamic mosaic of regional vegetation.

The maintenance of biodiversity in plant communities has been the subject of much discussion for nearly a century now. The classic explanation has been that niche differences allow species to coexist because resources are partitioned slightly differently among species and that species with similar niches cannot co-occur indefinitely. But a competing theory, the neutral theory of biodiversity, states that niches are not important, and that all competitors are equally competent, which is what allows species to

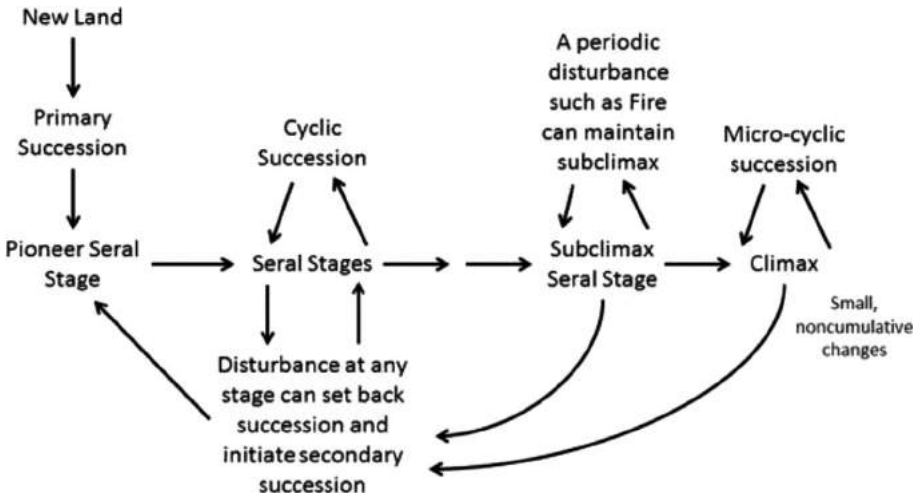

Fig. 17 A diagram of various successional pathways in plant communities. Primary succession occurs on newly exposed land, such as land exposed after glaciers retreat, or is newly produced by lava flows from volcanoes. Various plant species establish over time leading to a series of successional stages that culminate in a dynamic climax community. Some successional stages may oscillate or revert back to earlier stages (cyclic succession), while periodic disturbances may set succession back to earlier several stages. At the climax stage, there are small-scale changes in the plant communities (micro-cyclic succession), dependent on localized plant death (disease) and disturbance (wind throw), and which occur in a mosaic of patches across the landscape. Redrawn from: Barbour, M.G., Burk, J.H., Pitts, W.D., Gilliam F.S. and Schwartz, M.S. (1999). *Terrestrial Plant Ecology*, 3rd edn, Menlo Park, CA: Addison Wesley Longman, Inc.

co-exist. Recent research suggests that niche diversity allows the maintenance of competing species for the following reasons. When a species is rare in the community, it is more likely to compete with other individuals of that same species, who also share essentially the same niche. They are less likely to compete with another different species, so most of the competition is with members of its own species. Only when that species becomes more abundant will its effects on competing species become significant. The per capita growth rate of the population then, is higher when that species is rare and its competitors common, which results in a stabilizing effect, because it prevents the competitors from displacing them from the community (Fig. 18).

Disturbance is characteristic of most plant communities. Natural disturbance includes fire, wind damage, grazing, insect damage, frost heaving, flooding, disease, and other causes. The spatial extent of disturbance may differ from an individual to large regional effects. Disturbance has two attributes affecting vegetation: frequency (or return interval) and intensity. Fire is one disturbance that illustrates these attributes (Fig. 19).

Fire has an important influence on community structure in most semiarid regions including biomes such as grasslands, savanna, and Mediterranean scrub. Fire also is suggested to be important in boreal forests, coniferous and deciduous forests, and even in bogs. Fires may reoccur at frequencies of 1–5 years in grasslands, 25–100 years in Mediterranean scrub communities and eucalypt forests, and 100–500 years in coniferous and deciduous forest communities, although these return frequencies can vary depending on edaphic conditions, such as soil depth and susceptibility to drought. For example, in the Linville Gorge Wilderness Area in the mountains of western North Carolina, the lower slopes are dominated by deciduous forest while on the thin-soiled ridges, fire-adapted species such as Table Mountain Pine (*Pinus pungens*) predominate. Historical records suggest that the return frequency for ground fires ranges between 5 and 12 years, while catastrophic crown fires occur about every 75 years. As a consequence, many species have unique adaptions to fire. Table Mountain Pine (and its close relative pitch pine, *Pinus rigida*) both have *serotinous pine cones*, which only open and disperse their seeds after being heated in a fire.

Each fire frequency results in different modifications to the species and communities that persist in the region. In the absence of frequent fires communities may change in composition and structure. For example, as a result of anthropogenic decreases in fire frequencies, the vegetation of the prairie peninsula of Midwestern United States was converted from grasslands to deciduous forest. In the eastern United States, fire intolerant species, such as red maple (*Acer rubrum*) have become more common. Furthermore, the absence of fire results in a buildup of litter on the forest floor, creating a large fuel load that when ignited, leads to catastrophic crown fires that can devastate an area and destroy the forest. Once the forest is lost, rain events can lead to uncontrolled soil erosion, which may delay successional recovery for decades. In bogs, which can occasionally become dry during years of low rainfall, the absence of fires allows woody shrubs to invade, which then shade out various light-demanding herbaceous species, such as the charismatic and carnivorous Venus fly-trap (*Dionaea muscipula*).

The intensity of a fire can be gauged by the level of its destruction. Fires may be classified as high, moderate, or low intensity. Highly destructive fires kill all the aboveground living matter, and only seeds, rootstocks, and rhizomes that are far enough underground to avoid the extremely high temperatures remain to repopulate the community. Such is the case in grassland fires, Mediterranean scrub, and some coniferous fires, especially those with large fuel loads (see above).

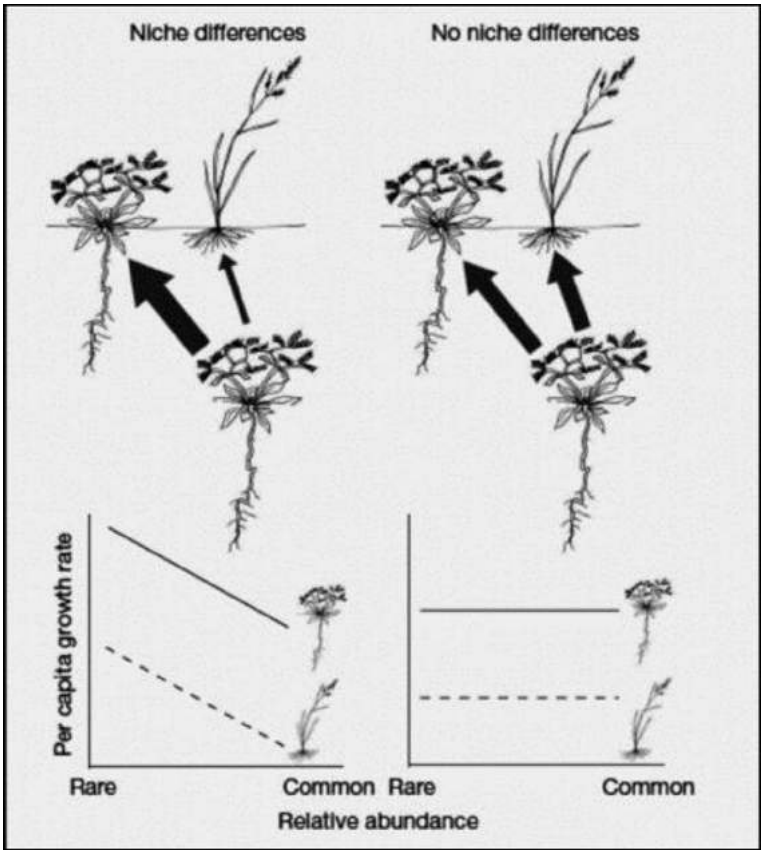

Fig. 18 An example of how differences in niches may maintain species diversity in plant communities. In this case, two species differ in rooting depth and most likely withdraw water and nutrients from different soil compartments. The larger the width of the arrow, the greater is the competitive influence of that species. When a species is rare (see graph and figures on *left*), it is more likely to compete against another species which is common. Since the two species differ in their belowground niche spaces, interspecific competition is minimal and the rare species can have high per capita growth rates. When rare species increase in abundance, they begin to compete more among themselves and less against their competitors, which reduces their per capita growth rates. If there were no niche differences (see graph and figures on *right*), then species would limit themselves as much as their competitors, whether rare or common, and per capita growth rates would remain unchanged. These dynamics then allow the maintenance of a high diversity of plant species in the community, despite the apparent similarity in their resource requirements. Figure courtesy: Levine, J.M. and HilleRisLambers, J. (2009). The importance of niches for the maintenance of species diversity. *Nature* **461**, 254–258.

Moderate-intensity fires kill photosynthetic structures and some meristematic tissues. Standing vegetation may resprout and produce new photosynthetic structures, for example, the Pine Barrens of New Jersey, United States, where pitch pine produces new branches from epicormic buds beneath the bark and Mediterranean ecosystems, wherein shrub species sprout prolifically after fires. The germination of some Mediterranean species occurs only after exposure to smoke, insuring that seedlings germinate when the probability of competition from vegetation is low and environmental resources such as light and nutrients are high.

Finally, low-intensity fires can affect the ground layer of vegetation without a dramatic effect on the canopy. The effect of this type of fire is to control the composition and reproduction of the community. Examples of these communities include the ponderosa pine forests of western North America and the longleaf pine–wire grass communities of the southeastern Coastal Plain of North America. In both cases, frequent fires maintain the dominant overstory trees (*Pinus ponderosa* or *Pinus palustris*, respectively) by reducing the successful establishment of broad-leaved competitors as well as eliminating diseases that attack the pines. Fire interacts with an additional disturbance regime—tropical storms/hurricanes—to maintain the structure and function of longleaf pine ecosystems.

Each type of disturbance produces different ecological and evolutionary constraints on the vegetation. Frequent, low-intensity disturbance results in a distinctively different vegetation than infrequent, high-intensity disturbance. Each of these vegetation types will have a different response to the disturbance. With frequent, low-intensity disturbance there may be little compositional change following the disturbance. The plants of this vegetation have adaptations that allow rapid recovery following the disturbance. Conversely, with infrequent, high-intensity disturbance a successional sequence may occur because the adaptations of initial invaders that favor response to disturbance may not convey adaptive advantage in competition over time.

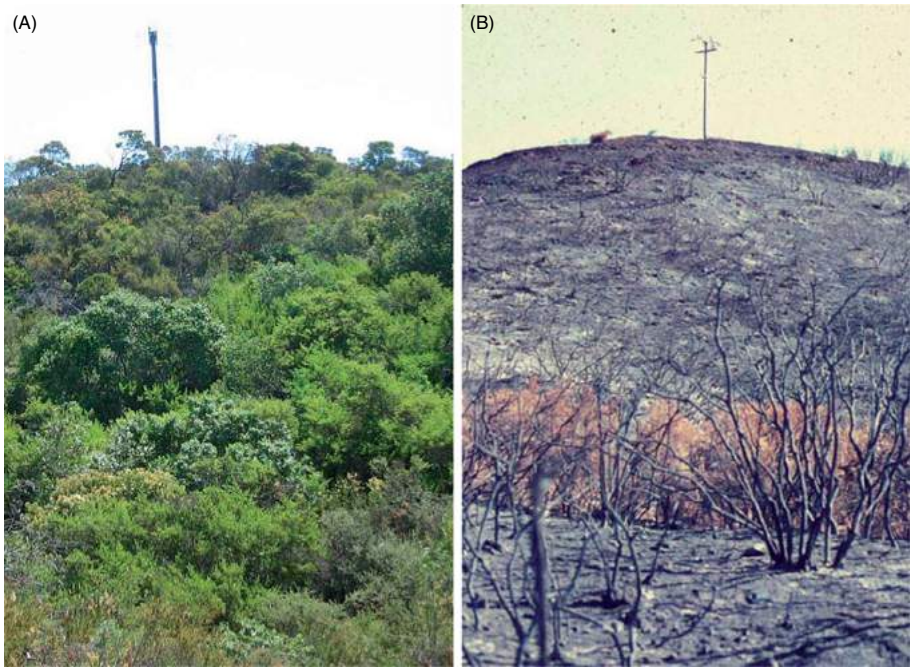

Fig. 19 Unburned and burned chaparral in Santa Barbara County, CA, United States. Both photographs were taken of the same area but separated by 32 years. (A) Typical unburned chaparral in 2003 consisting of chamise (*Adenostoma fasciculatum*), California lilacs (*Ceanothus* spp.), and toyon (*Heteromeles arbutifolia*). (B) Burned chaparral following an intense fire in 1971. The utility pole serves as a reference point. The photographs indicate the rapid recovery of the vegetation following fire.

Summary

The sessile nature of plants requires they integrate the immediate environment for the duration of their lives. The presence of a plant suggests that, for the period of occupying that site, the environment has met all minimal requirements for light, water, and nutrients while not surpassing the tolerances of the plant to abiotic and biotic factors. Plant interactions alter the physical and biotic effects of the environment and may lead to alteration in community composition. When plants are no longer able to alter the environment beyond the tolerance of the occupants, a dynamic stability in community composition is established. This composition is often changed as a result of disturbance in the form of herbivory, wind, flooding, or fire. Depending upon the frequency and intensity of disturbance, an altered and dynamic community may occupy the site.

Acknowledgments

The authors would like to thank Drs. Lara Souza and Catherine Cole for helpful improvements to the manuscript.

Plant Physiology☆

Ulrich Lüttge, Technical University of Darmstadt, Darmstadt, Germany

What Is Physiology? What Is Ecology?

A well-known dictionary of the English language says that physiology is "the science of the function of living organisms and their parts" and that ecology is "the branch of biology dealing with the relations of organisms to one another and to their physiological surroundings" and if we follow more closely Ernst Haeckel's original definition when he first introduced the term ecology in 1866 we have it as "the entire science of the relations of the organism to its surrounding environment, comprising in a broader sense all conditions of its existence." Hence, if we want to bridge the interface between general ecology and plant physiology we must consider functions of parts and the whole of organisms on the one hand and all conditions of their existence on the other hand and integrate both. It shall be done by looking first at plant physiology and then at ecology and finally by combining both, choosing physiological ecology of photosynthesis as a case study because photosynthesis with its primary production of new biomass from inorganic precursors is of paramount importance for all life on Earth.

Plant Physiology: Function of Plants and Their Parts

The Parts

In a hierarchical order the parts of plants are molecules, membranes, organelles, cells, tissues, and organs. Macromolecules such as polynucleic acids, proteins, polysaccharides (carbohydrates), and lipids may have both structural and functional roles. Biological membranes composed of lipids and proteins (lipoprotein membranes) border the living cells at their surface (the plasma membrane) and separate and conceal various compartments inside the cells, for example, the central cell sap vacuole (the tonoplast) typical of plant cells. Important organelles within cells are the mitochondria and the chloroplasts. The plant cells are surrounded by cell walls composed of polysaccharides, most importantly cellulose. Individual cells can already be independent autotrophic organisms, such as prokaryotic photosynthetically active bacteria and cyanobacteria, which as endosymbionts also have become the evolutionary precursors of chloroplasts, and eukaryotic unicellular algae. In the pluricellular algae, bryophytes, and vascular plants, many cells build up tissues, different tissues form organs and various organs, such as roots, stems, leaves, and flowers make up the whole vascular plant. Eukaryotic plant cells have a nucleus with chromosomes where the central genome is located, but they have two additional genomes in the two organelles, the mitochondria and the chloroplasts, which as original endosymbionts in the phylogenetic history of the eukaryotic cells have retained their own deoxyribonucleic acid (DNA) carrying genetic information.

The Functions

The main concern of plant physiology is the causality of functions. A basic property of life is metabolism. Therefore, we may distinguish functions of biochemistry and functions of development.

☆*Change History:* March 2018. Irene Martins made minor changes to the text and references.

Biochemical Functions

A major distinction of biochemical functions is dissimilation and assimilation. Dissimilation breaks down substrates for energy metabolism and also for the formation of monomeric building blocks for the synthesis of macromolecules. Assimilation in photosynthetically active plants is the most noble character of plants because the strictly autotrophic plants can build up their entire organic biomass from inorganic precursors, not only carbon compounds from carbon dioxide and water in photosynthesis, but also nitrogen- and sulfur-containing organic molecules from inorganic ammonia and nitrate, sulfate and sulfide. This is of eminent basic ecological importance as it is the only pathway for the entry of inorganic matter into the organic biomass on Earth.

Dissimilative processes are fermentation in the cytoplasm and respiration in the mitochondria breaking down carbohydrates and serving energy metabolism as well as providing building stones for the synthesis of proteins and lipids. Similarly the breakdown of proteins and lipids (fatty acids) to their monomeric building stones are dissimilative processes which also can considerably contribute to energy metabolism in the case of lipids. The major assimilative process is photosynthesis. The biosynthesis of structural and functional macromolecules uses the monomeric building stones of organic bases and pentoses (five carbon sugars) for polynucleic acids, amino acids for proteins, various monomeric sugars for polysaccharides, and activated acetic acid (acetyl-coenzyme A) for lipids. A list of important compounds in the biochemistry of plants and their functions is given in Table 1. The major role of polynucleic acids is in storage, transmittance, and active use of genetic information. Proteins serve structural functions but are particularly important as biocatalyzers in enzymatic reactions. Lipids together with proteins build up the lipoprotein biomembranes. Carbohydrates have major structural functions in the cell walls of plants and, in this way, also are the basis of the formation of wood in the stems of plants and the trunks of large trees.

In addition, we must note that plants are the most inventive biochemists we can imagine. They can produce a vast diversity of natural products some of which may be classified as terpenoids, phenolic compounds and organic bases, and alkaloids (Table 1). Among the latter the stimulating compounds of coffee, tea, and tobacco as well as drugs such as atropine, chinine, curare, opium, cocaine, mescaline, and coniine, are well known.

Having mentioned the separate biochemical functions of cytoplasm, mitochondria, and chloroplasts above, it should be evident that metabolism in plant cells is compartmentalized. This is possible by the separating functions of membranes concealing the compartments. However, like any good border such membrane borders must not block off the various compartments hermetically from each other. On the contrary, they must allow a controlled and regulated cooperation of compartments. This is provided by transport proteins crossing the membranes, that is, carriers and channels for substrates mediating the exchange between the compartments. Separate biochemical and physiological functions of the organs leaves, roots, and flowers need translocation in the long-distance transport pathways of the phloem for assimilates and the xylem for water plus mineral nutrients.

Analytical techniques have now advanced to the extent that one can collect information about entire complements of various compounds. We call this "omics," such as genomics deciphering entire genomes, transcriptomics covering gene transcripts, proteomics analyzing sets of proteins, and metabolomics assessing occurrence of metabolites. This is very descriptive of the functional system of organisms and provides huge sets of data. New theoretical approaches are developed to digest this information for the quest of understanding causality, for example, network dynamics (Fig. 1).

Table 1 Important chemical compounds and their major functions in plants

Compound class	*Monomers*	*Polymers*	*Functions*
Primary metabolism and functions			
Carbohydrates	Monosaccharides (pentoses, C_5; hexoses, C_6)	Polysaccharides	Structure Storage (e.g., starch)
Proteins	Amino acids	Proteins	Biocatalyzers Structure (membranes) Storage
Lipids	Activated acetyl Glycerol	Fatty acids Lipids	Structure (membranes) Storage (fats)
Nucleic acids	Organic bases, pentoses (ribose) (deoxyribose)	Polynucleic acids: ribonucleic acid (RNA), deoxyribonucleic acid (DNA)	Genetic information
Natural products and their functions			
Terpenoids	Isopentenyl-pyrophosphate (C_5)	Mono- (C_{10}), di- (C_{20}), tri- (C_{30}), tetra- (C_{40}), poly- ($C_{500-5000}$) terpenes	Phytohormones, scent compounds, pigments, defense, resins
Phenolic compounds	Phenol	Flavones Flavonols	Electron transport Pigments Structure (the lignin of wood)
Anthocyanidines			
Alkaloids	Amino acids Organic bases		Defense Nitrogen storage

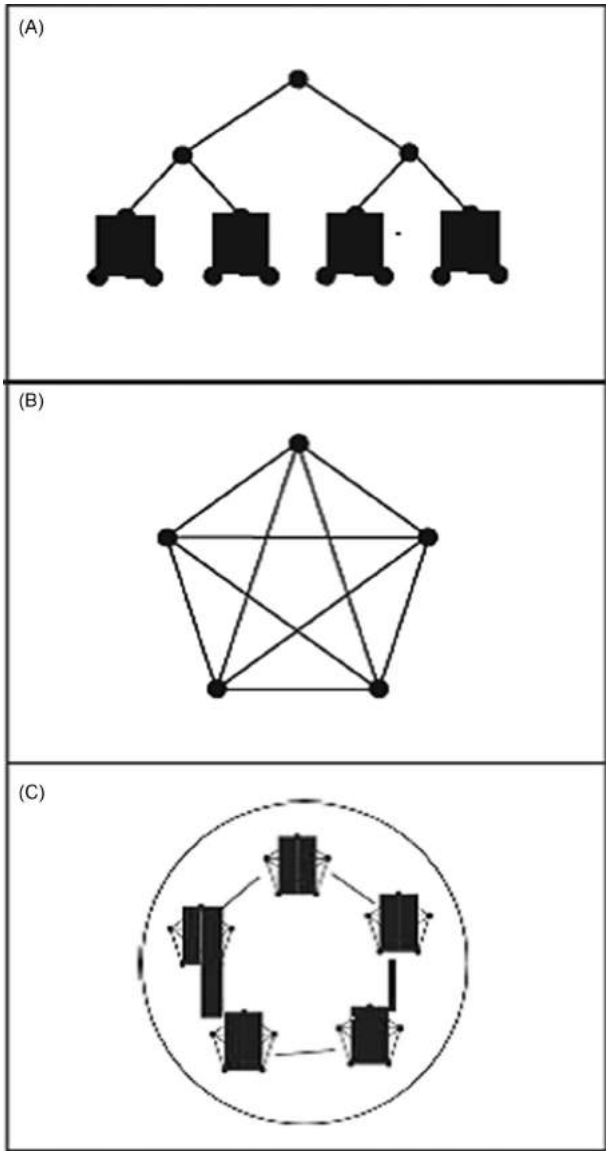

Fig. 1 Schemes of different types of networks: (A) open network with a hierarchy of levels, (B) closed network with (knots) and edges (connecting lines) where the hierarchy of levels is lost, (C) complex network composed of different closed networks, where each of the subnetworks composing it can be considered as a knot and where the supernetwork itself may become a knot in a yet more highly integrated supranetwork.

Developmental Functions

The life cycle of higher plants comprises germination of seeds, growth, flowering, fertilization, and sexual reproduction forming seeds. Since plants normally cannot move around and are bound to a given location their orientations in space also are largely given by developmental processes. These processes involve increases in plant size and mass by assimilation. However, life cycles also require the most complex differentiations. These are regulated by effectors which can be external or internal control parameters and which evoke differential activation/inactivation of genes. External control parameters are environmental cues linking developmental functions to ecological responses. Internal control parameters among others are various phytohormones controlling different developmental functions. External and internal control parameters interact. There are primary and secondary messengers. All of this is interwoven in signaling networks of an extraordinarily high degree of complexity, an example of which is shown in Fig. 2 where the signal transduction pathways from an effector to the phosphorylation of proteins are depicted. Protein phosphorylation is an essential element in differential gene regulation as well as directly in cellular metabolic functions.

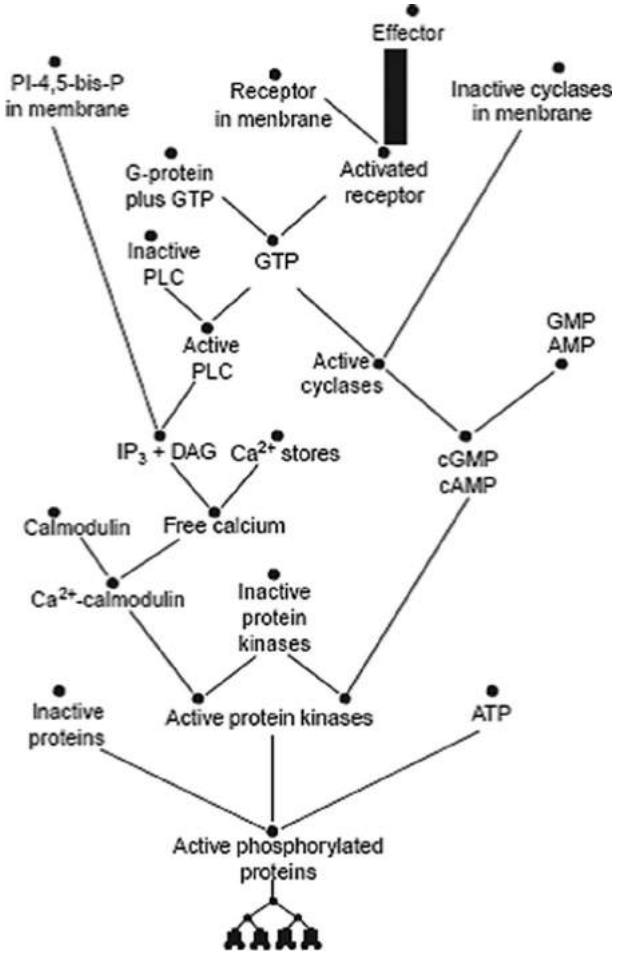

Fig. 2 Molecular regulation network in the signaling cascade from effector to active phosphorylated proteins. An effector which can be any external factor including light, that is, mainly blue and red light, or any internal factor including metabolites and phytohormones reacts with an appropriate receptor (mainly in a membrane, e.g., the plasma membrane). The activated receptor releases guanosine-triphosphate (GTP) from a GTB-binding so-called G-protein, which binds to and activates phospholipase C (PLC), active PLC hydrolyzes membrane-bound phosphatidyl-inositol-4,5-bisphosphate (PI-4,5-bis-P) to inositol-1,4,5-tris-phosphate (IP_3) and diacyl glycerol (DAG) which elicit the release of the second messenger calcium from membrane-bound Ca^{2p}-storing compartments, free Ca^{2p} ions bind to the small peptide calmodulin, and Ca^{2p}-calmodulin activates protein kinases. GTP also can activate membrane-bound cyclases which from guanosine- and adenosine-monophosphates (GMP, AMP) form the respective cyclic derivatives cGMP and cAMP which then activate protein kinases. Activated protein kinases phosphorylate proteins, and the activated proteins can either directly affect metabolic processes or move into the nucleus and function as gene regulation factors.

Plant Ecology: All Conditions of Its Existence

The conditions of the existence of organisms in their environment are given by abiotic and biotic factors. In or near their optimum these factors or external control parameters fulfill basic requirements. However, according to the biological stress concept any of a vast multitude of factors can become a stress factor or "stressor" when its dosage is either too low or too high.

Abiotic Factors

The most important abiotic factors for plants are light, carbon dioxide, water, temperature, nutrients, and salinity. Their actions are interrelated in a functional network involving all major processes of plant physiology in the ecological performance of plants (Fig. 3).

Light drives photosynthetic CO_2 fixation and also photorespiration and excess light can lead to overenergization of the photosynthetic apparatus and formation of reactive oxygen species (ROS) and oxidative stress. Light is heating up the leaves. Light may also have a signaling function. Day length (photoperiod) may have developmental consequences. Particularly, red and blue light can function as effectors in signaling networks (Fig. 2) and in this way, light can also lead to the developmental formation of sun and shade leaves. Light affects the movements of stomatal guard cells, opening and closing of stomatal pores in leaves which regulate gas exchange, that is, CO_2 uptake and loss of water vapor by transpiration. This affects CO_2 assimilation and also transpirational cooling of leaves. Temperature has important effects on metabolism. Heat, cold, and freezing are important

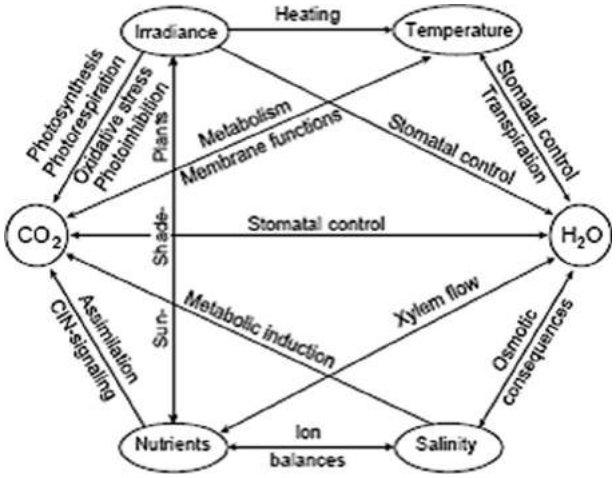

Fig. 3 Factor/function network of physiological ecology.

stressors. Transpiration and the xylem flow of water affect uptake and distribution of nutrients. Nutrients and light interact, for example, in the formation of sun and shade plants, where the shade plants generally have a higher demand of nitrogen. CO_2 assimilation and nutrients interact in the assimilation of inorganic nitrogen and sulfur and in carbon/nitrogen signaling functions in the whole plant. Salinity is one of the outstanding ecological challenges worldwide and, in particular, is a great problem in irrigation agriculture. Salinity affects plant–water relations due to osmotic consequences and has adverse effects on ion nutrient balances, and especially the sodium ions of NaCl have adverse effects if accumulated in plant cells and not sequestered by transport across the tonoplast into the central cell vacuole. These are but a few of the possible interactions and the reader may discover others by moving around in a scheme like that of Fig. 3.

Biotic Factors

Important biotic factors are competitors and nurse plants, predators, parasites, and symbionts eliciting antagonisms and mutualisms. Competition between plants for light often is given by shading and also by filtering certain wavelengths out of the solar spectrum, especially in the red region, where they are important for photosynthesis and for signaling functions. In the soil, competition is for water and nutrients. Plants develop chemical defense mechanisms, so-called allelopathic reactions. Conversely, plants can also nurse other plant species allowing seedling establishment and early growth under their canopy, a phenomenon which like in ecology is also very important in agroforestry. Animal predators and microbial and animal parasites, of course, cause manifold stress situations which need not be enumerated here. Plants often develop characteristic responses against such parasites where, in a so-called hypersensitive reaction, they produce aggressive defense compounds, often ROS, sacrificing small parts of their own tissue and killing the intruders with it. Important plant/plant parasites are the hemipara-sites which are green and photosynthetically active but divert the xylem stream from their hosts parasitizing for water and nutrients, such as mistletoes and the agricultural weed Striga in the tropics. In plant/plant holoparasitism, the parasites are not active photosynthetically and tap both the phloem and the xylem of their hosts, obtaining assimilates together with water and nutrients. Mutualisms and important symbioses of plants are the mycorrhiza with fungi for obtaining water and nutrients in exchange against photosynthetic assimilates and the root nodules with bacteria fixing atmospheric nitrogen.

Photosynthesis: A Special Case Story

Green photosynthesizing prokaryotes, algae, and plants are the primary producers of ecosystems. Hence, it appears most appropriate to choose photosynthesis as a particular case to illustrate the close relations of plant physiology and ecology, physiological ecology as it were, and cast a bridge between the two disciplines.

Scalar Levels in Space and Time

Starting the hierarchical levels of the parts of plants above at the bottom of the scale with molecules was prudent but not quite right. When we look at photosynthesis we realize that we must extend the scale to a still very much finer level, that is, that of the elementary particles of physics, the photons and electrons. When the appropriate photons of the blue and the red part of the solar spectrum of wavelengths are absorbed by the molecules of chlorophyll, electrons are excited and moved along an electron transport chain in the internal membranes, the thylakoid membranes, of the chloroplasts to generate the reduction equivalents and chemical energy required for the assimilation of CO_2. At the other end of the scale, we move from leaves to canopies entire ecosystems,

biomes, and even the whole planet. Thus, the spatial scale taken in one dimension (meters) from molecules to the entire globe covers about 15–16 orders of magnitude. For the timescale, we note that the half-life of excited states of chlorophyll are 10^{-15} to 10^{-13} s for the so-called second singlet state attained after the absorption of a blue photon and 10^{-11} to 10^{-9} s for the first singlet state after absorption of a red photon. Time constants for electron transport in the membranes of chloroplasts are up to the range of seconds. Activation of the CO_2-reducing Calvin cycle of photosynthesis takes minutes. Stomatal responses in photosynthetic gas exchange may reach several tens of minutes. Time constants of photosynthetic productivity in whole plants, trees, forests, ecosystems, and biomes are weeks, months, and years, decades, and hundreds of years, and the evolution of life on Earth took about $(3–4) \times 10^9$ years. Thus, the temporal scale (seconds) covers at least 32 orders of magnitude (Fig. 4). Another couple of numbers illustrating the vast range of scales covered is that the surface of the globe receives a solar irradiance energy of about 7×10^{16} Js^{-1}, while the energy content of one exciton stable for 10^{-15} to 10^{-9} s after the absorption of a photon by a chlorophyll molecule is $(30–45) \times 10^{-20}$ J.

Environmental Control Parameters

Water, irradiance, and carbon dioxide (CO_2) are the dominating environmental control parameters in the physiological ecology of photosynthesis and frequently stress limitations are due to water supply and high irradiance. The interaction of these factors can be assessed using Fig. 3 and will be discussed below.

Hydraulic Limitation

The most important regulatory response of photosynthesizing plant leaves to problematic water supply is stomatal closure by guard cell movements. This prevents or at least highly reduces the loss of water in the gaseous form by transpiration. However, it must be considered a compromise and also has negative effects. The most obvious one is that as long as stomata are closed CO_2 cannot be taken up from the atmosphere and production of assimilates stalls. Stomatal closure also amplifies adverse effects of high irradiance. It prevents transpirational cooling when high insulation heats up the leaves. Blocking CO_2 uptake, stomatal closure contributes much to overenergization of the photosynthetic apparatus because the remaining CO_2 in the internal airspaces of leaves is rapidly fixed in photosynthesis and then CO_2 is lacking as an acceptor for the reduction and energy equivalents of reduced nicotinamide adenine dinucleotide phosphate (NADPH) and adenosine triphosphate (ATP) (Fig. 5) produced in photosynthetic electron transport.

High Irradiance

When the production of NADH and ATP is faster than their consumption by the energy-demanding photochemical work of CO_2 reduction and assimilation the molecular elements of the photosynthetic electron transport chain rapidly get reduced and closed for

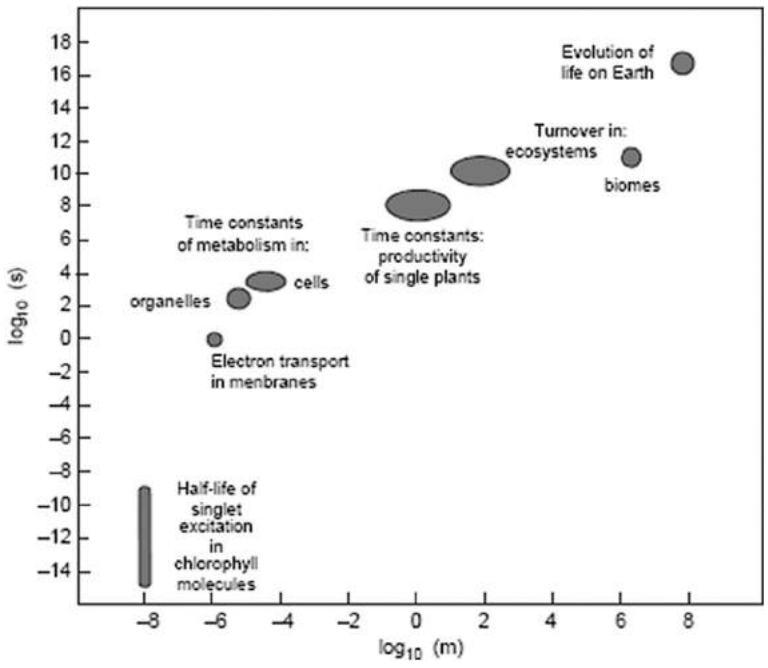

Fig. 4 Scalar levels of structures (in a one-dimensional notation of meters) and time constants of functions (in seconds) in relation to photosynthesis and dependent processes.

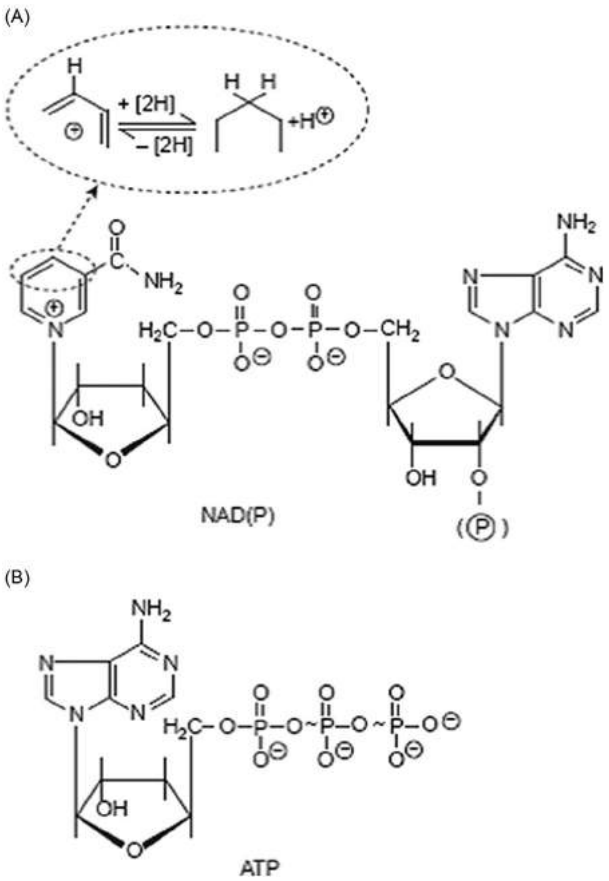

Fig. 5 Chemical structures of (A) nicotine adenine dinucleotide (phosphate) (NAD(P)) and (B) adenosine triphosphate (ATP), where the insert at the upper left corner in (A) shows the transfer of a reduction equivalent [2H] and the squiggled bonds in (B) indicate energy-rich phosphate bonds of energy equivalents.

further electrons. This occurs at high irradiance when not all of the excitation energy of chlorophyll can be used in photochemical work and the excited chlorophyll cannot relax in this way. The plant has evolved several protection mechanisms for this situation.

First, there is photorespiration. This is based on the dual affinity of the CO_2-fixing enzyme ribulose-bis-phos-phate carboxylase/oxygenase (RubisCO) for both CO_2 and oxygen (O_2). When it reacts with O_2, at low CO_2/O_2 concentration ratios in the leaves, carbon and metabolite flow occurs through the cycle of photorespiration. This is also photochemical work, but it is futile and dissipates energy. Second, the energy absorbing and transferring photosystems of the thylakoid membranes have a very complex sophisticated structure, and there are pigments absorbing light energy in the light-harvesting antennas of photosystems and diverting the excitation away from the central reaction centers of the photosystems as well as futile cycles of oxidation (forming epoxides)/reduction of xanthophyll-type pigments dissipating energy in the form of heat. Third, partial and reversible destruction of structural components reduces the light-absorbing activity of photosystems. This involves turnover of proteins as well as the arrangement of antennas and cores of photosystems in the thylakoid membranes. Fourth, the ROS formed from excited electrons of chlorophyll molecules notwithstanding the first three protective mechanisms can be deactivated by superoxide dismutases, and biochemical redox active mechanisms, like the glutathione/ascorbate cycle.

We realize that there are cascades of measures to overcome high irradiance stress. They are related to the phenomenon called photoinhibition which may be protective even if partially destructive, when destruction is reversible. Finally, when the intensity of stress overrules the protective measures parts of the plant or the whole plants may die: they are literally burnt by the ROS.

Carbon Dioxide (CO_2)

Currently anxieties are nourished by dramatic anthropogenic increases of atmospheric CO_2 concentrations. However, we may note that during the geological history of our planet and the evolution of photosynthesis, CO_2 concentrations have fluctuated very much, for example, 230 million years ago they were about 6 times the present levels, 270–310 million years ago they were similar, and 460–535 million years ago they were much higher, that is, about 20 times more than right now. Thus, the affinity to its substrate which the key enzyme of primary photosynthetic CO_2 fixation, RubisCO, has evolved is not so high that it could operate at

saturation under the current atmospheric CO_2 concentration. This problem is amplified for water plants by the low solubility of CO_2 which dissolves in the form of bicarbonate (HCO_3^-) while the actual substrate of RubisCO is CO_2. Hence, many photosynthesizing water plants, cyanobacteria, and algae, have developed carbon-concentrating mechanisms in which carbonic anhydrase, the enzyme catalyzing the $CO_2 = HCO_3^-$ equilibrium, plays a central role.

Among the terrestrial higher plants two different mechanisms of carbon concentrating have evolved which are of eminent ecophysiological relevance, especially in relation to hydraulic and irradiance stress. These are C4 photosynthesis and Crassulacean acid metabolism (CAM). The standard photosynthetic pathway is C3 photosynthesis named after the first stable compound produced after fixation of CO_2 by RubisCO, the three'carbon organic acid 3-phosphoglyceric acid (3PGS), which is then reduced to carbohydrate in the Calvin cycle. C4 photosynthesis and CAM are modifications of this pathway, where, in both cases, the primary fixation of CO_2 is not by RubisCO but by phosphoenolpyruvate carboxylase (PEPC) and the first stable fixation product is the four carbon organic acid malic acid (or malate the anion of this acid). This gave C4 photosynthesis its name. Subsequently, malate is decarboxylated again and the CO_2 regenerated is refixed and assimilated via RubisCO. Why this detour via PEPC and what is the difference between C4 photosynthesis and CAM? The CO_2 affinity of primary fixation by PEPC is 60 times higher than that of RubisCO. This enables PEPC to operate at substrate saturation and drive CO_2-concentrating mechanisms.

In C4 photosynthesis, primary CO_2 fixation by PEPC occurs in an outer tissue (the so-called mesophyll tissue), the malate produced is transported into an inner tissue around the veins or bundles of the leaves (the so-called bundle sheath tissue) where decarboxylation and CO_2 concentrating to about six times that of the ambient atmosphere for subsequent fixation by RubisCO takes place. At this elevated CO_2, RubisCO works close to its saturation and can use a higher proportion of excitation energy for photochemical work. Even if stomata are partially closed to reduce transpiration, still enough CO_2 can diffuse into the leaves for high-affinity fixation by PEPC. We can see that compared to C3 photosynthesis C4 photosynthesis is better suited to deal with stress due to hydraulic limitation and high irradiance.

CAM occurs in many different families of vascular plants, but the name is derived from the family of Crassulaceae (Crassulacean acid metabolism, CAM) where it was first discovered. In C3 and C4 plants, CO_2 fixation and the light-dependent reactions of photosynthetic electron transport must run simultaneously which includes the dilemma that during CO_2 uptake water vapor is lost by transpiration through open stomata. In CAM, primary CO_2 fixation occurs in darkness during the night when the driving force for transpiration, that is, warm and dry ambient air, is highly reduced and loss of water vapor is minimized. The malic acid produced is stored overnight in the central cell sap vacuoles and is remobilized and decarboxylated during the day. In this phase, stomata are closed and very high internal CO_2 concentrations between 2-fold and 60-fold atmospheres are built up so that RubisCO works at substrate saturation while transpiratory loss of water is prevented. Again, this is an effective mechanism of dealing with hydraulic limitation and high irradiance. The principal difference between C4 photosynthesis and CAM is that the two carboxylation processes are separated in space (mesophyll and bundle sheath) in the former and in time (night and day) in the latter, that is, that CO_2 concentrating is restricted in space (bundle sheath in C4 photosynthesis) and time (light period in CAM), respectively.

The three modes of photosynthesis are constitutive in many plant species. However, there are also C3/CAM intermediate plants. Constitutive CAM itself is already quite plastic because when water stress is not severe, CAM plants can open the stomata in the later afternoon, when the nocturnally stored malic acid is consumed, and take up and fix atmospheric CO_2 like C3 plants. In the truly C3/CAM intermediate species, the expression of either of the two photosynthetic phenotypes is flexible and, in many cases, reversible depending on the environmental conditions. For various intrinsic physiological and biochemical reasons the productivity of CAM is lower than that of C3 photosynthesis, and therefore it is only profitable for the plant to perform CAM when the environmental situation is stressful and it is preferable to perform C3 photosynthesis when water availability is sufficient.

Impact at the Community Level: From Physiological Autecology to Physiological Synecology

Primarily, physiological ecology is autecology assessing the physiological traits of individual plants or species in relation to ecological performance. Conversely, synecology covers larger vegetation units, ecosystems, or biomes and is mainly based on floristic, phytosociological, and phytogeographical approaches. However, physiological ecology can also develop to synecology when larger data sets on physiological reactions for different plants composing the vegetation can be obtained. This is increasingly facilitated in the physiological ecology of photosynthesis due to miniaturization of equipment for measuring gas exchange (CO_2 and water vapor) and parameters of photosynthetic electron transport. The former is assessed by infrared gas analysis (IRGA). The latter is particularly easy to achieve by measurements of chlorophyll fluorescence. When discussing the above the various ways of energy dissipation of activated chlorophyll, fluorescence has not been mentioned yet. In fact, a small part of the energy not used for photochemical work can be released again by emission of light, that is, fluorescence, which is readily recorded using miniaturized pulse amplitude-modulated fluorometers. In addition, appropriate sampling for analyses of metabolic compounds and also stable isotopes (mainly ^2H or deuterium, ^{13}C, ^{18}O, ^{15}N) provides a wealth of information. There are several isotope effects in metabolism in general and in photosynthesis in particular. For example, the discrimination of RubisCO against the rare ^{13}C isotope in the substrate CO_2 as compared to the abundant ^{12}C isotope is much larger than that of PEPC, and thus, with the appropriate precautions mass spectrographic analyses of carbon isotope ratios in dried plant material allows to distinguish C3, C4, and CAM plants.

General Importance of Physiological Processes for Fitness at the Community Level

Fitness is frequently defined and quantified as the number of seeds produced ("Darwinian fitness"). However, this may cause difficulties, because it is too limited a view. This is readily recognized when we consider, for example, *K*- and *r*-strategies of plants with small and high seed numbers, respectively, or clonal growth, where particular plant species may dominate entire ecosystems without any generative propagation. Germination of seeds and establishment and survival of seedlings are essential. Thus, we see that the entire complement of physiological processes contributes to fitness, for example, in addition to the capacity of photosynthesis treated above in some detail as a special case story, and similarly important functions such as dormancy of seeds with germination at the ecologically appropriate time and the physiology of development, competition, defense, and mutualism as alluded to above.

Pollination

E Pacini, Università di Siena, Siena, Italy

Introduction and Definitions

Pollen is the male gametophyte of gymnosperms and angiosperms. Its size ranges from 15 to 200 μm. Pollination is transport of pollen from its site of production to the female landing site. If successful, it is followed by fertilization and seed development. Irrespective of systematic group, pollination is always affected by biotic and abiotic factors (**Table 1**).

Pollen presentation is the manner in which pollen is presented for dispersal. Pollen may be dispersed as single grains, as in many plants relying on wind dispersal, or in groups of grains, as in almost all zoophilous species. Pollen grains may be held together by:

1. common walls, as in tetrads where grains derived from the same meiotic division stay together, or multiple tetrads which may number up to several thousand, as in orchids;
2. threads on the pollen surface or derived from the anther; and
3. viscous fluids, of which pollenkitt is the most common, which also have other functions, such as to keep pollen in the anther until dispersal, to stick pollen to pollinators, to make pollen attractive through scent or color, and to hide or expose pollen to insect sight.

Pollen dispersal in clumps is typical of angiosperms.

Gymnosperm pollen is produced by pollen sacs in male cones. It is transported by air currents to the ovule micropyle. Angiosperm pollen is produced by anthers of flowers. It is carried to stigmas by animals, air currents, and sometimes water (**Table 2**).

At the end of its flight, pollen may land on female parts of the same or another species, giving rise to legitimate and illegitimate pollination, respectively (**Fig.1**). Pollen has two walls and when accepted by the female part, emits a tube leading the male gametes toward the female ones inside the ovule. Possible crosses in angiosperms depend on the sexual expression of the plant and on pollen vectors (**Fig.1**).

Pollination From an Evolutionary Point of View

Gymnosperm pollination is invariably anemophilous (primary); only recently evolved genera as *Ephedra* and *Welwitschia* are pollinated by insects. There is general agreement that early angiosperms were pollinated by Coleoptera and Diptera. Woody and herbaceous secondary anemophilous angiosperms may descend from zoophilous species. Hydrophily is probably derived from anemophily. Hydrophilous pollen of seagrasses characterized by submarine pollination is 2–3 mm long and a few dozen microns wide. The genus *Callitriche* has terrestrial, amphibious, and submerged freshwater species; their pollen is spherical and that of submerged species is devoid of exine, as in all species with submarine pollination.

Competition to attract pollinators is high when many entomophilous species bloom at the same time and pollinators are few. This is avoided by different blooming periods and anemophily. Examples of entomophilous families with anemophilous members are: Ranunculaceae, *Thalictrum*; Euphorbiaceae, *Mercurialis* and castor bean *(Ricinus)*; Asteraceae, ragweed (*Ambrosia*) and *Artemisia*. Few entomophilous species bloom at the same time in January and February in Northern Hemisphere Mediterranean

Table 1 Effects of the main climatic parameters on pollination

Temperature	High *T* damages flowers and pollen duringpresentation or dispersal
	Moderate *T* facilitates flower and antheropeningLow *T* slows pollen ripening and flower openingand reduces pollinator activity
Rain and mist	Purge pollen from air, especially at low *T*
	Slow flower opening and anther-pollendehydration
	May inappropriately rehydrate and reactivatepollen
	Hinder small animal movements
Sky brightness	Brightness facilitates diurnal pollinator flight Dullness hinders diurnal pollinator flight
Air currents	Facilitate pollen removal and dispersal inanemophilous species
	Facilitate flower opening and antherdehydration
	High wind speeds hinder pollinator flight
Pressure variations	Ascending air currents facilitate long-distancepollen dispersal
	Descending air currents facilitate pollen fallout

 doi:10.1016/B978-0-444-63768-0.00859-3

Table 2 Features of major pollen vectors. Honeybees are the best pollinators because they visit flowers of a given species for as long as they are available, and store pollen for their progeny, unlike nonsocial insects

Pollen vectors			*Specificity (with respect to a flower attractant)*	*Efficiency*[a]	*Distances*[a] *(minimum and maximum)*
Animals	Insects	Honeybees	Very high	Very high	Several cm → few hundred m
		Solitary bees and wasps	High	High	Several cm → few hundred m
		Flies	Low	Moderate	Several cm → few hundred m
		Butterflies and moths	Low[d]	Low[d]	Several cm → few hundred m
		Coleoptera[b]	Low	Low	Several cm → few hundred m
	Birds		Moderate	Moderate–high	Few m → few hundred m
	Flying animals and small marsupials		Low	Low	Several cm → few hundred m
Air currents	Breezes		Low[e]	Low	Few cm → few hundred m
	Strong winds		Very low	Very low	Few hundred m → several km
Water	Salt[c]		Very low	Very low	Some m → several hundred m
	Fresh		Very low	Very low	Few dm → several hundred m

[a]Biotic and abiotic environmental parameters may radically affect efficiency and distance traveled.
[b]Coleoptera are not good pollinators because they have few hairs and their chewing mouthparts damage flowers.
[c]Underwater pollination occurs in all seaweeds.
[d]Efficiency is low because these animals feed only on nectar and must visit different species in order to have a balanced diet.
[e]Specificity is low but species with this pollination syndrome often grow close to each other, as in the case of grasses and tress.

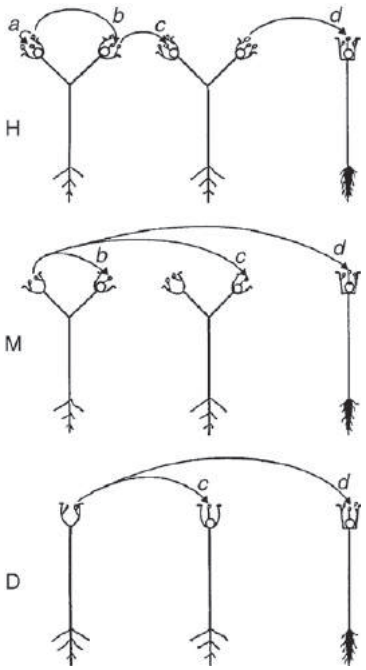

Fig. 1 Scheme of hermaphrodite and unisexual flowers and possible crosses in angiosperms according to plant sexual expression H = plant with hermaphrodite flowers; M = monoecious plant with flowers of both sexes; D = dioecious plant with male and female flowers on different plants. Two plants of the same and one of another species are shown for each type of sexual expression. *a* = autogamy, *b* = geitonogamy, and *c* = heterogamy are legitimate pollination styles though they imply different genetic reassortment; *d* = xenogamy is illegitimate pollination and gives rise to hybrids in the absence of barriers. Plants with hermaphrodite flowers have all possible crosses; these reduce progressively in monoecious and dioecious plants. Pollen vectors determine pollen cross types. Air and water currents are agents of all types of crosses. Social bees are commonly responsible for *a*, *b*, and *c*, rarely *d*. Butterflies and moths are most often agents of *d*, because they only feed on nectar and must visit different flowers to have a balanced diet.

environments, when few insects are active. *Helleborus bocconei* and *H. foetidus* grow in similar environments and share the same pollinator, but pollen attaches to different parts of the pollinator body, so that useless pollination is avoided. Anemophilous species of *Juniperus* growing in the same environments disperse pollen in different periods.

Preparing for Dispersal

A fluid fills the anther cavity in which pollen develops. It disappears by evaporation and/or resorption when pollen is ripe, prior to pollen dispersal. Pollen sacs, anthers, and pollen also lose some water. Pollen could be damaged if it were released with a high water content and high metabolic activity. In order to avoid this possibility, pollen is dispersed in a quiescent state, in which cell division and metabolism are arrested. Two classes of pollen, with different levels of developmental arrest, are determined on the basis of their water content at dispersal: partially dehydrated pollen (PDP) has a water content of less than 30% and partially hydrated pollen (PHP) has a water content of more than 30%. The former has metabolic devices to keep its low water content constant; the latter does not have devices and loses water quickly, especially in dry environments. PDP and PHP may be transported by animals or air currents. Both have advantages and disadvantages as well as devices to ensure successful pollination. PDP survives longer at low relative humidity, whereas PHP dries out readily and dies. However, the latter germinates quickly, taking only a few minutes after landing on a stigma. PDP is more common in dry temperate environments and is dispersed during the dry hours of the day. PHP is more common in the Tropics and wet environments; in temperate regions, it is presented for dispersal when RH is high, such as at night or in winter and autumn. Species belonging to these two groups have physiological and ecological strategies to ensure safe pollination journeys, which are quick and short in the case of PHP.

Pollen Presentation and Dispersal Mechanisms

When the anther opens, pollen is presented for dispersal and may (1) be launched from the anther by ballistic movements of the anther or stamen and dispersed by air currents, as in *Parietaria* and castor bean (*Ricinus communis*); (2) be scattered from the anther by flower movements caused by an insect in search of nectar, and loaded on insect hairs as in *Spartium junceum* and other Phaseolaceae; (3) be dropped by the anther for lack of any forces to keep it attached, as in grasses and many herbaceous and woody anemophilous species; (4) remain stuck to the anther by pollenkitt or other sticky fluids or threads, pending removal by animals or air currents; (5) be kept in anthers having only small apertures, being released in small doses when the flower is shaken by animals or breezes, as in tomato (*Solanum lycopersicum)* and Ericaceae; and (6) be dislodged from the anther and presented in another part of the flower (secondary presentation), when flowers are small and disposed in inflorescences where there is no space to expose pollen in the anther, as in daisies such as *Bellis*.

Pollen may be presented for different lengths of time: for zero time, when it is launched, leaving the anther when it opens, as in many anemophilous species having PHP; for a few hours to a month, as in many entomophilous species having PDP; for longer, in the case of orchids.

Pollen presentation ceases when the flower closes, as in some species with PHP, probably to avoid dispersal of unviable pollen, or when the anthers are discarded.

Animals are attracted to flowers by the prospect of rewards or shelter, or by misleading messages (deception). Common rewards include pollen and nectar, both rich in nutrients: the former contains more proteins whereas the latter contains more carbohydrates. Pollen is collected actively by animals that feed on it and/or passively by those collecting nectar. Each visit to a flower is associated with pollen uptake and discharge.

Factors Affecting Pollen Exposure, Dispersal, and Success

The timing for anther opening and pollen release varies with geographical area and season. There are few reports of anthers closing when the weather is wet or during rain. Many flowers open when insects start to fly. In an anemophilous temperate-zone species such as *Mercurialis annua,* that blooms all year around, anthers open around 7 a.m. in summer and 11–12 a.m. in winter. In temperate zones, anthers of anemophilous and entomophilous flowers generally open from 8 a.m. to 2 p.m., night pollination is restricted to dry summer periods, and night mists purge the air of pollen. In tropical countries, pollination occurs around the clock, but night pollination is always zoophilous. In temperate countries, pollen vectors vary with the seasons, anemophilous trees pollinating in late autumn and late winter–early spring, when many have shed their leaves. The period when entomophilous pollination may occur progressively reduces from the tropics to the poles. **Table 1** shows the main environmental parameters affecting pollination.

Pollen may have different probabilities of effecting legitimate pollination (**Fig.1**), depending on the dispersing vector, and the distances it may travel vary (**Table 2**). Pollen vectors have different specificities, that is, possibility of transporting pollen to the right landing site. **Table 2** shows the specificity, efficiency, and distances reached with different pollination vectors. The main features of anemophilous and entomophilous pollination are shown in **Table 3**.

Table 3 Features of common pollination syndromes

Features	*Entomophily*	*Anemophily*
Habitus	Isolated herbs, shrubs, and trees	Trees and social herbs such as grasses
Environment and season	Tropical, all year aroundTemperate, only spring and summer	Tropical, only dry periodsTemperate, mainly late autumn and late winter
Inflorescence	Different types or solitary flowers	Often pendulous and monoecious
Flowers	Hemaphrodite, rarely monoecious or dioecious	Monoecious, dioecious, rarely hermaphrodite
	Large	Inconspicuous, not attractive
	Stamen and stigma often inside corolla	Pendulous stamen with long filaments and stigma often outside corolla
Pollen	With abundant ornamentation	With reduced ornamentation
	With pollenkitt or devices for mass transport	Free, independent grains
Ovules/ovary	Generally many	Generally one

Abiotic pollination appears random since there are no mechanisms to ensure cross-pollination. Pollen is released into air or water, the movements of which disperse and transport it. When air or water speed is high, pollen may be dispersed long distances, to places where no individuals of the species grow. The further the pollen is dispersed, the less its chance of finding the right female counterpart. Pollen flight is quick and short in farmed anemophilous species, such as wheat, oats, rice, and corn, all of which have PHP.

Although anemophily may seem random, in some gymnosperms and angiosperms at least, anemphilous pollen dispersal ceases being random when pollen grains approach the tip of a cone or flower. By virtue of the shape of the grains and female parts, pollen is conveyed by air currents to the right landing site. Pollen lands on the stigma by gravity (anemophily), or because a pollen-dusted insect incidentally touches the stigma. Electrostatic forces are invoked to explain pollen uptake by insects and release on the stigma.

Biotic pollination first occurred when an animal touched an anther and incidentally delivered pollen to the female counterpart. Interactions between partners began in this way, sometimes leading to species-specific relationships, which are dangerous because if the pollinator becomes extinct or rarefied, the plant can no longer reproduce sexually and will die out if unable to reproduce vegetatively. While pollination is important for plants, being one of the first steps of plant sexual reproduction, for the animal counterpart it represents a source of food: pollen and/or nectar. Abiotic pollination is less expensive for plants because investment in rewards is not necessary; however, investment in an excess of pollen is necessary for random dispersal.

Principal Components Analysis☆

Craig Syms, James Cook University, Townsville, QLD, Australia

Glossary

Biplot An ordination diagram that simultaneously presents dependent variables.
Centroid The (weighted) mean of a multivariate data set. Can be represented by a vector.
Correlation coefficient A measure of strength of the relationship between two variables.
Eigenanalysis The process of finding eigenvectors and eigenvalues of a matrix. Sample scores are often eigenvectors while eigenvalues are usually ranked from highest to lowest, and termed the first, second, third, etc. eigenvalues.
Matrix A set of numbers arranged in rows and columns. A correlation matrix consists of correlation coefficients and is an example of a square symmetric mtrix. The rows and the columns represent the variables. A Covariance matrix consists of covariant entries, where the diagonal elements will equal the variances. A similarity matrix reflects the degree of similarity or dissimilarity between groups and are easily produced from, or converted into, a distance matrix.
Ordination The ordering of a set of data points with respect to one or more axes so that relationships among the points in any number of dimensions can be visible on inspection.
Principal Components The axes of a principal components analysis. The first principal component will, ideally, represent the dominant gradient. The second component will be orthogonal to the first, and will explain some of the residual variation. The third will be orthogonal to the first and second components, and so on.

Introduction

Principal components analysis (PCA) is a distance-based ordination technique used primarily to display patterns in multivariate data. It aims to display the relative positions of data points in fewer dimensions while retaining as much information as possible, and explore relationships between dependent variables. In general, it is a hypothesis-generating technique that is intended to describe patterns, rather than test formal statistical hypotheses. Although PCA was originally developed to analyze continuous variables, it can also be used on ordinal and presence–absence data.

PCA is carried out on the response of dependent variables in a multivariate data set. Consequently it is an unconstrained ordination, in which hypothetical causal independent variables are not explicitly included in the analysis. For example, if the abundance of several species of fish (the response or dependent variables) were measured at a range of different sites with different characteristics such as wave exposure (causal or independent variables), the exposure information would not be explicitly included in the analysis. Patterns recovered in PCA are solely a function of relationships between the dependent variables. For this reason, PCA can also be classified as an indirect gradient analysis, in which hypothetical causal processes such as exposure, moisture, etc., are inferred from patterns in the dependent variables. PCA assumes that the relationships between dependent variables are linear. This implies that PCA should be applied when most dependent variables have nonzero values across most of the samples, and that bivariate scatterplots of each variable against each other variable should be linear or at least monotonically increasing or decreasing. PCA is a very useful analytical tool, and is one of the most widely used ordination methods in ecology.

☆*Change History*: March 2018. H R Pethybridge included the addition of a glossary and keywords, updates to the abstract, and a revised references list.

An Informal Explanation

Given a multivariate data set consisting of a number of samples in which many variables have been recorded intuitively, PCA is a process in which the original variable axes are aligned along lines of variation in the data and the values for each sample on those new axes are calculated. For example, consider a data set containing 10 samples of abundances of two species. The relative position of each sample in two dimensions can be displayed with a scatterplot of species A versus species B (Fig. 1A). A new set of ordination axes can be generated by moving the old axes to the center of the data set by subtracting the mean of each variable from the sample values—a process known as centering—then rotating these axes so that they lie along the major lines of variation (Fig. 1B). In PCA, the first axis (principal component 1) lies along the greatest line of variation, the second axis lies along the next greatest line of variation on the condition that it lies at right angles to the first, and so on for subsequent axes. This guarantees a property known as orthogonality; which means that each axis is independent of each other. The next step is to project the sample positions onto these new axes—these axes are called principal components (PCs) (Fig. 1C).

In this two-species example, it is possible to display all the variation in a two-dimensional (2D) scatterplot of the original variables. However, if the aim was to explain as much variation as possible in only one dimension (i.e., a line) then the PCs have an important advantage over the variable values. In this example the species explain similar amounts of variation because their variance is approximately the same. At best, about 50% of the entire variation in the data could be displayed in one dimension by plotting values for a single species. In contrast, a plot of the first PCs in this example would explain 85.5% of the total variation in the data set. PCA partitions the variation so that the first PCs will explain more variation than any single variable, assuming there is some correlation between variables. The importance of this is apparent when there are more than two species in a sample. More variation can be presented in a plot of two PCs than can be presented by plotting any pair of species. The PCs can also be interpreted in terms of the original species abundances. A projection of the original centered species axes into the reduced space plot can be used to derive a measure of association of that species with the PC axis (Fig. 1D). In this example, samples that lie on the left of the axis had low abundances of both species A and species B, whereas samples that lie to the right of the axis had high numbers of both species.

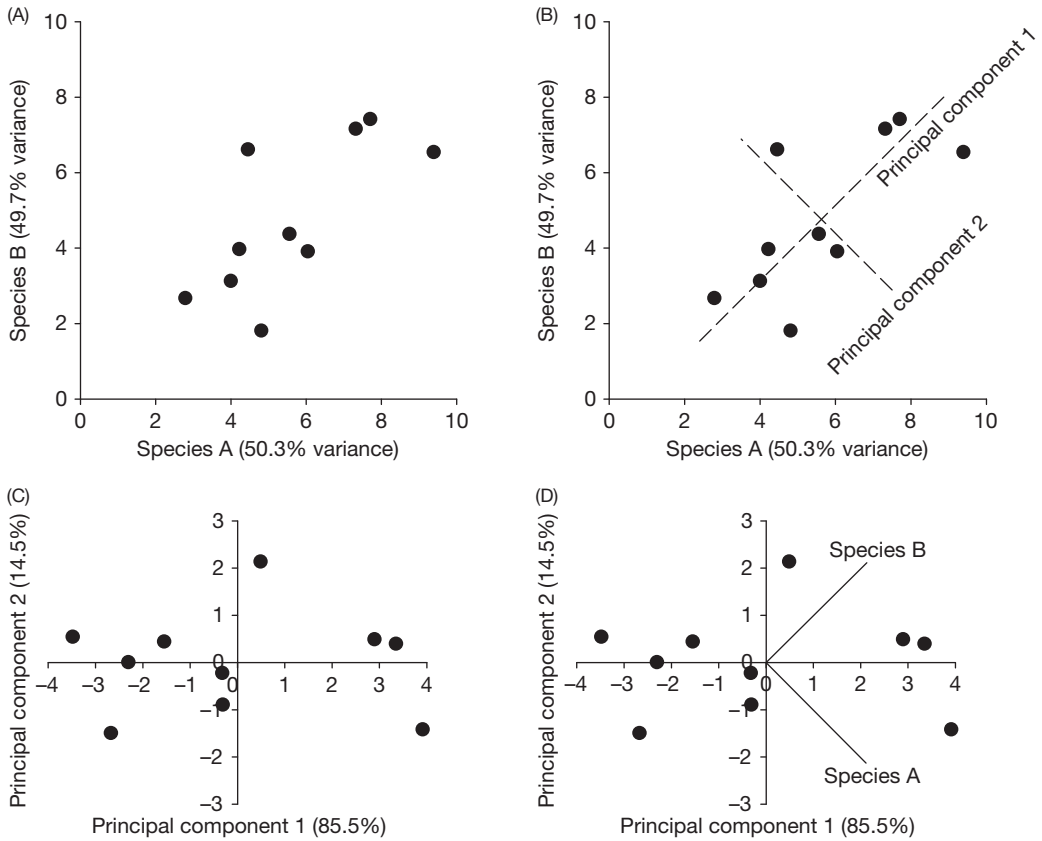

Fig. 1 Deriving principal component (PC) axes of a two-species data set. (A) The original data points can be displayed as a scatterplot of the two species. (B) A new set of axes (PCs) can be derived by placing axes at the center of the data mass, rotating the first axis along the main line of variation in the data set, and rotating the second axis along the next line of variation, conditional on independence with the first axis. (C) The position of the data points on the PCs can be plotted as a reduced space plot. (D) The direction of the original centered species axes can also be projected into the space to generate a biplot.

Calculation of PCA

Mathematically, PCA can be calculated from a mean-centered (i.e., the mean of each variable is subtracted from all values of that variable) data matrix, **Y**. From **Y**, the covariance matrix is calculated using the formula: $1/(n-1)\mathbf{Y}'\mathbf{Y}$ (i.e., the sums of squares and cross-products matrix, rescaled by the n – 1 degrees of freedom). This square, symmetric matrix can be decomposed by an eigenanalysis or "singular value decomposition" into eigenvalues (**L**) and eigenvectors (**U**), which are normalized or scaled to a length of 1. The eigenvalues represent the amount of variation explained by each axis and are usually expressed as a proportion or percentage of the sum of all the eigenvalues. The PCs (**F**) are calculated by projecting the mean-centered data into the ordination space by postmultiplying the centered data by the eigenvectors: $\mathbf{F} = \mathbf{YU}$. An important point to note is that the value of a sample on the PC is a linear combination of the values of the variables in the sample, multiplied by their corresponding eigenvectors. The eigenvectors represent the projection of the old species axes into the new ordination space.

An alternative method of calculating PCA is to use an iterative method such as the two-way weighted summation (TWWS) algorithm. This method starts with a mean-centered data matrix, and arbitrary initial scores on the first PC axis are assigned. The eigenvectors on the initial PC scores are calculated, and then the sample PC scores on these eigenvectors are calculated and rescaled to a length of 1. An estimate of the eigenvalue is obtained from the standard deviation divided by the number of samples, and the procedure is rerun until the eigenvalue does not change with further iterations. Upon convergence, the eigenvectors are scaled to a length of 1, and the PCs are scaled to the eigenvalue. Subsequent axes are calculated in a similar way, except that the PC score estimates at each iteration stage are made uncorrelated with previous ones using the Gram–Schmidt orthogonalization procedure. Both methods yield the same result (within iterative tolerance limits). The eigenanalysis method is easier to program in languages that support matrix operations, whereas the TWWS algorithm can be more efficient for very large data sets because each PC axis is calculated sequentially.

Presentation and Interpretation of PCA Results

A plot of the samples on the PC axes is the primary output of PCA. This reduced space plot displays the relative positions of samples in multivariate space in fewer dimensions. Although a simple scatterplot of samples on the PC axes might provide some useful information on data structure—for example, whether samples are clustered together or occupy a gradient—additional information is usually included on the plot to assist interpretation. This can be illustrated by a PCA of triplefin (Pisces: Tripterygiidae) fish abundance at a range of sites in northeastern New Zealand. The data were collected from sites with different exposure and location characteristics and so graph symbols could be used to reflect these characteristics of the samples (Fig. 2A). This contributes to the interpretation of patterns in the samples based on additional information and is an informal exploration that can identify hypotheses about causal processes. There appears to be a gradient in triplefin assemblages across exposure gradients from sheltered to exposed sites, but assemblages on offshore exposed and sheltered mainland sites are distinct from the semiexposed and exposed mainland sites (Fig. 2A). Information about the value of individual variables can also be included in the reduced space plot to identify which variables are responsible for the observed patterns. If plot symbols are scaled to reflect the value of a single variable in the analysis we see that the triplefin *Forsterygion varium* was more abundant in semiexposed and exposed mainland sites, but relatively uncommon on sheltered mainland sites and practically absent from exposed offshore sites (Fig. 2B). Presenting multiple bubble plots of species abundances is often not a suitable option due to the large number of graphs required; so a more compact and formal presentation of the dependent variables can be generated by plotting the eigenvectors into the reduced space plot (Fig. 2C). This presentation is known as a biplot, and follows from the mathematics of PCA in which the samples are projected into the space by premultiplication of the eigenvectors. In this example the importance of *F. varium* in characterizing mainland exposed/semiexposed sites is clear from the length and direction of its eigenvector. *Notoclinops segmentatus* is characteristic of exposed sites, regardless of mainland or offshore status, and *F. lapillum* is characteristic of sheltered sites. Examination of bubble plots and species–frequency histograms at each site support this interpretation.

Numerical Scale: Transformation and Standardization

Like most (if not all) multivariate methods PCA can be sensitive to data transformation and standardization. Because PCA is an eigenanalysis of a variance–covariance matrix, which is dependent on the numerical scale of the data, variables with large absolute values will dominate the data structure. If the data table consisted of variables measured on different scales (e.g., abundance, kilograms, milliliters, pH) then this scale dependency could exert unwanted effects on the analysis. In addition, a quantity such as a volume if measured in milliliters in one sample, for example, would exert more effect than a volume measured in liters in another sample, even if both samples contained the same volume. In the triplefin example, the PCA of the covariance of untransformed triplefin abundance data was dominated by the numerically dominant species, *N. segmentatus* and *F. varium* (Fig. 3A) and largely insensitive to less-common species. This may be a problem if the intent of the analysis is to retain information on less-abundant species or, more generally, variables with small but biologically important values.

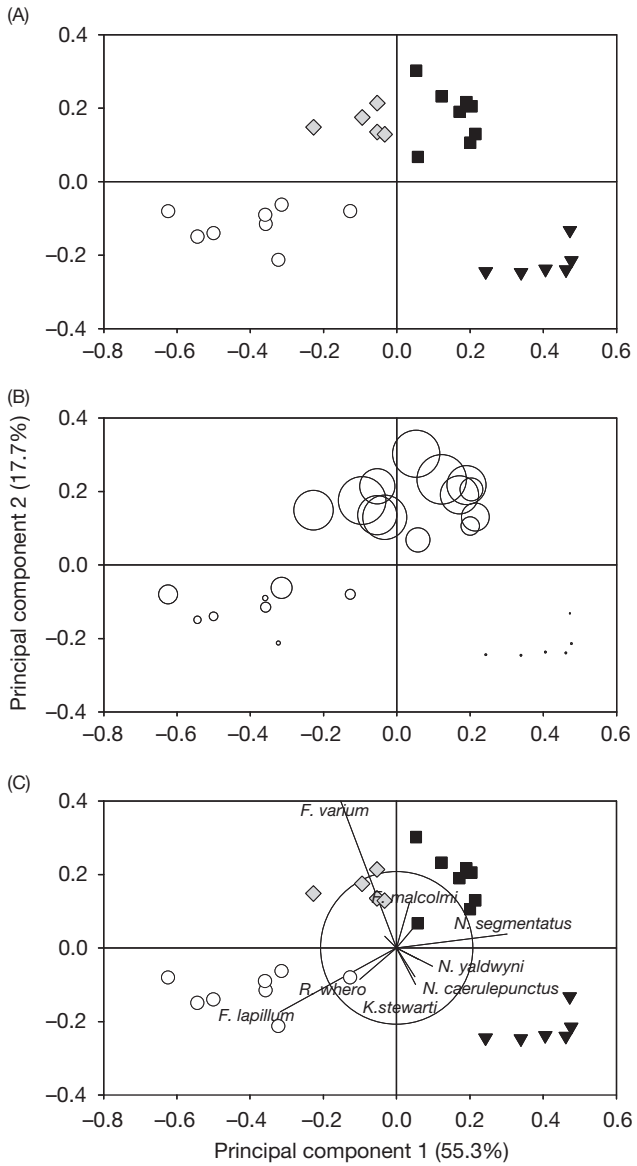

Fig. 2 Reduced space plots of a principal components analysis (PCA) of triplefin fish (Family: Tripterygiidae) abundances. The PCA was calculated using the covariance matrix of the square root of the proportional species abundance in a sample. Percent variance explained is derived from the eigenvalues. Note the equal scaling of the *x* and *y* axes—this ensures the ordination space is not distorted in the plot. (A) Information about wave exposure and location of sites is added by changing *plot* symbols: *circle* indicates sheltered mainland; diamond indicates semiexposed mainland; square indicates exposed mainland; downward triangle indicates exposed offshore. (B) Symbol size can be scaled in proportion to the value of the variables, in this case triplefin species abundance. *Forsterygion varium* is characteristic of exposed and semiexposed mainland sites, uncommon in sheltered sites, and practically absent from offshore exposed sites. (C) A joint presentation of the reduced space and eigenvectors forms a biplot. Distances between sites approximate the Euclidean distance of the transformed data and the eigenvectors are the projection of the original species axes into the space. Eigenvectors have been rescaled to half of their original value for clarity in the plot. The circle is the equilibrium contribution of the eigenvectors. Species outside this circle are influential in defining the ordination space. In this example, *Notoclinops segmentatus* is characteristic of exposed offshore and exposed mainland sites, *F. varium* is characteristic of exposed and semiexposed mainland sites, and *F. lapillum* is characteristic of sheltered sites.

There are two ways to reduce the effect of variables with large absolute values, and increase the effect or weight of variables with small values. First, the data can be centered and transformed to standard deviation units. This process is called standardization, and is implicit in many software implementations of PCA. If data are standardized to unit variance prior to the analysis, then PCA becomes an eigenanalysis of a correlation rather than a covariance matrix. The effect of this standardization is to give all variables equal weight in the analysis and is commonly used and recommended in ecological applications. In contrast with the covariance matrix PCA, an analysis of the correlation matrix of untransformed triplefin abundance data yields an ordination in which both common and uncommon species are important in defining the ordination space (Fig. 3B). Second, data can be numerically transformed using functions such as a square-root, fourth-root, and log transform. Transformations are often used to improve linearity between variables or to reduce the effect of variables with large values in the analysis. However different transformations

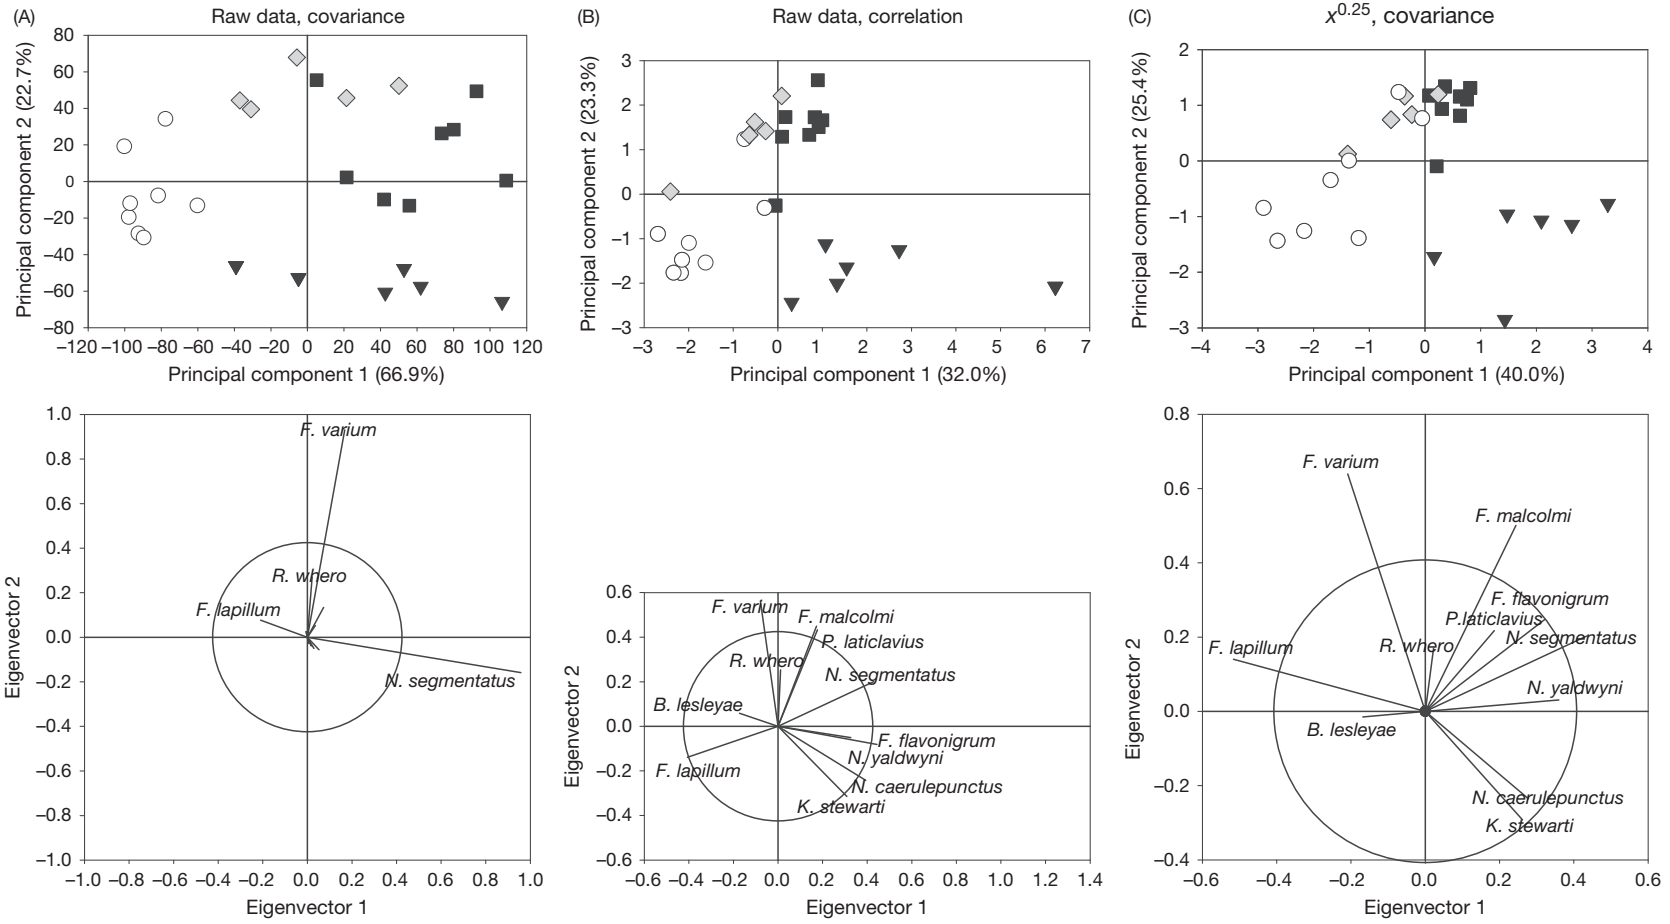

Fig. 3 Effects of data transformation and standardization on PCA of triplefin assemblages. Top row of graphs are the reduced space *p* corresponding eigenvector plots with equilibrium contribution circles. (A) Untransformed covariance matrix analysis is strongly influenced species, *Notoclinops segmentatus* and *Forsterygion varium*. (B) Untransformed correlation matrix analysis reduces the influence of the nu increases the weight of the rarer species. (C) Covariance analysis of fourth-root transformed data also reduces the influence of the numerically dominant species, and increases the weight of the rarer species.

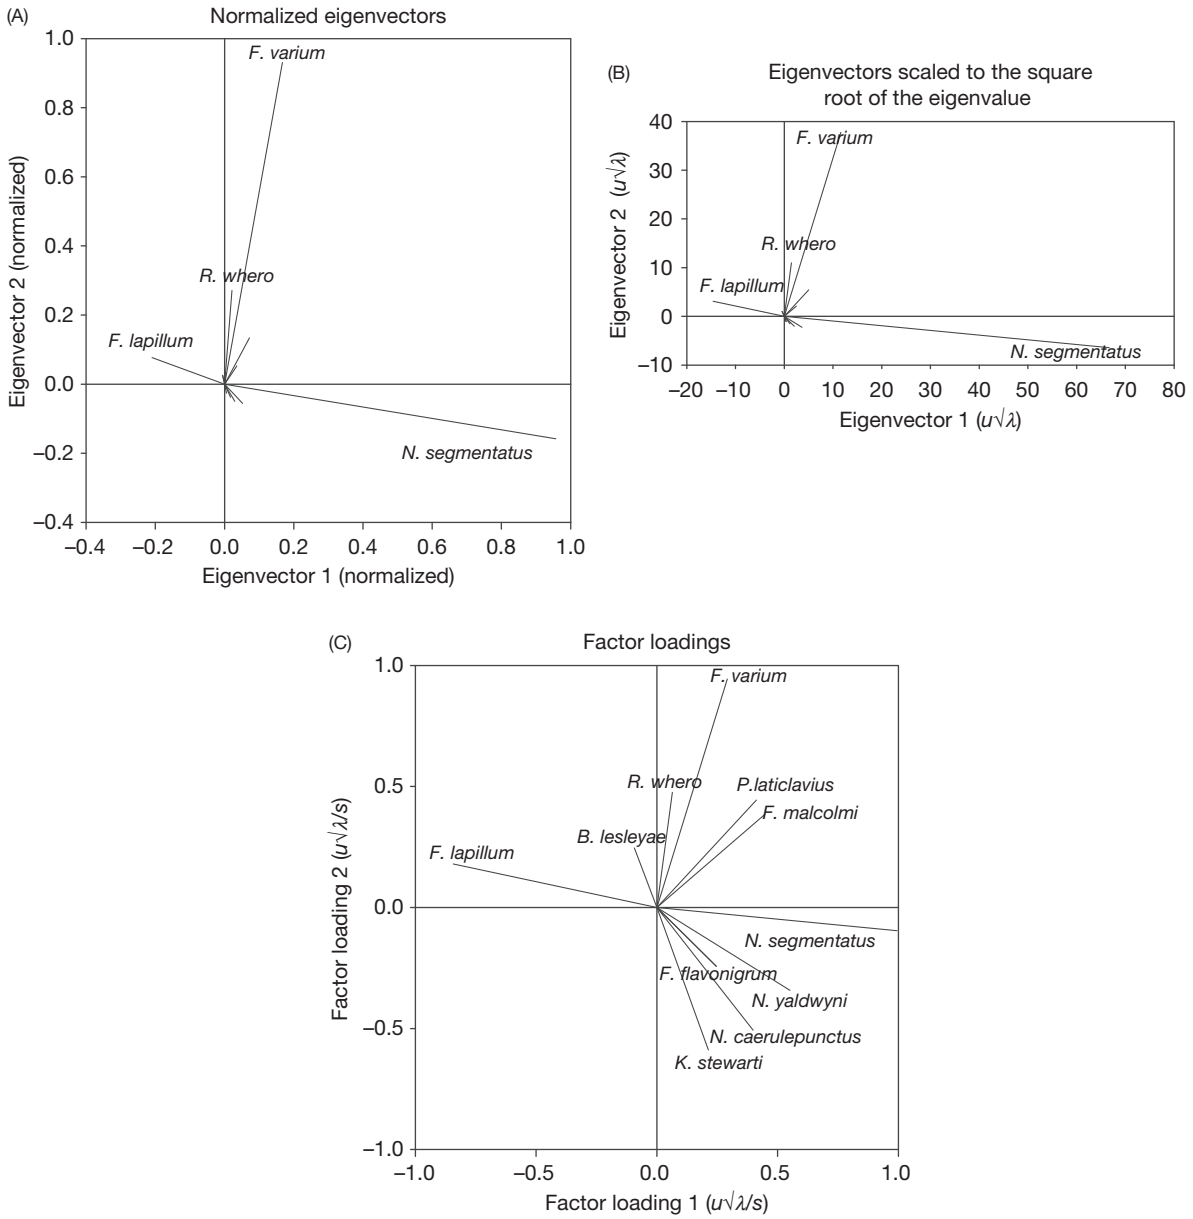

Fig. 4 Effects of eigenvector scaling on a PCA of the raw covariance matrix. (A) Normalized eigenvectors associated with distance biplots are scaled to a length of 1. (B) Covariance biplots scale the eigenvectors so that the length of the vector approximates their standard deviation, and the cosine of the angle between variables approximates their covariance. (C) Factor loadings rescale the covariance biplot scaling by the standard deviation of the variable. This gives an estimate of the importance of the axis in explaining the variance of the variable—it does not represent the importance of the variable in explaining the axis. Note that if the PCA was carried on the correlation matrix the factor loadings would be equal to the covariance biplot because each variable's standard deviation is made equal to 1. In this example the ordination space is defined primarily by two species—*Notoclinops segmentatus* and *Forsterygion varium*.

will alter the importance of different variables in defining the ordination space, and hence may alter the ecological interpretation. In general, increasing levels of transformation (e.g., $x^{0.5}$, $x^{0.25}$, $\log(x)$) will progressively shift analytical emphasis from abundance to compositional aspects of the data. For example, less-abundant triplefin species assume more importance in a covariance matrix PCA with a fourth-root transform ($x^{0.25}$), although not to the same extent as a PCA on the correlation matrix (Fig. 3C).

Biplot Scaling

In addition to data-scaling considerations, biplots can also be scaled differently, which may in turn alter their interpretation. Two common biplot scalings are used to display PCA. A superimposed plot of the PCs (**F**) and the normalized eigenvectors (**U**) is known as a distance or Euclidean biplot. In this biplot, the PC scores are scaled so that their sums of squares equals the eigenvalue (λ) for a given axis, the positions of samples in ordination space approximate their distance in Euclidean space, and the eigenvectors represent the projection of the dependent variable axes into the ordination space (Fig. 4A). The length of the eigenvector indicates

the contribution of the variable to the space—an eigenvector approaching a length of 1 indicates that the variable contributes strongly to defining the ordination space. In addition, the approximate values of the dependent variables in each sample can be reconstructed by projection at right angles of the sample values onto the eigenvector axes. Another common scaling is to scale the eigenvectors to equal their standard deviation ($\mathbf{UL}^{0.5}$) and standardize the PC scores to unit sum of squares ($\mathbf{G} = \mathbf{FL}^{-0.5}$). This is the covariance (or correlation if the data have been standardized) biplot. Unlike the Euclidean biplot, the distances between samples in the reduced space do not approximate their Euclidean distances—they have been standardized by a variance measure. In the covariance biplot the eigenvectors are rescaled to equal the square root of the eigenvalue (cf. normalized in the Euclidean biplot). This projection effectively rescales the eigenvectors to standard deviation units, and has some interesting properties. The length of the vector approximates the standard deviation of the variable, not its contribution to the ordination space. The angle between dependent variable vectors provides a measure of their covariance: covariance $\approx \cos\theta$, where θ is the angle between dependent variable vectors (Fig. 4B). If the PCA has been carried out on standardized data, then this angle will represent the correlation. These angles will only provide a good covariance or correlation estimate if the number of samples is large, the vectors are well represented in the analysis, and the variation explained by the axes is large. Both biplots have the property that the centered data can be reconstructed from the sample scores and the variable vectors: $\mathbf{FU}' = \mathbf{G}(\mathrm{UL}^{0.5})' = \mathbf{Y}$.

The correlations between the original variables and the values of the samples on the Euclidean PC axes may also be used to project dependent variables into a reduced space plot. These values are often termed factor loadings or factor patterns, but their usage should be treated with caution. If the PCA has been carried out on standardized data (i.e., the correlation matrix) then the covariance biplot eigenvector scaling ($\mathbf{UL}^{0.5}$) is equal to the factor unimportant. Conversely variables with large variance might appear to be strongly associated with an axis, when in fact they contribute nothing to its construction. Factor loadings describe how important an axis is to a variable, not how important a variable is to an axis (Fig. 4C). The rationale for this approach comes from a related method—"factor analysis"—which considers measured variables as a function of a hypothesized causal process represented by the PCs, rather than the variables defining a reduced ordination space.

Adequacy of the PCA Solution

PCA generates as many PC axes as there are variables. The axes with the larger eigenvalues hopefully describe trends in the data, whereas the axes with smaller eigenvalues simply represent random variation. There are no authoritative rules for deciding how many PCs are interpretable. Initial recommendations were based on the cumulative percentage of variation explained by the eigenvalues. However ecological data sets differ in their correlation structure, so defining an arbitrary level of variation (e.g., 75%–95%) is not a biologically relevant criterion and its use has been widely disregarded. The plot of the eigenvalues against the axis order (a scree plot) can guide the identification of "important" PCs (Fig. 5). Scree plots can be used to visually identify breaks between PCs that potentially explain trends, and those that represent statistical noise. Typically the trivial eigenvectors on the right of the scree plot will form a linear series, and major magnitude changes on the left may represent trends. The efficacy of this visual determination of breaks is dependent on the underlying data structure. The Kaiser–Guttman criterion requires that eigenvalues that exceed the average expectation should be retained. In a PCA of the correlation matrix, all variables have equal variances and hence the sum of eigenvalues is equal to the number of variables. Consequently the Kaiser–Guttman criterion on a PCA on the

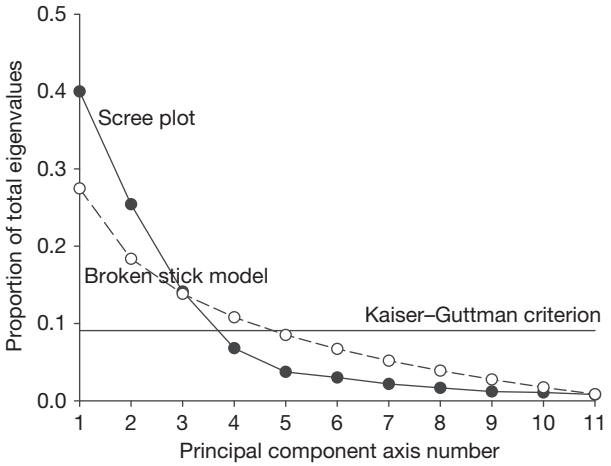

Fig. 5 Scree plot of the proportion of variation explained by each successive principal component (PC) of an analysis on the covariance matrix of $x^{0.25}$-transformed triplefin data (*filled circle*). The Kaiser–Guttman criterion (average proportion explained by eigenvalues) suggests that three axes should be retained for analysis. The intersection of the broken stick model (*open circle*) with the scree plot suggests that two axes should be retained for analysis. The inflection point of the scree plot also suggests that three axes should be retained. While it is clear that at least two axes should be retained, most users of PCA would also examine the third axis to ascertain if it described some ecologically interpretable pattern.

correlation matrix is that eigenvalues greater than 1 should be interpreted. While intuitively the Kaiser–Guttman criterion seems reasonable, there is sampling variability in ecological data sets and so the average expectation may not be a suitable null model. An alternative approach is to use the "broken stick model" to identify the null distribution of eigenvalues, if there was no structure in the data (Fig. 5). Expected eigenvalues for a given axis under the broken stick model can be calculated as $b_k = 1/p \sum_{i=k}^{p} 1/i$, where p is the number of variables, and b_k is the expected proportional eigenvalue for the kth component. Computationally intensive randomization tests such as bootstrap confidence intervals can also be used to identify which eigenvalues are nontrivial. Formal statistical tests such as Bartlett's test of sphericity, and both Bartlett's and Lawley's test of homogeneity of the correlation have generally fared poorly in simulations. A general recommendation would be to use the broken stick model to identify nontrivial PC axes if bootstrapping was not available.

Similar issues exist for interpreting which eigenvectors are important in a PCA. When eigenvectors are normalized, their total length is 1. Consequently if an eigenvector on a particular PC axis has a value close to 1 then that variable is well represented on that axis and less well represented on other axes. However if a variable is not strongly associated with any PC, the eigenvectors for that variable should be equal across axes. The expected eigenvector for a variable that is not associated with any PCs is known as the equilibrium contribution, p and is given by $\sqrt{d/p}$, where d is the number of dimensions of interest, and p is the number of variables. Eigenvectors with values larger than the equilibrium contribution for a single axis can be considered to be associated with that axis. Similarly eigenvectors with values larger than the equilibrium contribution for two axes could be considered to be associated with forming a 2D space. If the eigenvectors are not normalized then the equilibrium contribution must be calculated separately p for each variable and is given by $s_j \sqrt{d/p}$, where s_j is the standard deviation of the jth variable. If the eigenvectors are normalized, the equilibrium contribution can be presented on a graph as a circle (e.g., Fig. 2C).

Assumptions, Limitations, and Other Considerations

PCA was originally developed to describe patterns in multivariate normal (MVN) data. However, deviations from MVN are generally not as critical to the success of unless there are fewer samples in the data set than there are variables. Most software packages will still calculate the analysis under this condition, with the restriction that the number of PCs will equal the number of samples rather than the number of variables. In general, the first PC axes will still be interpretable but minor axes may not be because of overfitting of the model. This is analogous to multiple regression analysis in which fitting too many variables with too few data points will yield a degenerate solution. Several guidelines have been suggested for establishing appropriate sample sizes to generate robust PCA solutions. Some researchers have suggested that studies should aim to achieve absolute sample sizes ranging from 50 (very poor) through 200 (fair), 300 (good) up to 1000 or (excellent). Others have suggested that the ratio of samples to variables is of more importance, with minimum values of 5:1–10:1. It is important to note that these recommendations have generally been recommended by users of "factor analysis," in which robust covariance estimates are key to identifying stable analytical solutions. In addition, many of these suggestions stem from the social sciences in which raw data, such as questionnaire responses, are often "indicators" of variables, rather than direct measures of the variable itself. In most ecological applications these sample sizes are unrealistic and the focus of the analysis is on description of an assemblage, rather than the "factor analysis" objective of recovering underlying causal factors. For most purposes, a rule of thumb for PCA would be to ensure that there are more replicates than variables. In general, the greater the ratio of replicates to variables, the better. PCA is a data exploration and display tool—not a hypothesis-testing method subject to strict distributional assumptions—so it should yield useful insight into data set structure even if the replication is not as great as desired. Robustness of the PCA solution can always be evaluated by bootstrapping, as described above for eigenvalues and eigenvectors.

It is important to be aware of software idiosyncrasies when calculating PCA. Many software implementations calculate PCA on the correlation matrix by default. In addition, PCA is mathematically related to "factor analysis" (FA), a method used widely in the social sciences. The main conceptual difference between PCA and FA is that PCA considers the ordination axes as a product of the variables—they are a linear combination of the eigenvectors. FA considers the variables as a product of the axes themselves. In this interpretation, the variable values are "caused" by the hypothetical ordination axes rather than the axes simply reflecting patterns in the data. The mathematical similarity of the two approaches has led to many software packages combining PCA routines into FA routines. Implementations that incorporate FA and PCA may, by default, yield a covariance biplot of the correlation matrix, with the sample scores scaled to 1 and the eigenvectors scaled to their standard deviation (the factor loading or pattern). FA uses the correlation matrix by default, so as outlined above an analysis of the covariance matrix may substantially change the interpretation of the resulting biplot. FA software also offers the option of axis rotations. Rotations are intended to align axes so that factor loadings are maximized, that is, to make variables associated with single axes. These procedures should not be used for PCA, unless the intent is to use PCA in an exploratory FA and not as a descriptor of ecological data. As with all ecological data analysis, it is important to ensure the correct technique is being employed.

PCA is a very flexible procedure. In its basic form, it is an eigenanalysis of a covariance or correlation matrix. Consequently, it is possible to calculate PCA on a nonparametric correlation matrix such as Spearman's rank correlation. This approach can be useful to deal with nonlinearity of variables. It also follows that PCA can also be calculated on a partial correlation or covariance matrix. A partial correlation coefficient is one that has been statistically adjusted for another variable, essentially correcting for a covariate. Ecological applications of partial PCA are rare, but morphometric studies frequently use partial PCA to assess relationships between morphometric variables after correcting for size of the organism. The ecological application is clear. Dominant variables such as

wave exposure, moisture gradients, etc., could be effectively removed from the analysis prior to PCA to yield an ordination that statistically 'corrects' for dominant variables.

Although PCA was developed as an ordination method to summarize patterns in multivariate data, it also has a range of other uses. PCA can be used in multiple regression to detect collinearity of predictor variables, and as a variable-reduction tool. For example, collinear variables could be replaced in a multiple regression with their first PC. This reduction in number of regression coefficients will increase the power and stability of a multiple regression by reducing the number of variables and improving independence of the coefficients. PCs can themselves be used in data presentations and analyses. For example, a contour plot of PCs of spatially structured data could provide information on a range of variables in a single graph.

Rhizosphere Ecology☆

Corey D Broeckling, Mark W Paschke, and Jorge M Vivanco, Colorado State University, Fort Collins, CO, United States
Daniel Manter, USDA-ARS, Fort Collins, CO, United States

Introduction

The rhizosphere is defined as the region of soil surrounding plant roots which is under the influence of the root. This region is centered around the root, and is best defined by the biotic response to the influence of the root (Fig. 1). Practically, this region is measured using biological indicators such as microbial density, enzymatic activity, or mapping root-derived chemical gradients. Thus, the spatial limits of the rhizosphere are determined by the soil biotic community under the direct or indirect influence of plant roots. The composition and dynamics of this biotic community is dependent on plant species, root architecture, plant carbon allocation, soil physical and chemical properties, microbial population diversity, among a host of other factors.

The plant root system, though comprising approximately half of a given plant's biomass, is relatively poorly studied compared to aboveground tissues. Consequently, examination of the ecological interactions in the rhizosphere lags behind aerial studies. This is primarily due to the technical challenges of working in a complex soil matrix. More problematic still is that much of the rhizosphere community is microbial, and only a fraction of microbe species are amenable to laboratory culture (see below). Though root biology and ecology are more challenging than aboveground studies, the biological and ecological importance of the root system and surrounding rhizosphere has prompted many detailed studies of root biology and rhizosphere interactions.

Roots are highly branched organs which aid the plant in uptake of water and nutrients from the soil. This branched nature results in a vast surface area available for colonization by soil organisms. Due to the challenges associated with quantifying root characteristics in a natural soil matrix, estimates of root surface area vary by orders of magnitude. One study reported that 1 m^2 of soil in temperate grassland ecosystems contains an estimated 80 m^2 of root surface area. Another study reported that a single 1-month-old rye plant can generate 620 km of root length, with over a billion root hairs, and over 600 m^2 of total surface area. Regardless of the precise values (which vary by plant species, soil type, nutrient status, etc.), this incredible surface area generates an abundant and heterogeneous matrix for soil biota to thrive.

The rhizosphere contains a complex food web with the plant as the primary source of carbon. Aerial plant parts convert carbon dioxide to carbohydrates through the process of photosynthesis. Fixed carbon is transferred through the plant vasculature to the root system, generally in the form of carbohydrates, amino acids, and other primary plant metabolites. These compounds serve as carbon and nitrogen substrates to support root system growth and this growth subsequently impacts the rhizosphere by modulating interactions with rhizosphere organisms through the secretion of organic compounds into the soil (root exudation), regulation of border cell release to the soil, and the alteration of the physical properties of individual root cells, the root system as a whole, and the physical properties of the soil. Plant-derived contributions to the rhizosphere subsequently influence the physiology, behavior, fitness, and interactions of the organisms inhabiting that area. These interactions can be positive, negative, or neutral to plant fitness, and each specific contribution to the rhizosphere may induce a specific change in community activity or structure.

Rhizosphere Food Web

The rhizosphere is an exceptionally nutrient-dense region compared to bulk soil, with energy derived from root exudates, sloughed root cells, dead and decaying root tissue, cellular leakage derived from herbivory and pathogen attack, proteinaceous secretions (mucilage), and symbiotic relationships between plants and microorganisms which shuttle carbon from the root to surrounding soil. This rich nutrient source supports a dense and diverse population of primary consumers and an elaborate trophic web with the root as the primary carbon source. The length of a trophic chain depends on the amount of input from the primary producer: the more nutrient input, the longer the theoretical upper limit of chain length. In the rhizosphere, plant roots are the primary source of carbon, with roots serving as a sink for aboveground photosynthetically fixed atmospheric carbon. Detrital food webs are able to

☆*Change History:* March 2018. Irene Martins made minor changes to the text and references.

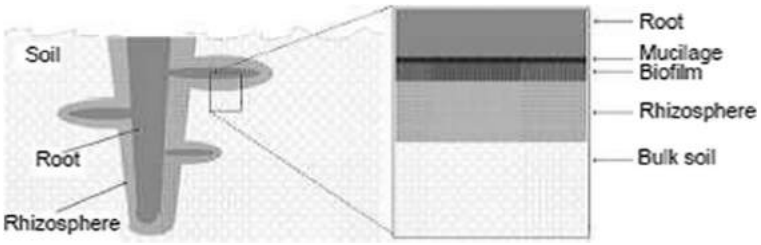

Fig. 1 Schematic representation of a plant root and surrounding rhizosphere. Though drawn here as a discrete boundary, the precise delineation separating bulk and rhizosphere soil is typically vague. Mucilage is secreted by plant roots and typically is composed of polymers such as polysaccharides and polypeptides. Biofilm is a dense microbial layer immediately adhering to the root surface. Shading is approximately proportional to nutrient density in the soil, with a decreasing gradient from the root surface toward the bulk soil.

support anywhere from three to eight trophic nodes, and the rhizosphere food web is predicted to support a web of similar length and complexity.

The primary consumers of plant exudates are microbes including bacteria and fungi. The nutrient source for these organisms includes small metabolites, which may be either actively or passively released by the plant into the surrounding soil. Root exudates include metabolites such as amino acids, organic acids such as citric and malic acids, and secondary plant compounds such as flavonoids and terpenoids. The microbial community is able to utilize these various compounds with some specificity, with individual microbial species more effectively utilizing a given carbon substrate than another species. Further, the root exudates from two different varieties of the same plant can select for different genotypes of the same bacterial species, in part through a differing transcriptional (gene expression) response by the bacteria to the exudates. Plant secondary metabolites, which often contain phenolic ring structures, are particularly resistant to general microbial degradation. However, certain microbial species are capable of utilizing these compounds, despite the fact that these compounds often display general antimicrobial activity. Larger metabolites and biopolymers such as polysaccharides and polypeptides are also actively secreted from the root, which can be degraded and utilized by rhizosphere microbes. Additionally, soil microbes can be pathogenic to the plant, invading and killing the root or root system. Death of a root will rapidly generate a large detrital nutrient pool, containing both intracellular contents and cell wall and membrane components, which can then be utilized by saprophytic fungi or bacteria.

Invertebrates including insects, noninsect arthropods, and nematodes may also be primary consumers, feeding on live, dead, or decaying plant material. The most common root herbivores are soil nematodes, which feed on living root tissue via piercing/sucking mouthparts. The digestive system of herbivorous nematodes serves as a conduit for plant nutrient to be passed from the root to the soil via defecation. Likewise, nematode feeding can induce the death of the root in that region, feeding the saprophytic food web. Alternatively, arthropods such as collembola and soil mites may feed on dead or decaying vegetation. These arthropods will also commonly feed on rhizosphere microbes, thus as a class they may be considered either primary or secondary consumers. Predatory amoeba will feed on soil bacteria and can be consumed by nematodes. Likewise, certain nematode species feed on fungi, bacteria, or even other nematodes, so can be considered primary, secondary, or even higher-order consumers. However, feeding preference will generally be species-specific, with a given species either herbivorous or predatory. Many insect species spend part of their life cycle beneath the soil, and many are specifically adapted for root herbivory. Consumption of the root by an insect (commonly the immature larval stages of beetles) will result in wounds that expose plant cellular contents to the microbial community. Often the larval stage will complete development below ground, and much of the material consumed by the insect passes through the digestive system, again increasing nutrient availability for microbes. Predatory arthropods including insects and mites may also be tightly associated with the rhizosphere, feeding on nematodes, collembola, and mites. So a theoretical food chain might proceed from plant root exudate through bacteria, amoeba, nematode, predatory nematode, predatory mite, predatory insect larvae. These insect larvae can then serve as a food source for larger vertebrates such as mice or birds—extending the food chain above ground.

Rhizosphere trophic cascades are documented in which predatory nematodes cause a decrease in root damage inflicted by an herbivorous moth species. When the predatory nematodes are present, the host plant demonstrates increased growth and seed set over the course of a single growing season. The logical extension of the observed effects (increased growth of the host plant, in this case a member of the leguminous *Lupinus* genus) is that with increased growth and seed production may come increased *Lupinus* biomass and hence increased levels of symbiotic nitrogen fixation by rhizobia.

Biotic and Abiotic Influences on Rhizosphere Properties

The rhizosphere is a highly dynamic region, the properties of which are directly influenced by abiotic factors such as mineral composition and physical properties of the soil. Physical properties such as water permeability, soil texture, abrasiveness, and mineral composition and distribution can determine which plant species survive. Mineral concentrations in even a small region of soil can vary in concentration by 100–10,000-fold. Additionally, minerals can bind to plant-derived organic compounds (a process known as chelating), potentially altering their availability to soil microorganisms. These and similar soil characteristics can affect both plant growth and the microbial community. In this way, abiotic factors can influence root growth and can dictate the biotic effects on the rhizosphere physical and chemical properties (Fig. 2).

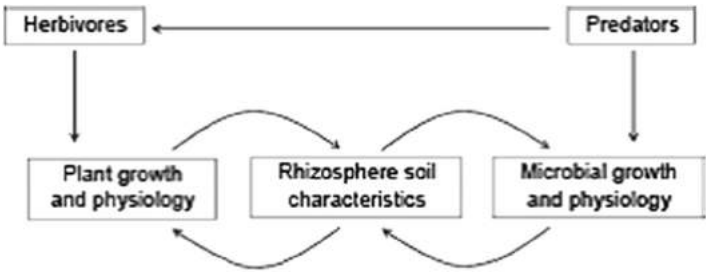

Fig. 2 Simple model of the biotic interactions influencing the rhizosphere.

Plant Modification of Soil Characteristics

After a given plant is established at a site, the soil characteristics will influence rhizosphere properties through effects on plant growth and physiology. Roots function in the uptake of nutrients, and the relative immobility of certain nutrients (particularly phosphate, potassium, and ammonium) in the soil results in local depletion of essential nutrients, which demands new root growth to probe for nutrient-rich regions. Individual plant roots are relatively short-lived. For many agricultural crops, approximately 20%–50% of the individual roots die within a week, an indicator of the dynamic nature of the root system. This implies that any abiotic factor that a plant can detect and respond to may affect the rhizosphere through root death or new growth.

Soil physical characteristics will directly impact plant growth and physiology through a variety of mechanisms. For example, physical abrasion in sandy soil may result in elevated rates of carbon transfer from root to rhizosphere, likely through increased sloughing of cells and secretion of polysaccharide mucilage to prevent root damage. Likewise, a highly compacted soil becomes difficult for plant roots to penetrate, and thereby restricts root mass and surface area, and hence rhizosphere volume.

Plant root architecture is also influenced by nutrient availability. Soils that are low in phosphate, for example, may induce increased production of fine root hairs with a decrease in secondary roots. Likewise, nutrient depletion often results in an increased root: shoot ratio, often with decreased absolute biomass of the root system. Nutrient deficiency or mineral toxicity (such as aluminum) will often result in an increased secretion of organic materials into the rhizosphere. These compounds may be organic acids, which regulate rhizosphere pH and thus reduce the solubility of aluminum in soil water, or higher molecular weight proteins, which are thought to bind and sequester aluminum. Likewise, plants can alter exudation in response to phosphorus deficiency. These secretions may increase availability of sparse minerals and decrease the toxicity of overly abundant minerals. Though a plant may secrete such compounds into the soil for the purpose of detoxification of minerals, such secretion will simultaneously increase carbon availability in the rhizosphere, as many microbes can metabolize these compounds.

Biotic Influences on Rhizosphere Properties

The highly dynamic nature of the rhizosphere is governed in part simply by plant growth and death. However, this view is simplistic in that the inhabitants of the rhizosphere impact soil nutrient status and plant physiology. The plant response to these stresses will further affect rhizosphere characteristics. The rhizosphere is a continuously evolving habitat, the characteristics of which are impacted by interacting biotic components.

Both bacterial and fungal species produce secondary metabolites that are of biological and ecological importance to rhizosphere dynamics. Both clades are capable of producing metabolites that mimic plant hormones such as auxin and gibberellins. As plant growth is governed, at least in part, by hormone signaling, these metabolic products can directly impact root growth and therefore rhizosphere dynamics. Additionally, expression of the genes responsible for biosynthesis of these secondary metabolites can be regulated by environmental factors such as carbon status of the plant, nitrogen status of the soil, and rhizosphere pH—all of which are impacted by plant physiological mechanisms. Further, some of the secondary metabolites of fungi have antimicrobial properties, and bacterial products can inhibit growth of other bacteria or fungi. Thus microbial competition in the rhizosphere is partially mediated by secondary metabolites, in addition to direct competition for organic and inorganic resources. In addition, plant secondary metabolites can influence this competition, favoring those microbes that can metabolize the specific molecules in the root exudates. Further, plant exudates have been demonstrated to regulate the virulence of the soil microbes—that is, whether a particular microbial species is pathogenic (virulent) to the plant or is simply a rhizosphere inhabitant (avirulent).

Microbes may form symbiotic relationships with plants which benefit the plant through increased growth and/or seed production. This relationship can be formed by certain taxonomic groups of fungi and bacteria. In the case of mycorrhizal fungi, the fungus transfers primarily mineral nutrients and water to the plant in exchange for photosynthetically derived carbon. The carbon supports extensive growth of the fungus outside of the rhizosphere, which increases the area available for nutrient uptake by the fungus. This relationship then benefits both partners. Fungal hyphae can extend well beyond the reach of the root system, and this network of fungal influence is called the mycorhizosphere. Dinitrogen-fixing bacteria (diazotrophs) can either be contained within specialized root organs called nodules or living in the soil matrix surrounding the root. Diazotrophs such as *Rhizobia* spp. and *Frankia* spp. are contained within root nodules, and thus contribute little to the rhizosphere nitrogen pool directly. They directly transfer fixed nitrogen to host plants. Nitrogen is a limiting nutrient in many ecosystems, and plants that are able to form symbioses

with nitrogenfixing bacteria often display increased growth following nodulation, which indirectly increases the size and complexity of the rhizosphere.

Plant-growth-promoting rhizobacteria constitute another functionally (not necessarily taxonomically) related group that influences plant growth. However, this class does so without developing an endosymbiosis. In this class, the presence of specific bacterial species in the rhizosphere promotes the growth of the plant through associative dinitrogen fixation, nutrient mineralization and chelation, and protection from pathogens. Many diazotrophs are rhizobacteria and they can directly contribute available nitrogen to the rhizosphere. One study revealed that a possible mode of communication between rhizobacteria and plants is through volatile metabolites produced by the rhizobacteria. When the plant was exposed to these compounds, it responded with increased growth rate.

The properties of the rhizosphere are also dependent on the properties of the aboveground portion of the plant. Herbivory on leaf tissue can alter gene expression in the root system, often resulting in altered susceptibility to soil pathogens. Aboveground wounding can increase the rates of symbiosis between plants and arbuscular mycorrhizal colonization. This wounding has also been demonstrated to result in increased quantities of bacterial-feeding nematodes in the rhizosphere. Conversely, root herbivory will effect aboveground physiology and can reduce fitness parameters, such as seed production. Nutrient status can also affect the ability of a plant to mount an induced defense upon exposure to aboveground herbivory. The major wound hormone of plants, jasmonic acid, can be transported from shoot to root, allowing leaf herbivory to elicit defense responses in roots.

Soil nutrient status will also affect the interactions between rhizosphere inhabitants. Symbiosis between diazotrophs and leguminous or actinorhizal plants is more likely to be established in soil of low-nitrogen availability than soil with abundant nitrogen. Under low-nitrogen conditions, leguminous plants will increase production of flavonoid secondary metabolites which, when released into the soil, serve a communicative role to nodule-forming rhizobia. Likewise, when the rhizobia recognize the presence of a legume root (via detection of the flavonoid signal), they release lipooligosaccharides into the soil which the plant recognizes to initiate nodule formation. These compounds clearly serve a role in communication between two highly coevolved species. Following the establishment of nodules, plants respond with increased growth and the rhizosphere microbial community becomes more active, presumably due to increased carbon availability in the rhizosphere.

Plant roots have the ability to not only contribute carbon to the rhizosphere, but to take organic metabolites from the rhizosphere. The sum of the rate of efflux and influx provides a measure of net contribution to the rhizosphere. Microbial secondary metabolites have been demonstrated to increase the efflux of plant-derived amino acids from the root into the rhizosphere by 200%–2000%. Bacterial *Pseudomonas* spp. produce a metabolite, 2,4-diacetylphloroglucinol, which was found to block amino acid uptake by the plant, while fungal *Fusarium* spp. produce a metabolite, zearalenone, which increases amino acid efflux from the roots of alfalfa. In this way microbes are thought to play an active role in the plants' ability to modify the rhizosphere.

Methods of Studying Rhizosphere Ecology

Understanding rhizosphere ecology and the interactions between plants and soil-borne organisms often requires determination of the identity and distribution of the vast diversity of organism(s) (bacteria, fungi, arthropods, etc.). However, it is this diversity that makes the rhizosphere one of the most difficult communities to study, often dictating the use of a variety of methodologies dependent upon the research objectives and organisms of interest. Traditional methods based on the isolation and growth of live organisms in culture may significantly limit the population being evaluated. For example, it has been suggested that only 1% of a bacterial population can be cultured by common laboratory techniques. It is unknown if this limited sample is representative of the entire population and is unculturable due to a physiological state, or a highly selective sample that is phenotypically and/or genetically suited for laboratory growth on artificial media. To overcome these problems, a variety of methods have been developed including direct observation, fatty acid analysis, chemical, and molecular techniques (DNA and RNA), etc. A detailed discussion of each of these techniques is beyond the scope of this article and the reader should consult one of the many reviews that discuss the advantages and disadvantages in more detail. A brief introduction to some of the available techniques is shown in Table 1. As

Table 1 Summary of some methods for studying the rhizosphere

General methodology	*Example techniques*	*Target organism*
Direct observation	Serial plating counts, trapping	Fungi, bacteria, arthropods
	Rhizotron	Macroinvertebrates, roots
	Funnels, trapping	Arthropods
	Ergosterol, chitin, fatty acid markers	Fungi, bacteria
	Fluorescence microscopy	Fungi, bacteria
Molecular markers	Non-PCR techniques (GC content, reassociation, and hybridization, microarrays)	All
	PCR techniques (DGGE, TGGE, SSCP, RFLP, T-RFLP, RISA)	All—primer specific
Functional measures	Carbon utilization (e.g., Biolog plates)	Bacteria
	Nitrogen fixation rate	Diazotrophs
	Respiration rate	Bacteria, fungi, roots

should be obvious from Table 1, the methodology chosen may significantly influence the type and diversity of organisms identified in rhizosphere ecology studies. In addition, the research must also consider a number of other factors in the design and analysis of rhizosphere ecology studies. For example, considerable temporal and spatial heterogeneity may be observed associated with factors such as plant species and distribution, microclimate, soil physical and chemical properties, and the life stage or physiological state of rhizosphere microorganisms.

Detection and/or isolation by any of the above methods may not lead to a definitive identification of an organism. For many taxonomic groups, there is no official definition of species. For example, the genetic plasticity of bacteria allowing DNA transfer through plasmids, bacteriophages, and transposons complicates the concept of species. Fungal taxonomy has similar problems in identifying vegetative structures, as most taxonomy is based on sexual structures. Species-level arthropod identification is time consuming and typically conducted by systematists, especially when examining immature (larval) specimen. Molecular techniques may alleviate some of these problems but are still limited due to incomplete databases, genetic polymorphyisms, multiple gene copies, and intraspecies variation. The utility of some molecular approaches for studying rhizosphere ecology may also be limited by their inability to separate organisms that are dormant and/or not participating in rhizosphere processes from those organisms that play key roles in the rhizosphere.

Larger-scale techniques such as microscopy and rhizotron-based observation have also been used to examine higher-order rhizosphere structure and organization. Fluorescent microscopy of bacteria, either naturally fluorescing (such as *Pseudomonas* spp.) or strains expressing a fluorescent protein, allows for detailed spatial organization of microbial communities in a relatively intact setting. Rhizotrons are essentially buried glass-walled containers that allow viewing of intact rhizosphere as it expands to the glass surface. Such devices are of limited use for microbial spatial dynamics, but can be valuable as tools for studying larger arthropods and root–root interactions.

Summary

The rhizosphere is a nutrient-rich region of the soil immediately surrounding the plant root. This region is highly dynamic and supports a dense and diverse fauna. Despite the challenges associated with studying ecological interactions in a soil matrix, researchers are beginning to understand the complex ecological interactions occurring in the rhizosphere. Chemical communication plays an integral role in the ecology of the rhizosphere, and new functions for intra- and interspecific signals continue to surface. Much of the knowledge on rhizosphere biology has been revealed by agricultural researchers, who have studied many of the positive and negative relationships between plants and soil microbes. Though detailed descriptions exist for many rhizosphere interactions, the complex and cryptic nature of the rhizosphere will continue to challenge scientists interested in the ecology of the plant–soil interface and its associate biota.

Salinity

DM Talley, San Francisco Bay National Estuarine Research Reserve, Tiburon, CA, USA
TS Talley, University of California, Davis, Davis, CA, USA

Introduction

Salt has played an important role in human history, serving as a currency, figuring prominently in fables and expressions, and being an important nutritional and culinary element. Salt also plays a crucial role in the structuring of organismal assemblages and ecosystems. Salt is an essential element for all living organisms, and is critical to many metabolic functions, including nerve and muscle action, blood pH and electrolyte balance, and cell regulation. Salt is, however, only salubrious within a certain range, with too little or too much leading to metabolic failure. Because of this, salt is a common and often dominant abiotic factor structuring ecological communities. For example, transitions from fields of grasses, herbs, and succulents to tall stands of reeds and cattails as one heads upstream from an ocean is in large part due to the effects of decreasing salinity.

Definitions and Measures

While common `table salt' is sodium chloride (NaCl), salts can more broadly be defined as the product formed from neutralizing an acid, where a metal atom (or positively charged radical) replaces one or more of the acid's hydrogen atoms. Salts are thus neutral ionic compounds composed of positively charged ions (`cations'; e.g., calcium, magnesium, potassium, sodium) and negatively charged ions (`anions'; e.g., bicarbonate, carbonate, chloride, nitrate, sulfate).

Salinity is a measure of the `saltiness' or concentration of salt in water or soil. Salinity is synonymous with halinity, which derives from the word halides meaning chloride, and means the total concentration of soluble salts. An oft-ignored convention is for oceanographers to use the term `halinity' when referring to oceanic conditions, due to the dominance of NaCl in seawater, and `salinity' being used for soil or freshwater systems. Salinity historically has been measured as the ratio of the mass of dissolved salts to the solution in which it is dissolved (e.g., parts per thousand or ppt). More recently, salinity has been measured in terms of practical salinity units (psu) – the ratio of the conductivity of the sample water to a potassium chloride standard (32.435 6 g KCl/kg water); psu is a ratio, and thus is a dimensionless measure of salinity.

Salinity is often measured using conductivity meters, which measure the conductance of electricity through solution. Since salt ions conduct electricity, conductivity is proportional to the concentration of salts in a solution. While measures of conductivity can be converted to salinity, and vice versa, the algorithms can be complex as they also depend upon temperature and pressure. Measurements of salinity can also be inferred through refractance, water density, and sound speed. Refractometers measure refractance, or the bending of light waves as they pass through a solution. Both refractometers and salinity meters require a fluid solution, while conductivity meters can measure conductance of moist sediment slurry.

There are a number of systems for classifying aquatic environments based on salinity. For marine waters, the `Venice system' (or some variation thereof) is commonly used, with freshwater (<0.5), oligohaline (0.5–5), mesohaline (5–18), polyhaline (18–30), euhaline (30–40), and hyperhaline (>40). Other commonly used categories include brackish (0.5–30) and brine (>50). Seawater salinity usually ranges from 32 to 38 and is an average of 35.

Organisms can also be classified with regard to their salt tolerance. Those that can tolerate a wide range of salinities are called euryhaline (e.g., many intertidal fishes, mussels), while those with narrow salinity tolerances are `stenohaline' (e.g., most ascidians, freshwater fishes). Some organisms complete different stages of their life cycle in different salinity regimes. For example, fish that live most of their lives in the sea but that breed in freshwater are called anadromous (e.g., salmon). Conversely, catadromous organisms are those that live in freshwater but breed in saltwater (e.g., eels, Chinese mitten crabs).

Sources of Salt

The seas originally received their salt when a young Earth's atmosphere, filled with hydrogen chloride and other materials, dissolved into the primitive ocean. The majority of the salt, however, gets added to the ocean through the gradual weathering of terrestrial rocks by water (and a smaller percentage through hydrothermal or volcanic inputs). Precipitation is slightly acidic due to carbonic acid that forms when water interacts with atmospheric carbon dioxide. Rain thus not only erodes the rock but its acidity also dissolves minerals and salts, carrying them in solution downstream to the ocean. Additionally, the sodium and chloride ions that are present in freshwater sources are mostly not used by organisms and are transported to the ocean, where evaporation concentrates in flowing water leading to saline conditions. There are also mechanisms by which salt gets removed from the ocean,

Fig. 1 Halophytic plants, such as the pickleweed (*Salicornia bigelovii*) depicted here, have adaptations to allow them to deal with the excess salts in their environment. Pickleweed actively transports excess salt to the tips of the terminal jointed leaves, which are then shed. Photo credit: D. Talley.

keeping the system in steady state, such as corals using calcium to build reefs, ions attaching to clay particles, and salts precipitating out of solution.

Inland water bodies receive salts in a similar manner. In arid regions and water bodies that have no outflow, evaporation can lead to salinization and the formation of inland seas. Examples include the Great Salt Lake in Utah, and the Salton Sea and Mono Lake in California (USA), the Dead Sea in Israel, and the Caspian Sea in Eurasia.

Terrestrial systems may also be saline. Salt may be carried inland from the ocean in prevailing winds and deposited in rainfall and dust, creating salt deposits in sediments. Erosion and release of salts from parent rocks, as well as the isolation and evaporation of ancient seas, may also contribute to the formation of saline soils. Often salts remain buried within the sediment profile, but agricultural practices such as irrigation and the removal and replacement of deep-rooted woody plants with shallow-rooted crops tend to increase salinities. Woody plants with roots of varying depths draw up fresh groundwater and shade the soil surface, thereby reducing evaporation and salinization. Shallow-rooted crops, on the other hand, do little to shade surface soils and do not tap into the groundwater, thereby allowing it to rise upward, pushing hovering salt layers to the surface. Furthermore, irrigation water is often high in minerals and salts, further exacerbating salinization. This has caused a shift in some arid regions from native flora and fauna and valuable agricultural species to salt-tolerant natives and exotics and barren areas, such as in the wheat belt in Australia.

Adaptations to Salinity

Salt affects organisms through alteration of the water balance of cells and through salt toxicity. Since osmotic pressure pushes water toward tissues with higher solute concentrations, and seawater is often more concentrated than the cells of organisms, water tends to flow out of cells in aquatic organisms in the presence of seawater. Similarly, water uptake into organisms and cells is impaired when in saline solutions, resulting in water limitation similar to what occurs in arid systems. Salt toxicity results when salt affects enzymatic activities and energy processes, such as reductions in photosynthesis and respiration. Organisms living in saline environments have two general adaptive strategies – tolerating and avoiding salt stress. Organisms adapted to live in saline environments are called halophiles; in particular, such plants are called halophytes (**Fig. 1**).

Stress tolerance is generally achieved through metabolic or physiological adaptations. Both plants and animals have a diversity of adaptations to various levels of salinity in the environment, as either hyper- or hyposalinity can cause physiological stress. Osmoconformers are organisms that keep their internal fluids isotonic to their environment, that is, they maintain an internal salinity similar to their ambient conditions (e.g., most marine invertebrates, seagrass). Osmoregulators, conversely, maintain a constant osmotic pressure within their bodies by balancing water uptake and loss through the controlled movement of solutes across membranes between internal fluids and the external environment (e.g., most aquatic vertebrates, some marine invertebrates such as fiddler crabs). Organisms may have selective cellular uptake of particular salts, for example, preventing sodium but allowing potassium uptake (salt grass, cordgrass). Plants and animals may take saline water into their tissues but then accumulate organic compounds to increase cell osmotic potential to prevent cellular explosion (e.g., cordgrass). Other organisms have glands through which salt is excreted (e.g., gulls, some salt marsh plants), tissues through which they take up salts to maintain osmotic balance (e.g., freshwater fishes), or move salt to cells which are eventually lost, such as the specialized hairs or leaf tips of halophytes (e.g., salt marsh plants such as pickleweed and black grass) (**Fig. 2**). Succulent plants dilute salts by taking up more water, but still have to regulate salts by sequestering them in cell vacuoles, isolated from the cytoplasm and organelles of the cells.

Fig. 2 This species of side-blotched lizard, *Uta tumidarostra*, lives on islands in the Gulf of California where *in situ* terrestrial production is quite low, and thus feeds extensively on intertidal invertebrates. This species has evolved large nasal salt glands that allow it to excrete the excess salts consumed with its prey. Reproduced by permission of L. Grismer.

Stress avoidance includes regulation or direct avoidance of salt, either through structural adaptations or behavioral responses. In halophytes, for example, structural adaptations may include specialized root cells that may filter out salt and result in the sap consisting of pure water. Other organisms have behavioral adaptations, such as timing of reproduction, emergence, or dispersal to avoid undesirable conditions (e.g., insects, crab larvae). Mobile organisms, such as fish or crustaceans, may be able to avoid hypo- or hypersaline conditions by moving out of an area.

All of these adaptations come at a cost – the energy used to perform these functions is thus unavailable for other physiological demands, such as growth and reproduction. Therefore, organisms dealing with salt stress, like other physical stresses, are usually faced with a tradeoff between coping with salt and facing competition or predation in less saline areas. Most vascular plants, for example, are salt tolerant but would perform better in fresher conditions if not for competition with taller brackish and freshwater plants.

Many of these factors broadly apply to terrestrial organisms as well. Here, osmoregulation is often handled through specialized organs (e.g., kidneys, Malpighian tubules), and a common physiological stress is a lack of salt, as opposed to an overabundance. Nonetheless, similar issues of adaptation and tolerance for high or low salinity environments apply.

Scales of Salinity Variations

Salinity varies over a vast range of temporal and spatial scales, with profound effects on ecological processes at each scale.

Fine Spatial Scales

Patchy salinity patterns. Even within a very localized system, there can be fine-scale variations in salinity influenced by other abiotic variables, such as substrate type and microtopography, and biotic variables, such as substrate organic content and the presence or activity of local species. Substrates of fine particle size and high organic matter, for example, may maintain lower salinities due to lower evaporation rates than coarser, more mineral soils. The presence of microtopography (depressions, peaks, slopes) may also vary evaporation rates and therefore salinity. The presence of organisms that directly or indirectly alter salinity and, in turn, the associated community (i.e., ecosystem engineers) may contribute to fine-scale salinity variability. The presence of shade-casting species, such as plants with dense canopy like trees, grasses, or mat-forming species would likely maintain lower salinities than areas without such (or any) plants. Activities of organisms present could also alter salinity – bioturbators might turn surface soils minimizing evaporation and salinity accumulation, and salt-excreting species, such as tamarisk, may increase local salinities.

Vertical gradients. Salinity gradients exist across intertidal zones, with distance from the sea into the upland. Whether tidal flats, marsh, rocky intertidal, or sandy beach, salinities generally increase in arid regions and decrease in nonarid regions as one heads from lower to upper intertidal. Freshwater upland runoff and evaporation rates of tidal water, wave swash, and sea spray determine the extent and severity of the gradient. Organisms are thought to be limited by abiotic factors, such as high salinity and desiccation or freshwater runoff, in the upper intertidal and biotic factors, such as predation or competition, in the lower intertidal where stresses are not limiting.

Salinity gradients can also be found in water columns. In estuaries where wave energy and turbulence is low, salinity can have complex vertical patterns. Fresher river water often flows over the denser seawater in estuaries, forming a salinity wedge that migrates horizontally with the tides. The duration and thickness of the wedge varies with rainfall and runoff, as well as amount of mixing due to wind and water turbulence. Some organisms, such as crab larvae, may use these salinity gradients and boundaries as

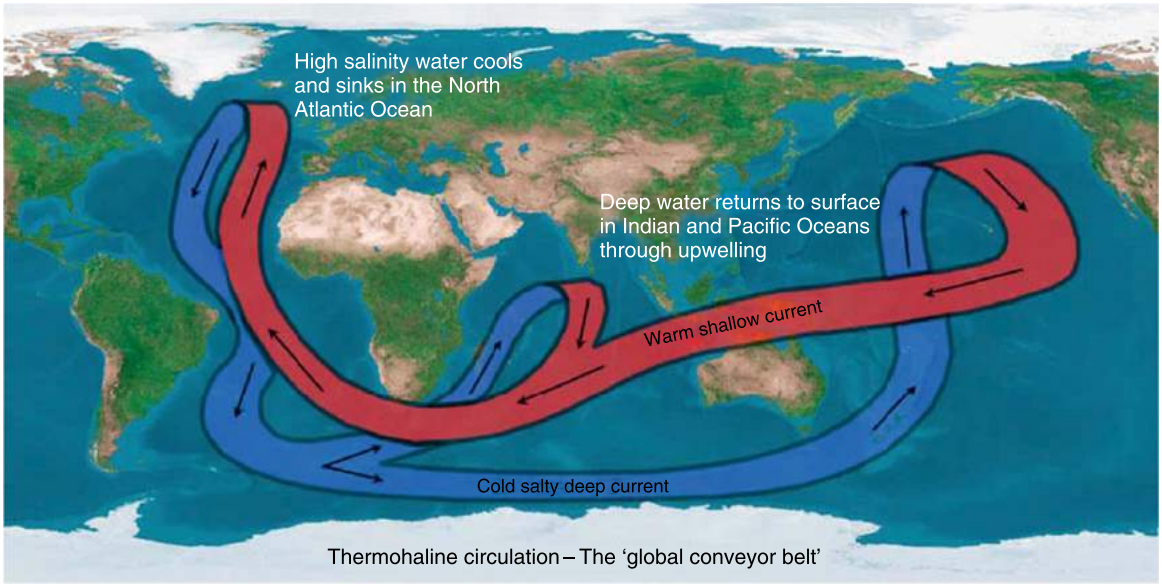

Fig. 3 global thermohaline circulation. Density patterns caused by differences in salinity and temperature drive global oceanic circulation patterns.

a cue for migration direction or settlement. While mobile species may be able to avoid undesirable salinities, less mobile species need to be able to tolerate the daily and seasonal fluctuations associated with tidal cycles and weather patterns.

Broad Spatial Scales

Whole ecosystem. When we think of saline systems, we generally think of marine systems, or those influenced by seawater. Estuaries often form where rivers flow into the sea, resulting in a gradient of salinity that decreases with distance upstream from the ocean. Reverse estuaries form where gently sloped, relatively arid coastal areas are flooded by the sea, resulting in salinity gradients that increase with distance from the ocean due to evaporation and lack of fresh water inputs toward the head of the estuary. The structure of associated communities corresponds to changes in salinity, with shifts from higher proportions of marine taxa, such as polychaete worms, large clams, oceanic fish and crustaceans and seaweeds, to higher proportions of brackish and freshwater taxa, such as insects, aquatic vegetation, small clams and mussels, estuarine fish and crustaceans.

Latitudinal variation. Latitudinal variation in climate may influence the levels of salt stress, which in turn affect the structure and controls on associated communities. For example, coastal marshes of the eastern United States generally have higher salinities in the southern, hotter climate than in the northern, cooler climate. The southern marshes are dominated by succulents, with high salinity restricting the lower tidal limits of non-salt-tolerant plants. In comparison, grasses and herbs dominated northern marshes where flooding determined lower limits.

Global patterns. There are global-scale patterns of salinity, both horizontally (regional high sea-surface salinities; e.g., the Pacific Ocean is fresher than the Atlantic) and vertically (e.g., the North Atlantic Deep Water (NADW) is a mass of dense, salty water, part of which flows at a depth of 2000–4000 m on the Atlantic coast of North America). Both precipitation and evaporation affect salinity making the relatively shallow, semienclosed seas of arid climates hypersaline. These include the Red Sea, the Mediterranean Sea, and the Caspian Sea, among others. In fact, it is the large-scale vertical and horizontal distribution of salinity that helps drive global ocean circulation patterns (the thermohaline circulation of the `global conveyor belt'; **Fig. 3**). These patterns of circulation have profound effects on the ecology of the world, driving climate patterns, propagule distribution, and numerous other large-scale ecological patterns.

Fine Temporal Scales

Transient fluctuations. The salinity of a particular location may be temporarily influenced by transient abiotic or biotic conditions. Temporary reductions in local salinity could be caused by the short-term inputs of freshwater or shading, such as during rain or flood events and additions of wrack mats, detritus, short-lived plants, or algal blooms. Salinity increases could result from removal of freshwater or structure, or addition of saline water, such as during high tide events or tidal surges that scour ground cover and increase seawater inundation, or during short periods of dry, hot temperature (**Fig. 4**). The effects of such events may persist for a time after the actual event ends, for example, salt residue may remain in the upper intertidal following a high tide series.

Cyclic fluctuations. Frequent events such as daily and monthly tidal cycles can cause concomitant fluctuations in salinity of soils and water. Organisms within the tidal zone are either adapted to the salinity shifts or move in and out with the tides.

Fig. 4 Intertidal pools in salt marshes have salinities that are strongly affected by meteorological events (e.g., rainfall, wind), timing of inundation, and ambient air temperature. These pools can change in salinity from more than 125 psu to virtually freshwater in the course of just hours. Photo credit: D. Talley.

Seasonal fluctuation in climate and tides have similar but longer-term effects on the salinity of systems. In many arid and temperate regions, winter and early spring bring precipitation and long pulses of fresh and brackish conditions, while summer and early fall bring drier and therefore more saline conditions. Tropic regions may experience the highest salinities in the winter dry season and the lowest during summer tropical storm events. Organisms not adapted to these conditions die off or move to more favorable environments (downstream to more saline waters if marine, or upstream to fresher conditions if not marine).

Broad Temporal Scales

Succession. Shifts in salinity in systems over longer timescales may in part be driven by succession and also play a part in succession. For example, in disturbed or newly created salt marshes, the first colonizers, consisting only of salt-tolerant species, may shade (e.g., annual succulents) or rework (e.g., rove beetles, burrowing crabs) the substrate surface, reducing evaporation and moderating salinity. Subsequent species may need to be less salt tolerant. As cover of the substrate increases, salinity is further reduced and buffered from dramatic fluctuations.

Decadal and longer. Longer-term fluctuations in the environment and climate may lead to alteration of salinity patterns. For example, the El Niño/Southern Oscillation (ENSO) events can alter patterns of precipitation and current flow, with cascading effects on salinity patterns worldwide. Over geologic timescales, alterations in aquatic salinity patterns have been profound, coupled with changes in oceanic circulation, glaciation and deglaciation, etc., with all of the potential ecological consequences of altered salinity on a global scale.

Summary

Salinity is one of the dominant physical factors structuring terrestrial and aquatic ecosystems, with both overabundance and paucity creating physiological stress. Organisms have evolved a number of adaptations to deal with these stresses, which can affect successional patterns, competitive interactions, and species diversity and distribution. The salinity of any given environment is controlled by both physical and biological processes, and varies over spatial scales ranging from centimeters (e.g., vertical distribution in sediments) to thousands of kilometers (oceanic), and over temporal scales from minutes (e.g., ocean waves cresting a berm) to geologic (the evolution of saline conditions in the oceans).

Scavengers

OJ Schmitz, HP Jones, and BT Barton, Yale University, New Haven, CT, USA

Introduction

Ecological communities can be envisioned as collections of species that are organized into food chains and webs in which each species is a consumer of resources and is itself a resource for other consumers. Ecologists call these consumptive interactions trophic interactions. And so, species engaging in a particular kind of trophic interaction are said to belong to a distinct trophic group. Ecologists routinely idealize food chains and webs as being comprised of four trophic groups. Species that consume mineralized nutrients and CO_2 in order to photosynthesize carbohydrates belong to the plant trophic group, species that consume living plant tissue belong to the herbivore trophic group, species that prey on herbivores belong to the carnivore trophic group, and species that recycle dead organic material back into the nutrient pool belong to the decomposer trophic group.

Such classic idealization of ecological systems typically ignores another trophic group, scavengers. After all, mobs of bloody headed vultures vying for their share of a carcass or insect larvae crawling in stinking, rotting meat do not engender the same sense of awe and natural wonder as do grazing antelope and lions coexisting on the Serengeti plains of Africa. Scavengers get short shrift in ecological thinking because their role is typically viewed as being a repulsive behavioral curiosity or the ecological equivalent of garbage men that sustain themselves on nature's offals. Scavengers are sometimes viewed merely as parasites that steal food – called kleptoparasitism – from the more noble carnivores. These are, however, unfortunate and inaccurate characterizations of scavenging. As we will show below, scavenging serves an important role to the welfare of many species and it can be an important determinant of the structure and functioning of ecological communities. Moreover, scavenging involves many more species than those few specialists that are routinely highlighted as serving this role.

Scavenging as a Trophic Interaction

Scavenging, like carnivory, involves the act of consuming the flesh of dead animals – carrion. Technically, however, scavenging differs from carnivory in that it does not actively involve killing animals. Scavengers also differ from decomposers. Decomposers like bacteria and fungi break down the protein of dead animals into its constituent carbon-, nitrogen-, and hydrogen-based elements (**Figure 1**). Those elements are then broken down further into mineralized form to be taken up later by plants. Scavengers, on the other hand, consume organismal protein and convert it into their own body tissue (**Fig. 1**).

Research has shown that many organisms die from sources other than predation. Although the exact value varies among species and sizes of prey, predation accounts for between 2% and 75% of organism losses annually, thus leaving 25%–98% to be scavenged. In the Serengeti alone, the annual amount available to scavengers is estimated to be on the order of 26 million kg. Clearly, neither the Serengeti plains, nor any other location globally, is littered with dead animal carcasses, testimony to the magnitude of this trophic interaction. Depending on the size and species of carrion, a carcass can be despatched within hours to days. Research has also shown that scavenging efficiency, defined as the proportion of a carcass that was consumed within this time frame, averages 75%, a value that rivals the efficiencies of carnivores consuming their hunted prey.

Scavenging can be temperature dependent because of interplay between microbial decomposition and chemical detection of carcasses. This interplay leads to intermediate, optimal temperatures for scavenging, especially within temperature regions of the globe. Decomposers alone are rarely able to utilize entire carcasses. So, to avoid competition with scavengers, decomposers have evolved capacities to produce noxious and odorous chemicals that can make the entire carcass distasteful or even toxic. At moderate temperatures (e.g., 10–15 °C) microbial decomposition is at a level that produces modest concentration of chemicals leading to putrid odors that signal the location of edible carrion to scavengers. Indeed, experimental studies have demonstrated that under such conditions scavengers can find and begin to remove carrion within minutes to hours after becoming available. Higher temperatures and associated higher rates of decomposition lead to higher concentrations of toxic amines and sulfur compounds that signal to scavengers that the item is inedible. Lower temperatures are less favorable for microbial activity and accordingly there is little or no production of chemical odors. Scavenging may thus be limited at low temperatures because, without the chemical cues, scavengers may have difficulty finding a potentially edible carcass.

Who Scavenges?

Carrion tends to be an unreliable resource in any one location or point in time. This has hindered the evolution of strict or obligate scavenging behavior, except in a few notable species like vultures or certain flying insects. Vultures in particular have several traits that facilitate specialization as scavengers. First, they have large broad wings that enable them to expend minimal energy by soaring

 doi:10.1016/B978-0-444-63768-0.00544-8

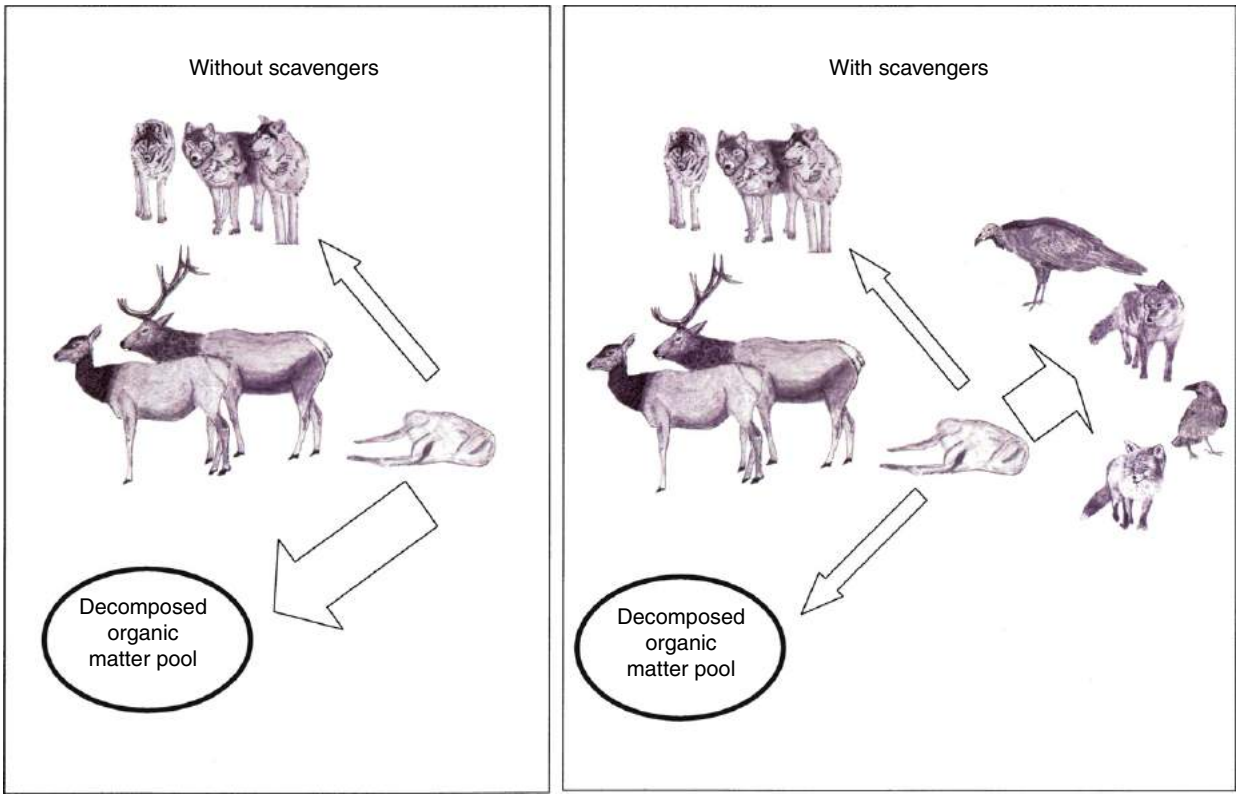

Fig. 1 In many systems, including the example of wolves preying on elk, predation accounts for 2%–75% of losses of individual prey annually (denoted by thin arrow from the elk carcass to wolves). The remaining 25%–98% of all individuals that die annual succumb to nonpredation causes. Much of this abundant carrion can be broken down into constituent chemical elements by decomposers (denoted by thick arrow from elk carcass to the decomposed organic matter pool) if scavengers are absent. In many cases, however, it is redirected to bolster populations of a diversity of scavenger species, including turkey vultures, coyotes, ravens, and foxes (denoted by thick arrow from elk carcass to scavengers and thin arrows to decomposed organic pool). Hence, scavengers compete with decomposers for carrion. Scavengers, however, are often more efficient than decomposers at despatching carrion.

over vast areas to locate carrion. They have sharp eyesight and a keen sense of smell. They also are able to consume carcasses very rapidly once they have been discovered. Even so, they represent a very small faction of the range of species that scavenge.

Most scavenging is facultative; in essence a dietary supplement. It is undertaken by a broad range of species. Most notably carnivores of all stripes, including the majestic birds of prey such as eagles, hawks and falcons but also other birds such as ravens and magpies; canid, felid, ursid, and hyenid mammal predators; snakes, lizards, and spiders all consume fresh carrion when it is found. After all, it does not make evolutionary sense (in terms of improving individual survival and reproduction) to pass up a free meal, one that effectively differs little from a hunted prey item, whenever it is encountered. The proportion of the diet that comes from carrion, however, can vary widely among carnivore species, making some species like hyenas and ravens seem close to being obligate in their scavenging.

Many seemingly unlikely species such as herbivores also scavenge. For example, on islands in Lake Michigan, white-tailed deer consume large quantities of dead alewives, herring-like freshwater fish that undergo annual mass die offs and wash onto shore in spring. It has been estimated that alewives comprise 30%–54% of the daily diet of individual deer during the spring period. Such purposeful scavenging appears to provide the deer with an important dietary supplement during a period when terrestrial food resources are in critically low supply after lengthy winter browsing. Alewives have higher protein, fat, energy, and mineral (especially salt) contents and are more easily digested than the heavily browsed plants on the islands. Other herbivores including grasshoppers and hippopotamus also readily engage in scavenging.

Ecological Effects of Scavengers

Behavior Modification of Carnivores

Scavengers do not actively hunt and kill prey. Instead, they must seek out carrion across broad distances on landscapes. But carrion is highly ephemeral in space and time and so it can be quite difficult to find it unless one can search wide distances quickly and

efficiently. Most scavengers do not have this searching ability. So they beat the odds against finding carcasses by associating themselves with species that actively hunt and kill prey.

A classic example of such association is between wolves and ravens. Ravens are typically present at wolf-killed carcasses and in some locations such as on Isle Royale in Lake Superior they are omnipresent. There are even cases in which ravens are rarely found on the landscape except in close association with wolves. Ravens can derive a very good livelihood from scavenging carcasses. An individual can ingest and hoard between 0.5 and 2 kg of wolf-killed prey per day. Thus, wolves may routinely lose between 2 and 20 kg of food per day to flocks of ravens. There are notable cases in which flocks of ravens devour up to half of the moose carcasses.

Such a high level of scavenging imposes strong competitive pressure on wolves to the extent that it may alter wolf grouping dynamics. A classically held belief is that groups of wolves comprise related kin in which altruistic behavior of the kin contribute toward overall family welfare (survival and reproduction). But recent research shows that wolf packs contain unrelated individuals. Moreover, pack sizes are often larger than one would expect if individual wolves were attempting to maximize their foraging returns. Such behavior is not expected to be favored by natural selection. This counterintuitive behavior can, however, be reconciled if we add in the costs of food loss to scavengers. In the absence of scavenging, wolves maximize their foraging returns by associating in groups of two or three individuals because one individual alone is inefficient at killing prey and beyond two or three individuals competition for access to a carcass increases with group size leading to diminishing per individual foraging return rate. Loss of food to scavengers may change this structure because it forces wolves to hunt more frequently. Larger packs tend to be more efficient at killing prey frequently. Also, individual foraging return varies little with group size under conditions of scavenging and frequent hunting. Thus, the foraging cost of living in large groups may be offset by the benefit of frequent prey capture in wolves and perhaps in other social carnivores like lions that also face competition with scavengers.

Behavior Modification of Herbivores

Because scavengers associate closely with predators, their vocalizations and movement behavior may signal imminent predation risk to prey. Moose in boreal forest ecosystems that face high predation risk have been shown to respond dramatically to this signal. In boreal forests, ravens associate closely with wolves, especially during wolf hunting forays. In these regions, the probability of survival, especially of young individuals, can often be as low as 30%. Research using playback calls of ravens has shown that moose in such high risk areas decrease their foraging rates and become increasingly vigilant by being watchful of imminent danger. This contrasts sharply with a lack of a behavioral response to playback of raven calls in geographic locations where wolves and other predators of moose have long been extirpated. In such areas, survival probability is at least three times higher than in the high risk areas. Differences in foraging rates between high and low risk areas are known to have differential effects on ecosystems because they lead to differences in the abundance of plant species that comprise the herbivore's forage.

Carnivore–Scavenger Interactions

Because carnivores hunt year-round, they often provide a steady supply of carrion. The exact supply rate of such a resource is known to change the seasonal behavior of scavenger species as well as be an important determinant of the spatial composition of scavenging species within landscapes.

Grizzly bears are important scavengers throughout most of their geographic range. In most cases, however, they hibernate during the winter months as a means to survive periods of chronic food shortages. However, Grizzly bears are known to forego hibernation in conditions when the supply of carrion is high. This may often happen in winters with high snow depth because moose and elk species that comprise the prey base for wolves are encumbered by deep snow and thus are especially vulnerable to being captured. Under such conditions, wolves frequently abandon partially eaten carcasses in favor of capturing new prey, leaving a continuous and plentiful supply of left-over meat, bone and hide to be scavenged.

Scavenging is undertaken by many generalist species that opportunistically use carrion when it is available while sustaining themselves on other resources when carrion is unavailable. These species do not live in isolation of one another on landscapes. So the availability of carrion within the landscape can lead to strong interactions among species as they vie for their share of the resource. Moreover, the nature of carrion supply in space and time can have an important bearing on the kinds of scavenger species found within a location.

If the amount of carrion provided by carnivores is small and much localized, then this resource will attract scavenger species with small foraging radii – those species that forage largely within a small local area. This highly limited resource will be most likely consumed by species that are competitively dominant. These are typically the more fearsome species like coyotes or hyenas that are able to usurp the food by scaring away other species. If the local supply of carrion is large, then it will saturate the ability of the local, competitively dominant scavengers to consume the carrion in its entirety. In such cases, wandering species – those with large foraging radii – will also be attracted to the resource leading to a high diversity of scavenger species at a carcass. The plentiful supply of the resource also diminishes the intensity of competitive interactions among the scavenger species. Because many of these scavengers are also generalist carnivores, such a high, local resource supply represents an important survival subsidy that maintains the multiple trophic level structure of ecological food chains and webs. Predator species that temporarily resorted to scavenging can resume their normal carnivore role once the pulse of carrion supply subsides.

In addition, carnivores, by adding to natural mortality of prey, can add to the spatial and temporal supply of carrion. In the absence of carnivores, herbivore species often die in high numbers during parts of the year in which resources are in short supply or poor in quality such as drought periods in savanna grasslands or late winter in northern temperate regions. Scavengers take advantage of these short pulses of resources to sustain their populations. Nevertheless, their population dynamics are influenced by the vagaries of this carrion supply because it can fluctuate widely with weather conditions from year to year. Large hunting carnivores can change the temporal dynamics of carrion supply from a short seasonal pulse to one that is more even and protracted throughout the year. This subsidy in turn can help to stabilize the long-term population dynamics of carnivore species that scavenge opportunistically, leading to a higher diversity of species on the landscape.

Energetic subsidies in the form of carrion can also undergird food chain structure in locations where long food chains are unlikely to be sustained by local levels of resource production. Arid oceanic island ecosystems off Baja Mexico normally provide an inhospitable environment: they are covered with *Opuntia* cactus and myriad species of flying insects and their web-building spider predators. Curiously, however, the islands support extraordinarily high densities of spider predators. This occurs because a considerable abundance of nutrient-rich resources in the form of drowned animal carcasses washes up onto the shore from oceanic drift. This resource input sustains insect species that scavenge the decomposing carcasses, thereby creating a highly abundant resource for carnivore species, especially on islands where there is little plant production and hence limited production of herbivore prey. The marine-island food energy conduit thus bolsters the structure of the island food web. In turn, the abnormally high abundance of spiders led to an unusually high capacity to control the abundance of the island's herbivorous insects, thereby lessening the insect damage to plants. Thus, the effects of the subsidy, mediated by scavenging, reverberate through the whole island system. Shut off the supply of carrion and the island ecosystem could collapse to a comparatively barren desert.

Summary

The view that scavengers are repugnant, behavioral oddities is an unfortunate and inaccurate representation of an ecological role. Scavenging provides an important means to bolster the structure and functioning of ecological systems because it mediates the ebb and flow of a major resource in space and time. It seems evident that in its absence, many ecological systems would have considerably lower species diversity because of reduced productivity and longevity of the myriad species that avail themselves of carrion when it is in supply. In addition, scavenging may serve an important and integral role in the functioning of ecosystems in that it provides a source of energy to top carnivores that that can rival or exceed in magnitude levels of energy supply provided by the supply chain from plants through herbivores to carnivores.

Seasonality

GH Dayton, Moss Landing Marine Laboratories, Moss Landing, CA, USA

Introduction

Seasonal shifts in environmental conditions play a fundamental role in influencing the abundance and distribution of organisms throughout space and time. These seasonal factors ultimately influence key biological parameters of organisms (Table 1). Changes in climatic conditions directly impact primary producers, which in turn influence secondary consumers throughout the food web. Fluctuations of vegetative growth between the growing and nongrowing season result in patchy concentrations of essential resources such as food, water, and energy. Thus, energetic resources for primary and secondary consumers are largely driven by changes in seasonality. These shifts in resources have direct and indirect effects on the ecology of all organisms. Beyond energetic constraints, seasonal variation in climatic conditions influence when and where particular organisms can persist. As a result, many species exhibit highly adaptive traits and life histories that enable them to persist in changing environments. This is especially true in higher latitudes where climatic conditions change more drastically throughout the year in comparison with low latitudes where climatic fluctuations are less variable. In this article, the author outlines some of the seasonal factors that affect organisms, as well as highlights examples of how these factors drive seasonal shifts in the abundance and distribution of various species. It is important to note that many, if not all, of the seasonal factors discussed below are correlated with one another and in many cases it is difficult to disentangle the factors individually. For example, seasonal shifts in photoperiod and temperature (tightly correlated with one another) play important roles in the ecology of many organisms; however, these factors are determined by the tilt of the axis of rotation of the Earth.

Rainfall

Seasonal shifts in rainfall have a pronounced impact on aquatic organisms; this is particularly true in ephemeral water bodies. The highest diversity of aquatic organisms occurs in temporary water bodies that are seasonal in nature – filling after cyclic rains and drying during nonrainy periods. Species that are dependent upon these habitats exhibit life history strategies that enable them to exploit seasonal aquatic habitats as well as to persist during dry periods. Many of these organisms have stages in their life cycles in which they enter diapause (a period of quiescence characterized by the cessation of growth and reduction of metabolic activity) or remain dormant during the dry season. For example, several species of aquatic invertebrates lay eggs in temporary pools, after which the eggs settle into sediments where they remain dormant during the dry period until seasonal rains once again flood the site and the aquatic larvae life stages emerge. Eggs of some aquatic invertebrates can remain dormant for over 125 years. Plant species associated with vernal pools follow a predictable flowering phenology after seasonal rains; these species are primarily annual and reproduce as pools draw down during the spring and summer months. Spring wildflowers in vernal pool ecosystems provide important resources for pollinating insects, some of which only collect pollen from vernal pool plant species.

Seasonal rains also play a vital role in sustaining organisms that live in permanent water bodies. Most large riverine systems throughout the world experience annual floods during wet seasons. These floods expand the spatial extent of rivers into habitats that for most of the year remain dry. Water spills over the riverbanks, flooding forest habitats and connecting water bodies that are usually isolated from one another. As a result, aquatic organisms are able to exploit habitats that are inaccessible throughout much of the year. As swelling rivers move into upland habitat, nutrients leach into the water, increasing primary production. Aquatic plants assimilate these nutrients that are eventually recycled back into the environment via decomposition. This pulse of nutrients plays a significant role in supporting the base of the food web and in turn sustains an increased number of herbivores and predators. Seasonal floods are common in large tropical riverine systems, which support a diverse assemblage of fish. One of the factors thought to have led to the diversity of fishes in these systems is the accessibility to a wide breadth of feeding niches that are available during seasonal flood events. Fish are able to exploit inundated upland habitats and thus are able to gain access to a wide

Table 1 Organismal responses to seasonally varying factors

variety of resources. As a result, fish assemblages in large tropical rivers exhibit a wide variety of feeding strategies and have a disproportionately greater number of herbivorous, detritivorous, and omnivorous feeding behaviors.

Desert regions, by definition, have very little rainfall throughout the year, with most of the precipitation occurring in seasonal storms during a 2–3 month period. Similar to environments that experience freezing temperatures during winter months, organisms that inhabit deserts are adapted to exploit patchily distributed resources throughout the year. The tight correlation between rainfall and seed production in desert regions has played an adaptive role in selecting for life history strategies that favor individuals that breed during wet periods of the year when resources are abundant. Many species of granivorous rodents, ants, and birds show predictable fluctuations in abundance throughout the year; peaks are associated during the winter and/or summer rain periods when seed production is high (**Fig. 1**). Organisms that inhabit desert environments throughout the year have adaptations that enable them to persist during times of low resource availability and extreme temperatures. Several desert species exhibit behavioral modifications that enable them to persist through drastic seasonal shifts in the environment. Amphibians, for example, bury themselves underground or take refuge beneath cover during dry months. These behaviors prevent desiccation and reduce their energetic requirements during times of low resource availability. Other organisms, such as the kangaroo rat which has highly specialized kidneys that are extremely efficient at conserving water, have physiological modifications that enable them to persist during times of low resource availability.

Oceanic Upwelling

Seasonal and periodic upwelling of deep nutrient-rich water to shallow depths plays a major role in supporting marine organisms worldwide. Upwelling occurs when cold nutrient-rich deep water replaces warmer nutrient-poor surface water. Increases in nutrients promote growth of marine algae and phytoplankton, which in turn provide the basis of the food web for many fish, marine mammals, and marine birds. These shifts in resources influence the abundance of marine organisms throughout the world. Upwelling events provide animals such as humpback whales, shearwaters (a largely pelagic bird), many tuna, and other primary and secondary consumers, with a significant portion of their annual energy requirements.

Photoperiod

Photoperiod (day length) plays an important role in regulating the timing of migration as changes in photoperiod influence temperature, rainfall, and ultimately primary productivity. Most plants respond to changes in photoperiod by producing seeds, new growth, and/or fruit at specific times of the year. A common animal response to shifts in vegetative production is migration. A

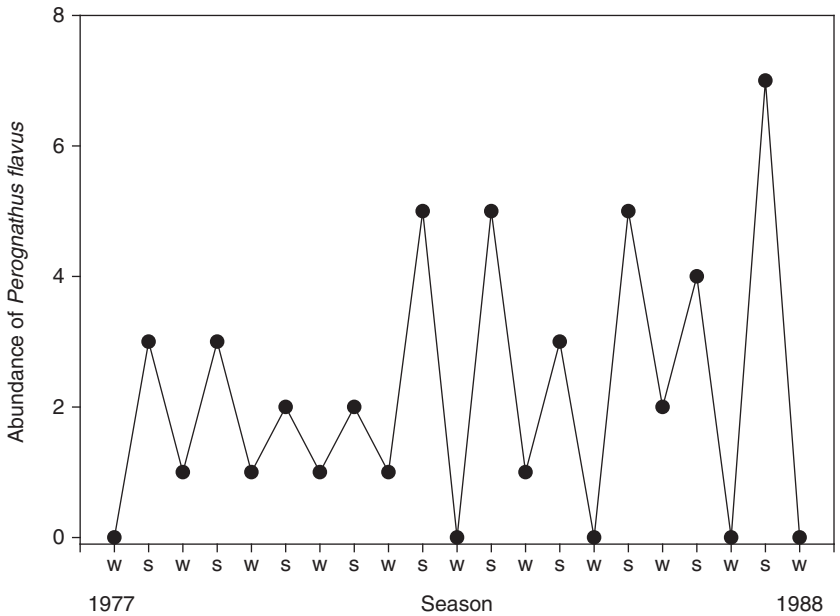

Fig. 1 Changes in abundance of the Silky Pocket Mouse (*Perognathus flavus*) over a 10 year period in the Chihuahuan Desert (w = winter; s = summer). Abundance was calculated as the 6 month average. Seasonal peaks in abundance are correlated with summer precipitation events and are likely largely due to increased primary productivity associated with rain events. Adapted from Brown JH and Henske EJ (1990) Temporal changes in a Chihuahuan Desert rodent community. *Oikos:* 59: 290–302.

classic example of a migrating species is the Serengeti wildebeest which migrates from areas of low resource production to areas of high resource production on an annual basis. Wildebeests occur throughout the Serengeti ecosystem which extends along the border region of Tanzania and Kenya. Forty percent of the Serengeti is comprised of grassland habitat which is the primary food source for wildebeests. Seasonality in rainfall throughout this region results in a dichotomous climate in which most of the rainfall occurs in the wet season from January–May, with very little rainfall occurring during the dry season (June–August). Grass production is high during the wet periods and virtually nonexistent during much of the dry season. Throughout the year, wildebeest will move from areas of low grassland productivity to areas of high grassland productivity.

Migratory species often modify the habitat in the area they migrate to, themselves having a seasonal impact on the environment. For example, many waterfowl congregate at breeding grounds where they reproduce and feed prior to migrating back to their winter habitat. It is not uncommon for breeding grounds to have tens of thousands of birds concentrated in relatively small areas for 2–3 months at a time. During these events, foraging birds have direct impacts on the plants they feed upon. Grubbing (digging up plant roots) by large numbers of waterfowl can have detrimental consequences on the environment as these areas are stripped of vegetation and plant community composition is significantly altered. However, for some plant species, heavy grazing (foraging on aboveground plant material) actually increases the overall net aboveground primary production, and plays a critical role in maintaining aboveground biomass and species composition of the vegetation. This occurs because although birds are eating plants, they are not killing them; and while foraging they are defecating on the ground, essentially adding fertilizer for plant growth. In wintering grounds, migratory waterfowl primarily roost in wetlands and spend most of the day foraging in upland habitats. Daily foraging forays to uplands followed by returns to roosting sites creates an agent for nutrient transport between habitats, which in turn can influence local ecosystem processes. The transfer of nutrients into wetlands have positive impacts on many aquatic plant and animal species; however, large numbers of migratory waterfowl roosting in small wetlands can result in high levels of nutrient loading which can be detrimental to water quality and ultimately the aquatic ecosystem.

Seasonal shifts in primary productivity driven by changes in photoperiod and/or rainfall have consequently played an important role in selecting for behavior of many species such as wildebeests and waterfowl, to move between hospitable habitats on an annual basis. This in turn influences the habitat in the areas they migrate to. Furthermore, top predators, such as lions and foxes, gain a substantial amount of their annual energy budget from migratory animals as they migrate through, or into, their ranges. Thus, these migratory behaviors in turn have direct and indirect impacts on the environment, which can result in large ecological effects that ripple throughout the food web.

Temperature

While many animals exhibit life history strategies that take advantage of patchy resources (both spatial and temporal) by moving between areas where resources are available throughout the year, other species have life histories that enable them to remain dormant during periods of low resource availability. Species that inhabit extreme environments, such as deserts and regions that experience frequent freezing temperatures, have evolved mechanisms to deal with the consequences of seasonal variation in environmental conditions. Nonmigratory species that inhabit areas remaining under snow for periods of the year have to cope with seasonal changes in resources by significantly reducing activity or by lowering their metabolic rate during cold periods. Reduction of metabolic processes saves energy during times when food resources are not available.

Several species cope with seasonal shifts in resources by caching food during times when resources are plentiful in order to survive periods when food is scarce or nonexistent. Many members of the avian family *Corvidae* harvest seeds throughout the spring, summer, and fall months and cache them in various locations in order to have a food source during the winter and early spring when seeds are not being produced. A classic example of such a species is Clark's nutcracker, which is known to cache over 30 000 seeds at greater than 7000 individual cache sites over a spatial extent of greater than 20 linear km. The Clark's nutcracker will bury seeds beneath soil and plant material throughout the summer and fall. During the winter and early spring, nutcrackers will return to their cache sites by utilizing landmarks and will then unbury their seeds. Clearly, seasonality has played a large role in the selective pressures that have led to the adaptations that facilitate behavior and cognitive abilities of the Clark's nutcracker. Indeed, when a comparative approach is taken, researchers have shown that Corvid species that are less reliant upon stored food for survival are not as diligent at caching food nor are they as good at relocating caches compared to Corvid species that inhabit harsher environments and thus largely rely upon cached seeds for survival.

Summary

Seasonality plays a critical role in influencing the persistence of all living organisms. Seasonal shifts in climatic conditions influence the availability of resources, which in turn influences the presence or absence of species throughout the environment at both the temporal and spatial scale. Over time, natural selection has favored individuals that display behaviors, phenotypes, and physiological adaptations that enable them to maximize seasonally patchy resources and cope with extreme environmental conditions. Individuals that persist in seasonal environments are better suited to adapt to shifts in environmental conditions, and

thus are able to exploit a vacant niche. When examining factors that effect the distribution and abundance of organisms, it is imperative to consider how seasonality has, and continues to, influence species persistence.

Seed Dispersal☆

Anna Traveset, Institut Mediterrani d'Estudis Avançats (CSIC-UIB), Mallorca, Balearic Islands, Spain
Javier Rodríguez-Pérez, University of Évora, Évora, Portugal; Aranzadi—Society of Sciences, Donostia/San Sebastian, Spain

Glossary

Dispersal effectiveness The contribution that each frugivore/seed disperser species within a community makes to plant fitness; in other words, the number of new adult plants produced by the disperser's activity relative to the rest of dispersers in the community.

Dispersal kernel Function summarizing the frequency of seed density after arrival from dispersal sources. The "dispersal kernel" is a population-based characteristic defined by a specific shape of an unimodal leptokurtic statistical function with a peak at or close to the origin, followed by a rapid decline and a long, more or less fat, tail.

Dispersal syndrome Particular combination of fruit and seed traits that are associated to a dispersal vector (e.g., water, wind, animal). The morphological characteristics of a dispersal syndrome are shared by phylogenetically unrelated species and have emerged as a consequence of parallel evolution forces.

Janzen-Connell hypothesis It proposes a trade-off between seed dispersal distance, which is maximum around mother plant, and the pressure of herbivores, pathogens and natural enemies which are maximum at high seed densities. This hypothesis predicts that the maximum probability of seed and seedling survival occurs at medium distances from origin. Despite it was developed to explain the high diversity in tropical forests, it has been demonstrated in other ecosystems as well.

Secondary seed dispersal Multi-step process of seed dispersal, that is, involving at least one more stage of seed dispersal after a primary seed dispersal. It may include either biotic or abiotic vectors not directly related to primary seed dispersal process.

Seed rain The spatial distribution of dispersed seeds within a landscape as a consequence of multiple dispersal events, sources and agents. Seed rain provides important population-based processes related to the density and richness of seeds.

Seed shadow The spatial location of seeds around a source point after being dispersed. The spatial location of each seed will determine the location where it will be established within the landscape.

Background

The ecology of seed dispersal is a topic of much interest to naturalists, although it has not been until the last three decades that has received considerable attention by scientists. Seed dispersal is one of the key phases in the process of plant regeneration, as it determines the potential area of recruitment at the same time that acts as a template for the rest of phases in such process. Dispersal can be defined as the process by which individuals move from the immediate environment of their parents to establish in an area more or less distant from them. In contrast to animal dispersal, plant dispersal is always passive in the sense that seeds have no control of where they will end up; moreover, seed dispersal is more determined by the traits of the parents than by the traits of the seeds themselves. Two widely used terms in the study of seed dispersal "seed shadow" and "seed rain" represent individual and population-based perspectives, respectively, which are needed if we are to understand the shaping of the spatial seed distribution and, ultimately, the evolutionary and demographic processes affecting plant recruitment.

☆*Change History*: October 2017. Javier Rodríguez-Pérez extended sections, included glossary and updated Abstract, included new references and added Figures 2, 4 and 5. A Traveset revised text.

Traits of Propagules and Dispersal Vectors

Seeds are dispersed in a great variety of ways. The morphological devices that enhance dispersal are usually quite evident and interpretable. Thus, for instance, we find wind-borne diaspores bearing wings, hairs or plumes that increase air resistance and slow the rate of fall (a dispersal syndrome named anemochory), seeds that float in the water by means of a buoy (hydrochory), seeds with hooks or barbs that adhere to the exteriors of animal vectors (exozoochory), seeds with elaiosomes for ant dispersal (myrmechochory), or diaspores with flesh appendages or coverings that are consumed by animals which later eject the seeds (i.e., endozoochory). Some plants disperse their offspring ballistically, by the explosive opening of the fruits or the springing of a trip-lever. Other species lack any evident dispersal device, which makes us wonder whether dispersal is less advantageous in these species or how they achieve effective dispersal.

The dispersal mode of seeds has commonly been associated with seed size; thus, for instance, species dispersed ballistically have significantly larger seeds than those dispersed by anemochory. This occurs even within a genus, such as in *Pinus*, in which seeds weighing less than c. 100 mg are wind dispersed whereas heavier seeds tend to have adaptations for either ballistic or animal dispersal. The relationship between particular seed traits and vectors has been called "dispersal syndrome." However, the usefulness of dispersal syndromes has often been questioned, especially for vertebrate seed dispersal, as fruit traits often are more influenced by plant phylogeny than by vertebrates. In fact, after accounting for phylogeny, fruit size seems to be the only trait—out of a large number of fruit traits considered in a review—significantly associated to dispersal (Fig. 1).

Seeds may have more than one opportunity of being dispersed. After a first phase consisting on the initial movement of seeds away from mother plant (primary dispersal), there may be a second phase (secondary dispersal) in which seeds are further dispersed, usually by another mechanism or agent. This is common in plants which are first dispersed by endozoochory or ballistically and are subsequently moved by ants, dung beetles, rodents, birds or even predators of such frugivores that carry seeds in their digestive tracts. There are cases where seeds have reward structures to attract ants, such as elaiosomes or flesh appendages which are removed once the seeds are dispersed. In other species, however, primarily dispersed seeds are removed by seed predators (e.g., rodents, granivorous ants) that store a fraction of them in sites—like holes in trees or in soil, ant nests, etc.—, and that later "forget" to collect them.

Plant and Animal Adaptations

The dispersal mode of any plant species is the result of many different pressures and constraints. Phylogenetic constraints are responsible for the fact that entire families or genera usually exhibit only slight variations on a single mode of dispersal. Nonetheless, large variation in some families or genera evidences that these constraints are not universal but contingent on the selective pressures and environmental variability which constrains the seed dispersal process.

From the plant's viewpoint, the timing of fruit maturation is key to enhance the seed dispersal process. A few general patterns in dispersal phenology have been described. Wind-dispersed neotropical trees, for instance, mature their fruits during the dry season, when trade winds are strong and trees are leafless, contrasting with the more or less constant throughout the year production of fleshy or dry fruits. By contrast, in the north temperate zones, mature fruits are produced in late summer and autumn, when avian frugivores are usually abundant, whereas further south, ripe fruits are also found through the winter, when flocks of wintering migrant birds are foraging. Nevertheless, such fruiting patterns do not need to be interpreted as adaptations to dispersal, as constraints to such timing may derive from selection to avoid pathogens or predators, to shift the flowering time or to modify the length required for fruit maturation. It is widely accepted that seasonality in temperature and water availability set limits on the time of fruit and seed development and maturation.

Fruit consumption by frugivores, and in particular vertebrates, has selected for fruit traits that enhance their detectability such as advertisement and/or visual chemical signals. Fruits, thus, tend to have a conspicuous coloration, distinctive odor or a combination of both. A common pattern found both in the tropics and in the temperate zones is that bird-dispersed plants usually have red or black-colored fruits. In some species, a bicolored fruit advertisement, contrasting the ripe fruits with the surrounding foliage is what presumably gives visual conspicuousness (what has been termed the "foliar flag" hypothesis). Also, some ripe fruits reflect ultraviolet light which enhances the detectability by birds, as their color vision extends to the near UV. The fruits dispersed by vertebrates also tend to have a pulp rich in water and carbohydrates whilst are poor in protein and lipids; however, there is much interspecific variability in nutrient composition, and fruit pulp quality does not show to be a trait reflecting plants' adaptations to dispersers. Fruit pulp usually contains also secondary metabolites (phenolics, alkaloids, etc.), sometimes to the point of being lethal to animals, which require an adaptive explanation not yet found. One possibility is that such compounds serve as defense against microbial pathogens and invertebrate pests that preclude the consumption of the fruits by legitimate dispersers.

Regarding animal adaptations, the majority of frugivores do not require important morphological and physiological adaptations, especially those that feed occasionally on fruits; in temperate climates, fruit resources are seasonally available and thus frugivores need to cope with periods of fruit scarcity or high fruit abundance. In the tropics, by contrast, there are frugivore species highly adapted to fruit consumption due to high availability of such resource there. Frugivores there can have the following distinctive traits: birds tend to have shorter, broader and flatter bills, and wider gapes than those not consuming fruits; some birds also have smaller and less muscular gizzards, larger livers and shorter intestines; frugivorous bats have shorter canines and broader palates than insectivorous ones; frugivorous lizards have longer intestines than those consuming mostly animal material. This is probably the reason why there are not frugivores specializing on only one or a few plant species.

Evolutionary Advantages

From the broad range of dispersal strategies, evolutionary or selective forces could shape the rich diversity of strategies found in nature. In general, seed dispersal strategies (or the selective forces that shape them) tend to increase seed dispersal rates from source point, providing individuals and/or species more capable to generate offspring. Hence, the two major benefits of seed dispersal are: (1) departure from the mother plant, which usually avoids sibling competition and reduces offspring mortality by predators or pathogens; and (2) colonization of new sites. Seed density usually is maximum at short distances from the mother plant (Fig. 2). Deviations from this conventional seed shadow shape can result from patchiness of habitat structure or from other ecological factors such as the frugivores' behavior, which can promote nucleation process (for instance, by depositing seeds under particular trees used for resting).

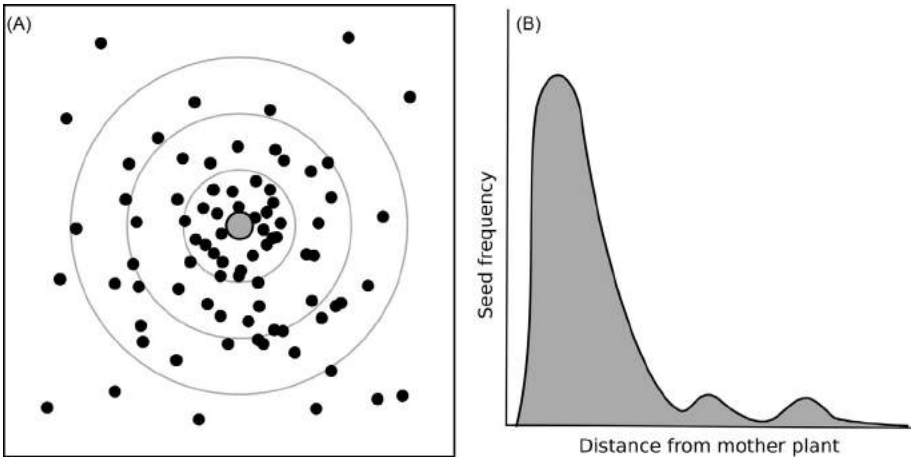

Fig. 2 Example of seed shadow and relationship between dispersal distance and probability of seed dispersal. In the left panel, *black* points represent the individual location of dispersed seed at increasing distances from the origin (mother plant in *gray*). In the right panel dispersal kernel of seed frequency at increasing distances from origin.

Frequently, the benefits of leaving the immediate vicinity of the mother plant depend upon the advantages obtained by (1) increasing the distance to it and (2) avoiding a highly intense sibling competition; the effects of both factors are not easy discernible without field experimentation. Regarding the advantage of colonizing new sites, seeds that leave mother plants have the capacity of occupying vacant habitats and suitable microhabitats for either germination and growth. This allows, for instance, the latitudinal or altitudinal migration of many plants in front of climate changes, the recolonization of a land after a volcanic eruption, the colonization of rapid-growth species of an abandoned field, enhancing thus the ecological succession, etc. There are also species that have "directed seed dispersal," benefiting from it as seeds are deposited in sites or microsites that are especially suitable for germination and seedling establishment. Seed mistletoes, for instance, are usually defecated by birds on host twigs, which are required for germination and seedling recruitment. From the evolutionary point of view, processes against dispersal could additionally act as selective forces upon propagule traits, at the expenses to loss propagule viability (i.e., seed germination and seedling growth). Under latter circumstances, the mechanisms against seed dispersal may occur, especially in plants inhabiting extreme habitats (i.e., cliffs or mountains) with very small distribution ranges, and that usually have promotes evolutionary processes of local adaptation and low genetic variability in plant populations.

Patterns of Dispersal from Entire Plant

Once released from mother plant, the movement of seeds may be governed by the laws of the probability, with different chances to stay close or far away from origin (mother plant). As discussed in previous sections, seed traits could determine, at first glance, the origin and end points of each dispersal event. However, seed traits do not necessarily guarantee such dispersal properties but depend on stochastic processes affecting the spatial and temporal dynamics of each locality. For wind-dispersed species, for instance, the processes that influence dispersal distances are either atmospheric (the spatial and temporal statistics of the wind velocity field—vertical, longitudinal, and latitudinal—their covariance structure and their integral time scale properties) or biological (terminal velocity of the dispersal unit, release height, and timing of release) factors. In the case of seed dispersal by animals, seed shadows could be additionally modified by environment or the attraction to animals to suitable habitats. For such reason, the magnitude and direction of each dispersal event is random and we thus need to approach statistical functions to better predict the probability that each dispersal event arrives to a given end. Borrowing concepts and methodologies from mathematics, the statistical distribution of dispersal distances in a plant population is called the "dispersal kernel" (Fig. 2). Thus, the shape of the dispersal kernel impacts on many plant population processes at local or population scales, such as the recruitment patterns, genetic structure and community diversity processes.

Despite the majority of seed dispersal events occur in the vicinity of mother plants, recent population and community studies show that the low-likely events associated to extreme dispersal distances are critical for rates of range expansion, speciation and, genetic connectivity between distant populations. Such long-dispersal events are extremely difficult to capture in nature and, thus, the use of simulation models based on assuming that a complex system can be subdivided into discrete processes (i.e., abiotic and biotic) are a promising tool because it provides reliable predictions of standard (local dispersal) as well as nonstandard (long-distance dispersal LDD) dispersal events. In the case of wind-dispersed species, knowledge of the average wind velocities appears to be sufficient to predict local dispersal and thus, to predict LDD, we need additional information on extreme events of updrafts and strong gusts is needed. By contrast, seed dispersal distance in endozoochorous species is mostly a function of seed retention time in

the frugivore's digestive tract and of frugivore's movement patterns (home range, habitat use, daily activity patterns) and thus migration movements of frugivores could give clues about LDD. These simulation models are predicting that dispersal could be up to two orders of magnitude higher than those previously obtained by empirical methods.

Quantitative and Qualitative Components of Seed Dispersal Effectiveness

The seed dispersal's effectiveness, or the contribution that frugivores make to plant fitness, can be considered at a variety of scales (from individuals to species communities) and decomposed in quantitative and qualitative components in terms of the effect of disperser to plant regeneration. The seed dispersal concept is more developed from the viewpoint of biotic seed dispersal of fleshy-fruited plants and thus more extensive modifications should be necessary for abiotic seed dispersal. In the case of biotic dispersal, the quantitative component is dependent upon the number of visits made on fruiting plants, upon the number of seeds dispersed in each visit, and is influenced by factors that are either intrinsic to the mother plant (e.g., size, fruit crop size, pulp/seed ratio) or extrinsic to it (e.g., fruit crops of neighbors, surrounding vegetation). In addition, the biology of frugivores is related to the species traits and activity (gape size, fruit-handling methods, degree of trophic generalism, etc.). By contrast, the quality of seed dispersal, usually more difficult to evaluate, is a function of (1) the quality of the dispersed seed (often associated with fruit and/or seed size and rather variable within an individual plant, and influenced by factors such as number of seeds/fruit); (2) the quality of seed treatment in each digestive tract of the frugivores (in turn dependent upon traits like seed coat thickness, chemical composition of pulp, gut passage time, morphology and physiology of the digestive tract, type of food ingested along with seeds, etc.); and (3) the quality of the microhabitat where the seed is deposited, which will ultimately determine the probability of germination and establishment; the sites where the seeds are deposited will be determined by factors such as frugivore movements after fruit removal, frugivore habitat preferences, etc. whilst the quality of the microsite will depend on abiotic (light levels, soil texture and humidity, etc.) and biotic conditions (levels of predation, competition, herbivory, etc.).

A successful plant recruitment depends on frugivore activity, on what type of fruit is selected, how it is processed, and the movements of the dispersers after seed ingestion, and is further determined by the biotic and abiotic factors prevailing in the recipient microhabitat where the seed is dropped. All together, this is crucial if we are to assess the demographic and evolutionary consequences of frugivore activity. With the available information, we know that the effects of the qualitative components of dispersal may erase the initial differences among frugivores in their quantity component, but more studies are needed to know which is more important determining the final pattern of plant recruitment.

Linking Seed Dispersal Patterns to Plant Establishment

Dispersal is the first of a series of stages that affects the subsequent plant regeneration process (Fig. 3), determining the spatial arrangement and, consequently, the population dynamics of most plant species. In the case of fleshy-fruited plants, the facilitation effect of nurse or shelter plants is in turn enhanced by the fact that most seeds are deposited under shrubs that act as feeding source and shelter for frugivores (the so-called perching effect). The effect of nurse plants seems to be crucial in many ecosystems because they ameliorate the negative effect of summer drought in seedling survival, at least when resources are limiting, as it occurs in arid ecosystems. However, in most cases the recruitment dynamics is usually very complex, and thus the seed template produced by seed dispersal can be subsequently modified by other regeneration stages (from seed dispersal to seedling establishment). This is because processes acting at different stages are usually independent and "uncoupled," and promote subsequently seed-seedling conflicts. One of the major hypothesis to explain the maintenance of tree species biodiversity is the "Janzen-Connell hypothesis" which coined the importance of seed dispersal mechanisms to avoid the negative effect of herbivores, host–pathogens and natural enemies in the vicinity of mother plants (Fig. 4). Hence, the deposition of large amounts of seeds by frugivores in the close vicinity of mother plants (despite microhabitat could be adequate there) may be subjected to intense post-dispersal seed predation and/or be unsuitable for emergence or recruitment of seedlings. Moreover, such uncoupling among regeneration stages may be also variable

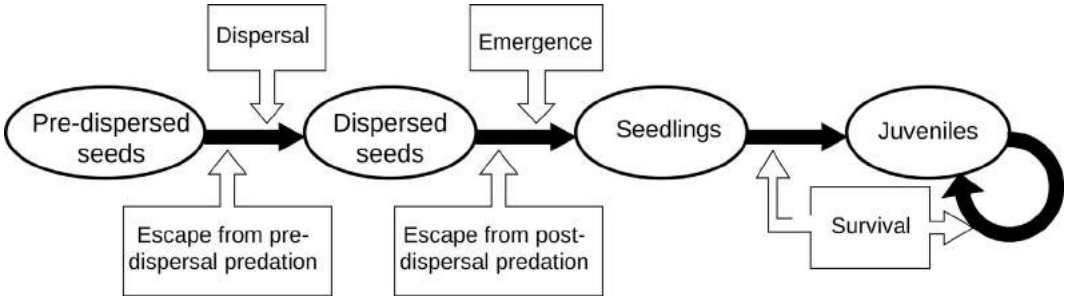

Fig. 3 Diagram representing the different stages (in *circles*) and processes (in *squares*) affecting them along the plant regeneration cycle. The overall probability of recruitment is obtained from the product of the partial probabilities of recruitment of each stage.

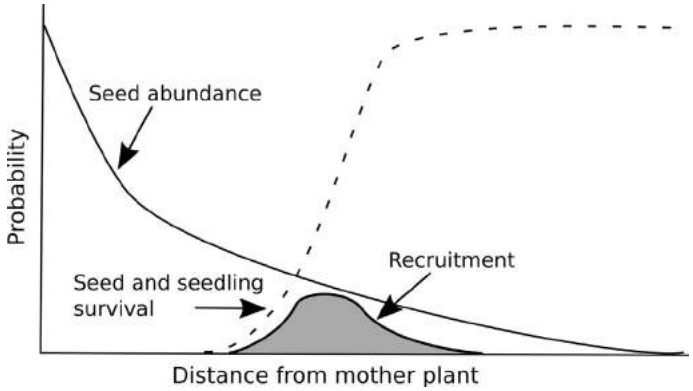

Fig. 4 Janzen-Connell hypothesis represented as the probability of distance from mother plant and the probability of survival to reproduction. The hypothesis predict that the expected maximum probability of seed survival occurs at intermediate distances from mother plants.

across spatial and temporal scales producing unpredictability of the plant regeneration process. Still, another possible source of conflict in the plant regeneration process is seed size. In general, larger seeds tend to have a higher chance of seedling emergence or establishment but may also have a lower probability of being ingested by frugivores or escaping from post-dispersal seed predators. These conflictive pressures will consequently affect the optimal value of seed size in many species to maximize the fitness through the overall regeneration process.

Consequences to Population Genetic Structure

In contrast to the great effort dedicated to figuring out demographic consequences, the effects of seed dispersal on the genetic structure of populations have received less attention, although information on this aspect is growing rapidly. Plant genes are dispersed either through haploid pollen or diploid seeds, and inheritance may be maternal (chloroplast DNA in angiosperms), paternal (chloroplast DNA in conifers) or biparental (nuclear DNA). Recent studies have revealed that plant species dispersed by animals have characteristically high levels of within-population genetic variation compared to other seed-dispersal vectors, and that variation is associated with extensive gene flow via seed dispersal in addition to outbreeding via pollen flow. Moreover, when plant populations dispersed by animals are structured in space (e.g., fragmented populations, metapopulations), frugivores have shown to strongly influence the among-population gene flow via seeds. The tools provided by microsatellites have also shown unequivocal genetic fingerprints of source mother plants in the population, revealing a marked heterogeneity in the genetic composition of the seed rain in different microhabitats, and also making it possible to know the fraction of seeds that come from other populations. Therefore, despite their low occurrence in nature, long-distance dispersal (LDD) events can now be tracked at different scales (i.e., landscape, regional or continental) by these genetic markers.

Plant–Frugivore Networks: Interpreting the Biodiversity of Interactions

In many ecological communities, plant–frugivore interactions are a key ecological process for maintaining biodiversity. At the community level, species interact with each other in a variety of ways and thus the interaction between plants and frugivores could be integrated in complex webs which help to contextualize the complexity of natural histories of partner species. Graph theory offers an analytical methodology with tremendous implications in the study of ecology of food webs, and has also offered an ideal conceptual framework for the study of such mutualistic networks integrated within species communities. This approach allows the description of the macroscopic structure of the entire web at the time that allows determining how fragile such species interactions are in front of different types of disturbances (e.g., introduction of alien species, changes in the abundance, or extinctions of particular species) (Fig. 5).

In the particular case of plant–frugivore interactions, common patterns emerging from studies of ecological networks are: (1) a low number of strong dependencies, (2) a high level of asymmetry in the interactions; thus if a plant depends strongly on a frugivore species, the animal depends weakly on the plant, and (3) a great heterogeneity in the strength of interactions among species. The three characteristics contribute to the maintenance of species coexistence in the community. As it occurs in many mutualisms between species there exist a high abundance of interactions not observed (forbidden links) which are usually prevented by either species traits and/or habitat specificity. For plant–frugivore interactions, the majority of frugivores cannot consume large-sided fruits (i.e., gape-size limitations), whereas non-overlapping phenologies of fleshy-fruited plants impede the temporal encounter between potentially interacting species. Thus, forbidden interactions are of major importance to understand the architecture of ecological

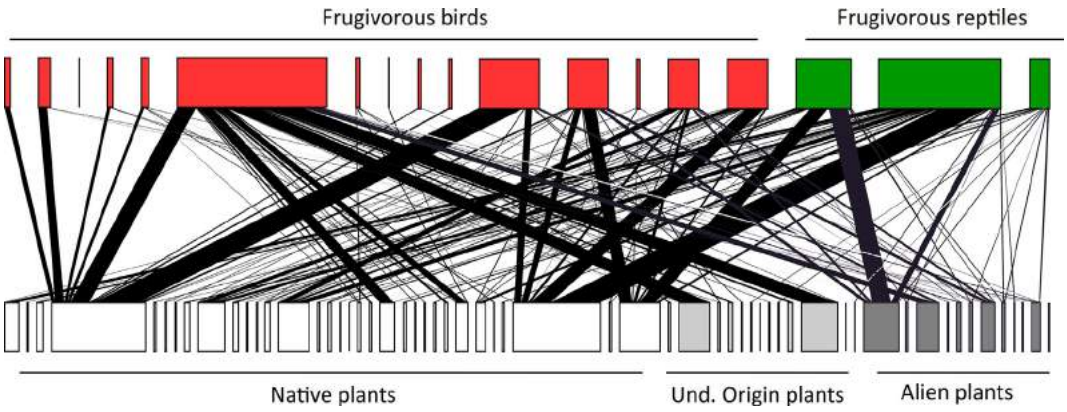

Fig. 5 Mutualistic network between fleshy-fruited plants and frugivore vertebrates in Galapagos archipelago. Nodes represent frugivore species (*upper boxes*) and plant species (*lower boxes*) whereas lines links between plant species and frugivores, that is, fruit consumption. Node size represents the relative occurrence of each interaction, in terms of the number of seeds of plant species consumed by frugivore species.

networks, and they allow us to weight the relative contribution of neutral mechanisms (i.e., abundant species have higher change to interact each other) or trait-matching (i.e., frugivores with large gape-sizes can consume the majority of fleshy-fruit species).

Seed Dispersal as Key Ecosystem Function and Service

Seed dispersal may drive plant gene flow, plant population dynamics and functional connectivity along landscapes and affect to key ecosystem functions related to (a) revegetation, recolonization and population dynamics of vegetation, and (b) the connectance and connectivity of information (species and genetic diversity), and it intimately depends on the scale of landscape structure of habitat. Due to these roles, seed dispersal is now considered a key ecosystem function as it has major implication for the colonization and recovery of fragmented and altered landscapes and the conservation and resilience of native ecosystems. Seed dispersal outcome may even be quantified in economic terms, when linking the process of vegetation recovery to recreation or carbon-sink uses as seed dispersal enhances the ecological succession. As suggested for other provisioning ecosystem services, at least three relevant components may be distinguished in seed dispersal function: the magnitude of seed delivery (abundance of seeds), the composition of seed input (richness of species dispersed), and the spatial pattern of seed rain which cascades into those processes structuring species communities.

In the case of seed dispersal by animals, frugivores are considered to be mobile links as they are able to connect habitat patches across landscapes. A large proportion of plants in tropical and temperate ecosystems bear fleshy fruits and thus the plant species richness there should be highly dependent on the relationship between the plant spatial pattern within the landscape and the activity of frugivorous animals. Frugivores may drop many seeds under plant canopies, and this deposition may be highly contingent to the individual plant location relative to co-fruiting partners, which strongly vary yearly. In this sense, seed dispersal by frugivores could additionally has properties related to spatially-explicit ecological networks, defined by nodes (represented by individual habitat patches or individual trees) and links (represented by the probability of dispersal among individual habitat patches or trees).

Loss of Seed Dispersal Function to Plant Communities

Seed dispersal is universally considered important for biodiversity conservation. The structure of the landscape has strong effects on the distances traveled by seeds, regardless whether they are dispersed by abiotic factors (wind) or by animals. Therefore, any type of disturbance, such as habitat fragmentation or habitat modification by an invasive plant species for instance, is likely to change the patterns of seed movement, the patterns of seed recruitment as well as the genetic structure of the plant populations. For wind-dispersed species, it is known that seeds travel much further distances in open landscapes than in dense forest, due to differences in the shape of the wind profile. On the other hand, plants depending on animals for seed movement are susceptible to dispersal failure when their seed vectors become rare or extinct. Disruption of the seed dispersal mutualism can have serious consequences for the maintenance of the plant populations. In tropical areas in particular, the widespread decimation of frugivores by overhunting and habitat loss has devastating demographic, genetic and evolutionary consequences for the maintenance of tree species diversity. In island ecosystems, such defaunation processes have even worse consequences due to the more simple communities found in them and thus due to the lower probability of species redundancy. A number of examples from islands has shown that the extinction or decimation of the main disperser of a plant has lead it to the near or even total extinction. An excessive long distance

dispersal of elements alien to ecosystems represents also a threat to biodiversity, especially if it goes along an insufficient dispersal of native species. In any case, long-lived plant populations could still reproduce and persist for decades without apparent seed dispersal processes, producing an "extinction debt" for their seed dispersal function after the vector is lost.

Seed Dispersal Under Global Change

It is expected that the current biodiversity crisis associated to anthropogenic alterations would promote functional consequences of ecological functions and services at multiple scales. Habitat destruction and fragmentation, overexploitation, biological invasions and climate change may likely cascade into deterministic species extinctions, loss of seed dispersal function and loss of ecosystem resilience. In the case of fragmentation of native habitats, decline of habitat areas and increasing isolation of native habitats have been found to reduce both the quantity of fruit removal and seed dispersal distances and the fruit removal by frugivores within and between fragments. An increasing number of studies are showing how the populations of frugivores are being decimated, both in the tropics and in the temperate zones, and how this translates into a lower dispersal success of the plants depending upon them. Biological invasions, or the introduction of novel species within species communities, create profound changes in the abundance, distribution and behavior of native species, most of them negative. After the introduction of alien plant species, for instance, native frugivores consume either alien and native plant species and thus potentially reduce the function provided to native plant species (see Fig. 5 for an example about this). The introduction of alien frugivores, by contrast, may provide either beneficial or negative effects on seed dispersal, depending if the alien frugivore is more or less effective dispersing plant species. Still, climate change is a factor producing loss of seed dispersal function, but there is still few evidence of its relevance in the long-term. Most evidence predicting changes in plant distribution ranges under climate change uses the "climate envelope" models relating future climate scenarios with changes in species distribution. However, such geographic models paradoxically usually ignore the majority of processes affecting vegetation changes, in particular species interactions and seed dispersal among others. Finally, global change drivers frequently act in combination with others, which is key to evaluate the synergistic, additive and antagonistic effect on the plant population resilience.

Poikilotherms☆

Inna Sokolova, University of North Carolina at Charlotte, Charlotte, NC, United States

Etymology and Definitions

Poikilotherms (Greek poikilos—"various, spotted," and therme—"heat") are defined as organisms with variable body temperature (T_b) (Fig. 1). Typically, T_b in poikilotherms changes as a function of the temperature of their surroundings under normal physiological and environmental conditions. The opposite of this term is homeotherm (Greek homo—"the same," and therme —"heat"), which refers to organisms maintaining constant or nearly constant body temperature. The concept of poikilothermy originated in and was predominantly used for animal studies, but is in principle applicable to any organism. Poikilothermy is determined by the combination of extrinsic factors (i.e., variation of environmental temperature) with intrinsic (physiological) constraints of the organism such as low levels of metabolic heat production, rapid heat dissipation due to the small body size, high heat conductivity of the external medium (for soil dwellers and aquatic organisms), or excessive energy costs associated with the maintenance of the constant T_b. Although there is no explicit consensus about how broad the variations in T_b should be for an organism to be considered a poikilotherm, it is generally accepted that if the body temperature changes by more than 1.5°C–2°C under physiological conditions, the organism is a poikilotherm. Of cours
e, this rule of thumb excludes pathological conditions such as fever or specialized adaptations such as the regulated drop in T_b during entrance into hibernation or torpor in mammals and small birds, when a change in body temperature can considerably exceed 2°C.

Poikilotherm is one of the oldest terms in ecological physiology, and probably also one with the longest history of confusion. It would be impossible to understand the place of the concept of poikilothermy in thermal biology without clearing away some old but very persistent fallacies. In many texts as well as in vernacular language, poikilotherms are often incorrectly called "cold-blooded" organisms, in contrast to the "warm-blooded" homeotherms. In addition to muddling the meaning of poikilothermy, this statement is simply not true. In fact, poikilotherms can have body temperature similar to or even higher than in homeotherms. For example, some desert reptiles and insects can have T_b up to 40°C–44°C so that there is nothing "cold-blooded" about these poikilotherms. Overall, the cold-blooded and warm-blooded terminology has no real value for understanding of biological mechanisms or physiological consequences of thermoregulation and is best avoided. Similarly, poikilothermy should not be confused with ectothermy, which indicates the predominant reliance of an organism on external heat sources for thermoregulation. Although ectothermic thermoregulation is rarely efficient enough to provide constant T_b in thermally variable environments and most ectothermic organisms are in practice poikilotherms, there are several important exceptions from this rule, and poikilotherms can be found among endotherms as well as ectotherms.

Evolutionary Adaptations to Poikilothermy and Its Ecological Implications

Evolutionary adaptations of poikilotherms are dictated by the necessity to withstand a substantial variation in body temperature. Across the animal kingdom, different species of poikilotherms have evolved to operate at body temperatures from −1.86°C (e.g., some polar fish and invertebrates) to up to 44°C–45°C in certain tropical fish, desert insects, and reptiles, while dormant or quiescent life stages of some animals (such as some rotifers and tardigrades) can survive temperatures spanning from nearly −273 to over 100°C. Within each species of poikilotherms, the range of tolerated body temperatures is smaller, but can still be very appreciable. Thus, in temperate and subpolar poikilotherms, seasonal temperature changes may lead to a gradual change in T_b by 15°C–30°C. On a short-term basis, some land insects and reptiles from temperate climates and marine intertidal invertebrates may experience rapid variations of T_b in excess of 20°C–30°C during diurnal or tidal cycles. Behavioral escape mechanisms (such as migration or habitat choice) may reduce thermal stress but are rarely sufficient to completely prevent a change in T_b. As a result, physiological and biochemical functions of poikilotherms have evolved to withstand a wide range of fluctuations in T_b which would be immediately lethal for most active homeotherms.

Temperature change directly affects the rates of all biological processes as well as stability of macromolecules and membrane structures. At high temperatures, increasing molecular motion may lead to structural destabilization and eventually damage. At low temperatures, a decrease in kinetic energy of the molecules results in low rates of biochemical reactions and the loss of membrane fluidity incompatible with sustaining active life. If the temperature drops further, below the freezing point of intracellular fluids, water crystallization and resulting mechanical damage to the cells becomes a problem. Therefore, a major challenge of poikilothermy is to maintain cellular and systemic homeostasis in the face of temperature-induced functional and structural

alterations in their cells. Poikilotherms have evolved multiple ways to achieve this homeostasis, which include profound alterations of intracellular milieu, membrane composition and properties, enzyme activities, and concentrations of molecular chaperones and cryoprotectants.

Biological membranes are among the most temperature-sensitive cellular sites in poikilotherms. Changes in T_b strongly affect membrane fluidity, which in turn may affect its integrity and permeability, as well as signal transduction and function of membrane-associated proteins and cytoskeleton. A suite of biochemical mechanisms known as homeoviscous adaptation allows poikilotherms to maintain optimal levels of membrane fluidity in the face of temperature change. These mechanisms involve adaptive changes in the degree of acyl chain saturation of the membrane phospholipids, changes in the cholesterol content and ratio of different phospholipid classes (phosphatidyl choline to phosphatidyl ethanolamine) in the membrane. In different poikilotherms, homeoviscous adaptation may be brought about by the de novo synthesis of certain lipid classes, biochemical modification of existing membrane lipids, cholesterol synthesis or breakdown, as well as by seasonal changes in the diet. Some mammalian hibernators selectively feed on plants rich in polyunsaturated fatty acids before entering into hibernation. This leads to an increase of the unsaturated lipid content in their membranes and fat depots, lower temperature set points during hibernation, and improved winter survival rates. Interestingly, diet can also affect temperature preference of

an organism resulting in modified behavior. For example, Australian shingleback skinks select cooler environments when fed diets artificially enriched in polyunsaturated fatty acids, and this diet-induced shift in the preferred body temperature may reach 5°C.

Another key aspect of the variable T_b in poikilotherms is variation in the rates of enzymatic reactions, which has profound "ripple" effects on the rates of all integrative processes, from metabolism and growth to neurotransmission and behavior. Decrease in body temperature results in slowing down the rates of enzymatic reactions, which may in turn result in reduced rates of growth and reproduction, as well as impaired locomotion and ability to escape predators or to find food. On the short-term scale, homeostasis of enzymatic reaction rates may be achieved by changing concentrations of reaction substrates and products, or variation in intracellular levels of allosteric regulators of enzyme activity. During a prolonged decrease in T_b (e.g., during seasonal cold acclimatization), decreasing reaction rates can be compensated by elevated enzyme concentrations, expression of less-temperature-sensitive isoforms of enzymes, or both. However, this compensation is often incomplete, and in most poikilotherms a decrease in body temperature is associated with a decreased activity and growth rate.

Although elevated temperatures enhance rates of enzymatic processes (and thus, "the rate of living") in poikilotherms, an excessive increase in T_b is damaging and potentially lethal due to the destabilization and eventual denaturation of cellular proteins. In order to protect against such denaturation, poikilotherms may express molecular chaperones (particularly so-called heat shock proteins, or HSPs), which assist in proper folding of partially denatured proteins and stabilization of their native conformation. Expression of HSPs is almost universal response to heat stress in the animal kingdom and found in all poikilotherms, as well as most homeotherms. The only known exception is some extremely stenothermal and cold-adapted Antarctic fish species which have lost the ability to induce HSPs in response to heat stress. Increasing T_b also results in a decline in intracellular pH in poikilotherms, which helps to support normal folding and function of intracellular proteins through the maintenance of constant levels of protonation of their critical o:-imidazol groups. Taken together, these changes in intracellular milieu help to maintain structural integrity and cellular homeostasis in poikilotherms facing a change in T_b.

Preventing ice formation is a significant challenge for poikilotherms living in habitats where environmental temperatures fall below the freezing point of intracellular fluids. Many poikilothermic species such as Arctic and Antarctic fishes, terrestrial arthropods and amphibians, plants and fungi are known to seasonally synthesize and accumulate antifreeze agents such as glycerol, sorbitol (and other polyols), trimethylamine-*N*-oxide (TMAO), as well as specialized antifreeze proteins and glycoproteins. These compounds decrease the freezing point of intracellular fluids and some of them also provide thermal hysteresis (lowering of the temperature required for crystal growth beyond that needed for crystal melting), thus preventing formation and growth of intracellular ice crystals. Owing to these mechanisms, some glycerol-rich insects may supercool to -60°C without freezing. Caterpillars of the butterflies *Aporia crataegi* can survive several months with body temperature as low as -50°C; to achieve such remarkable hardiness, 14% of their body weight is composed of cryoprotectants. In hibernating land frogs, high tissue levels of glucose serve as cryoprotectants. Synthesis of the cryoprotectants in poikilotherms is regulated by hormonal systems, which in turn are typically activated by photoperiod rather than temperature. This allows animals to accumulate sufficient levels of cryoprotectants in their tissues before the environmental temperature actually drops below freezing.

It is worth noting that most of the above-described adaptive changes to maintain homeostasis in the face of changing T_b require considerable times to be accomplished (e.g., days to weeks) and are typically associated with long-term acclimation or acclimatization of poikilotherms to the changed thermal environment, for example, during seasonal temperature changes or evolutionary adaptation to different climates. During short-term temperature fluctuations, poikilotherms have to put up with temporary disturbances of cellular homeostasis and must depend on the robustness of their intracellular systems to survive those disturbances. Due to the inevitable constraints on structure and function of macromolecules (and thus on the range of the temperatures to which the organisms may be successfully adapted), there is no species that "could take it all" and could survive the changes of T_b spanning over the whole range of temperatures consistent with active life. Due to the varying T_b as a function of ambient temperature and the high temperature sensitivity of their physiology, distribution patterns of poikilotherms often closely follow gradients or discontinuities in environmental temperature. It is perhaps no wonder that the most striking examples of the temperature-induced shifts in species distribution come from poikilotherm species. The threshold effects of temperature (i.e., the minimum amount of the temperature change which is sufficient to result in a significant shift of the species distribution limits) may be quite sublime, and a change of the mean temperature by 1°C–2°C can strongly shift the geographical distribution of poikilotherms. This high temperature dependence of poikilotherm biogeography is evidenced not only by paleontological record but also by the recent observations of major distribution shifts in aquatic and terrestrial poikilotherms which are correlated with (and likely caused by) increases in ambient temperature of about 1.2°C–2.2°C in the last century. A less-than-exhaustive list of recent climate-driven changes in poikilotherm distribution include major faunal shifts in shallow-water marine habitats, local extinctions of poikilotherm populations at the southern limits of the distribution range, declines in zooplankton abundance, extensive bleaching of coral reefs, increases in mosquito-borne diseases in highlands, and the northward shift of ranges of nonmigratory insects. With the global climate change, more research will be needed to improve our understanding of physiological and biochemical mechanisms underlying the distribution shifts of poikilotherm populations and to analyze the profound ecosystem-level effects of these shifts.

Soil Ecology

MA Pavao-Zuckerman, University of Arizona, Tucson, AZ, USA

Introduction

Soils are an essential component of the world's ecosystems, providing rooting medium for plants and serving as the habitat for the saprophytic organisms that recycle energy, matter, and nutrients through the decomposition process. Soils have been an essential provider of ecosystem services throughout human history, as most food comes ultimately from plants that grow in soils and sediments. Ancient societies dating back to the Mesopotamians and Egyptians have recognized the importance of soils. We can see the deep importance of soils in the root and origins of many words, for example, the shared root of the words humus and human. While the relationship between soil organisms and soil health has been linked for centuries, the discipline of soil ecology has its origins in microbial ecology of the nineteenth and twentieth centuries, soil science of the early twentieth century, and soil management (particularly agricultural systems) in the mid-twentieth century. Recent efforts in soil ecology have focused on developing a mechanistic understanding of how organisms and soils interact to yield patterns of soil biodiversity, nutrient cycling function within ecosystems, and feedbacks to global change mechanisms.

Soil ecology is concerned with interactions, be it between organisms or between organisms and the soil environment. Soil ecology has its origins in soil biology and soil zoology, the study of organisms in the soil habitat. Soil ecology and soil science are related, yet different disciplines, with soil science focusing more on physical processes, the classification and genesis of soils, soil chemistry, and soil physics. When we ask ecological questions about soils from an ecosystems perspective, the inclusion of physical and chemical interactions with organisms extends this overlap between soil ecology and soil science. The conceptual and analytical tools between the two disciplines differ because they have different epistemological and metaphysical foci. The breadth of the conceptual domain of the discipline of soil ecology can be seen in **Fig. 1**.

Components and Characteristics of Soils

Soils are a mixture of weathered mineral rock particles, organic matter (i.e., both living, and dead and decaying), water, and air. Soils can be thought of as functional entities that are the resulting products of the interaction of physical, chemical, and biological processes. Soil mineral particles are usually described based upon their relationship to soil texture, and include sand (0.05–2.0 mm), silt (0.002–0.05 mm), and clay (<0.002 mm). The relative distribution of these particles is used to describe different soils, and affects soil properties such as bulk density, pore space, and particle density. Variation in these physical properties structure habitats

for different soil microbes and fauna. Soils are also composed of organic materials, which include the partially fragmented and decomposed remains of plant material, animals, microbes, and feces. Organisms are also an important organic constituent of soils, and their activity can influence soil properties (e.g., porosity), the binding of inorganic materials into soil aggregates, and nutrient cycling in soils. Soil air is the gases that are present in soil pores that are not filled with water. Oxygen and carbon dioxide (CO_2) are important constituents, and their concentration in the soil affects many processes (e.g., nitrification and denitrification). Soil water can contribute up to 30% of soil volume, and is essential for the activity and physiological functioning of organisms in the soil.

Soil structure is a description of the spatial arrangement of soil particles into aggregates. Several hierarchical schemes for classifying soil structure have been proposed that link soil aggregates across several orders of magnitude of scale, from the submicron level (microaggregates) to several square meters (the pedon). The aggregate structure of soils has important implications for the distribution of pores in soils, which affects the distribution and availability of water and gasses. While soil structure generally refers to this aggregate structure, soils also have a spatial structure with depth. Soils in general are composed of different horizons, if one views them in profile. On the surface is a layer of recently fallen plant litter, with smaller amounts of excreta and dead bodies. Below this litter layer is a horizon enriched in organic material from the breakdown of the litter layer, and further below are mineral horizons of various textures and thicknesses. This vertical structure derives from the varying influence of soil formation processes with depth. In the 1940s, Jenny described the formation of soils as an ecological process that results from the interactions of factors, including climate, organisms, parent material, and relief. More recent theoretical advances resulting from agroecological and urban ecosystem research have extended the `organisms' category to explicitly include the actions of humans in the formation of soils and soil structure. These physical, chemical, and biotic formation factors lead to variations in the distribution to depth of various mineral, chemical, and organic components of soil, giving soils a depth profile (**Fig. 2**).

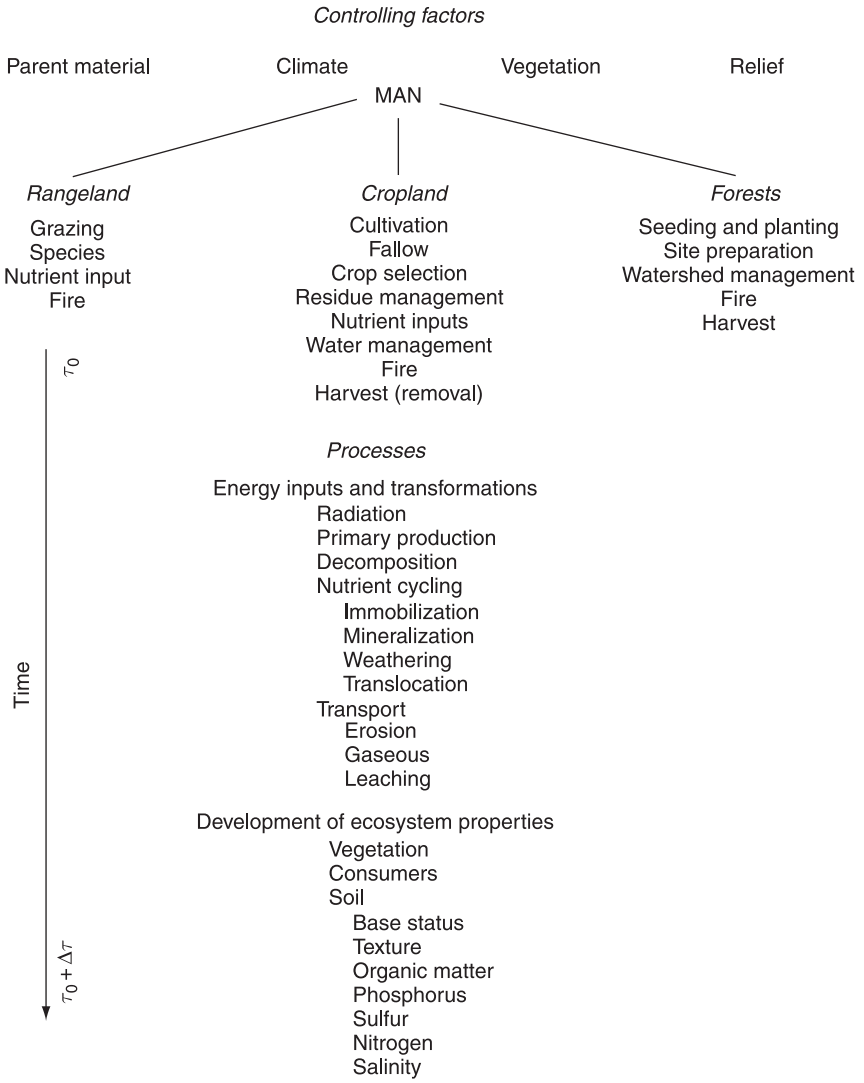

Fig. 2 Factors that control soil formation. Soil formation is an ecological process that involves the interactions of climate, organisms, parent material, and relief. Soil Biota

Soil ecology has part of its roots in soil zoology, and places heavy emphasis on the study of organisms within the context of the unique soil habitat. While historically emphasis had been placed upon the description and classification of soil organisms, contemporary focus links biodiversity and interactions of soil organisms to broader-scale ecological phenomena, including carbon fluxes, nutrient cycling, and biogeography. It should be noted that general understanding of biodiversity in soils has been historically undeveloped in part because *in situ* identification of soil microbes has been problematic; only around 10% of soil microbes have been successfully identified via *in vitro* culturing, and the taxonomic resolution of soil fauna is incomplete. Complicating matters further, soils are a complex and opaque medium, rendering even the *in situ* observation of macrofauna problematic. However, recent applications of genomic techniques to soil microbes and biogeographic perspectives on soil taxonomy have helped to increase our basic understanding of the diversity, abundance, and distribution of soil organisms.

Diversity of Soil Organisms

Soils are a highly diverse habitat and harbor such high levels of biodiversity that they are often referred to as `the poor person's rainforest'. Microbes, including bacteria, fungi, and cyanobacteria are the most numerous and diverse taxonomic groups in the soil. There are also many species of animals that live in the soil, including single-celled amoebae, free-living and parasitic nematode worms, Acari, oligochetes, and insects. In addition to these `permanent' and `periodic' soil residents, animals can also be `temporary' or `transient' residents of soil as life cycle stages may be completed below ground (i.e., egg and larval stages of Diptera) or behaviors may drive organisms below ground (i.e., nesting of many small birds, reptiles, and mammals). Plant roots are also important biotic components of soil that both influence soil physical structure and contribute organic detritus to soil food webs.

Conceptual Organization of Soil Organisms

Soil ecologists rely upon several classification schemes to conceptually link the diversity of soil organisms to ecological functions and processes. One of the more useful classifications is based upon size and uses body diameter to distinguish soil biota into microflora (<2 μm), microfauna (2–100 μm), mesofauna (0.1–2 mm), macrofauna (>2 mm), and megafauna (>20 mm). Organisms in different size classes have different spatial effects in soils and interact with different soil processes. Individually, microflora impact relatively small spatial scales and are important in the breakdown of organic residues and the production of exudates that form soil aggregates; microfauna are important in regulating these processes. Meso- and macrofauna operate at larger spatial scales, and physically breakdown plant residues, create pore structure, and mix and redistribute mineral and organic soil components (**Fig. 3**).

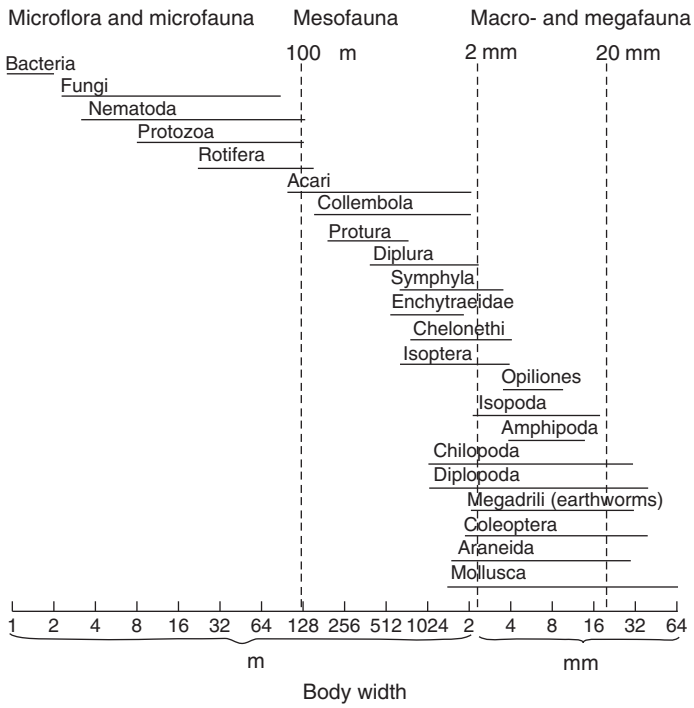
Much success is also found from viewing soil organisms from a food web or trophic perspective. Problems associated with *in situ* identification of microbes and the degree of unnamed species of soil fauna makes the use of broader taxonomic groups necessary, including functional groupings of organisms. Soil organisms are commonly grouped based upon feeding habits, including microbe feeders (microbivores), those that feed on litter and organic matter (detritivores), those that feed off or parasitize plant roots (herbivores), or those that feed on other soil animals (carnivores). Soil food web dynamics are elucidated through a mixture of lab, field, and modeling exercises. The use of radioactive and stable (both pulses additions of labels and natural abundances) isotopic tracers and statistical techniques (such as interaction strength and path analysis) have been important in determining the spatial and temporal dynamics of soil food webs. Generally, it is thought that the interaction of bottom-up (productivity based) and top-down (predatory) controls lend to the stability of soil food webs. Soil food web analyses have been important in demonstrating the roles of microbe feeders (e.g., nematodes and protozoa) on regulating both microbial populations and decomposition and nutrient dynamics in soil ecosystems. Experimental research suggests that there are two distinct pathways in the soil food web: (1) a `fast' bacterial pathway, and (2) a `slow' fungal pathway. A third pathway via the activity of root grazers (e.g., plant parasitic nematodes) is also possible, but is theoretically less developed. Observations in experiments and field studies of nematode-trapping fungi and ectomycorrhizal fungi that prey upon collembolans complicate the trophic structure traditionally conceptualized in soil food webs, and while they have not yet been integrated into soil food web models, they point to the degree of trophic linkages possible in soils (**Fig. 4**).

A third approach integrates spatial scale and trophic perspectives, linking specific spatial scales to soil processes. Ecosystem engineers, such as earthworms and termites, can indirectly influence the cycling of nutrients through direct impacts on soil structure. A second group is considered the litter transformers (micro- and macroarthropods) and fragments or comminutes litter into smaller pieces, thereby increasing the surface area available to microbial decomposition. Members of a third group are part of a `micro-food web', and include microbes and microfaunal predators (primarily nematodes and protozoa). Each level in this conceptual scheme influences ecosystem properties through actions at different size, space, and timescales.

The Role of Organisms in Soil Functions and Processes

Soil organisms play key roles in ecosystems through their effects on physical properties and processes, and the biological contributions to carbon and energy fluxes and cycling of nutrients. The importance of soil fauna for soil physical properties generally

(a)



(b)

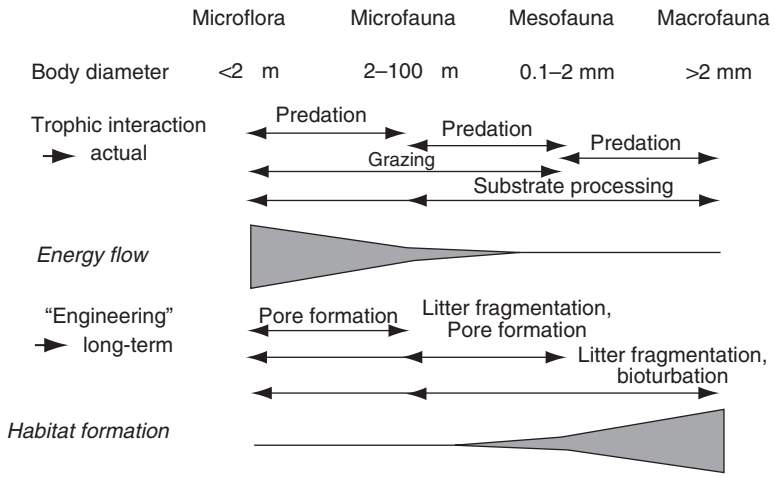


Fig. 3 (a) Size classification of soil organisms by body width. (b) The interactions of soil organisms are dependent on size of the organism. Depicted here are trophic interactions and ecosystem engineering effects. Note that with increasing size the relative effects on energy flow decrease, while the effects on habitat formation increase. The soil food web: Structure and perspectives. In: Tscharntke, B., Hawkins, B.A. (Eds.), Multitrophic Level Interactions. Cambridge, UK: Cambridge University Press, pp. 223–264.

increases with larger body sizes. Soil macrofauna, such as earthworms, ants, and termites, can have dramatic effects on soil porosity, creating macropores and tunnels that allow for preferential flow of water into the soil profile. The movement of macrofauna through the soil profile (such as some species of earthworms) can mix mineral particles from one horizon into another, and can bring fragments of leaf litter from the surface to mineral soil horizons, thus affecting soil texture, bulk density, and organic matter contents. A notable exception to this size relationship is the role of microbes in the formation of soil aggregates. The activity of microbes, particularly myccorhizal fungi, produces exudates that help to bind together soil particles into aggregates.

Roughly 80–90% of net primary production enters the soil as dead plant material (e.g., leaf litter, stems, roots) or organic exudates from roots. This is decomposed primarily by bacteria and fungi in the soil and surface litter layer. It is the physiological

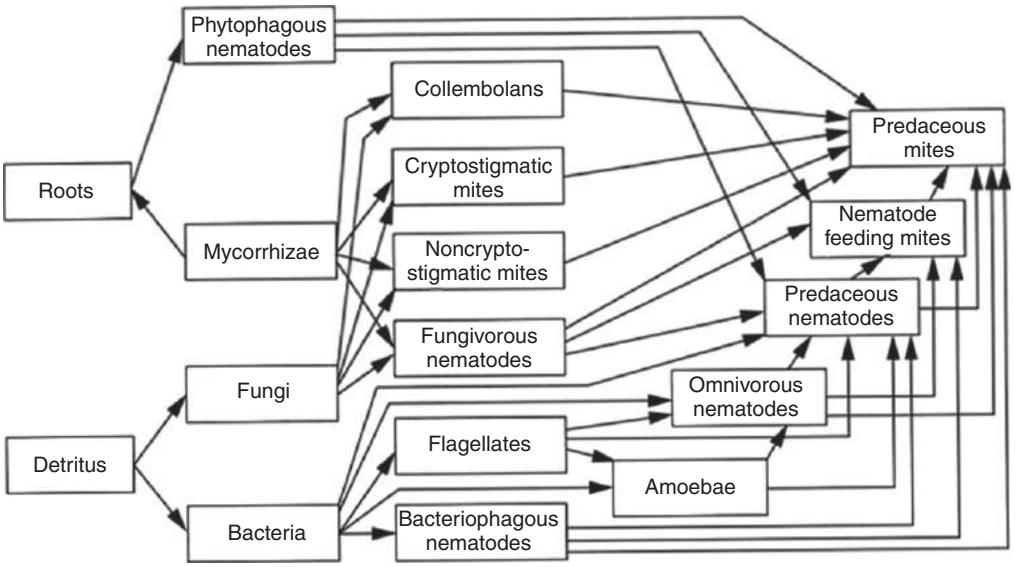

Fig. 4 A conceptual model of a shortgrass prairie soil food web. From Bardgett, R.D., 2005. The Biology of Soil: A Community and Ecosystem Approach (Biology of Habitats). Oxford: Oxford University Press. Adapted from deRuiter, P.C., Neutel, A.-M., Moore, J.C., 1995. Energetics, patterns of interaction strengths, and stability in real ecosystems. processes of, and enzymatic digestion by the microbes, as well as the trophic interactions in the soil food web that control the cycling of nutrients in the soil. Decomposition is the transformation of an organic substrate from one form to another, and is the source of CO_2 that is respired from soils, and the recycling of nutrients.

Decomposition is controlled by the interactions of the physical environment, the quality of the substrate, and the community decomposer organisms. Temperature and soil moisture are the dominant controls on decomposition, with warmer, wetter soils generally having faster rates of organic matter decomposition. Substrate quality is a function of the stoichiometry of the plant material and the composition of the litter in terms of structural components (lignin, cellulose) and secondary metabolites (tannins, phenolics), which can decrease the palatability of litter and make it more recalcitrant. The composition of the community of soil organisms mediates decomposition because different organisms have different functional roles in soils. For example, the fungal community will display successional patterns as leaf chemistry is changed during the process of decomposition, matching the suite of active fungi to substrate quality. Exclusion studies have demonstrated that soil fauna also play a role in controlling the decomposition process. The microbial loop refers to the stimulation of nutrient availability via the trophic interactions between bacteria and their consumers (protozoa and nematodes), where predation on microbes stimulates their population growth and enhances rates of nutrient cycling. Earthworm casts provide a physical and chemical environment that is more suited to microbial activity than the surrounding bulk soil. So, while decomposition processes are driven by the extracellular enzymes of microbes, the production of enzymes and the environment in which they function is regulated by soil fauna.

Soils are notoriously heterogeneous habitats when viewed from the perspective of the soil flora and fauna. Over the scale of micro- and millimeters organisms may encounter films of water clinging to soil particles, air-filled soil pores, concentrations of organic material, aggregates of soil, and plant root hairs. One conceptual construct for managing the complexity of soils in ecological studies is to think of `hot spots' of activity, where because of concentrations of available resources and/or microclimatic conditions, organism growth and activity is concentrated. These hot spots in soils make up a small portion of the total volume of soil (up to 10%) but will contain the majority of biological activity in soils (over 90%). The hot spots are located in (1) the drillosphere (area influenced by earthworm burrows), (2) the rhizosphere (area influenced by plant roots), (3) the aggregatusphere (soil aggregates where soil mineral particles are bound with organic materials), (4) the detritusphere (larger concentrations of leaf litter and organic matter), and (5) the porosphere (the spaces between soil aggregates). It is within these hot spots that habitats and resources are suitable for soil organisms, and where most decomposition and nutrient cycling happens in soils. Because of their effect on the spatial distribution of these hot spots, the distribution, composition, and physiology of the plant community thus can have very strong controls on organism activities in soils. Through their controls on nutrient cycling, the availability of nutrients in the soil, and soil physical characteristics, the activity and composition of the soil microbes and fauna, in turn, has a strong influence on the plant community. The nature and degree of such above- and belowground linkages is a major research question in contemporary soil ecology.

While specific soil organisms or functional types are linked to decomposition and nutrient-cycling processes, the explicit link between levels of biodiversity and soil ecosystem function is still in question. While this is likely the result of the high functional redundancy in the community of soil organism, this trend is also partly due to problems of taxonomic resolution mentioned above. However, recent advances in molecular techniques hold the promise of being able to move past problems of *in situ* identification of soil microbes. Techniques can now identify the presence of genes that code for specific biogeochemical processes

(such as, lignin decomposition, nitrification, and phosphorus utilization), and some techniques are roughly quantifiable, so it is possible to see how much of a particular gene is in the soil, actively working on an enzymatic process. The integration of these molecular techniques into studies of biogeochemistry is in its infancy, but holds strong promise for allowing researchers to link specific organisms and physiological processes at the level of microbes to a specific nutrient cycling pathway in ways that were previously unthinkable.

Conclusions

Soils are key sites of ecosystem functions, providing catabolic analogs to the aboveground processes of photosynthesis, assimilation, and primary production. Decomposition of plant material drives the cycling of nutrients, and it is the activity of microbes that controls the availability of nutrients in the soil. The role of soil biota in ecosystem processes and functions has long been recognized as important, yet the specific nature of these interactions and effects is still under investigation. Particularly of interest are linkages across broad spatial and temporal scales. There is much to be learned about how processes that occur at the micro- and millimeter-scale in soils (and is observed in meter-scale plot research) can be scaled up to the level of ecosystems and the biosphere. This has implications that extend beyond basic scientific research. The majority of carbon that is stored in terrestrial ecosystems exists in soil organic matter. The response of soils to global change processes is an important control and feedback point in global biogeochemical cycles. For example, an important aspect unknown is how soils will respond to potential shifts in detritus quantity and quality that comes about from plant responses to global climate change. Further complicating matters is that global change factors such as elevated atmospheric CO_2 levels, global climate change, chronic N-deposition, and landscape transformations will have interactive effects on soils, yet we do not know if they will be additive or multiplicative interactions. The implications of these interactions for the management of soils within the context of global change, ecological restoration, and landscape transformations remain an important component of understanding and managing the resilience and sustainability of ecological systems.

Stable Isotope Ecology

Alexandra Baeta, MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal

Isotope Basics

What Are Isotopes?

All atoms of a given element have the same number of protons and electrons, but some atoms have more neutrons than other atoms of the same element and therefore weigh more (Fig. 1). These particular forms of an element defined by a specific number of neutrons are referred to as isotopes of the element. Isotopes are denoted by an atomic "formula." The atomic number symbolizes the number of protons in the nucleus of each atom of an element, and is used to identify the position of the element on the periodic table. The mass number is the total number of neutrons and protons present in its nucleus.

In nature, an element occurs as a mixture of its isotopes. The element hydrogen, for example, has three naturally occurring isotopes. One, simply known as hydrogen, ^{1}H (usually written as simply H; also called protium), has one proton and no neutrons; the deuterium isotope (or D), ^{2}H, contains one proton and one neutron; and tritium (or T), ^{3}H, has one proton and two neutrons (Fig. 1). Hydrogen is the only element whose isotopes are given different names. As another example, consider the three isotopes of the element carbon, which has the atomic number 6. The most common isotope is carbon-12, ^{12}C, which accounts for about 99% of the carbon in nature, has six neutrons. Most of the remaining 1% of carbon consists of atoms of the isotope ^{13}C, with seven neutrons. A third isotope, ^{14}C, has eight neutrons; it is present in the environment in minute quantities. Notice that all three isotopes of carbon have six protons—otherwise, they would not be carbon. Because isotopes differ in mass, they have slightly different physical properties (=characteristics), but they always have similar chemical properties. The similarity occurs because only the electrons are used in chemical reactions, not the neutrons or protons.

Word Origin and History

The term "isotope" is formed from the Greek roots *isos* ("equal") and topos ("place"), meaning "at the same place," thus the word "isotope" comes from consideration of the periodic table of the elements, and means that different isotopes of a single element occupy the same position on the periodic table of the elements.

The existence of isotopes was first suggested by the British chemist Frederick Soddy, in 1913, based on studies of radioactive decay chains that indicated about 40 different species referred to as *radioelements* (i.e., radioactive elements) between uranium and lead, although the periodic table only allowed for 11 elements from uranium to lead. Soddy proposed that several types of atoms (differing in radioactive properties) could occupy the same place in the table. The term "isotope" was suggested to Soddy by Dr. Margaret Todd, a Scottish physician and family friend, in 1913, during a conversation in which he explained his ideas to her. This term was accepted and used by Soddy, and has become standard scientific nomenclature. In 1921, he received the Nobel Prize in Chemistry "for his contributions to our knowledge of the chemistry of radioactive substances, and his investigations into the origin and nature of isotopes" (see http://nobelprize.org/chemistry/laureates/1921).

Measurement, Notation and Terminology

Mass spectrometry is the analytical technique used to make precise determinations of the isotopic ratios. The complete process involves the conversion of the sample into gaseous ions, with or without fragmentation (usually by combustion), which are then characterized by their mass to charge ratios (m/z) and relative abundances. The isotope ratio mass spectrometer (IRMS) is a specialization of mass spectrometry, and is the most common method to quantify stable isotopes: after conversion of a sample to

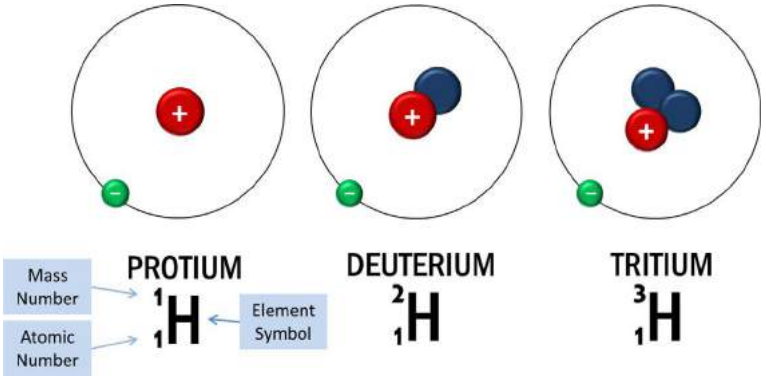

Fig. 1 The three naturally occurring isotopes of hydrogen, showing their protons (marked in *red*, with positive charge), neutrons (*blue*, with no charge), and electrons (*green*, with negative charge). Based on http://nuclearconnect.org/know-nuclear/science/isotopes and https://www.giss.nasa.gov/research/briefs/schmidt_03/.

gaseous form (e.g., for C, it would be converted to CO_2), it is introduced into an ionizing source and the results are then compared to a standard. Thus, the IRMS is generally coupled to an elemental analyzer, in which the sample is converted to a gas. The isotopic composition of the pure gas is measured using IRMS.

For quality assurance and quality control purposes, the two most important factors to consider when working with an IRMS laboratory is the calibration, that should occur regularly, and standards used. Calibration should occur regularly and the laboratory should be able to demonstrate that their current measures match either international or laboratory standards (or both) to within ±1‰. To demonstrate this, laboratories generally incorporate standards at the start or finish (or both) of each "run" (i.e., a discrete set of samples analyzed continuously). The instrument is calibrated with samples of a standard mass; when samples are prepared, an effort should be made to conform all sample masses to the amount indicated by the laboratory or the results can be biased. When analyzing samples, the analytical facility should introduce replicate standards at regular intervals (e.g., every 10–12 samples in the run) for quality assurance. For acceptable precision, replicate reference material should have an error ≤ 0.2‰. Rapid technological advances over the past decade have greatly stimulated the use of isotope analyses, and this analytical approach is now among the most popular in ecology because of the insights provided by isotope ratios at natural abundance levels. The main stable isotopes used in ecology are ^{13}C, ^{15}N, ^{18}O, ^{2}H, ^{34}S, and sample preparation will depend on the physical form of the sample and the element to be measured.

Isotopic composition is reported relative to an internationally accepted standard and expressed in "parts per mil" (‰) deviation from that standard following the formula: $\delta(‰) = [(R_{sample}/R_{standard}) - 1] \times 10^3$, where R is the ratio of heavy-to-light isotope, R_{sample} is that in the standard. For example, the defined reference standard for ^{13}C is the Pee Dee Belemnite (PDB) limestone, while for ^{15}N the atmospheric nitrogen. These analytical reference materials can be obtained from the IAEA (International Atomic Energy Agency). Isotopic values were expressed in the δ unit notation. The Greek letter delta, Δ or δ (capital and small letter delta, respectively), symbolizes change, and expresses the relative differences in isotopic ratios between samples and standards that are measured by isotope ratio mass spectrometry. A positive δ value means that the ratio of the heavy to the light isotope (e.g., ^{2}H:^{1}H, ^{13}C:^{12}C, ^{15}N:^{14}N, ^{34}S:^{32}S) is higher in the sample than it is in the standard, whereas a negative delta value has the opposite meaning. Heavy isotopes are usually much rarer than light isotopes so the ratio can be very small. Because the ratio is so small, it is multiplied by 1000 for a more useable value, and as a result, the notation is parts per mil (‰). For example, the ^{13}C:^{12}C (R) for the PDB standard is 0.0112372, or about 1.12 ^{13}C atoms for every 100 ^{12}C atoms. If a sample has 1.11 ^{13}C atoms for every 100 ^{12}C, then the $\delta^{13}C$ value would be −21.1‰. In ecological studies, for example, the difference in $\delta^{13}C$ values between two locations is often 5‰ to 15‰, which is a small difference in the natural abundance of ^{13}C.

There are several common means to compare the isotopic composition of two materials (including, e.g., "heavy" vs. "light," "high" vs. "low" values, "enriched" vs. "depleted"), and it is therefore essential to use correct, clear and consistent terminology, and phraseology, in studies using isotope analysis. For example, the recommended terms for expression of the stable carbon isotope ratio are "$\delta^{13}C$ value," "carbon isotope composition," "^{13}C-depleted (or enriched) sample," and "high (low) $\delta^{13}C$ values."

Types of Isotopes

There are two types of isotopes, stable and radioactive isotopes. For example, both ^{12}C and ^{13}C are stable isotopes, meaning that their nuclei do not have a tendency to lose particles (stable over time). The isotopes ^{1}H and ^{2}H are also examples of stable isotopes. An isotope tends to be stable when the number of neutrons (N) and the number of protons (Z) are quite similar ($N/Z \leq 1.5$). The isotopes ^{14}C and ^{3}H, however, are unstable, or radioactive. A radioactive isotope has an unstable nucleus that decays spontaneously, giving off particles and energy (emitting alpha, beta, or gamma rays), until stability is reached. When they decay, they release particles that may be harmful. This is why radioactive isotopes are dangerous. A loss of nuclear particles transforms the atom to an atom of a different element. For example, radioactive carbon decays to form nitrogen-14, while tritium decays into helium-3.

Eighty out of the first 82 elements in the periodic table have stable isotopes. In the total, there are ~300 stable isotopes, over 1200 radioactive isotopes. The distribution between light and heavy isotope in nature varies among isotopes, but for most cases the light isotope is the most abundant. As such the natural abundance of the lightest stable isotope of the elements hydrogen (H), carbon (C), nitrogen (N), oxygen (O), and sulfur (S) is >95% (Table 1). On the contrary, the heavy stable isotopes of some elements such as boron (B) and lithium (Li) are the abundant isotopes, >80% of the total. Only a few elements such as bromine (Br), silver (Ag), and europium (Eu) show approximately equal distribution between light and heavy stable isotopes. By definition, natural abundance is the measure of the average amount of a given isotope naturally occurring on Earth. Most elements have more than one stable isotope; only 21 elements that are known to have only one isotope. For example, hydrogen has two ^{1}H and ^{2}H, with the lighter isotope being much more abundant (Table 1).

Uses of Radioisotopes

Radioactive isotopes have many useful applications. In biology, for example, researchers use the ^{14}C, a radioactive isotope of carbon, to measure the age of ancient biological materials, a method known as radiocarbon dating (also referred to as carbon dating or carbon-14 dating). In agriculture radioisotopes also show wide applications to develop better fertilizers, control insects and improve plant breeds, as well as in food processing and preservation.

Radioisotopes are also useful as tracers to follow atoms through metabolism, with various uses in medicine (medical therapy, diagnostics and research), since cells use the radioactive atoms as they would nonradioactive isotopes of the same element, but the radioactive tracers can be detected. Nuclear medicine, for example, is a field of medicine that uses a trace amount of radioactive substances for the diagnosis and treatment of many health conditions such as certain types of cancer, and neurological and heart diseases. In medicine, two of the most commonly used radioisotopes are technetium-99m and iodine-131. Radioactive isotopes are also used for medical research to study normal and abnormal functioning of organs and systems.

Although radioactive isotopes are very useful in biological research and medicine, radiation from these decaying isotopes also poses a hazard to life by damaging cellular molecules. The severity of these damages depends on the type and amount of radiation an organism absorbs. One of the most serious environmental threats is radioactive fallout from nuclear accidents.

Application of Stable Isotopes

Today, stable isotopes play an important role in science. Their unique properties enable them to be used in a broad variety of applications across diverse scientific disciplines including hydrology, oceanography, geology, (paleo)climatology, biogeochemistry, archeology, biology, ecology, physiology, astronomy, medicine, forensics, among many others (Fig. 2).

In hydrology, for example, stable isotopes are useful tools for characterizing several different water dynamics within a watershed. Isotope hydrology is based on the notion of tracing a water molecule through the hydrological cycle. Water is the most fundamental component of the Earth's climate. Its presence in all three phases—liquid, solid and gas—defines our planet in a very profound way. Tracking the movements of water through the system—in oceans, air, clouds, rain, snow, ice, lakes, rivers, and back to the oceans—is therefore a primary concern of climatologists. Where does the water come from? Where does it go? What feedbacks are involved? Common stable isotopes used in hydrology as conservative tracers are ^{2}H and ^{18}O. These isotopes occur naturally in the environment, but their natural abundance differs with different environmental conditions. These environmental isotopes (applied through meteoric processes) can be used to trace and identify different air and water masses contributing precipitation to a watershed since the stable isotope composition of water changes only through mixing and well-known fractionation processes

Table 1 Average abundances of stable isotopes that are important for understanding ecological systems

Element	*Isotope*	*Average abundance (%)*
Hydrogen	^{1}H	99.985
	^{2}H	0.015
Carbon	^{12}C	98.89
	^{13}C	1.11
Nitrogen	^{14}N	99.63
	^{15}N	0.37
Oxygen	^{16}O	99.759
	^{17}O	0.037
	^{18}O	0.204
Sulfur	^{32}S	95.00
	^{33}S	0.76
	^{34}S	4.22
	^{35}S	0.014

From West, J.B., Bowen, G.J., Cerling, T.E., Ehleringer, J.R. (2006). Stable isotopes as one of nature's ecological recorders. *Trends in Ecology and Evolution* **21**, 408–414.

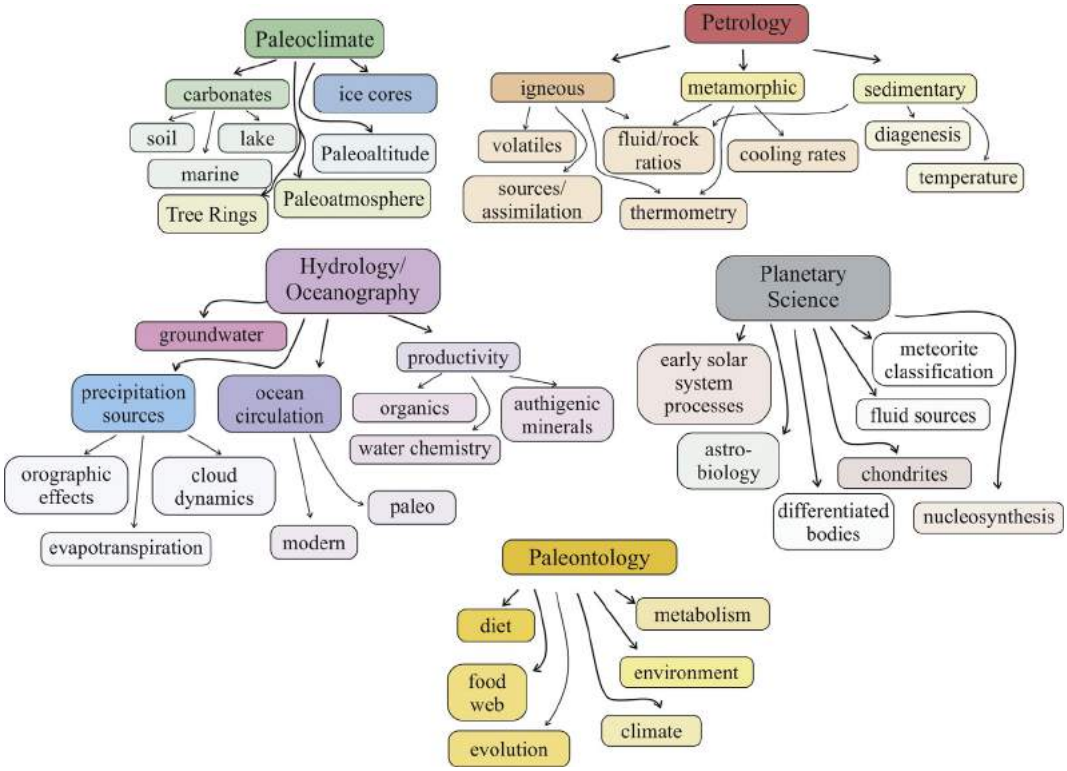

Fig. 2 Examples of the various fields and types of applications of stable isotopes. From Sharp, Z. (2017). *Principles of stableisotope geochemistry* (2nd edn.). https://doi.org/10.5072/FK2GB24S9F, reprinted with permission.

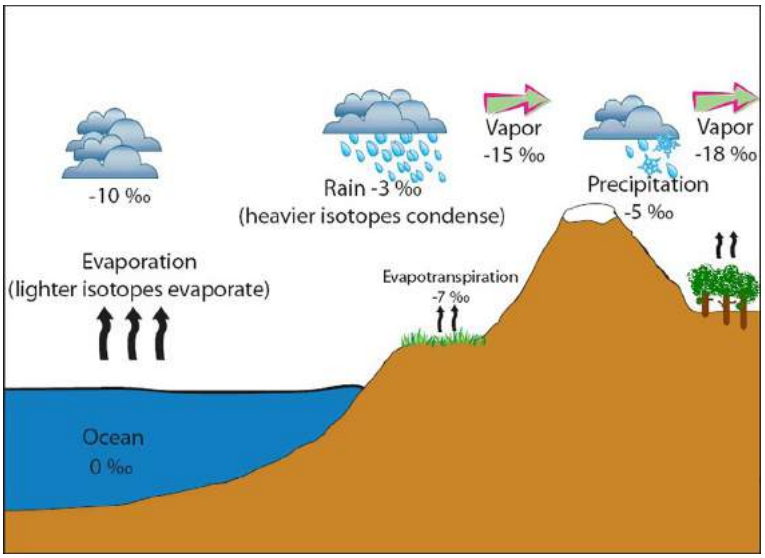

Fig. 3 A schematic diagram of the isotope fractionation process via evaporation, condensation, and evapotranspiration (combination of evaporation and transpiration). Notice that waters are lighter when they evaporate and are relatively heavier when condensed in the form of precipitation. From Bruckner, M. Z. (2007) Stable isotope primer and some hydrological applications, microbial life educational resources. Retrieved with permission from https://serc.carleton.edu/microbelife/research_methods/environ_sampling/stableisotopes.html (30th April, 2018).

that occur during evaporation and condensation (Fig. 3). For water in the climate system, the most important fractionations occur when water evaporates from the ocean (the evaporating water is slightly lighter, or more depleted, than the ocean water it came from) and when it condenses in clouds (the condensate is a littler heavier, or more enriched, than the water vapor). This pattern leads to a very clear pattern of progressively more depleted isotopes as you move toward the poles from the equator (Fig. 4). Thus, water from different places or processes can have a different isotope signal, a characteristic fingerprint of its origin and therefore can

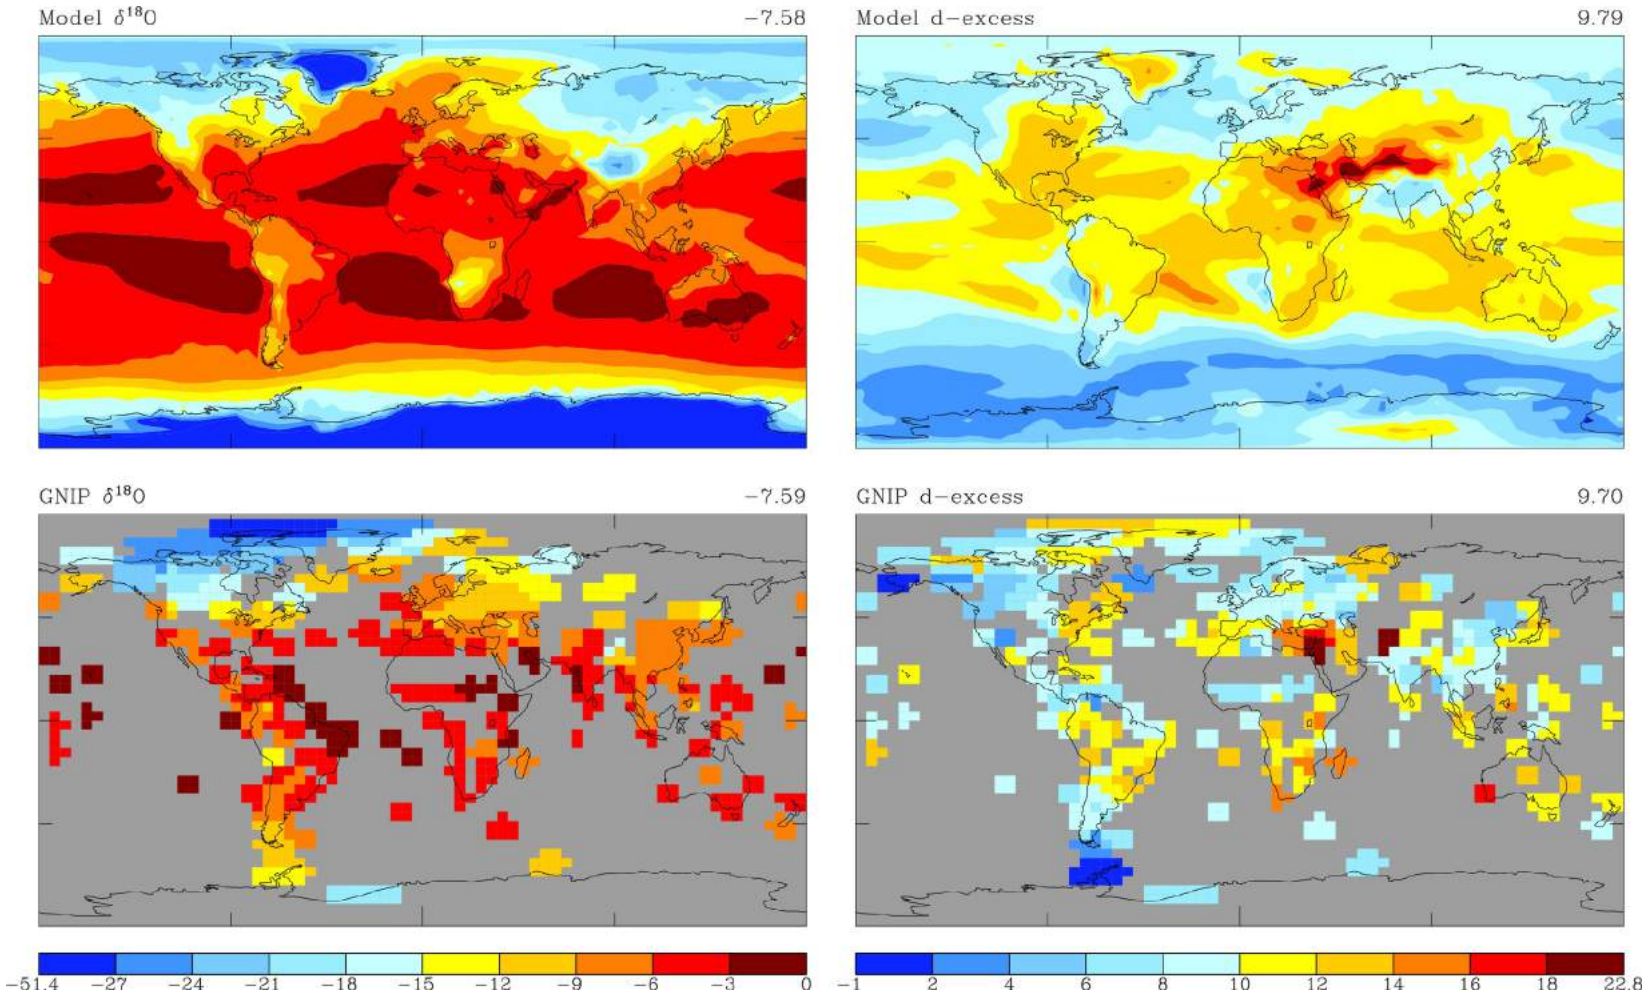

Fig. 4 Annual mean $\delta^{18}O‰$ (the isotopic ratio in precipitation) in a control simulation (averaged over last 5 years; *top*) compared to observations (*bottom*) in the GNIP database. Ratios are measured as a deviation from a standard, with more negative values implying less heavy isotopes than normal, positive values indicating more. The general pattern is for more depletion as you go toward the pole or away from the coast. *Reproduced with permission from* Aleinov, I. and Schmidt, G.A. (2006). Water isotopes in the GISS ModelE land surface scheme. *Global and Planetary Change* **51**, 108–120.

help identify where the water in the stream comes from. This happens in polar studies where the proportion of ice melt can be tracked through the ocean, and in hydrology where seasonal variations in isotopes can be tracked through a watershed. In paleoclimate studies, for example, the ratio of ^{18}O to ^{16}O in ice cores and fossil remains of microorganisms is commonly used to identify colder versus warmer periods in the Earth's past; higher abundances of ^{16}O indicate warmer periods (increased evaporation), whereas higher abundances of ^{18}O indicate cooler periods (decreased evaporation).

Natural stable isotope abundance techniques are also used by ecological researchers globally as an important tool to understand origins, migration and other movements (e.g., birds and fishes), resource portioning, host–parasite interactions, plant water use and nutrient status, ecophysiological processes, ecosystem fluxes of carbon, nitrogen and water, pollution, food webs, and sources of organic matter. For this purpose, stable isotopes of carbon and nitrogen are of specific interest.

In fact, the versatility of stable isotope applications has greatly expanded the variety of studies possible. Therefore, this article will focus on the application of stable isotopes in food web research.

Stable Isotopes in Food Web Research

At present, the major goal for ecology is to understand how communities and ecosystems will change following pollution, habitat destruction, overexploitation, invasion, and climate change. Such changes have triggered and accelerated the decrease in biodiversity and modified the structure and functioning of ecosystems, thereby jeopardizing the maintenance of goods and services provided to humans. A vision of community and ecosystem changes related to trophic interactions may allow a more holistic understanding of how communities and functioning may change in response to global. Under this framework, food web studies should take into account the dynamic nature of the trophic relationships, which vary following species behaviors and population dynamics as well as for spatial and temporal variability of the habitat considered. Such an approach may contribute to the preservation and management of ecosystems in view of global change.

It is not surprisingly that the benefit of using stable isotope analysis (SIA) approach to elucidate trophic interactions is high, with significant advantages over traditional methods (e.g., stomach content analysis). For example, the stable isotope approach, particularly those of nitrogen and carbon, provides a number of potential advantages over dietary methods, and has enhanced our understanding of trophic structure and dynamics of ecological communities, as well as ontogenetic shifts in consumer diet. Stable isotopes offer three potential advantages in terms of food web analysis; firstly, the $\delta^{13}C$ and $\delta^{15}N$ ratios of animal tissue represent the integration of carbon and nitrogen over a prolonged period (conservative markers; integration of different functions and environmental events over time periods); secondly, they are based on assimilation rather than ingestion (measurement of the effective use of food); and third they can be measured from comparatively small samples. In addition to time-integrated trophic information, isotope signatures have the potential to simultaneously capture complex interactions, including trophic omnivory, and to track energy or mass flow through ecological communities.

Stable Isotopes of Nitrogen and Carbon

The central assumption of SIA in trophic ecology is perhaps best represented by the observation first pointed out by DeNiro and Epstein (1976) "You are what you eat (plus a few per mil)". Thus, the isotopic structure of the prey is roughly assumed by the predator, based on that assumption. Indeed, predator metabolism operate a selection between the isotopic forms, preferentially respiring the light C isotope (^{12}C) and excreting the light N isotope (^{14}N). As a result consumers tend to be isotopically heavier than its food source (since lighter isotopes are preferentially used in metabolism) (Figs. 5 and 6), a process called discrimination factor (also fractionation factor or trophic enrichment) ($\Delta^{13}C$ and $\Delta^{15}N$ for carbon and nitrogen, respectively). This effect is more pronounced in nitrogen and leads to increases in $\delta^{15}N$ of approximately 3‰–4‰ at each trophic level. Thus, "you are what you eat (or more correctly assimilate) plus a few per mil." Because of the discrimination that occurs with trophic transfers, $\delta^{15}N$ can be used as a proxy for trophic positions.

Stable carbon isotope ratios vary substantially among primary producers with different photosynthetic pathways, but change little with trophic transfers, generally from 1‰ to 2‰ from prey to predator. Therefore, $\delta^{13}C$ are typically used to determine which primary producer components are the ultimate carbon source. For example, comparing marine and freshwater systems, marine phytoplankton have a $\delta^{13}C$ value of ca. −24‰ to −19‰ because the $\delta^{13}C$ of total dissolved inorganic CO_2 (DIC) in the ocean is about 0‰ and the incorporation of carbon by C3 plants proceeds with a fractionation of about −21‰. Riverine sources, such as matter derived from terrestrial vegetation (C3 plants, ca. −27‰ $\delta^{13}C$), soils (ca. −26‰ $\delta^{13}C$), and phytoplankton (< -30‰ $\delta^{13}C$), generally are depleted in ^{13}C compared to the estuary and marine systems (Figs. 6 and 7). Thus, freshwater organisms may be ^{15}N-depleted compared to marine organisms because terrestrial derived organic matter and freshwater algae often have a $\delta^{15}N$ value of −2‰ to 7‰, which is generally less than estuarine and coastal marine phytoplankton (7‰ to 10‰). These different isotopic compositions of primary producers are reflected in the tissues of their consumers, and again in the next level up the food web.

Natural-abundance SIA provides ecological information not only on food web structure, trophic interactions, and nutrient flux, but offers also a method for retrospective geolocation. The correct interpretation of stable isotope data requires an understanding of spatial and temporal variation in the isotopic compositions at the base of the food web. Incomplete knowledge of the likely spatio-temporal variation in baseline isotope values over an animal's foraging range, and/or over seasonal, annual, or multiannual cycles, can lead to poor sampling design and inaccurate interpretation of results.

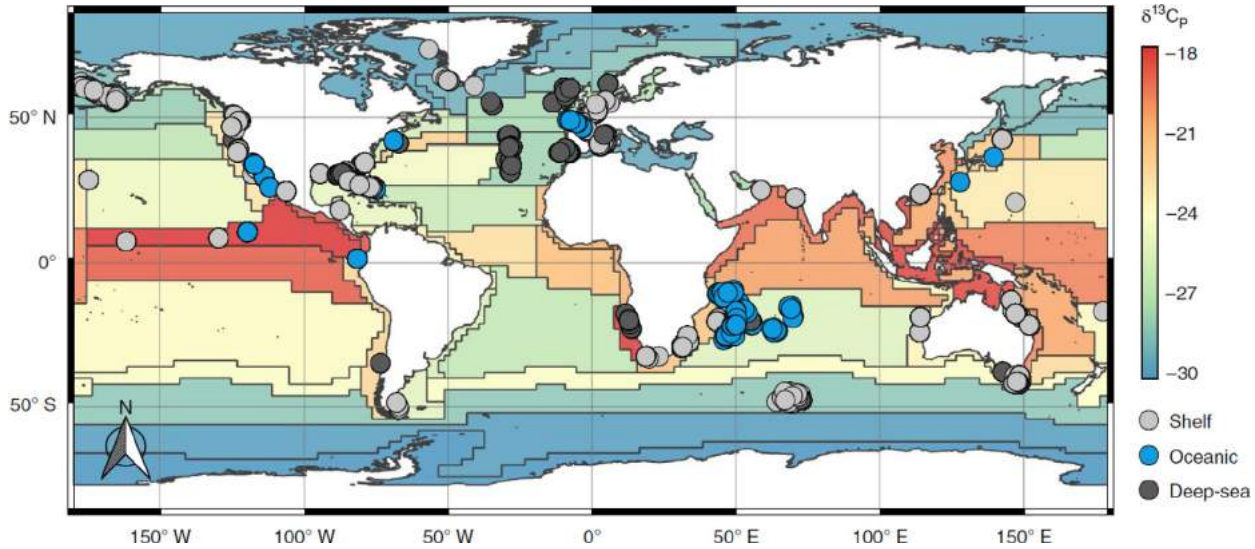

Fig. 8 Distribution of compiled shark data overlaid on a spatial model of annual average biomass weighted $\delta^{13}C_P$ within Longhurst biogeographic provinces from the median sampling year (2009). The colored points signify the habitat classification of those samples. Most studies provided one location for multiple samples. From Bird, C.S., Veríssimo, A., and Trueman, C.N. (2018). A global perspective on the trophic geography of sharks. *Nature Ecology & Evolution* **2**, 299–305.

Bird et al. (2018), for example, studied the global feeding habits of sharks by using stable isotopes of carbon in shark muscle as a natural tracer. The relative abundances of the two stable isotopes of carbon ^{12}C and ^{13}C in marine phytoplankton vary systematically with latitude, and among different coastal primary producers such as algae, seagrasses and mangroves. Differences in carbon isotope compositions are then passed from phytoplankton to consumers throughout food webs during feeding. This works of the premise of "you are what you eat" and also "you are *where* you ate." In this study, by tracking the original site of photosynthetic fixation of carbon atoms that were ultimately assimilated into muscle tissues of sharks, it was possible to identify globally consistent biogeographic traits in trophic interactions between sharks found in different habitats. Sharks that live near to the coast or in shelf seas appear to get most of their food from local phytoplankton based food webs (regional pelagic sources), but contain individuals that populations of these shelf sharks appear to be made up of individuals that forage within additional isotopically diverse local food webs, such as those supported by terrestrial plant sources, benthic production and macrophytes. In contrast, oceanic sharks that are found throughout the world's oceans seem to get most of their food from phytoplankton based food webs in areas of cooler water in the northern and southern hemispheres, between 30° and 50° of latitude from the Equator. Accordingly, increased understanding of species feeding ecology is essential to design more effective protection measures to conserve biodiversity and ecosystems (Fig. 8).

$\delta^{15}N$ as an Indicator of Nitrogen Pollution to Ecosystems

Isotopes are also useful tracers in ecological systems. For example, $\delta^{15}N$ is an effective tool to track natural and anthropogenic nitrate pollution sources to marine, freshwater, and terrestrial systems. Due to the wide variety of sources, nitrogen can enter in these systems in the form of nitrate (NO_3^-), nitrite (NO_2^-), and ammonium (NH_4^+). Moreover, nitrogen can be converted from one form into another through various reactions and processes.

In marine systems, for example, high levels of $\delta^{15}N$ in basal sources can be used as an alternative method to establish the level of human eutrophication, since anthropogenic sources of nitrogen are generally enriched in the heavy isotope when compared to natural ones. Actually, several studies have shown the utility of stable isotopes in trophic interactions studies, highlighting the relevance of the stable nitrogen isotope a reliable bioindicator to detect patterns of anthropogenic nitrogen contamination in several ecosystems. This is because different N sources have different relative abundances of $\delta^{15}N$, it is possible to evaluate the contribution of nitrogen sources to the local N pool, at least qualitative. For example, nitrate (NO_3^-) from human and animal waste is enriched in $\delta^{15}N$, with isotopic compositions of 10‰ to 22‰, whereas nitrate in synthetic fertilizer, which is fixed from atmospheric N, generally has much lower $\delta^{15}N$, with values ranging from −3‰ to 3‰.

Baeta et al. (2017), for example, correlated changes in the natural abundance of $\delta^{15}N$ in fish larvae to anthropogenic N inputs from both waste water and agricultural sources. Inferring, however, which specific nitrogen sources contribute to elevate $\delta^{15}N$ might be difficult in ecosystems that contain a variety of different pollution sources that contribute to the nitrogen load to these systems, and additional studies would be necessary. Stable isotopes used in conjunction with other techniques, such as compound-specific stable isotope analysis (CSIA) of natural isotopic abundance, may greatly enhance the evaluation of sources and transformation processes of pollutants, relevant to environmental decision makers. By increasing greatly the resolution of SIA, advances in CSIA will provide new opportunities and applications for stable isotopes studies throughout ecology.

Applying Stable Isotopes to Examine Food-Web Structure: Mixing Models, Ecological Networks, and Limitations

Stable isotopes have been also used to quantify the contribution of different food sources in the diet of an organism. Stable isotope mixing models (SIMM) have been proposed to reconstruct consumer diets, by assessing the proportions of food sources assimilated by a consumer (not just ingested by the consumer). Ecological researchers use mixing models to achieve as accurate as possible depiction of the trophic links in a food web. However, a good understanding of the study system is essential before using these models to determine the diet of consumer, because researchers need to know some aspects of an animal's diet a priori such as the identification of food sources that might be in the diet of the study species. Once the dietary sources have been identified, SIMM offer an excellent way to quantify diet, by estimating the proportional contribution of each dietary source to the diet of a consumer. Over the last two decades, a number of isotope mixing models have been proposed. These techniques range from simple, qualitative inferences based on the isotopic niche, to Bayesian mixing models that can be used to characterize food web structure at multiple hierarchical levels. In fact, current models have become more sophisticated, estimating probability distributions of source contributions, and incorporating complexities such as variability in isotope signatures, discrimination factors, hierarchical variance structure, covariates, and concentration dependence.

Another promising approach is the use of stable isotopes in the modeling of food web network structure. By combining stable isotope techniques with quantitative modeling approaches, it will be possible to gain additional insight in the structure of food webs (Fig. 9). Understanding how ecosystems react to and recover from perturbations is a fundamental goal of ecology. The increasing interest toward ecosystem status and performance, and the need to approach complex environmental problems, stimulate the application of tools for whole-system assessment. With the advent of quantitative ecosystem modeling tools, food web analysis is leading toward a better understanding of food web structure and the design of better management strategies for conservation. Accordingly, incorporation of diet information derived from SIMM to mass-balance models (that represent a "snapshot" of the trophic flows in the ecosystem and can be used to describe at least part of the reality) results in more constrained food web models.

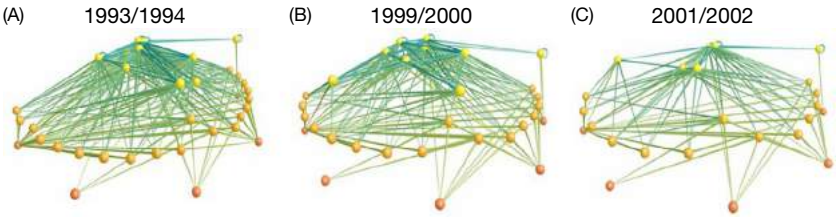

Fig. 9 3D representation of three food webs from the *Zostera* site in the Mondego estuary, Portugal. (A–C) *Zostera* site in 1993/1994, 1999/2000 and 2001/2002 respectively. Images were produced with FoodWeb3D written by R.J. Williams, Pacific Ecoinformatics and Computational Ecology Laboratory. The different *colored dots* represent functional groups from different trophic levels: *red* = primary producers, *orange* = primary consumers, and *yellow* = secondary consumers. The *light* and *dark gray* links represent feeding links. Adapted from Baeta, A., Niquil, N., Marques, J.C., and Patrício, J. (2011). Modelling the effects of eutrophication, mitigation measures and an extreme flood event on estuarine benthic food webs. *Ecological Modeling* **222**, 1209–1221.

Despite the multiple advantages of the natural isotope tracing approach, this technique, as with all tools, bears some notable limitations. In food web studies, the use of stable isotopes is based on an understanding of how the isotopic composition of animal diet and tissues are related. There are two main aspects to this. First, there is substantial unexplained variation in isotope composition of a given tissue, across taxa, and across tissue types. Therefore, the use of appropriate consumer-diet discrimination is crucial. The use of SIMM for diet reconstruction is characterized by an overreliance on literature values for key parameters. The use of constant discrimination factors declines the predictive power of models and inferences become limited—the models may illustrate general patterns, but not reliable and precise diets reconstruction and trophic positions. The second relates to tissue turnover time: an animal tissue does not immediately reflect the isotopic composition of its diet, but rather integrates over some period of time. Isotope turnover is a function of somatic growth and metabolism. Somatic growth-based isotope turnover occurs as the animal adds new tissue, diluting the pool of tissue derived from the diet in its previous location. Metabolic isotope turnover occurs as tissue is broken down and new tissue is synthesized. In general, tissues with fast growth and high metabolism have quicker turnover rates. For example, isotopic signatures in bone may integrate diets over the course of a year, hair over a few months, muscle over several weeks, and blood plasma over several days. Understanding the dynamics of isotopic turnover may allow ecologists to detect seasonal, or even episodic, changes in an animal's diet. Accordingly, further experimental investigation (laboratory and field) to quantify accurate values of consumer-resource discrimination and turnover rates of tissues is essential to inform scientifically sound food web studies using SIA.

Succession

JM Pandolfi, University of Queensland, Brisbane, QLD, Australia

Introduction

This article explores the notion of ecological succession, one of ecology's oldest and most controversial concepts. Simply stated, succession is the orderly changes in communities of a specific place over a period of time. More formally, it is the orderly progression of directional community development that results from modification of the physical environment by the community and culminates in an ecosystem in which maximum biomass and interactions among component organisms are maintained. Many workers relate succession to disturbance (fires, hurricanes, drought, etc.), such that succession refers to changes in a community after a perturbation opens up ecospace. Most of the earlier work on succession (dating back to 1899!) described the sequential invasion of species invading a particular site; later studies deal with a whole range of community characteristics from both empirical and theoretical standpoints (Table 1). Most of the work on succession has been dominated by forest communities, but successional studies also exist for a number of other ecosystems including benthic and pelagic marine ecosystems.

Different Kinds of Succession

Two kinds of succession have been proposed. `Autogenic' succession refers to sequential changes in the community that are brought about by the influence and activities of the organisms themselves upon the environment or habitat. `Allogenic' succession occurs to communities through the influence of factors external to the organisms themselves. The utility of allogenic succession may be limited because it may be too broadly applicable to any temporally repetitive change. Most of the debates surrounding succession, and studies which provide detailed examples are concerned with autogenic succession.

`Primary' succession refers to the colonization of sites where a severe disturbance has left no trace of the preexisting community, or where entirely new ecospace has been created. These might include a terrestrial or submarine lava flow, glacial recession, or the movement of submarine or subaerial sand dunes. Harsh environments usually characterize the earliest phases of primary succession, and communities tend to develop more slowly than with more minor disturbances to the ecosystem. `Secondary' succession refers to colonization of sites which did have a previous community established, but a perturbation has removed a portion of it or all of it over a limited area. Here again, much of the debate surrounding succession and most of its examples come from secondary succession. However, most unassailable instances of succession are examples of primary succession.

Expected Community Trends of Succession

The expected community trends of succession are explicit and detailed (Table 1). They rely on an early-successional community that ultimately leads to the `climax' community, or the most stable state for the successional sequence. This climax community is maintained until an extrinsic disturbance resets the successional clock. The attributes are grouped according to community energetics, community structure, life-history characteristics, cycling of nutrients, selection pressure, and overall homeostasis. These trends follow from the notion that the climax community is a steady state maintained by internal feedback control mechanisms. But they break down if it is not, and there is little evidence so far that they are.

In forests there are a variety of aspects of production ecology which vary over the successional sequence including forest floor depth, chemistry and content of decaying wood, nutrient availability, leaf area, carbon allocation, species composition and their nutritional adaptations, the relative roles of trees and minor vegetation, the relative importance of geochemical, biogeochemical and internal cycles, rate of soil organic matter accumulation, and total ecosystem organic matter. Early-successional forest species generally are shade intolerant, require a mineral seedbed, may be fast-growing, can generally utilize nutrients that occur in newly formed gaps, may be nitrogen-fixing, are tolerant of microhabitats in newly disturbed settings, and are superior competitors in such settings. Late-successional forest species generally are shade tolerant where they are able to grow slowly, may require a more organic seedbed, and are generally poorly adapted to newly disturbed settings where they are poor competitors. Nutrients are generally gained from litter decomposition and mycorrhizae.

Models of Succession

Three alternative models have been proposed for determining the sequence of species that might occur after a perturbation. The first is the facilitation model in which only certain species (`early successional') are able to arrive immediately following a

 doi:10.1016/B978-0-444-63768-0.00547-3

Table 1 Predicted changes that occur in major structural and functional characteristics of a developing ecosystem during ecological succession

Ecosystem attributes	*Developmental stages*	*Mature stages*
Community energetics		
1. Gross production/community respiration (*P*/*R* ratio)	Greater or less than 1	Approaches 1
2. Gross production/standing crop biomass (*P*/*B* ratio)	High	Low
3. Biomass supported/unit energy flow (*B*/*E* ratio)	Low	High
4. Net community production (yield)	High	Low
5. Food chains	Linear, predominantly grazing	Weblike, predominantly detritus
Community structure		
6. Total organic matter	Small	Large
7. Inorganic nutrients	Extrabiotic	Intrabiotic
8. Species diversity – variety component	Low	High
9. Species diversity – equitability component	Low	High
10. Biochemical diversity	Low	High
11. Stratification and spatial heterogeneity (pattern diversity)	Poorly organized	Well-organized
Life history		
12. Niche specialization	Broad	Narrow
13. Size of organism	Small	Large
14. Life cycles	Short, simple	Long, complex
Nutrient cycling		
15. Mineral cycles	Open	Closed
16. Nutrient exchange rate, between organisms and environment	Rapid	Slow
17. Role of detritus in nutrient regeneration	Unimportant	Important
Selection pressure		
18. Growth form	For rapid growth (`r-selection')	For feedback control (`*K*-selection')
19. Production	Quantity	Quality
Overall homeostasis		
20. Internal symbiosis	Undeveloped	Developed
21. Nutrient conservation	Poor	Good
22. Stability (resistance to external perturbations)	Poor	Good
23. Entropy	High	Low
24. Information	Low	High

Analysis of these parameters provides empirical tests of the expected development of ecosystems during succession.

disturbance. The most important factor governing succession in the facilitation model is the degree to which early-successional species alter the environment for later-successional species. Later species can only colonize after these early-successional species have sufficiently modified the environmental conditions. For example, in forest communities the amount of net primary production of the plant community will influence its ability to alter the site. This model implies a high degree of organization in ecological communities. However, it may still operate in communities where such organization is not apparent, for example, in heterotrophic successions or primary successions.

The second is the tolerance model in which the sequence of species to inhabit an ecosystem after a disturbance is determined exclusively by their life-history characteristics. The species that occur are simply those that are most efficient in exploiting resources in a given time or place. Thus, the success of later species is unrelated to the species composition of the earlier community. Two circumstances have been forwarded where this model of succession might be most prevalent. The first is with certain groups of animals, such as large vertebrates or insects that display a high degree of social integration, that have evolved a high degree of independence from both biotic and physical environments. The second is in situations where populations are limited more by resources than natural enemies or environmental stress. In the tolerance model, life-history characteristics such as the relative longevity, growth form, reproductive mode, and size of the early versus later species becomes paramount. A further elaboration of this model is given below in the section titled `The role of competition and life history'.

The third is the inhibition model in which early-successional species inhibit the success and growth of later-successional species. Those species that happen to occupy the site first maintain their membership in the community until their populations are damaged or die, only then enabling later species to invade. As such, the species composition gradually shifts to species with greater longevities. No special mechanism need be invoked for the inhibition model of succession.

Most models of succession have been criticized. Some authors treat them as purely descriptive and, like the entire successional process, a particular manifestation of the outcome of interacting individual life histories. In fact, one of the original authors of these three models has recently acknowledged that directional species replacement is only one change that might occur after a disturbance, and is often not the most likely change.

Some authors have taken these three models and related them to the search for ecological assembly rules during succession and compared them with a fourth alternative, the random colonization model, where chance survival of different species initiates the successional sequence; subsequent associations occur as a result of subsequent random colonization by new species. The search for assembly rules in ecology has a rich and controversial history that parallels that in succession. In fact, successional changes in community composition might be viewed as a special case of an overall search for deterministic processes in the maintenance and diversity of ecological communities.

Factors Influencing Succession

There are a number of factors that can influence the way in which community succession proceeds, if at all. Probably the most important of all are differences in life-history traits such as dispersal, ability to establish in open sites, shade tolerance, etc. The tradeoff between the availability of seeds and propagules of later-successional species versus the degree to which the early-successional community is resistant to invasion will influence the degree to which the former can increase at the successional site. Invasion success itself is dependent upon a large number of factors including, but not limited to, changes in microclimate or microhabitats, the composition of the seedbed, diseases, predators, and competition. Superimposed upon all of these are factors external to the organisms themselves, such as precipitation, temperature, salinity, and disturbance regime which can serve to reset the successional sequence.

The Role of Competition and Life History

Patterns from succession are numerous and varied, and have been mainly reported from the population and ecosystem level. However, a generalized theory of succession has been proposed for plants based on individual organisms. It is based on a model with three features: (1) the demographic history (birth, growth, death) of each individual is tracked through time; (2) every individual is assigned a suite of species-specific life-history traits (e.g., size, maximum age, and shade tolerance); and (3) competition and resource availability (light) is modeled explicitly through varying each individual's growth and mortality based on its degree of shade tolerance and light availability. The model successfully produces a significant portion of the variability in successional patterns using the mechanism of competition. Again, the importance of life-history traits among interacting plants is manifested.

Two-species simulations from the model were classified into five groupings based on the temporal patterns of species divergence (**Fig. 1**). The first was classical successional replacement where one species was able to dominate early in succession and the other species later, and is due to the correlation among life-history parameters of the two species. Divergence occurs when competitive ability starts out the same, but then one species outcompetes the other whereas convergence is the opposite: species are unequal in competitive ability early in succession but this equals out later in succession. Total suppression occurs when one species has the competitive advantage throughout the entire successional development. Finally, pseudocyclic replacement occurs when a temporary period of dominance or co-dominance by the initial cohort of species 2 results during the period between the senescence of the initial cohort of species 1 and the maximum lifespan of species 2. Thus early succession is characterized by the establishment of both species, but the initial cohort of species 2 persists longer than that of species 1. Species 2 is later replaced by the competitively superior species 1. The outcomes of the simulations depend more upon the equality of the life-history characteristics among species as opposed to the absolute values of the characteristics themselves; thus outcomes are governed by the qualitative relationship between the species with respect to their competitive abilities through time. Results of the simulations were similar to the two-species models when more than two species were considered and when multiple resources were considered. To summarize this important model to the concept of succession, the summary of the authors is quoted:

> An approach based on competition among individual plants is presented as an explanation for species replacements during plant succession. Inverse correlations among life-history and physiological traits that confer competitive ability under different environmental conditions are shown to be sufficient to produce successional replacements but not sufficient for understanding the complex variety of successional patterns unless they are applied at the individual rather than at the population level or higher. With models based on competition among individual plants, various combinations of life-history and physiological traits can produce the great variety of population dynamics found in natural successions. The classic successional pattern of species replacement results from a particular structure of correlations among life-history sand physiological characteristics. Atypical patterns of succession result when this correlation structure is altered. Both primary and secondary succession are modeled as nonequilibrium processes capable of interacting with disturbances to produce steady-state communities whose properties depend on abiotic conditions, such as temperature and resource levels, and on the type and frequency of disturbances. (Huston and Smith, 1987, p. 193)

Before leaving the subject of competition, it must be noted that there may well be a role for positive interactions among species comprising a community. There is increasing evidence that direct positive interaction, or facilitations, among species can play a vital role in ecological communities. While relatively unexplored in successional studies, the role of facilitations might provide an important context for testing the importance of successional patterns and processes in the maintenance of communities.

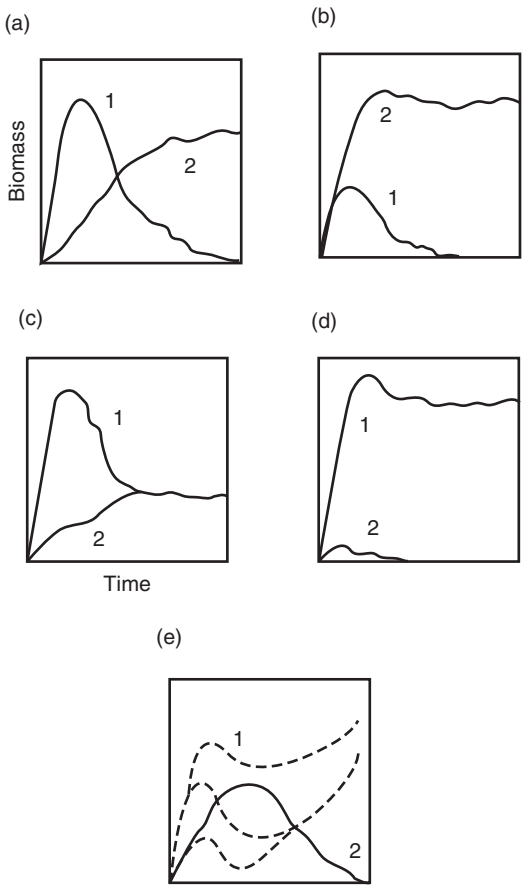

Fig. 1 General patterns of species interactions in a two-species succession. Competitive dominance occurs as a result of differing life-history traits. (a) Classical successional replacement that results from an inverse relationship between the two species in the attributes that confer early and late competitive advantage; (b) divergence that results when competitive abilities are equal early on, followed by a competitive advantage by one of the species; (c) convergence, the inverse of (b), that results when one species has a competitive advantage that equals out during the succession; (d) total suppression that results from one species having a competitive advantage over the other throughout succession; and (e) pseudocyclic replacement that results from alternating periods of dominance or co-dominance between the two species. From Huston MH and Smith T (1987) Plant succession: Life history and competition. *American Naturalist* 130: 168–198.

Is Succession Real?

Many models of succession are based on the idea that species that occur early in the successional sequence facilitate their own replacement by altering the environment to be more favorable to later species. Of course, this is anathema to natural selection – no species would `intentionally' create more favorable circumstances for any other species than itself (the `evolutionary paradox' of succession). For this reason the whole idea of succession has been questioned, and some authors consider it to be no more than the result of the passage of time, with no real mechanistic basis.

Many of the factors that might influence succession have been called into question, such that many authors believe that it is not a real phenomenon, or if it is, is unimportant in the maintenance of species diversity. Of critical importance is the degree to which communities act in changing the environment. Some reviews of the idea of succession conclude that most purported examples of succession do not fit the predicted trends: changes in structural and functional properties are not consistently associated with changes in species composition; successional stages are not consistently unidirectional; and effects of earlier species might just as easily delay or prevent as facilitate later-successional replacement.

Workers critical of successional theory have also put forward alternatives. One of these relates purported successional changes to consequences of differential growth, survival, and colonizing ability of species adapted to growth at different points on environmental gradients. Differences in taxonomic composition among successional stages are dependent upon interspecific competition while structural and functional changes in the community results in correlations in plants among size, longevity, and growth rate. In fact, successional changes may be exclusively governed by the presence of slower-growing later-successional species during the early phases of succession.

Much of the debate stems from the classic divergence in opinion about the influence of factors that result in the way in which species are maintained within ecological communities. On the one hand there may only be a loose association of species who

happen to inhabit the same habitat at the same time. In this model, species do not `feel' each other or interact much, or if they do, the effects of these interactions are minor in comparison with their shared environmental tolerances. In the extreme view, communities are just haphazard associations of species and any spatial or temporal continuity in the composition of a community is either minimal, or determined solely by environmental parameters.

A completely different view holds that biological communities are tightly integrated units composed of species that not only respond together to environmental changes, but also maintain linkages among each other that result in continuity of occurrence over broad spatial and temporal scales. Some caricatures of this model have even referred to the community as a `super-organism' with emergent properties that extend beyond individual species. While this view is probably overstated, there is a large amount of evidence that species interactions within communities result in spatial and temporal continuity of species assemblages within habitats. It is these interactions and other biological properties that have led many authors to believe that succession is a very plausible model for understanding changes in species composition over time.

Some Examples of Succession

Regardless of the continuing debates on whether there is any mechanistic basis for explaining directional patterns in species occurrences, excellent examples of the latter occur in nature. One of the best studies of primary succession was a test of the mechanisms involved in succession following deglaciation at Glacier Bay, Alaska. The main conclusion from this work was that no single factor or mechanism can totally account for primary succession. Plant life-history traits, such as seed size, growth rate, age at first reproduction, maximum height, and longevity played a fundamental role, but competition among species, and facilitation by addition of soil N and organic matter were also important. Although the relative importance of these factors was influenced by resource availability and environmental stress, they varied predictably through the successional sequence. The authors concluded that (1) life-history traits and availability of propagules determine the pattern of succession, (2) the mechanism for changes in species abundance patterns that accompanies succession is competition, and (3) the rate of change and nature of the climax community depends upon initial site conditions and the role of facilitation.

Perhaps one of the most famous and long-standing successional stories comes from the Krakatau Islands of Indonesia. The volcanic eruptions between May and August 1883 resulted in the almost complete `sterilization' of the islands. A classic primary successional sequence has been documented for the main volcanic island of Rakata which continues uninterrupted, whereas the other islands display characteristics of secondary succession (**Fig. 2**). On Rakata, a number of different successional pathways are being expressed (**Fig. 2a**). A similar diversity of succession characterizes the other islands, but eruptive activity of Anak Krakatau – a new volcano that was established in the center of the group between 1927 and 1930 – disrupted the vegetation of some of the other islands such as Serung and R. Kecil. There, varying disturbance events have reset the successional sequence (**Fig. 2b**).

Differences in vegetation and in the curves of species colonization among the Krakatau Islands have been attributed mainly to intermittent disturbances of varying intensities from Anak Krakatau. The importance of succession in viewing the history of terrestrial ecosystems of the Krakatau Islands is summed up by Whittaker *et al.*

> Neither the pattern of change in the flora, nor that for some groups of fauna, e.g., the birds and butterflies… can be understood without reference to vegetation succession and the key period in the 1920s when the savanna vegetation of the interiors gave way to forest. … a successional model of island recolonization is required, involving evaluation of habitat and dispersal mechanisms. (Whittaker *et al.*, 1989, p. 103)

Succession in the Fossil Record

One of the great limitations of assessing the frequency or validity of the processes of succession is that the complete successional sequence might take longer than the period of time over which most ecosystems are studied within scientific research programs. Since succession is by its very nature a process that occurs over time, it is not surprising that paleontologists have investigated the degree to which it can be understood from evidence in the fossil record. In contrast to modern ecologists working on mainly terrestrial forest communities, paleoecologists have focussed more on marine systems, studying succession in fossil coral reefs, marine hardgrounds, and some sandy substrates. A critical debate for paleoecologists is the degree to which species replacements in communities are ecological versus evolutionary phenomena.

Palaeontologists have used ancient reefs as model ecosystems in the study of succession. Four major phases of succession in eight ancient reefs ranging in age from the Early Ordovician (488 Ma) to the Late Cretaceous (65.5 Ma) have been established: stabilization, colonization, diversification, and domination. The stabilization stage involves the initial colonization of the seafloor that results in the establishment of a firm substrate. The colonization stage is characterized by encrusters and frame-builders, those organisms capable of colonizing a hard substrate and that begin to build three-dimensional structures above the sediment–water interface. Some authors consider the first two of these stages to be the same, equivalent to the pioneering stage of ecologists studying succession in living forest communities. The third stage in the succession of fossil reefs is referred to as the diversification stage, where maximum diversity of the reef community is developed. Diversity then decreases as a `domination' stage sets in whereby a single functional entity characterizes the reef community. As the communities ascend through the first three stages of succession, species diversity, degree of stratification and pattern diversity, niche specialization, and the complexity of food chains all increase. These successional sequences typically occur through significant intervals of time and are the result of the gradual

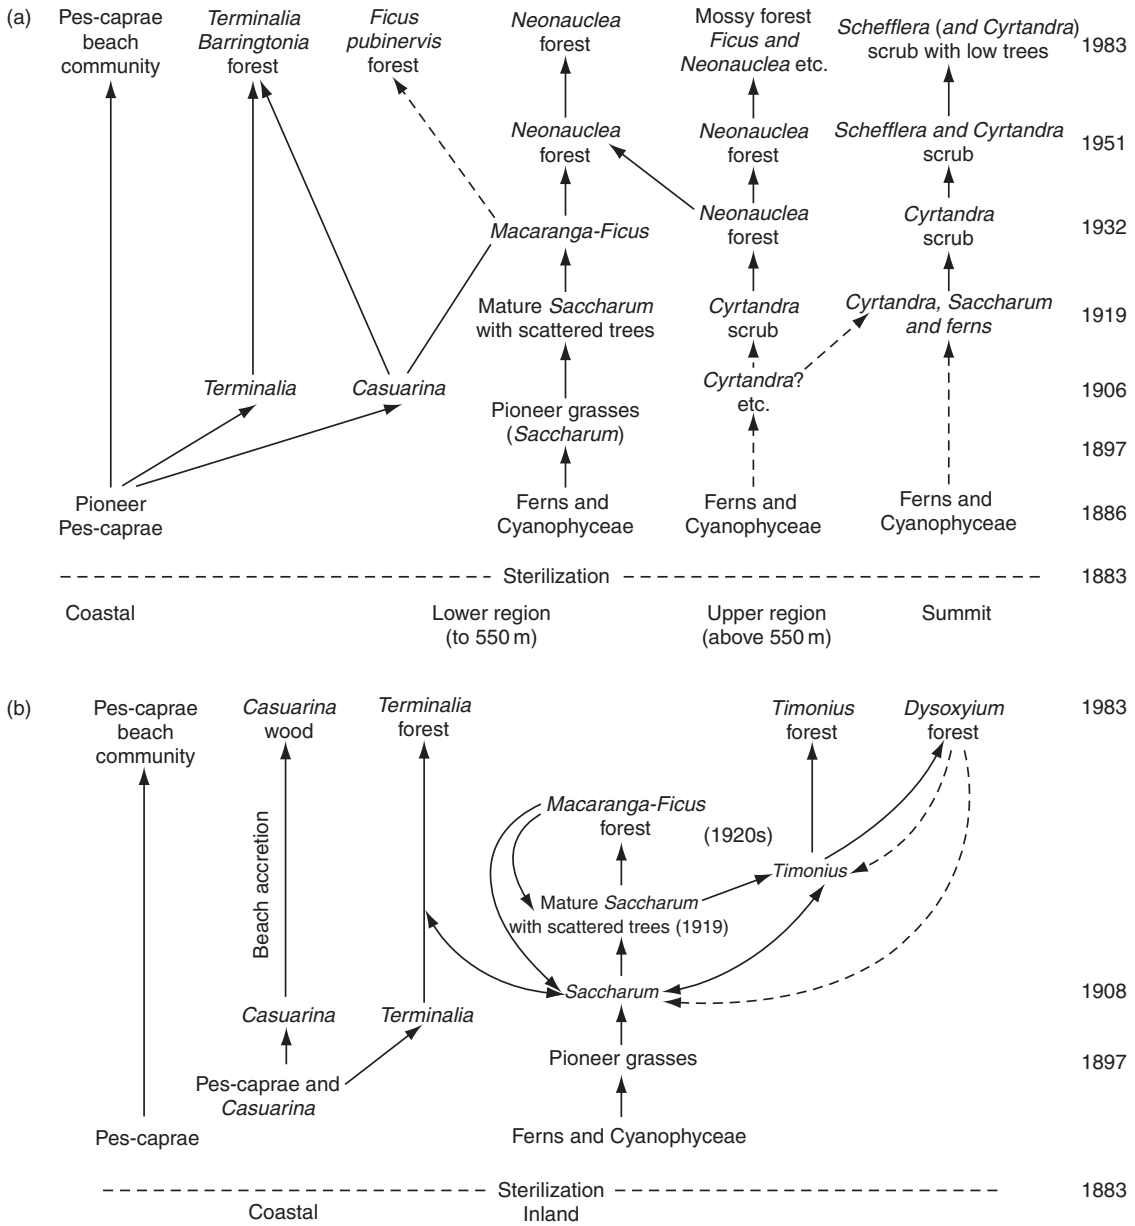

Fig. 2 Principal successional pathways on (a) Rakata and (b) Sertung and R. Kecil plant communities. Rakata has not experienced any volcanic disturbance for over 100 years, whereas forest development on Sertung and R. Kecil has been interrupted by volcanic activity several times since 1930 by Anak Krakatoa. Eruptive activity changed late-successional forest communities to early-successional or `pioneer' communities. From Whittaker RJ, Bush MB, and Richards K (1989) Plant recolonization and vegetation succession on the Krakatau Islands, Indonesia. *Ecological Monographs* 59: 59–123.

alteration of the submarine substratum by individual species, and the elaboration of energy-flow pathways as the community proceeds through time. Shorter-term successional episodes have also been observed where occasional environmental perturbations destroy the preexisting community. Here, subsequent community development involves a rapid biologically induced sequence of communities that culminate in the climax community that was established prior to the perturbation. Just as in the longer-term successional sequences, increases in major functional and structural attributes of the community accompany these shorter-term successional sequences.

There are, of course, a number of potential problems associated with the identification of succession in the fossil record. In the model above, an increase in diversity may come about just as easily from an increase in the zonation of the reef as to intrinsic biological changes. In the domination phase, the accompanying decrease in diversity may reflect a community that caps a reef after it dies, as opposed to a decrease during the life of the reef. However, in the fossil record of the Quaternary period (the past 1.8 Myr) these difficulties can often be overcome due to the precise age dating and sea-level history of the reefs.

In Kenya, `obligatory succession' in the Pleistocene consisted of an early assemblage of sediment-tolerant corals (dominated by massive or doming corals) that was replaced by predominantly branching and platy/encrusting corals. This kind of succession was mainly confined to the earliest portions of reef development on a bare substrate. Patterns through longer successional phases were varied, but under certain conditions massive or domed-shape corals might replace the branching assemblages. However, clearly defined zones were rare – most temporal changes in reef species associations were random or unstructured.

Applications to Restoration Ecology

The concepts of succession and community assembly have recently been taken up by the field of `restoration ecology'. The nature of community assembly and the degree to which communities can be expected to return on a path generally directed to their original states (though return to their exact previous state is probably not possible nor desirable) is of primary interest to restoration ecologists interested in mitigating and reversing the effects of human-induced habitat degradation. Because of this central concern and the fundamental questions which each theory provides, it is an important exercise to understand the similarities and differences between community succession and community assembly. Both concepts recognize the importance of historical events in shaping community composition, which develops over time toward a final state, and both recognize competition as a major driving force.

Single or multiple stable states are predicted for both concepts, but the way in which species are maintained in such states is very different. We have already discussed the idea of a climax community – the final stable state of a successional sequence. However, where succession occurs, multiple stable states can be maintained across an ecosystem by disturbances that keep the community in a variety of successional states, so the `climax' is never achieved at any one site or time. Where these disturbances are generated by the characteristics of the community itself (herbivory or fire) the community may be kept at an `arrested' successional state. Arrested succession might also arise where early-successional species maintain their advantage over later-successional species for extremely long periods of time. `Cyclic' succession occurs when there is no one stable successional state and all of the stages yield to others within the successional cycle. Stochastic differences in the arrival and colonization of late-successional species might also result in variability among ecosystems in their community composition.

Community assembly refers to the process by which species colonize, interact with other species and establish a community. This assembly may or may not be affected by `assembly rules' which predict community composition on the basis of a few key attributes such as size of the species pool, the abiotic environment, or interspecific interactions. Community assembly may also result in either a single community type or multiple stable states. Where there is a strong match between environment and community, then community composition should converge towards a single state where similar environmental conditions hold, regardless of the historical order in which the species invade. But multiple stable equilibria have also been observed with varying historical sequence of species invasions, so that different timing of introduction of species colonization leads to different species composition.

Regardless of whether species are maintained through a successional sequence, or the product of their sequence of invasion into an ecosystem, an understanding of the processes which bring about various community states is fundamental to those wishing to move the system in one direction or another. Even where such processes are particularly opaque, an understanding of the presence of particular states may help in providing goals for management and restoration. Some predictions about the likelihood of the existence of a single or multiple stable states have been put forward. While these need further testing, a single stable community state has been predicted to arise in ecosystems with small species pools, high levels of dispersal, low productivity, and high rates of disturbance; whereas multiple stable states should be more apparent in ecosystems with large species pools, low levels of dispersal, high productivity, and low rates of disturbance. Thus, an integrated approach to understanding the processes underlying the historical trajectory of ecosystems, coupled with an in-depth knowledge of life-history variability, and a few key attributes of the ecosystem can go far in our understanding of how communities are likely to respond in the future to environmental changes today.

Suspension Feeders☆

Brian T Hentschel, San Diego State University, San Diego, CA, United States
Jeff Shimeta, University of Melbourne, Parkville, VIC, Australia

What Is Suspension Feeding?

Suspension feeding is the capture and ingestion of food particles that are suspended in water. These particles can include phytoplankton, zooplankton, bacteria, and detritus. Some suspension feeders are primarily grazers of planktonic algae, while others are carnivores, and some that feed at the sediment–water interface are primarily detritivores. Some suspension feeders are largely nonselective omnivores, whereas others display strong preferences for certain particles according to size or chemical properties.

Suspension feeders are often described as employing passive or active means to capture particles. Passive suspension feeders depend entirely on ambient water flow to supply particles to their feeding structures (e.g., foraminiferans, corals, and brittle stars). In contrast, active suspension feeders usually create their own feeding current to enhance the local supply of food particles or actively swim or engage in other feeding-related behaviors when they sense the presence of nutritious particles (e.g., ciliates, sponges, crustaceans, and bivalves). Some animals can feed either passively or actively, for example, some barnacles, which wave their feeding appendages in weak flow but hold them steady in stronger flow. Many active suspension feeders are often referred to as "filter feeders" because they pump water through a structure that functions as a filter, removing particles from suspension (e.g., sea squirts, certain worms that secrete mucus nets, and baleen whales).

Organisms That Suspension Feed

All of the major animal clades include species that suspension feed (Table 1). Most small animals and protozoans that inhabit the plankton employ some form of suspension feeding, as do some larger drifters such as jellies and salps. Some nekton such as clupeiform fishes (herrings, sardines, anchovies, menhaden), manta rays, whale sharks, and baleen whales are suspension feeders. Numerous benthic invertebrates also remove particles from near-bottom waters. Many of these taxa obtain their nutrition almost exclusively by suspension feeding, for example, most species of sponges, hydroids, anemones, bivalve mollusks, bryozoans, phoronids, brachiopods, crinoids, sea squirts, and some polychaetes (such as fan worms) and crustaceans (such as barnacles and mole crabs). There are, however, several species of bivalves, polychaetes, and crustaceans that are known to switch between suspension feeding and deposit feeding depending on the supply of suspended particles in the near-bottom water.

A great variety of morphological structures, as well as secreted mucus structures, are used by suspension feeders to capture particles (Table 1 and Fig. 1). The taxonomic and morphological diversity of suspension-feeding organisms makes it difficult to draw many ecological generalities about suspension feeding as a process. Nonetheless, much has been learned by focusing attention on the small-scale mechanisms by which suspension feeders capture particles. Capture is a two-step process that involves contacting and retaining particles.

Mechanisms of Particle Contact

The simplest models of particle contact have considered nonturbulent flows that have Reynolds numbers much less than one, where the Reynolds number is a dimensionless ratio of inertial to viscous forces on a fluid. Four general mechanisms (Fig. 2) have been described and related to the form and function of animals' particle-collecting structures such as tentacles or setae, referred to here as particle collectors.

"Direct interception" occurs when particles follow the streamlines of the flow field and the center of a particle comes within one particle radius of the organism's collector. The area of the fluid that is sampled by direct interception at low Reynolds numbers is approximately twice the radius of the particle. The fluid velocity near the collector and the size of the particles determine the rate at which particles are contacted by direct interception. Direct interception is a common contact mechanism for animals that suspension feed with tentacles or setae, for example, polychaetes, echinoderms, crustaceans, etc. (Table 1).

"Inertial impaction" can bring more distant particles in contact with a collector when the specific gravity of the particle exceeds the specific gravity of the fluid. The momentum of a relatively heavy particle can transport it to the collector even if the streamlines

Table 1 Examples of marine suspension feeders and the structures used by adults to capture particles[a]

Phylum	*Examples*	*Particle-collecting structures*	*Habitat*
Protists	Flagellates, ciliates, foraminiferans, radiolarians, heliozoans	Flagella, microvilli, cell surface, cilia, pseudopodia, spines	Planktonic, benthic
Porifera	Sponges	Microvilli of choanocytes	Benthic
Cnidaria	Hydroids, hydromedusae, siphonophores, anemones, zoanthids, corals, sea pens, jellies	Tentacles, mucus nets	Planktonic, benthic
Ctenophora	Comb jellies	Tentacles	Planktonic
Rotifera	Rotifers	Ciliated corona	Planktonic, benthic
Entoprocta	Entoprocts	Ciliated tentacles	Benthic
Cycliophora	Cycliophorans	Cilia	Benthic
Sipuncula	Peanut worms	Ciliated tentacles	Benthic
Echiura	Inn-keeper worm	Mucus net	Benthic
Annelida	Polychaetes	Ciliated tentacles, mucus threads or nets	Benthic
Mollusca	Pteropods, snails, limpets, vermetids, clams, mussels, oysters, scallops	Ciliated gill filaments, ciliated parapodia, mucus threads	Planktonic, benthic
Arthropoda (subphylum Crustacea)	Copepods, krill, crabs, shrimps, cephalocarids, branchiopods, leptostracans, mysids, cumaceans, tanaids, barnacles, amphipods, ostracods	Setae, cirri	Planktonic, benthic
Bryozoa	Bryozoans	Ciliated tentacles	Benthic
Phoronida	Phoronids	Ciliated tentacles	Benthic
Brachiopoda	Lamp shells	Ciliated tentacles	Benthic
Echinodermata	Sea stars, brittles stars, basket stars, sea cucumbers, sea urchins, sand dollars, crinoids	Tube feet, spines, pinnules, tentacles, pedicellariae, mucus threads	Benthic
Hemichordata	Acorn worms, pterobranchs	Ciliated proboscis, ciliated tentacles, mucus nets	Benthic
Chordata	Sea squirts, salps, larvaceans, lancelets, fishes, baleen whales	Mucus nets, gill rakers, filter plates, baleen plates	Planktonic, nektonic, benthic

[a]Most of these animals also have a suspension-feeding larval stage in which particles are captured by setae (arthropods) or cilia (other taxa).

of the flow will not bring the particle to the collector via direct interception. The rate at which particles are contacted by inertial impaction is affected by the local velocity, the size of the particles, and the specific gravity of the particles relative to that of the fluid. Inertial impaction is especially important for animals that suspension feed on organic-mineral aggregates near the sediment–water interface, such as various worms, crustaceans, and echinoderms.

"Gravitational deposition" can also cause particles that have a relatively high specific gravity to contact the collector from above. Unlike direct interception and inertial impaction, the rate at which settling particles are contacted by gravitational deposition is not affected by the local fluid velocity at low Reynolds number. Gravitational deposition is especially important for drifting protozoans, pteropods, and benthic cnidarians.

"Diffusional deposition" occurs when the random motion of a particle causes it to cross fluid streamlines that would otherwise prevent it from contacting the collector by direct interception or inertial impaction. The rate at which particles are contacted is affected by the surface area of the collector, the concentration gradient of the particles, and the diffusivity constant of the particle which describes its rate of random motion. This mechanism can be especially important for contacting living, motile particles, for example, protozoa feeding on bacteria and cnidarians feeding on zooplankton.

These four mechanisms of particle contact can, and usually do, act in combination when suspension-feeding organisms live in natural mixtures of particles that have different sizes, shapes, concentrations, and specific gravities. The relative contributions of each contact mechanism can also vary due to fluid velocity. Together, these contact mechanisms can account for selective feeding due to differential contact rates among particle types.

When the Reynolds number of the collector approaches unity, which is the case if the diameter of the collector is approximately 0.01 cm and the local velocity is roughly 1 cm s^{-1}, streamlines become compressed near the sides of the collector and separate in the collector's lee (**Fig. 3**). The streamline compression along the sides of the collector results in sampling particles from a greater area of the fluid than when it occurs without streamline compression at low Reynolds number. Streamline compression also enhances particle contact by inertial impaction, gravitational deposition, and diffusional deposition.

When the Reynolds number of the collector is greater than 10, which can occur if the diameter of the collector is approximately 0.1 cm and the local velocity is roughly 1 cm s^{-1}, streamlines around the collector can separate and form downstream vortices (**Fig. 3**). These vortices allow for particle contact on the downstream side of the collector. Organisms themselves usually obstruct the flow and create downstream vortices. Many benthic suspension feeders, especially colonial

ones like bryozoans and corals, capture particles in the wake of upstream neighbors. Capture rates can be highest on the downstream edge of such colonies.

Retaining Contacted Particles

Particles contacted by the collector(s) of a suspension feeder are not necessarily captured and ingested. They must be retained during transport to the organism's mouth. To successfully retain a particle after its initial contact, some type of adhesive force is necessary to overcome the force of drag and the particle's inertia. Drag and inertia increase with particle size and with increasing

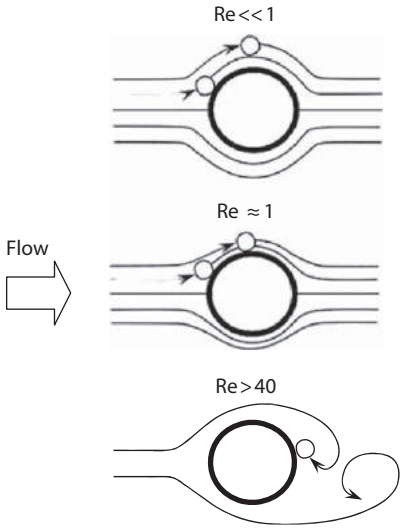

Fig. 3 Flow patterns and particle contact by direct interception for a cylindrical collector at various Reynolds numbers.

velocity. The inertia of a particle also increases with its specific gravity. Therefore, retention is greater at slower velocities and for smaller particles that have a low specific gravity. Because of this, most passive suspension feeders experience a maximal capture rate at an intermediate flow strength.

A variety of mechanisms serve in retaining particles. Mucus and other organic coatings secreted on the surface of feeding structures can enhance retention efficiency. For example, many benthic suspension feeders retain particles on strings or sheets of mucus that cover their tentacles, gills, or pharynx and are then transported to the mouth (e.g., various worms, bivalves, echinoderms, hemichordates, and sea squirts, **Table 1**). Similarly, particles that have sticky organic coatings are more likely to be retained than are relatively clean particles. The electrostatic charge or hydrophobicity of particles also influences their retention. In cnidarians, the nematocysts retain zooplankton prey with barbs and toxins. In filter feeders, networks of collectors form a sieve that retains all particles larger than the sieve's pore size (e.g., the overlapping setae on crustacean appendages, and the mucus nets of worms, sea squirts, and other invertebrate chordates, **Table 1**).

Suspension Feeding in More Complicated Flow Regimes

Although much has been learned from relatively simple modeling of the mechanisms underlying particle contact and retention, suspension feeders often live in flow environments that are much more complicated than steady, nonturbulent conditions. In some active suspension feeders, particle capture depends on strong velocity gradients produced by the feeding currents. For example, ciliary capture occurs in ciliates, polychaetes, entoprocts, bivalves, bryozoans, phoronids, brachiopods, and many invertebrate larvae (**Table 1**). In this capture mechanism, cilia or cirri redirect approaching particles onto a ciliary tract, often by a reversal of the ciliary beat direction. The particles are retained in mucus strings or within the currents of the ciliary tract, without necessarily contacting the cilia. As another example, copepods intercept and sieve particles with complex appendage motions that isolate and trap desired particles from the suspension.

Complexities in the ambient flow also have strong impacts on suspension feeders. The feeding rates of passive suspension feeders depend entirely on variability in the surrounding flow regime. Even the feeding rates of some active suspension feeders such as sponges can be enhanced by ambient flow. Strong flow can deform an animal's feeding structures or otherwise interfere with the animal's ability to create an effective feeding current. Bivalves and other active suspension feeders are known to alter their pumping rates in response to ambient velocities and the concentration of food particles. The growth form or orientation of some benthic suspension feeders is adjusted to maximize exposure to flow, for example, gorgonian corals, crinoids, brachiopods, and scallops.

Most benthic and planktonic suspension feeders experience fluid turbulence. Turbulence can affect the local velocities and the concentration gradients of food particles near suspension feeders. Turbulent pulses of increased velocity reduce particle retention due to greater drag on contacted particles. Under nonturbulent conditions, colonial or aggregated suspension feeders can deplete particle concentrations before the fluid reaches downstream regions of the colony. Under turbulent conditions, however, local depletion of particles is less likely to occur. Many planktonic protozoans were once thought to be smaller than turbulent eddies and, therefore, not affected by turbulent variability in fluid motions. Recent studies have, however, found that the feeding rates of some protozoans can increase or decrease significantly in response to moderate levels of turbulence.

Suspension feeders living in the benthic boundary layer face strong vertical gradients in velocity, turbulence, and particle concentrations. Many passive suspension feeders have a stalked morphology or build tubes that elevate their feeding structures to regions of enhanced particle supply (e.g., foraminiferans, sponges, hydroids, corals, polychaetes, crinoids, sea squirts). If the

concentration and horizontal flux of food particles reach a local maximum at some height above the bottom, many passive suspension feeders such as tube-building polychaetes can optimize the height at which they feed by varying the height of their tube or the extension of their feeding tentacles.

Many suspension feeders inhabiting shallow, coastal areas experience flow that oscillates in time due to wave motion. The behaviors of many benthic suspension feeders have been observed to differ between steady, unidirectional flows and oscillatory flows. Quantitative measures of particle contact, retention, and capture in oscillatory flows are, however, poorly understood relative to those in steady, unidirectional flows.

Ecological Interactions Related to Suspension Feeding

Like all trophic processes, suspension feeding is integral to many ecological interactions. For example, bacterivory by suspension-feeding protozoans and grazing on those protozoans by larger zooplankton are major linkages in pelagic food webs. Unlike many other predator–prey interactions, however, the activities of most suspension feeders extend beyond biotic interactions to affect a wide range of biogeochemical processes.

The vast majority of sessile invertebrates that colonize hard substrata are suspension feeders. These organisms include bryozoans, ascidians, hydroids, encrusting sponges, mussels, and barnacles. Dense assemblages of these sessile suspension feeders often form what are termed "fouling communities" that create unique microhabitats for other organisms. Suspension-feeding corals create an even more extensive habitat that supports diverse communities.

Another obvious impact that suspension feeders have on the environment involves the aggregation and removal of many small particles from suspension. Pelagic grazers such as copepods and ciliates process thousands of microalgal and bacterial cells every hour. The capture and ingestion of these small, dilute food items usually results in aggregation in the form of fecal pellets that sink more rapidly out of the water column and increase the export of organic material from the photic zone to deeper depths.

Benthic suspension feeders can also remove vast quantities of phytoplankton and other particles from suspension. Bivalve mollusks typically pump on the order of 10 L day^{-1}, but some large mussels and oysters have filtration rates as high as 1000 L day^{-1}. The unintentional introduction of zebra mussels (*Dreissena polymorpha*) into North American lakes and rivers has greatly altered the ecosystem because dense populations can effectively clear the entire bodies of water they inhabit of phytoplankton and other particles every few days

In soft-sediment habitats, some infauna suspension feed by pumping water through their burrows or tubes and capturing food particles with a mucus net. The echiuran "inn-keeper worm," Urechis campo, typically irrigates its burrow with 50–70 L day^{-1}. Chaetopterid polychaetes typically pump 10–20 L day^{-1} through their tubes. In addition to removing particles from suspension, this type of infaunal pumping irrigates subsurface, anoxic layers of sediment, creating suitable habitat for many small metazoans.

Suspension feeders that inhabit soft sediments tend to be more common in sandy substrates than in mud. Mud and silt particles accumulate only in regions of reduced water flow, which is not conducive to passive suspension feeding. In addition, fine-grained mud and silt can clog the filter elements of some suspension feeders.

Many benthic suspension feeders live in dense aggregations. In fact, many suspension feeders such as corals, bryozoans, and ascidians are colonial. Nearby neighbors can alter local flow fields and particle concentrations. Downstream members of a colony often experience reduced velocities and particle concentrations due to the "current shading" of upstream neighbors. When roughness elements that obstruct flow (e.g., whole organisms or their feeding appendages) have diverse sizes and shapes, as typically occurs in a mixed-species assemblage, the topographic complexity can lead to enhanced local velocities and feeding rates. When the density of roughness elements exceeds approximately 8% of the bottom area, the wakes surrounding individual organisms interact to create what is termed "skimming flow" around the entire aggregation. This can lead to reduced local velocities and depleted particle concentrations within the aggregation, for example, over stretches of coral reefs or mussel beds.

Synecology

ER Pianka, University of Texas, Austin, TX, USA

The *Encyclopædia Britannica* defines synecology as the study of a group or community of organisms and their relationships to each other and to their common environment. Whereas autecology is the study of interrelationships between organisms and their environments at the level of an individual, a population, or an entire species, synecology is concerned with the highest level of biological organization: entire systems of interacting populations in a complex and dynamic physical environmental setting. Synecology is the study of ecosystems, which include both the abiotic nonliving physical environment as well as a biotic component, the community (or biome) of living microbes, fungi, plants, and animals that occur together at any given spot. The concept of a community is itself an abstraction; communities are seldom clear cut and distinct but almost always grade into one another. By considering ecological systems as `open' rather than `closed', and by allowing for continual inflow and outflow of materials, energy, and organisms, this difficulty can be partially overcome and the community concept can be quite useful. Although communities change both in space and in time, they can be examined from an instantaneous view of a fairly localized portion of a larger community. Community ecology is the study of the distribution, abundance, demography, and interactions between populations of coexisting species. Synecology is the most abstract and most difficult kind of ecology, but it is also exceedingly tantalizing and vitally important, as well as extremely urgent as humans complete their domination and usurpation of planet Earth.

As in almost any academic endeavor, two, diametrically opposed, approaches to ecosystem ecology exist: one approach views ecological systems in terms of their component parts, nutrient pools coupled to complex networks of interacting populations. The other approach is more holistic, coming at ecosystems from the top down, rather than from the bottom up. These two perspectives each have their own advantages and limitations, but both are useful.

Community structure concerns all the various ways in which members of communities relate to and interact with one another, as well as any community-level properties that emerge from these interactions. Just as populations have properties that transcend those of the individuals comprising them, communities have both structure and properties that are not possessed by their component populations.

Community ecologists are still in the process of developing a vocabulary. Identification of appropriate aggregate variables or macrodescriptors is essential, but constitutes a double-edged sword; macrodescriptors allow progress but simultaneously constrain direction(s) that can be pursued. To be most useful, such macrodescriptors must simplify population-level processes while retaining their essence without fatal oversimplification. Examples include trophic structure (food webs), connectance, rates of energy fixation and flow, efficiency, diversity, stability, distributions of relative importance among species, niche relationships, resource partitioning, guild structure, assembly `rules', successional stages, and so on. At this early stage in community ecology, it seems prudent not to become overly `locked in' by words and concepts. Even the trophic level concept (producers, consumers (herbivores, omnivores, and carnivores), and decomposers) should not be inviolate (**Fig. 1**).

Clements saw communities as organized superorganisms, whereas Gleason envisioned them as merely statistical ensembles of individualistic species. This debate lives on today, albeit in a somewhat different form. Some putative system-level properties are undoubtedly simply epiphenomena that arise from pooling components; examples would presumably include trophic levels, subwebs, nutrient cycles, and ecological pyramids. But, do communities also possess truly emergent properties that transcend those of mere statistical collections of populations? For example, do patterns of resource utilization among coexisting species become coadjusted so that they mesh together in meaningful ways (see **Fig. 2**)?

If such resource partitioning occurs, truly emergent community-level properties arise as a result of orderly interactions among component populations. The null model approach has been exploited to search for such patterns by Winemiller and Pianka, who constructed randomized replicates of real communities termed `pseudo-communities' and compared these with their prototypes to detect guild structure and resource partitioning.

Such transcendent phenomena or epiphenomena simply cannot be studied at individual or population levels, but must be approached at the level of an entire assemblage or community.

A major problem for community and ecosystem ecologists is that communities are not acted upon directly by natural selection (as individual organisms are). We must keep clearly in mind that natural selection operates by differential reproductive success of individual organisms. It is tempting but dangerously misleading to view organisms or ecosystems as having been `designed' for orderly and efficient function. Antagonistic interactions at the level of individuals and populations (competition, predation, parasitism) must frequently impair certain aspects of ecosystem performance. Effective studies of community organization thus require a pluralism of approaches, including all of the following levels: individuals, family groups, populations, trophic levels, and community networks, as well as historical and biogeographic studies. All these approaches have something useful to offer. The approach taken must be fitted to the questions asked as well as to the peculiarities of the system under study. Much more effort needs to be devoted to connecting community-level attributes and phenomena to how natural selection operates on the behavior and ecology of individual organisms.

 doi:10.1016/B978-0-444-63768-0.00550-3

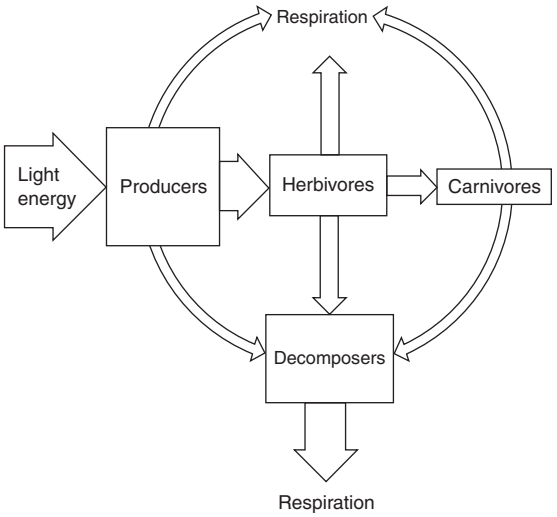

Fig. 1 A simple trophic level `compartment' model of a community, with arrows indicating flow of energy through the system. Widths of arrows reflect rate of flow of energy between particular parts of the system.

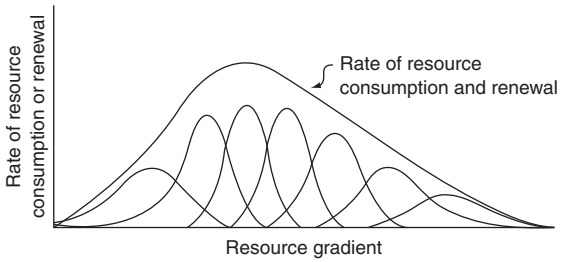

Fig. 2 Niche relationships among members of competitive communities can be represented with bell-shaped utilization curves along a resource spectrum such as height above ground or prey size. Among the seven hypothetical species shown, those toward the tails have broader utilization curves because their resources renew more slowly. In such a competitive community, consumers are at equilibrium with their resources and the rate of resource consumption is equal to the rate of renewal along the entire resource gradient (uppermost curve).

For example, efficiencies of transfer of energy from one trophic level to the next have been estimated to average ~10%–15%. Natural selection operating on individual prey organisms favors escape ability, which in turn reduces the rate of flow of matter and energy through that trophic level, decreasing ecological efficiency but increasing community stability. In contrast, predators evolve so as to be better able to capture their prey, which increases the efficiency of flow of energy through trophic levels but reduces a system's stability. In the coevolution of a predator and its prey, to avoid extinction, the prey must remain a step ahead of its predator. As a corollary, community-level properties of ecological efficiency and community stability may in fact be inversely related because natural selection operates at the level of individual predators and prey. Moreover, the apparent constancy and low level (10%–15%) of ecological efficiency could be a result of the `compromise' that must be reached between prey and their predators.

Ecosystem-level studies are also plagued by difficult problems of scale in both space and time. Patch size and dynamics, climatic events and climate change, nutrient cycles, disturbance frequency, and dispersal ability are just a few of many factors that vary widely within and among systems, as well as over space from local to geographic areas and through time from the short term to the long term.

A plethora of interesting questions can be asked about communities: What structure do they have that transcends population-level processes? What are the effects of community-level attributes on the component organisms living in a given community? What are the roles of parasitism, predation, mutualism, and interspecific competition in shaping community structure? How important are indirect interactions among species and to what extent do such interactions balance out direct effects? How many niche dimensions separate species, and which ones? To what extent are species spread out evenly in niche/resource space? (Such an overdispersion in niche space might be predicted under a competitive null hypothesis, with each species minimizing its interactions with all others.) Do clusters of functionally similar species (`guilds') exist? If so, how can such guild structure be detected and measured? What are its components? Are such guilds merely a result of built-in design constraints on consumer species, and/or do guilds simply reflect natural gaps in resource space? Can guild structure evolve even when resources are continuously distributed as a means of reducing diffuse competition? (A community without guild structure would presumably have greater

diffuse competition than one with guild structure.) Do more diverse communities have more guild structure than simpler communities? What factors determine the diversity and stability of communities and what is their relationship to one another?

Ultimately, we must be able to answer such fundamental questions about `how' natural systems are put together before we will even begin to be able to ask more interesting questions about `why' ecosystems have any particular observed properties, such as ``What are the effects of indirect interactions among populations and/or guild structure on the assembly, structure, stability, and diversity of communities?''

The extreme complexity of most ecosystems makes their study quite difficult but at the same time extremely challenging. Humans now dominate all of Earth's biomes – pristine natural ecosystems no longer exist. Unfortunately, we still know very little about how natural communities function, much to our peril as we continue to usurp whatever limited resources this planet has to offer. Community ecology has thus become exceedingly urgent: humans sorely need to understand how natural ecosystems function and evolve, if only so that we can manage our artificial human-engineered ecosystems more sensibly than we have so far.

Temperature Regulation☆

Inna Sokolova, University of Rostock, Rostock, Germany

Physiological Function of Thermoregulation (The "Why")

Regulation of body temperature (T_b) plays a key role in organism's physiology, ecology, and behavior and encompasses physiological and/or behavioral adaptations whose function is to alter the amount of body heat and thus T_b of the organism. The crucial role of thermoregulation is based on the fact that body temperature directly affects the rates of all biochemical and physiological processes and structure of biological macromolecules. This temperature-dependency of life is rooted in the basic laws of physics and chemistry, particularly in the direct relationship between the temperature and the amount of molecular motion. According to the collision theory of reaction rates, a chemical reaction occurs when the centers of mass of colliding reactants come close enough for a new bond to be formed or an existing bond to be broken. For this to happen, potential energy of the reactants must be equal or greater than a certain threshold energy level called activation energy (E_a) (Fig. 1A). Elevated temperature increases mean velocity of the reactant molecules and the fraction of the molecules with kinetic and potential energy above E_a (Fig. 1B) so that both frequency of molecular collisions and energy of these collisions increase leading to higher reaction rates. Additionally, in enzyme-catalyzed biological processes elevated temperature may convey conformational flexibility to enzymes favoring more rapid binding of their substrates and/or release of the products. Since ligand binding and release are often rate-limiting steps in enzymatic reactions, this temperature-conferred enzyme flexibility also increases reaction velocity. Thus, all other things being equal, higher body temperature (T_b) leads to higher rates of biochemical reactions and thus higher rates of integrative processes such as metabolism, neurotransmission, locomotion, reproduction, and growth.

Different species have evolved to normally function in different ranges of body temperatures. In the Earth's biosphere, the lowest recorded temperature is −89.2°C in continental Antarctica, and the highest is around 100°C in geothermal hot springs and 350°C in certain deep-sea hydrothermal vents. While prokaryotic life can be found over much of this temperature range, the limits of body temperatures compatible with active eukaryotic life are much narrower—from −1.86°C (freezing point of the ocean water) to +45–50°C (large polar mammals and birds which can tolerate external temperatures down to −60°C are no exception to this rule, as their body temperatures are maintained around 35–40°C). However, within each species the range of tolerated body temperatures is narrower still and centered on so called optimal T_b, which provides the highest level of physiological performance. At the molecular level, thermal optimum is determined by trade-off between the rate-enhancing effects of moderate increase in temperature on biochemical or physiological processes, on one hand, and the destructive effects of heat causing structural damage to proteins and excessive lability of biological membranes, on the other. At the whole-organism level, optimal body temperature is determined by integration of the thermal optima of different physiological and biochemical processes. The range of tolerated body temperatures is usually limited by the most temperature-sensitive process, which in many metazoans is neural function.

The proximate function of thermoregulation is to maintain T_b as close to the thermal optimum as possible within given physiological constraints of the organism and physical constraints of its environment. Physiological constraints which may limit the ability to maintain the optimum T_b are set by the rates at which heat is generated and retained by the organism. For example, low metabolic rates may limit the amount of metabolically generated heat available for thermoregulation, whereas the ability to retain body heat may be constrained by high surface-to-volume ratios in small animals or heat loss across the respiratory surfaces in aquatic organisms. On the other hand, physical constraints of the environment can make perfect thermoregulation energetically unfeasible even if physiologically possible due to excessive energy costs or limited access to food resources. Therefore, the degree of constancy of T_b as well as the nature of sources that are used for thermoregulation may greatly differ between the organisms. Based on the predominant sources of the heat used to maintain T_b, an organism can be classified as an ectotherm (i.e., predominantly using external heat sources to thermoregulate) or an endotherm (mostly relying on internal (metabolically generated) heat to maintain T_b). Irrespective of the nature of the heat sources used for thermoregulation, the end-result of it may be either (nearly)

☆*Change History*: March 2018. The author Sokolova updated section 'Metabolic heat generation' and 'Further reading.' Fig. 4 has been added.

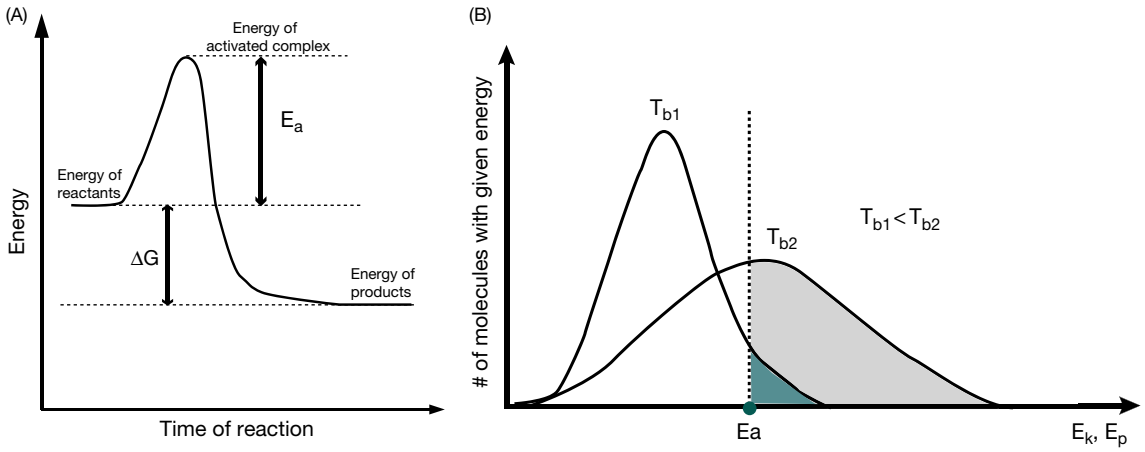

Fig. 1 (A) Activation energy (E_a) of a chemical reaction. ΔG—Gibbs free energy change of the chemical reaction. For the reaction to occur, the energy of reactants must be increased by the value of E_a, after which the reaction proceeds spontaneously. A key function of enzymes as biological catalysts is to reduce the activation energy barrier of activated complex and thus to facilitate biochemical reactions. (B) The rate of biochemical reactions increases with increasing body temperature (T_b) due to increase in the fraction of molecules with energy levels exceeding E_a.

constant T_b, in which case the organism is called a homeotherm, or T_b varying as a result of seasonal and/or diurnal changes in the habitat temperature, in which case the organism is classified as a poikilotherm. These two classification systems are closely related and complementary but not synonymous, as each provides different information about thermal physiology of an organism: the poikilotherm–homeotherm axis refers to the end result of thermoregulation, and the ectotherm–endotherm one—to the means by which it is achieved.

In practice, ectothermic thermoregulation is rarely efficient enough to provide the constant T_b, and most ectotherms are indeed poikilotherms (and vice versa, most endotherms are homeotherms). However, there are several important exceptions to this rule which emphasize that these two classification systems are best kept apart (Fig. 1). For example, a large group of aquatic ectotherms which live in thermally stable environments (such as some species of deep sea invertebrates, pelagic fishes and invertebrates of the open ocean, and Antarctic fish and invertebrates) are essentially homeotherms by the virtue of the constant temperature of their environments. Although lacking active physiological thermoregulation, these organisms have body temperatures that vary by $<0.5^{\circ}$C and are unable to withstand fluctuations of T_b exceeding a few degrees centigrade, similar to many "true" endothermic homeotherms such as mammals or birds. On the other end of the spectrum, several groups of endothermic animals are poikilotherms and experience large fluctuation of T_b under normal physiological and environmental conditions. In fact, most mammals and birds, which are endothermic homeotherms and maintain core T_b close to their physiological optimum (30–45°C for different species) as adults, are temporarily poikilothermic as neonates. Body temperature of newly born mammals and birds may significantly drop when parents leave the nest (by up to 8–10°C in some species) and return back to normal within minutes after the parents return to the nest to warm up the newborns. Some adult birds and mammals from temperate and polar climates can switch to temporary poikilothermy during hibernation or torpor. The degree of poikilothermy during hibernation varies; some species maintain their body temperature at a low but fairly constant set point whereas others allow T_b to follow that of the environment. Some small mammalian hibernators such as Arctic ground squirrels may allow their T_b to fall as low as -1.9°C. Finally, some endotherms (such as African mole rats and golden moles) retain true poikilothermy throughout their adult life. These highly specialized groups of mammals live in arid savannahs in a vast net of narrow burrows which they dig underground. Their bodies are permanently in a close contact with the walls of the burrows which results in a rapid conductive heat transfer between their bodies and the surrounding ground. Maintaining constant T_b would be energetically very expensive under these conditions, and the mole rats have evolved secondary poikilothermy permitting their body temperature to closely follow the temperature of the surrounding ground thereby reducing heat loss. In mammals, such poikilothermy is only possible in a thermally stable environment such as these underground burrows where variations of the temperature do not exceed a few degrees centigrade.

Biological Mechanisms of Thermoregulation (The "How")

Biological mechanisms of thermoregulation are grounded in the First Law of Thermodynamics, which creates physical basis for thermoregulation. The First Law states that the change of the internal energy of a system is equal to the heat added to the system minus the work done by the system. It implies that energy cannot be created or destroyed but it may be transformed or transferred between different systems (e.g., between an organism and its environment). As applied to thermoregulation, the consequence of this Law is that for any organism at any time, net rate of heat gain (ΔH) equals the rate of heat storage (ΔH_s).

$$\Delta H_s = \Delta H \tag{1}$$

For biological purposes, the net rate of heat gain (ΔH) can be broken down to construct a less rigorous but more physiologically meaningful equation of heat balance of an organism:

$$\Delta H_s = \Delta H_m \pm \Delta H_r \pm \Delta H_{cv} \pm \Delta H_{cd} - \Delta H_e \quad (2)$$

where H_s is total heat stored in the body, H_m—metabolically generated heat, H_r—heat gain or loss due to radiation, H_{cv}—heat gain or loss due to convection, H_{cd}—heat gain or loss due to conduction, and H_e—heat loss due to evaporation. If sum of all terms in the Eq. (1) equals to zero ($\Delta H_s = 0$), there is no net heat gain or loss in the organism, and its T_b is constant. In contrast, if ΔH_s is positive or negative, T_b of the organism will increase or decrease, respectively.

While the above outlined equation is in principle applicable to all living organisms, active thermoregulation is mostly restricted to animals and a few species of thermogenic plants, which will be focus of the following discussion. From the above equation it is also clear that thermoregulation can be achieved by physiological as well as by behavioral means using both external and external heat sinks and sources. There is no single mechanism of thermoregulation which works best in all environments, and different strategies can be equally efficient in providing regulation of T_b thus representing the many evolutionary ways to climb the same adaptive mountain.

Thermoregulation Using External Heat Sources

Conduction

Conductive heat transfer is transfer of heat down a temperature gradient between two bodies in close physical contact. The rate of conductive heat transfer depends on temperature gradient between the two bodies, the area of contact and the conductive properties of these bodies. In conductive heat transfer, heat always flows from the warmer body to the cooler one.

All organisms can manipulate conductive heat transfer to some extent, mostly through changing areas of contact between the body and the substrate (e.g., by changing posture) or selecting conductive properties of the substrate upon which they rest through habitat selection or use of insulating nesting materials. For example, penguins can reduce heat conduction from their feet to snow by standing on their heels and using tail feathers as a third point of a tripod to stabilize the posture. Because tail feathers have much lower heat conductivity than the feet, reducing of the area of contact between the feet and the snow greatly reduces heat loss to the environment. Many reptiles can press their body against a warm rock in order to gain heat or lift themselves from the cold substrate thereby reducing heat loss. In fact, if you have ever pressed your hands against a warm oven when you came back from a skiing trip or leaned with your cheek on a cool window pane on a hot summer day, you were using conduction to thermoregulate.

In endothermic mammals and birds, one of the most important long-term adaptations to minimize conductive heat loss is development of insulation, which reduces heat conductivity of the external body surfaces. These insulators can be internal (blubber, fat layer, internal air sacs) or external (feathers, furs, cuticular bristles). Typically, external insulation is much more efficient in preventing heat loss: for example, two centimeters of mammalian fur have about the same insulating properties as 60 cm thick layer of blubber.

Regional heterothermy is another adaptation to manipulate conductive heat flow, which involves regulation of the temperatures of exposed body parts in order to change the thermal gradient between the body surface and the environment in a desirable direction. In cold environments and especially in water where rapid conductive heat loss presents a danger, many species maintain the temperature of their extremities at a lower set point than the core T_b. For example, in otters, seals and arctic birds the temperature of feet, tails and flippers can be maintained at 15–20°C below the core T_b due to vasoconstriction and countercurrent heat exchange (Fig. 2). On the other hand, diving mammals can increase body flow to their flippers during extensive exercise to exhaust excess metabolic heat and to prevent overheating.

Convection

Convective heat transfer is the transfer of heat between two bodies by currents of moving gas or fluid. In free convection, air or water moves away from the heated body as the warm air or water rises and is replaced by a cooler parcel of air or water. In forced convection, air or water is forcibly moved across the body surface (such as in wind or wind-generated water currents) and efficiently removes heat from the body. Convection is a very efficient way of heat transfer because it maintains a steep temperature gradient between the body and surrounding air or water.

Evolutionary adaptations that prevent or enhance heat convection are important constituents of the mechanisms of thermoregulation. In mammals and birds from warm climates, forced convection plays a key role in preventing overheating of the body as heated blood moves from the core of the body towards the peripheral blood vessels where heat is dissipated to the environment. In cold climates, convective heat loss may be reduced by vasoconstriction of the peripheral blood vessels when exposed to cold, and especially by development of dense fur or down which creates a layer of still air next to the body and reduces convection currents. However, one of the most elegant examples how the convection principle was put to use to conserve metabolic heat, is represented by countercurrent blood circulation systems that have evolved independently in several groups of aquatic and terrestrial vertebrates. In countercurrent circulation, peripheral blood vessels are arranged in a spatially organized fashion in close proximity to each other forming nets called rete mirabile. In rete mirabile (the "wonderful net"), blood in arteries and veins flows in opposite direction, and the outward flowing arterial blood loses most of the heat to the colder inward-flowing venous blood (Fig. 2). The heat transfer between arterial and venous blood is very efficient due to the forced convection which maintains temperature gradient between arteries and veins. Therefore, when arterial blood reaches body surface, it has cooled down so that the temperature gradient between the blood and the environment is much lower than between the core body temperature and the environment, and the heat loss is reduced. Metabolic heat received by the venous blood from arterial blood is carried by the venous blood back to the body core.

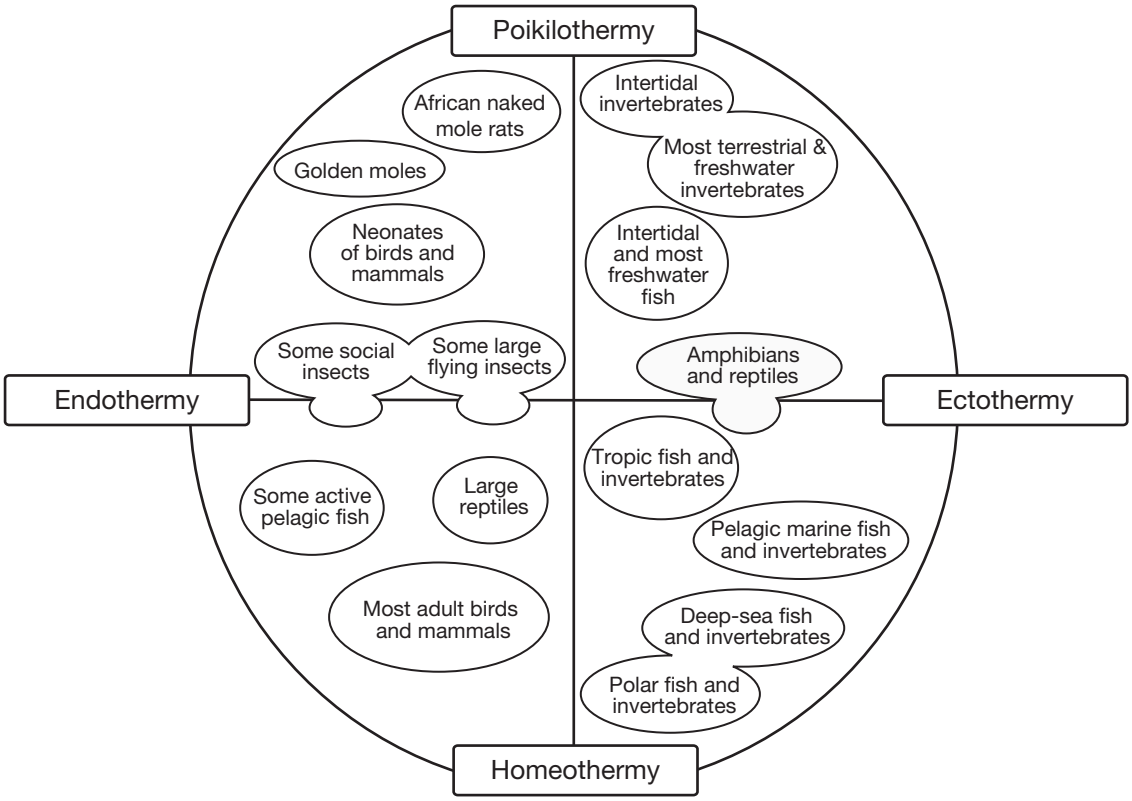

Fig. 2 Examples of organisms' classification in thermal biology based on the degree of constancy of their body temperature (poikilotherms–homeotherms) or on the heat sources used for thermoregulation (ectotherms–endotherms).

These countercurrent systems are used in extremities (feet) of many polar birds, in flippers of aquatic mammals and penguins, and in skin and peripheral muscles of tuna fish, allowing these animals to minimize heat loss despite high thermal conductivity and low temperature of their environments (Fig. 3).

Radiation

All physical bodies with temperature over absolute zero (0 K or −273°C) radiate energy in the form of electromagnetic waves. The wavelength of the radiated energy is directly dependent on the temperature: the hotter is the body, the shorter is the wavelength of the radiation, and the more energy can be transferred from that body to another one. Living creatures with the body temperatures between 0°C and 45°C radiate long-wave radiation in the infrared part of the spectrum thereby losing some of their body heat. They may also acquire heat from more heated objects radiating energy—the best example is sun radiation, which is widely used by both endotherms and ectotherms as an energetically "cheap" way to thermoregulate in cold environments.

In addition to behavioral adaptations to such as basking in the sun, physical properties of an organism may evolve to allow regulation of radiative heat exchange—in particularly, body color and reflective properties. Typically, darker bodies absorb more visible and infrared radiation than the light-colored ones, therefore increasing the rate of heat gain from the environment. For example, some insects and reptiles show latitudinal clines in body coloration with increasing frequency of dark morphs towards high latitudes. In some organisms variation in body coloration is associated with different microclimates on a small spatial scale. Thus, in intertidal snails light-colored morphs are often found on open, sun-lit rock surfaces whereas darker morphs are found in shady crevices, under stones and seaweeds. In some white morphs from open-rock habitats the shell surface consists of a highly reflective calcium carbonate layer which reflects >95% of radiation. This helps snails to prevent overheating during low tides when solar radiation is intense and heat loss is reduced in less conductive aerial environment. However, the relationship between body color and climate is by no means straightforward and should be treated with caution. Firstly, reflectance of the body surface is not always a direct function of color; for example, white and dark human skins have approximately same reflective properties. Similarly, shiny black insect cuticles have nearly the same reflectance as that of the pale matte counterparts. Most importantly, body coloration has many other important functions such as crypsis, mate choice and visual signals to conspecifics or potential predators which may conflict with thermoregulation—hence there are as many exceptions to the "darker in the cold" pattern as there are instances of it (consider for example white polar bears, or snowshoe hares which have dark fur in summer and white—in winter).

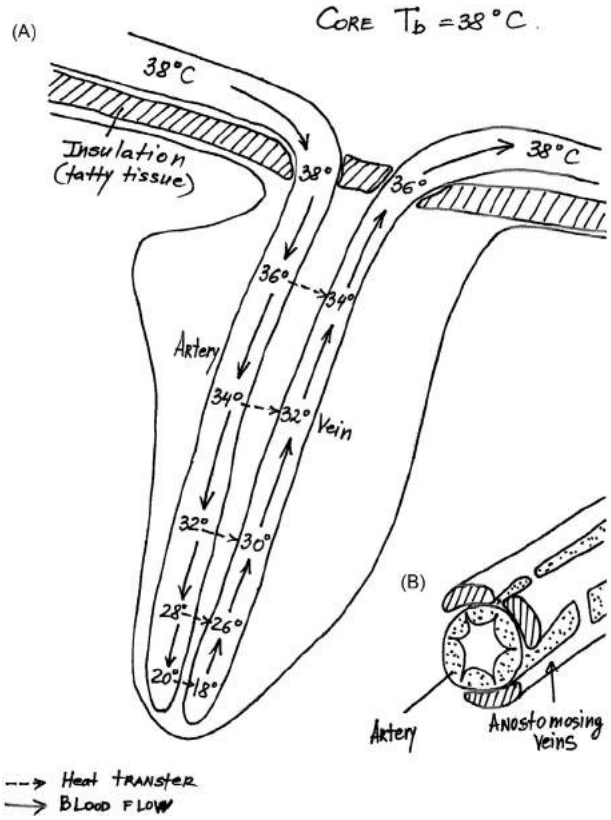

Fig. 3 A schematic representation of blood countercurrent in a penguin flipper (A) and an example of spatial arrangement of blood vessels (B) in rete mirabile.

Evaporation

Evaporation is an efficient means to get rid of the excessive body heat, which can be used by terrestrial and intertidal organisms. Due to high latent heat of vaporization of water (2.5 kJ g^{-1} at 0°C and 2.4 kJ g^{-1} at 40°C), evaporation carries off a significant amount of heat energy from the surface of the body, thereby effectively cooling it. However, using evaporation for cooling has an associated cost of high water loss. Along the latitudinal climatic gradient, evaporation is mostly used by organisms from cold or temperate climates, where water losses can be easily replenished. In arid climates where access to water is limited, evaporation is minimized and its role in thermoregulation is low due to the high risk of dehydration (although some level of evaporation is inevitably present due to gas exchange at the respiratory surfaces). This gradient in use of evaporation for thermoregulation is found not only along the large-scale climatic gradients but also on small scale—for example, along the vertical shore gradient in the intertidal zone of seas and oceans. In the low intertidal horizons where animals have regular access to water, they have developed behavioral adaptations preventing overheating by evaporation from the body surface that allow them to remain active during the low tide. In contrast, high-shore species which may be covered by water only once or twice in a fortnight during spring high tides, avoid evaporation by becoming inactive and isolating themselves from the environment in shelters or within the shells, which often leads to extremely high body temperatures, often in excess of 35–40°C during low tide.

Thermoregulation Using Internal Heat Sources

Metabolic heat generation

Due to the constraints on energy transformations imposed by the laws of thermodynamics, dissipation of energy in the form of heat is an inevitable by-product of metabolism in all organisms. Background metabolic heat production due to the intrinsic "inefficiency" of metabolic systems can be quite high and is similar in ectotherms and endotherms. For example, it is estimated that only about 40% of energy released during catabolism of glucose is conserved in the form of ATP, and 60% is released as heat. However, the amount of metabolic heat generated by ectotherms or endotherms is different due to the differences in the overall rates of metabolism. Most ectotherms belong to so called bradymetabolic organisms (Greek *brady-*, slow), which have low metabolic rates. In ectotherms, metabolic heat gain is insufficient to significantly increase the T_b in the face of the constant heat loss to the environment. In contrast, endotherms are typically tachymetabolic (Greek *tachy-*, fast), that is, characterized by high rates of metabolism, which allows them to use metabolic heat to maintain T_b above that of the surroundings. These differences in the rate of living are due to the intrinsic properties of metabolic machinery of ectotherms and endotherms and are not a simple reflection of

the difference in the body temperature. Even at the same T_b and size, metabolic rates of endotherms are 4–5 times higher than in ectotherms.

Endotherm adaptations to thermoregulation essentially represent evolutionary modifications of the biochemical systems, whose original functions were ATP synthesis, locomotion, ion transport or antioxidant defense. Typically, these modifications involve futile cycles or short circuits in energy production and ATP turnover, which allow these systems to "waste" energy in the form of heat for thermoregulation. In small mammals (such as rodents), all newborn mammals and mammalian hibernators during arousal hibernation, a major site of metabolic heat production is a specialized thermogenic tissue called brown adipose tissue (BAT). BAT is a highly vascularized tissue, rich in mitochondria (which give the tissue its characteristic brown color) and fat depots. The main function of BAT mitochondria is not ATP production, but generation of heat for thermoregulation through futile proton cycling, in a process called non-shivering thermogenesis. BAT mitochondria contain high levels of so called uncoupling protein 1 (UCP1), or thermogenin, which greatly facilitates proton conductance (so called proton leak) in BAT mitochondria. Due to the mitochondrial proton leak, the electrochemical gradient created by the electron transport chain is dissipated by UCP1 bypassing the mitochondrial ATP synthase; thus, besides the heat production, no other useful work is done. Heat generated during this process is carried out of the BAT by a well developed vascular net and distributed through the rest of the body.

Although BAT seems to be a strictly mammalian evolutionary invention, mitochondrial heat generation is used by other organisms for endothermic thermoregulation. In some thermogenic plants such as lotus and arum lilies, large amount of heat is produced in flowering parts to enhance production and volatilization of floral scents to attract pollinators and/or to prevent freezing of the plant reproductive organs. This elevated heat production is also largely due to the futile mitochondrial proton cycling, which is achieved by a mechanism very different from that of BAT—namely, through branching of the electron transport system (ETS) in the inner membrane of mitochondria to an enzyme called alternative oxidase (AOX) instead of cytochrome *c* oxidase. This alternative electron pathway bypasses energy-conserving sites of the ETS thus reducing the electrochemical proton gradient across the membrane and releasing chemical energy as heat. Uncoupling proteins homologous to UCP1 are also found in plants and may play a role in heat production, although their thermogenic function has not been unequivocally confirmed in plants. The arum lilies and sacred lotus can use the mitochondrial thermogenesis to increase temperature in their flowering parts up to 25–35°C above their surroundings, and to maintain it at a fairly constant temperature despite environmental fluctuations. In fact, metabolic rates and heat output in some of those plants can exceed those of the most active endotherm animals such as hummingbirds.

A significant proportion of metabolic heat generation is produced during locomotion and other types of muscular activity. In vertebrates, muscles represent 1/3 of the total body mass and have among the highest rates of ATP turnover of all tissues. Heat generated during muscle contraction provides a significant contribution to the overall metabolic heat production in endotherms. In fact, several species from predominantly ectotherm lineages (such as fishes) have developed regional or complete endothermy solely based on the muscle-generated heat. For example, in some highly active pelagic fish such as tunas and lamnid sharks, metabolic heat generation in white muscle is sufficient to maintain core T_b at a fairly constant level 10–15°C above the temperature of the surrounding water—a very impressive physiological feat given limitations of ectotherm metabolic heat production and high thermal conductivity of water. This locomotion-based regional endothermy is supported by morphological and anatomical adaptations such as the countercurrent retia mirabilia vasculature in the muscles and the gills which prevents excessive heat loss, and the fact that white muscles in tuna fish are located deep within the body and covered by a layer of the red muscles providing insulation to the heat-generating white muscle. A countercurrent heat retention system also helps maintaining the brain and eye temperatures of tunas at 5–6°C above the ambient. Despite these adaptations that keep the muscle and the brain warm, the rest of the sharks' and tunas' body remains at near the ambient temperature. Notably, the same mechanisms that result in regional endothermy in tunas and lamnid sharks (i.e., heat gain by locomotion combined with the heat conservation by insulation and counter-current retia mirabilia) led to the whole-body endothermy in at least one large species of pelagic fish—the moonfish, or opah (Fig. 4). In the opah, large amounts of metabolic heat are produced by the contraction of the massive pectoral fin muscles

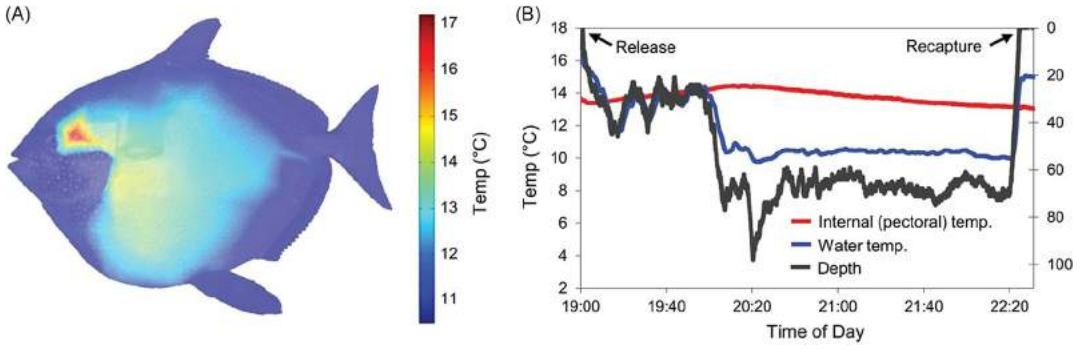

Fig. 4 Whole-body endothermy in the opah, *Lampris guttatus*. (A) In situ internal temperature profile (~4–5 cm below the skin) of an opah at an ambient temperature of 10.5°C. (B) In vivo pectoral muscle temperature for an opah swimming at depth. In both examples, large fish (39–40 kg body mass) were measured. Figure reproduced from Wegner N.C., Snodgrass O.E., Dewar H. and Hyde J.R. (2015). Whole-body endothermy in a mesopelagic fish, the opah, *Lampris guttatus*. *Science* **348**, 786–789 with permission from the American Association for the Advancement of Science.

(constituting 16% of the total body mass and nearly 40% of the total muscle mass) propelling the fish forward. The heat-generating muscle is insulated by a thick layer of fatty connective tissue, and heat is further conserved by the unusually extensive and tightly coupled retia mirabilia inside the gill that warm the oxygenated blood from the gills as it enters the body. To date, the opah is the only known fully endothermic fish species.

Heat generation due to the muscle contraction is also used by birds and mammals facing cold stress in so called shivering thermogenesis. Here an old mechanism of locomotion has been evolutionary modified to perform a new function of thermogenesis. Similar to a decoupling of ETC function from ATP synthesis in non-shivering thermogenesis, the mechanisms of increased heat production in shivering thermogenesis involve decoupling of ATP turnover from locomotion in contracting muscles. During shivering thermogenesis, sympathetic neural system activates actomyosin ATPases in locomotory muscles, but this activation results in uncoordinated small muscle contractions rather than locomotion. Interestingly, in some social insects (such as bees) elevated temperature of the colony can be maintained by a mechanism analogous to collective shivering thermogenesis brought about by rapid uncoordinated contractions of flying muscles of numerous workers in the hive. As a result of shivering thermogenesis, there is significant stationary heat generation but no net movement. The drawback of this mechanism is that it prevents locomotion, which may conflict with other functions such as search for food or escape from predators.

Muscle ATPases are also used as heat-generating engines in cranial heater organs which provide local endothermy to eyes and brain of some fish species such as marlins, swordfish and the butterfly mackerel. However, the futile ATP turnover which generates heat in these organs uses Ca^{2+} ATPases of endoplasmic reticulum (ER) rather than actomyosin ATPases. Neural stimulation results in massive release of Ca^{2+} from the ER of the cranial organ cells which is then pumped back using ATP. ATP is replenished by mitochondrial oxidative phosphorylation. The cycle is repeated as long as the neural stimulation is present using up ATP and resulting in heat generation. The cranial heat organs allow maintaining the brain and eye temperature fairly constant and 10–15°C higher than the temperature of the surrounding water thus providing sustained neural function in the cold and allowing these fish to hunt deep-living prey such as squid. Similar futile Ca^{2+} cycling can also lead to a pathology if runs uncontrolled—for example as in malignant hyperthermia, a genetic disorder in humans and pigs caused by a mutation of the Ca^{2+} release channel in the endoplasmic reticulum (so called ryanodine receptor). Under certain conditions (such as during stress or anesthesia) massive abnormal Ca^{2+} release may occur in the mutation-bearers resulting in intense thermogenesis and hyperthermia.

Endothermic thermoregulation offers many ecological advantages including a greater degree of autonomy from the thermal environment, ability to maintain nocturnal activity, high locomotory performance and stable levels of neural activity. However, it also comes at a considerable cost. High rates of heat loss in small animals due to high surface-to-volume ratio require high metabolic rate and access to plentiful food resources in order to maintain endothermy. In aquatic habitats, high heat loss is inevitably associated with respiratory gas exchange—the heat transfer across the gill surfaces occurs at 50 times higher rate than gas exchange. Some endothermic adaptations for thermoregulation (especially those using futile ATP or proton cycling) may conflict with other fitness-related functions of an organism diverting energy from growth, reproduction or locomotion to energetically "wasteful" heat generation. In contrast, ectothermy is associated with much lower costs of living and allows for a smaller body size, which provides access to ecological niches unavailable to endotherms. In fact, ectothermy appears to be a superior evolutionary strategy in many environments, and 99.9% of species on this planet are ectotherms.

Tolerance Range

AJ Cullum, Creighton University, Omaha, NE, USA

Introduction

The ability of an organism to survive and reproduce in a particular habitat depends on both the biotic and abiotic components of its environment. While the combination of all these components define the organism's ecological niche, the more specific term tolerance range can be used to define the maximum and minimum values of a particular abiotic variable that the organism can withstand. While it may seem obvious to the modern student of ecology that any number of abiotic factors may limit the fitness and distribution of species, this idea was not well developed until the publication of F. F. Blackman's law of limiting factors in 1908 and Victor Shelford's law of toleration in 1913. These laws included for the first time the concept of a minimum and maximum limit of toleration for different aspects of the environment.

The Physical Environment

The tolerance range of an organism can be defined for any of the abiotic – that is, nonliving, or physical or chemical – components of its environment. Abiotic variables commonly examined in this context include temperature, osmolarity or salinity, pH, oxygen and carbon dioxide levels, relative humidity, light levels, wind and water currents, hydrostatic pressure, and the levels of various specific ions, compounds, and toxins. These factors have been of interest because they tend to have significant effects on biological processes and hence on fitness. Some of these variables are relevant to all types of habitats (e.g., oxygen levels), while others obviously apply only to a subset (e.g., relative humidity to terrestrial environments). Additionally, some factors may be very stable in one type of habitat but highly variable in others (e.g., temperature in the ocean benthos versus temperature at the soil surface in a desert). One characteristic of all these variables, however, is that they can reach levels that will begin to have a significant impact on the fitness of organisms (see the section titled `Fitness effects'). When abiotic variables reach these levels, they are sometimes referred to as stressors. But note that a condition that might be stressful for one species may be benign for others.

Although all of the factors listed above have been investigated to some degree in the context of tolerance, by far the most widely studied aspect of the abiotic environment in this regard is temperature. There are a number of reasons for this. One is that temperature is a factor that is relevant to environments of all types and that has profound effects on living things. Another reason is that it varies tremendously across the inhabited environments of the earth, with organisms metabolically active at temperatures ranging from -70 to $+130$ °C. Third, temperature has the interesting property that, below about 0 °C, it causes a phase change in the primary component of both living things and many habitats (i.e., liquid water changes to ice). Finally, temperature can be measured easily in almost any habitat and manipulated easily for experimental purposes. As a result, the most complete descriptive and explicative data on tolerance ranges are for temperature, and thus many of the examples in this article, though not all, will relate to this variable.

Fitness Effects

In general, the tolerance range of an organism or population for a particular variable can be defined by the upper and lower limits at which some minimum level of fitness is achieved. (For the purposes of this article, the term `fitness' will be used in the broad sense (i.e., including both viability and fecundity) rather than the stricter Darwinian sense (i.e., inclusive fitness).) The relationship between fitness and an abiotic factor is normally one in which organisms exhibit maximal fitness over a limited range, with fitness decreasing the further outside this optimal range the abiotic factor varies. This relationship between an abiotic variable and fitness can be termed a tolerance or fitness curve; a hypothetical example is shown in **Fig. 1**. Typically, the term tolerance range is used to indicate the critical minimum and maximum values of the abiotic variable that allow long-term (i.e., effectively indefinite) survival (**Fig. 1**). In some cases, however, the term may reflect alternate levels of tolerance, and the limits for the range will almost always be different as a result. In the context of population sustainability or distribution, for example, the tolerance range would be defined by the limits at which individuals can reproduce (**Fig. 1**). Consider the brown alga *Tinocladia falklandica*, which can survive water temperatures up to 28 °C, but is restricted to the southernmost coasts of South America because reproduction does not appear to occur above about 15 °C. In other contexts, tolerance may be defined by short-term rather than long-term survival. Many insects, for example, can survive temperatures below 0 °C for no more than 24 h; however, if temperatures drop below freezing only at night and are warmer during the day, then long-term survival at such temperatures would not be necessary for long-term survival in this habitat.

Although this article focuses on the concept of tolerance range, it is worth considering a few points about tolerance curves. First, a more complete description of an individual or population's pattern of fitness across an environmental gradient can be provided by a complete tolerance curve, such as those shown in **Fig. 1**, rather than a simple tolerance range. But while tolerance curves offer

 doi:10.1016/B978-0-444-63768-0.00556-4

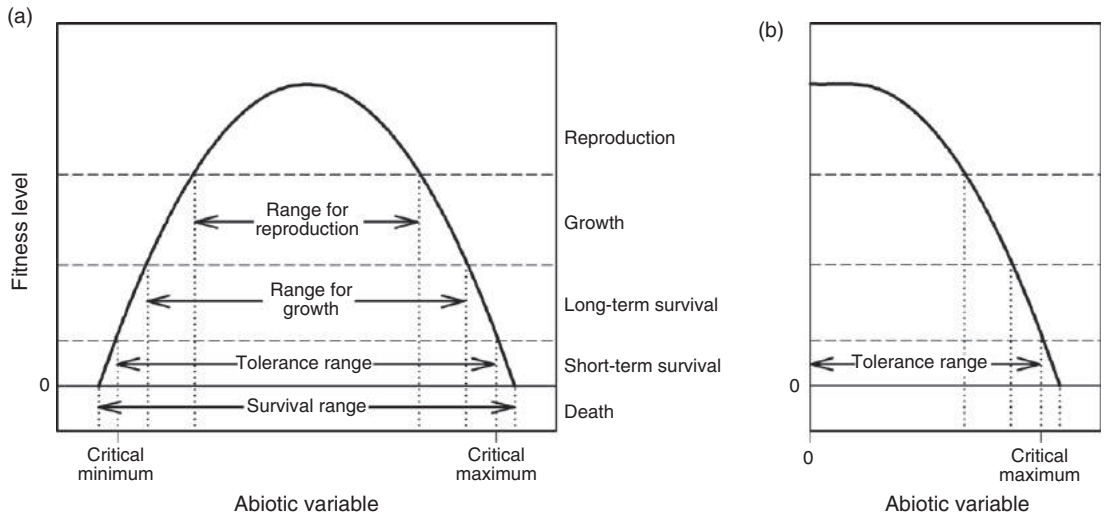

Fig. 1 Tolerance curves showing organismal fitness as determined by the value of an abiotic variable. The tolerance range for a variable is normally defined by the critical minimum and critical maximum values that allow long-term survival by the organism. Other fitness ranges of ecological significance include the survival range, representing the limits at which the organism can survive for brief periods, and the ranges over which reproduction or growth can occur. (a) A bilateral tolerance curve, with reduced fitness on either side of an optimum abiotic range. Such a curve might be seen for temperature or pH. (b) A unilateral tolerance curve, with optimal fitness when the abiotic variable is at or near zero, and declining as the variable increases. Such a curve might be seen for various toxic compounds.

the advantage of providing a specific fitness level for any value of an abiotic variable, tolerance ranges offer two more practical advantages. One is that they are relatively easy to determine, especially at the level of survival. It is much easier to conduct experiments to determine simple lethal limits than to derive detailed measures of fitness across the full range of an abiotic variable. The second is that they are much more concise to define, which can be useful for providing summary information.

A second point about tolerance curves concerns their shape. Note that Fig. 1a shows a symmetrical relationship between fitness and the abiotic variable on either side of an optimal value. However, for many variables the shape may be considerably skewed. In the case of temperature, for example, fitness may decrease much more rapidly on the right side of the curve (high temperatures) than the left (low temperatures). In the case of some variables, such as environmental toxins, the curve may be truncated; that is, maximal fitness is at a toxin concentration of zero, with decreasing fitness as concentrations increase (Fig. 1b).

Tolerance Ranges: Examples for Temperature

A complete review of tolerance ranges for all significant abiotic factors is beyond the scope of this entry. A brief discussion of some limits associated with temperature, however, will help to illustrate some of the patterns that may be seen for many abiotic variables.

Eurythermal species

The prefix eury- is used to indicate species with a wide tolerance range, in this case for temperature. Because organisms must be able to survive in an environment in order to persist in it, most species from habitats with moderately to highly variable temperatures are eurytherms. For aquatic environments, these habitats include shoreline areas and all but the larger freshwater bodies. Animal from these habitats can typically survive temperature ranges of 20 °C or more, and some can survive freezing temperatures. Terrestrial habitats can show an even greater temperature range, in some locations more than 75 °C, and there are birds and mammals that can tolerate this range (but the body temperatures of these endotherms do not, of course, vary by this magnitude). Among ectotherms, a more typical eurythemal range would be about 30 °C for long-term survival.

Stenothermal species

Among the most invariant thermal environments are those in the open ocean, particularly at depth or in polar regions. Species from these habitats typically have narrow thermotolerance ranges, with perhaps the narrowest being the notothenioid fishes of the Antarctic that survive only over a range from about -2 to $+4$ °C. Some freshwater and terrestrial microhabitats also have relatively constant temperatures, and in general tropical regions show less temperature variation than temperate regions. Species from these relatively stable habitats thus tend to have narrower tolerance ranges than those from more variable environments. Many coral species, for example, are having their upper tolerance limits exceeded by increases in ocean temperatures of as little as 1 °C.

Extreme limits

Organisms that thrive at high temperatures are known as thermophiles. Among terrestrial animals, sustained temperatures of 45 °C in vertebrates (the desert pupfish *Cyprinodon*) and 54 °C in arthropods (the desert ant *Cataglyphis*) represent known upper tolerance limits. A few invertebrates from deep-sea hydrothermal vent habitats appear to regularly tolerate temperatures of 60 °C or more. Some desert plants can also tolerate tissue temperatures up to 70 °C for part of the day. Thermophilic algae and fungi can tolerate about 60 °C, and eubacteria about 70 °C. But by far the most extreme thermophiles are among the archaea; the current record is held by a species known as `strain 121', also a hydrothermal vent species, which grows at 121 °C and survives 131 °C.

Cold-adapted organisms, or psychrophiles, are somewhat less variable in the range of limits seen, in large part because of the tendency of water to solidify below about 0 °C. Many species from all kingdoms do well at down to about −2 °C or so. Below this, species may survive but most become inactive, although some organisms remain metabolically active below −10 °C. Cold-adapted endotherms can, of course, stay active at low temperatures by maintaining much higher body temperatures; some mammals survive temperatures as low as −70 °C. In the inactive state, a variety of invertebrates can survive temperatures of −30 °C or lower, and some plants as low as −200 °C. Many single-celled organisms, as well as nematodes and tardigrades, can survive temperatures of −269 °C, or just above absolute zero.

Functional Determinants of Tolerance Limits

One of the most obvious questions to ask about the tolerance range of an organism or species is what determines these particular limits. This type of question had traditionally been addressed by physiologists or biochemists, but as biological inquiry has become more integrated across fields of study, many ecologists have taken a more direct interest in the underlying reasons for tolerance limits.

Physiological Mechanisms

Cells that live independently or as part of very simple multicellular organisms must be able to tolerate directly the range of abiotic environments they encounter if they are to survive (see below). More complex multicellular organisms, however, have the potential to provide an internal environment (a term coined by the famous nineteenth-century physiologist Claude Bernard) that differs from the external environment. Thus the osmolarity, solute composition, pH and even temperature of interstitial fluid, blood, and/or hemolymph of an organism can be maintained at levels different from those of the organism's habitat. This differentiation of the internal state from the external conditions occurs through active physiological regulation of the variable or variables in question, and organisms that maintain such differentiation are referred to as osmoregulators, thermoregulators, etc., as appropriate to the regulated variable. Not all variables need be regulated, however, and the term conformer is applied to organisms that allow an internal state to be at equilibrium with the environment.

For any abiotic factor for which an organism shows conformation, survival in a range of environments requires that cellular mechanisms (discussed below) be tolerant of this range, because internal conditions are similar to external ones. When a variable is regulated, on the other hand, this offers the advantage that individual cells need be tolerant of only a limited range of conditions for the variable in question. Organisms with strong regulation of a variable therefore tend to be able to tolerate a greater range of conditions than a conformer would, and increased regulatory ability has generally meant an increased ability to colonize habitats, such as dry terrestrial environments, that are unfavorable for simpler eukaryotic life.

Given the ability to regulate a variable, then, why do organisms still show some limit to their tolerance range? The general reason is that any regulatory system has a finite capacity to adjust rates of influx and efflux, and if the difference between the organism's internal and external conditions becomes too great, the regulatory system is overwhelmed and regulation fails. Once this occurs, an organism may experience a very rapid decline in fitness, because individual cells may be relatively intolerant of changing conditions.

Even in cases where regulation is possible over the short term, it may be unsustainable energetically. Regulation is an expensive process, and organisms in unfavorable habitats may spend more energy on regulation than they are taking in from the environment. Under these conditions, an individual may be able to live for a limited period of time, but the energy imbalance would make long-term survival impossible.

Biochemical and Cellular Factors

In organisms that either do not regulate a particular abiotic variable (see above) or in which regulation has failed, processes occurring at the cellular level must be tolerant of the changing values of this environmental factor. In cases where tolerance is not possible, injury or death is likely to occur. The particular reasons that cells reach their tolerance limits are, not surprisingly, quite variable, depending on both the environmental factor and the species involved. However, there are two general aspects of cellular biology that are influenced by many abiotic factors and thus merit a brief examination: enzyme activity and membrane biology.

Enzymes

Enzymes are the crucial catalysts in biochemical pathways, and hence are involved to some degree in just about all cellular activities. Changes in the amount of activity exhibited by a particular type of enzyme can cause a pathway to show increased or decreased throughput due to the catalytic effect on reaction rates. While in some cases such biochemical changes may be part of normal cellular control mechanisms, in other cases they can cause significant problems by limiting or bringing to a stop vital cellular processes.

The rate of an enzymatic reaction depends to a significant degree on the enzyme's molecular flexibility. To be effective in catalyzing a reaction, enzymes must have a relatively stable structure in order to present appropriate binding sites to reactants, but must also be flexible enough to rapidly undergo the changes in conformation necessary to allow the reaction to occur. Too much or too little flexibility causes an enzyme to show decreased activity. Temperature is well-known to affect protein flexibility, but pH, ion concentrations, and hydrostatic pressure also influence enzymes in this way. If changes in the organism's environment bring about intracellular changes in these variables, the result can be that enzyme stability and hence activity is affected. As these effects begin to disrupt cellular biochemistry, fitness will decrease.

Membranes

Biological membranes serve two key roles in cellular biology. One is to allow compartmentalization, both of cytosol for the cell as a whole and for the contents of individual organelles. The other is to support membrane-bound proteins and other molecules that allow generation of ATP, cell signaling, and the controlled transport of materials in and out of the cell, among other functions. Just as enzymes must exhibit an appropriate level of flexibility in order to function, biological membranes must exhibit appropriate levels of fluidity and phase structure to function. Even moderate changes in membrane fluidity can influence the permeability of the membrane to different solutes and the function of membrane-bound proteins. This in turn can lead to disruption in the ability of cells to maintain cytostolic composition, carry out some biochemical reactions, and gather information from the extracellular space.

The fluidity of a membrane is determined in part by its composition and in part by abiotic variables. Again, it is temperature that has the most well-characterized influence, with increasing temperature causing membranes to become more fluid. But as before, other environmental factors also affect the membrane's state, with pH, hydrostatic pressure, and the concentration of various solutes all influencing fluidity. When changes in fluidity begin to affect the viability of the cell, the organism may have reached its tolerance limit.

Behavioral Tricks

Tolerance limits that exist at the physiological or biochemical level may often be avoided by behavioral responses that can effectively alter the abiotic environment. Even when constrained to a particular macrohabitat, motile organisms may find more favorable conditions by the selection of an appropriate microhabitat. For example, many terrestrial animals make use of burrows to avoid high or low temperature extremes that may occur above the soil surface. Other types of behavioral strategies can also effectively increase tolerance limits, such as when some fish gulp air and force it across their gills if their aquatic environment becomes too hypoxic. Even relatively or completely sessile organisms can use behavior to effectively increase the range of environmental conditions they can withstand. For example, some desert plants change the orientation of their leaves to the sun during the day to avoid cellular temperatures that would damage living tissue.

Changes in Tolerance Range

The tolerance range or tolerance curve of an individual or a population may change over time. In the case of individuals, such changes are normally strictly phenotypic, with no alteration of the genome; the general term for this type of change is phenotypic plasticity. Shifts in tolerance ranges of populations or species over multiple generations, on the other hand, can include a genetic component and thus represent evolutionary changes.

Changes in tolerance range, whether genetically based or strictly phenotypic, could occur in a number of potential ways. Consider an example in which an organism or population experiences a change in its environment, with the level of an abiotic variable increasing as a result. Some of the possible changes in the pattern of tolerance are shown in Fig. 2. The result might be an increase in the optimum level of the variable as well as in increase in the upper and lower tolerance limits (Fig. 2a), or an increase in the optimal level with an increase in just the upper tolerance limit (Fig. 2b), or an increase in just the optimal level with no change in tolerance limits (Fig. 2c). Other patterns, including intermediates between some of these examples, are also of course possible.

Phenotypic Plasticity

Many organisms have the ability to alter some aspects of their biochemistry, physiology, and/or morphology in response to changes in the abiotic environment, or in anticipation of such changes, thus modifying their tolerance range. These modifications may take as little as a few minutes or as long as several months or even years (but always within the lifetime of the individual), and may be reversible or may be

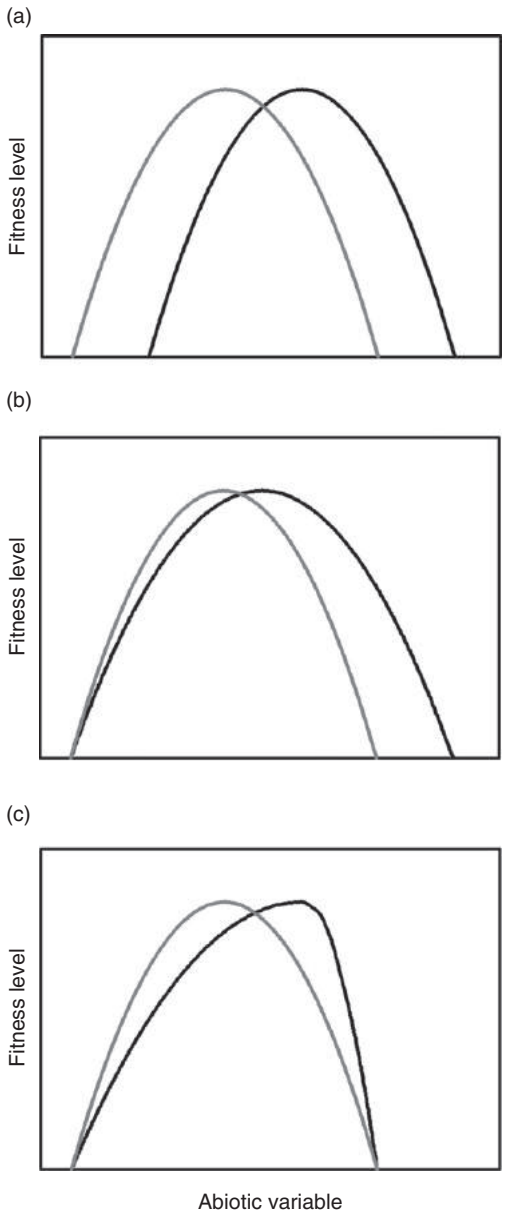

Fig. 2 Potential changes in tolerance curves due to phenotypic plasticity or evolution. Gray curves represent the initial curves, black curves the shifted curves. (a) A shift in the tolerance curve that results in an increase in both the critical minimum and maximum as well as optimal fitness value. (b) A shift in the tolerance curve that results in an increase in just the critical maximum and optimum. (c) A shift in the tolerance curve that results in an increase in the optimum but not in the critical minimum or maximum. These patterns represent just a few of the possible changes that could occur.

permanent. Although the general term phenotypic plasticity can be applied to any such changes, specific classes of change are recognized. Two of the more common such classes are acclimation and developmentally related changes.

Acclimation

Some responses to environmental change occur very quickly; these are normally considered part of cellular or physiological regulatory mechanisms and can be classified as acute responses. The term acclimation, on the other hand, is applied to organismal changes that may take longer to occur. Formally, acclimation refers to a response to changes in a single abiotic variable such as would occur in a controlled laboratory environment, while acclimatization refers to a response to changes in multiple variables such as occurs in nature during, for example, seasonal or altitudinal changes. Often, however, the term acclimation is used to cover both meanings, and that will be the convention here. (To add to the confusion, the term adaptation is sometimes used to refer to these sorts of phenotypic changes, especially by organismal biologists such as physiologists. Additionally, the terms heat-hardening and cold-hardening are also sometimes used to indicate temperature acclimation.)

Acclimatory responses tend to be especially common in organisms that experience large changes in environmental conditions on a regular basis. Although these responses are normally associated with physiological or morphological changes that may take days or weeks in response to seasonal changes, they may also occur in the space of an hour in response to daily environmental fluctuations. Other changes in organisms may take months or more and involve longer-term environmental changes. Whatever their timecourse, acclimatory changes are generally reversible, but there are some exceptions to this trend.

In the context of tolerance ranges, an acclimatory response to changed conditions by an organism would mean a shift in the tolerance curve (**Fig. 2**). The use of the term acclimation typically implies that this shift is favorable to the organism, by improving its fitness under the new or even more extreme conditions. Thus conditions that previously would have been lethal may now be tolerable. For example, sheepshead minnows that have been living at 21 °C for an extended period lose neurological function at 40.1 °C. But if allowed to acclimate for 30 days to 38 °C, a temperature near but still below their original upper thermal limit, this thermal limit increases to 44 °C. Thus a period of pre-exposure to an environmental change can provide a favorable change in tolerance limits, allowing an organism to survive or thrive in conditions that previously would have been detrimental or fatal. Note however that the magnitude of change in tolerance limits may be significantly smaller than the magnitude of change in environmental conditions.

The mechanisms by which acclimatory changes in tolerance occur are variable, but generally depend at least in part on factors discussed in the section titled `Functional determinants of tolerance limits'. In response to a change in an abiotic factor (or in some other variable that helps to predict a change in this factor) organisms can make partially or fully compensatory changes in enzyme activity by activating or deactivating existing enzyme molecules, synthesizing or degrading more molecules, or expressing different isoforms of an enzyme. They may also make changes in membrane composition to return them to appropriate levels of fluidity (a process known as homeoviscous adaptation). In addition, some short-term expansions of tolerance ranges can be achieved through increased synthesis of stress proteins (sometimes called heat shock proteins), which help to stabilize other molecules under conditions that would otherwise tend to cause them to denature or otherwise lose functionality.

The benefit provided by an acclimatory shift in tolerance range may not be without potential tradeoffs, however. Such tradeoffs may occur in several ways. First, any improvement in tolerance at one end of the range often involves a decrement to the tolerance limit at the opposite end of the range (**Fig. 2a**). In the case of the temperature acclimation by minnows discussed above, the lower critical limits for normal function also increased with increased acclimation temperature, from 6.9 °C in the 21 °C-acclimated fish to 11.3 °C in the 38 °C-acclimated fish. Thus colder temperatures that would not have been effectively lethal originally become so as the tolerance range shifts upward. A second cost can result from the expression of stress proteins. Although they allow survival in what might otherwise be lethal conditions, their expression in large amounts can have effects on growth and fecundity that persist even after the organism has returned to more benign conditions.

Note that acclimatory responses may not occur at all in many species, especially those that do not normally experience the sort of variation in the abiotic environment that could select for phenotypic plasticity. Thus these organisms have never evolved, or have secondarily lost, the cellular and physiological mechanisms that underlie the ability to change tolerance ranges. Also, although the term acclimation typically designates a beneficial change in a tolerance range or curve, in some cases the opposite pattern of change can result; that is, pre-exposure to an environmental change may actually decrease an organism's ability to survive further change. For example, while mayfly larvae (*Zephlebia dentata*) kept at 20 °C had higher survival rates at 26 °C than those kept at 15 °C, the opposite pattern was seen for stonefly larvae (*Zelandobius furcillatus*), with lower survival rates at 26 °C in the group kept at 20 °C than those kept at 15 °C. Again the reason for such a loss of tolerance may vary from case to case, but two likely causes are stress-based injury of cells and tissues, or the additional metabolic cost of compensating for the acclimation conditions, with a resulting reduction in energy reserves for surviving the more extreme conditions.

Development

Organisms may show substantial changes in their tolerance range for one or more abiotic factors during ontogeny. Some of these changes may be due to acclimatory responses, as discussed above; that is, different life stages may show different tolerances simply because each stage is acclimating to the different conditions in which it finds itself. If the environmental conditions were held constant, then the tolerance range would not change. One important aspect of acclimation that takes place during development, however, is that physiological or morphological changes that may occur in response to different conditions are more likely to be irreversible than are acclimatory changes in mature organisms.

Other changes in tolerance during development, however, are genetically programmed; that is, they occur to at least some degree regardless of the environment in which the organism actually finds itself. One major reason that such canalized changes in tolerance evolve is that they help prepare individuals for the conditions they will likely encounter at different life stages; that is, they are anticipatory rather than reactive. An example of this is the increase in salinity tolerance that is seen in some salmon species, such as the chum salmon, that occur just prior to the migration of young to marine environments.

Evolutionary Changes

Evolutionary changes in tolerance range (i.e., those having a genetic basis) will generally occur at the level of populations or species rather than individuals. When changes in the abiotic environment occur, populations must be able to survive and reproduce under these new conditions; those that fail to adapt will not persist. Thus a combination of successful adaptation and

extinction means that, over long timescales, species generally show tolerance curves that are suitable, if not optimal, for their habitats; this pattern was clear in the discussion of thermal tolerance ranges above.

But while this general, macroevolutionary relationship between tolerance and environment may be relatively predictable, the dynamics of the evolutionary process for tolerance ranges over shorter timescales are less clear. A change in the abiotic environment might lead to evolutionary changes in tolerance curves in any of the patterns shown in **Fig. 2**, depending in part on the available genetic diversity and appearance of new mutations in the population, and in part on the nature of the changes in the environment. All three of the patterns in **Fig. 2** are seen in nature, both among populations within species and among closely related species, when reproductively isolated groups experience different abiotic conditions. In addition, laboratory-based evolution experiments have shown the same variety of alterations to tolerance ranges under changing conditions. An illustrative example involves lines of *Escherichia coli* allowed to evolve at 20 °C or 42 °C; these temperatures are within a degree of the initial genotype's lower and upper thermal limits (37 °C is the historically optimal temperature for this strain). After 2000 generations, the 20 °C lines showed a decrease in both their upper and lower tolerance limits by 2 °C (the general patterns shown in **Fig. 2a**) compared to the ancestral genotype. Some of the 42 °C lines, on the other hand, showed an increase in their upper thermal limit by about 1 °C with no increase in their lower thermal limit (**Fig. 2b**), and a second group of 42 °C lines showed no change in either thermal limit despite a shift in the thermal optimum (**Fig. 2c**). Thus over microevolutionary timescales, it may be difficult to predict *a priori* how tolerance ranges may be altered in response to environmental changes.

Tolerance to Multiple Stressors

All of the discussions above have focused on tolerance when only a single abiotic variable is changing; that is, in the study on temperature acclimation in sheepshead minnows, for example, water salinity or pH was not changed at the same time. In nature, however, multiple abiotic variables may reach stressful values simultaneously. Such a relationship may occur for two primary reasons. One is that changes in one variable may directly cause changes in another. For example, as soils become more acidic, the change in pH often mobilizes toxic heavy metals that would otherwise be biologically inactive. The other reason for such simultaneous changes is that variables may covary in association with some other change. Consider an increase in altitude, which results in both low oxygen partial pressures and low water content in air.

Organisms exposed to nonoptimal levels of two or more abiotic variables simultaneously often have smaller tolerance ranges for each than they do when exposed to only one stressor at a time. This reduction in tolerance ranges may be due to a number of factors, including additive or even synergistic effects of the variables on cellular biochemistry, and the additional metabolic cost of regulation when multiple environmental challenges occur. An example of interacting effects between two abiotic variables is seen in the early larval stages of the wharf crab, *Sesarma cinereum*, which survive best in seawater of normal salinity and a 25 °C temperature. The largest salinity tolerance range for the species occurs at this 25 °C optimum, with a higher or lower temperature causing a decrease in the salinity tolerance range. Likewise, the maximum temperature tolerance range occurs at normal seawater salinity, and decreases as salinity increases or decreases relative to this optimum. Similar interacting effects are often observed for other combinations of variables.

Trophic Structure

E Preisser, University of Rhode Island, Kingston, RI, USA

Introduction

Trophic structure is defined as the partitioning of biomass between trophic levels (subsets of an ecological community that gather energy and nutrients in similar ways, that is, producers, carnivores). The forces controlling biomass accumulation at each trophic level have been a central concern of ecology dating from the early twentieth-century work of Elton and Lindeman. While interspecific interactions such as omnivory and intraguild predation can make it difficult to assign many organisms to a single trophic level, several broadly defined trophic levels are nonetheless clearly distinguishable. Primary producers, autotrophic organisms (primarily plants and algae) that convert light or chemical energy into biomass, make up the basal trophic level. Primary consumers, generally referred to as herbivores, feed on primary producers. Their consumption of individual producers can range anywhere from a small fraction of the total producer biomass (caterpillars feeding on trees) to the entire organism (fish feeding on algae). Secondary consumers kill and feed on heterotrophic organisms such as herbivores and/or detritivores. Although secondary consumers are referred to generally as predators, this trophic level includes parasites, parasitoids, and pathogens in addition to carnivores. Secondary carnivores, or top predators, are organisms that eat carnivores. The most common examples of this trophic level occur in aquatic systems, where piscivorous fish such as tuna or pike eat smaller fish that feed on zooplankton (which, in turn, feed on phytoplankton). Finally, detritivores derive sustenance from dead organic matter emerging from each of the above trophic levels. While relatively little attention is paid to this trophic level, decomposers process a large fraction of net primary productivity (`NPP') and are integral to nutrient cycling and ecosystem-level processes.

Control of Trophic Structure

Factors affecting the partitioning of biomass between trophic levels can be divided into two broad categories. The first of these categories, bottom-up control, emphasizes the role(s) played by nutrient limitation and energetic inputs to producers and the subsequent efficiency of energy transfer between trophic levels in determining the biomass accumulation at each trophic level. The second category, top-down control, emphasizes the importance of predation in producing patterns of biomass accumulation that are often at odds with those predicted by energy inputs alone. While recognizing the differences between these two factors, it is also important to emphasize that both bottom-up and top-down factors represent extremes along a continuum of importance for regulatory control. While ecologists debate the extent to which bottom-up versus top-down control influence trophic structure in particular ecosystems, there is a broad consensus that both need to be considered when considering community dynamics.

Bottom-Up Control

Bottom-up control of trophic structure means that the production of biomass at each trophic level is a function of energy input into the primary producer trophic level. Biomass accumulated by producers then passes to higher trophic levels as a function of the between-level transfer efficiency. The resulting biomass pyramids are generally characterized by abundant producer biomass and sharp reductions in each higher trophic level. An important exception to this pattern occurs in aquatic food webs, where `inverted biomass pyramids' can occur as a consequence of the extremely short generation time of unicellular producers relative to resident herbivores and predators (see the section titled `Aquatic versus terrestrial ecosystems').

Energy transfer to producers

Although a large amount of light energy is potentially available to producers, only a small fraction of the total is actually converted to producer biomass. Net photosynthetic efficiency (the percentage of available light energy that becomes biomass) in naturally occurring terrestrial and aquatic communities falls between 0.01% and 3%, with values approaching 10% for intensively managed agricultural systems. The resulting NPP is critically dependent on temperature and affected by water availability in terrestrial systems and nutrient levels in aquatic systems.

Energy transfer from producers to higher trophic levels

The overall transfer efficiency of energy between trophic levels is a function of three separate processes. The first of these, consumption efficiency, is the percentage of available productivity at a lower trophic level that is eaten by a higher trophic level. Grazers in temperate lakes, for example, remove nearly four times the fraction of primary productivity eaten by terrestrial grazers. The second process, the consumer's assimilation efficiency, determines what fraction of the biomass ingested by the consumer is

converted to energy. Finally, the consumer's production efficiency determines the percentage of assimilated energy that yields new biomass. Taking all three processes into account, the overall between-level transfer efficiency ranges from 2% to 24%.

System-wide patterns of consumer–resource transfer efficiency are also affected by ecological stoichiometry, the `match' between the nutrient needs of consumers and the nutrient supply of their resources. Transfer efficiencies are highest when consumers feed on resources whose nutrient ratios are similar to their own, and decrease sharply when they feed on resources with dissimilar ratios. Consumer–resource nutrient ratios in aquatic systems are more closely matched than in terrestrial systems, and in predator–herbivore versus herbivore–producer interactions. These facts have been invoked to explain why low transfer efficiencies are generally associated with herbivore–producer interactions and occur in terrestrial systems, while higher transfer efficiencies are characteristic of predator–prey interactions and occur in aquatic systems.

Patterns of biomass accumulation

As NPP and/or transfer efficiency increases, bottom-up control predicts an increasing number of trophic levels as well as an increase in biomass at each trophic level. As producer biomass changes over time, the effect `trickles up' to produce correlated changes in each of the higher trophic levels (Fig. 1, left panel).

Top-Down Control

Top-down control means that predation by higher trophic levels affect the accumulation of biomass at lower trophic levels. Top-down control does not negate the importance of energy input into the basal trophic level; however, it suggests that biomass accumulation at any one trophic level depends on the intensity of predation from the trophic level above.

The `green world' hypothesis

The concept of top-down control first gained widespread attention as a result of the `green world' hypothesis developed by Hairston, Smith, and Slobodkin (hereafter `HSS') in 1960. In brief, HSS posited that the relative rarity of natural disasters and obvious abundance of plant life implied that the producer trophic level was generally limited by competition for light, nutrients, space, and other resources. HSS further reasoned that the `green world' around us is *prima facie* evidence that herbivores do not limit plant abundance; if they did, herbivores would be far more common and plants far less. Given that herbivores seem surrounded by more food than they can eat, it seems unlikely that resource competition limits them; HSS argued that predators are responsible for suppressing herbivore abundance below the level at which they can regulate plant biomass. Predators, in turn, are often territorial and wide ranging in their search for food; this implies that they are self-limited by competition for their herbivore prey. Finally, the fact that we are not surrounded by masses of decaying matter suggests that decomposers quickly and effectively exploit virtually all of their food resources; as a result, this trophic level is likely self-limited as well. While numerous researchers have subsequently identified potential flaws, limitations, and inconsistencies in the HSS hypothesis, its simplicity, clarity, and intuitive logic catalyzed research into the potentially far-reaching consequences of trophic interactions.

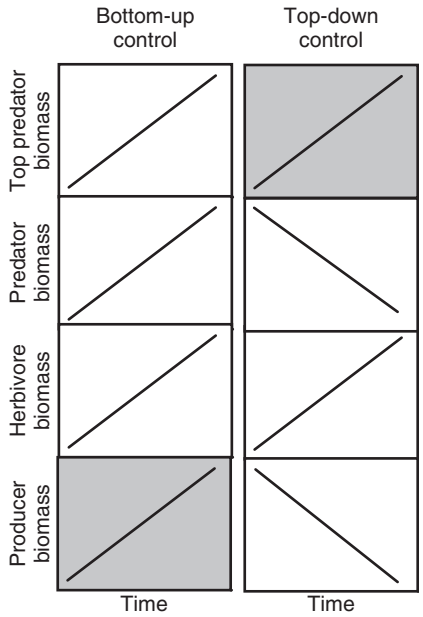

Fig. 1 (Left panel) Bottom-up control of a food chain. As producer biomass (gray box) increases over time, all other trophic levels show correlated increases in biomass. (Right panel) Top-down control of a food chain. As top predator biomass (gray box) increases over time, biomass in the trophic levels below either increase (herbivores) or decrease (predators and producers) in response.

Patterns of biomass accumulation

The hypothesis of top-down control predicts that trophic-level biomass is a function of the trophic interaction most influencing that level. The highest trophic level is always self-limited by competition, making the next-lowest trophic level limited by predation, which in turn allows the trophic level below it to again be limited by competition. In a three-level system, this means that predators and producers are limited by competition (thin top-down arrow) while herbivores are limited by predation (thick top-down arrow) (Fig. 2, a); in a four-level system, the top predators and herbivores are limited by competition while the predators and producers are limited by predation/herbivory (Fig. 2, b). Control exerted via the top trophic level also produces patterns of biomass accumulation distinct from those seen in bottom-up control (Fig. 1, right panel). In comparison to Fig. 1, an increase in top predator biomass leads to decreased predator biomass, thereby releasing herbivore populations which subsequently depress producer biomass.

Trophic cascades

The archetypal form of top-down control involves trophic cascades, where predators indirectly benefit producers by suppressing herbivores (Fig. 3). Such top-down control can be important in freshwater, marine, terrestrial, and belowground systems; in temperate lakes, it can produce visually spectacular differences in producer biomass. While trophic cascades are demonstrably important in many aquatic food webs, their importance in terrestrial systems has been the subject of vigorous debate. Current research seems to indicate that while predators suppress herbivores in both aquatic and terrestrial systems, indirect predator effects on producer biomass occur predominantly in aquatic systems. In terrestrial systems, predator addition often decreases herbivore damage to producers but has less of an impact on overall producer biomass.

Importance of Bottom-Up versus Top-Down Control

Biomass production at all trophic levels is ultimately dependent on the quantity and quality of resources comprising the basal trophic level. Experimental manipulations have generally found that biomass at all trophic levels increases with increased NPP. The ecosystem-level importance of bottom-up control is further underlined by the fact that global patterns of NPP correspond generally to predictions generated by models using only data on abiotic factors such as light, temperature, and water availability. There are also many systems, however, where top-down control clearly acts as a regulatory force; when unchecked by natural

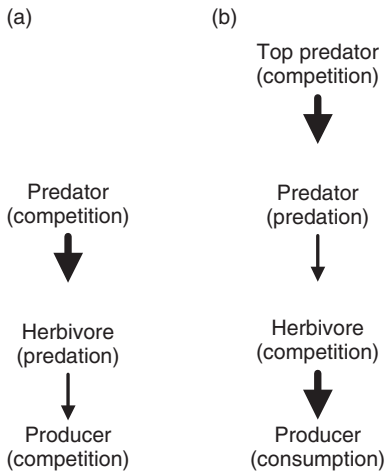

Fig. 2 Top-down control of a food chain. In a three-level food chain (a), predators are limited by competition for resources (thick arrow), herbivores are limited by predation and so cannot limit producers (thin arrow), which are thus limited by competition. In a four-level food chain (b) the pattern is reversed, with predators and producers limited by consumption and top predators and herbivores limited by resource competition.

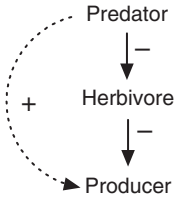

Fig. 3 A trophic cascade. Predators suppress herbivores (`−' arrow), which suppress producers (`−' arrow). By suppressing herbivore biomass, predators indirectly benefit plants (`+' dotted arrow).

enemies, herbivores are capable of population outbreaks that can devastate producer biomass. In agricultural systems, the biological control of crop pests is predicated on the ability of natural enemies to suppress herbivore abundance, reduce producer damage, and increase overall yield. Given that bottom-up control is essential to determining biomass production, the critical issue becomes understanding the conditions and systems in which top-down processes are also important.

Factors Affecting Control of Trophic Structure

A variety of factors affect the magnitude of top-down versus bottom-up control over trophic structure. While these factors can be a function of among- versus within-level trophic interactions, they can also emerge from the linkage between ecological communities and the surrounding environment.

Productivity

The bottom-up effects of increased productivity of the basal trophic level may be capable of influencing the strength of top-down control in a system and the patterns of biomass accumulation at subsequent trophic levels. The relationship between productivity and top-down control was first developed by Oksanen, Fretwell, and others as the `ecosystem exploitation hypothesis' (`EEH'). EEH suggests that as potential primary productivity (`PPP') increases, the equilibrium biomass at each trophic level in a food chain either increases linearly or shows no response (Fig. 4). At very low levels of PPP, there is insufficient producer biomass to support herbivores; as a result, producers are limited by resource competition and their abundance increases linearly as PPP increases (Fig. 4, part A). As PPP continues to increase, however, herbivores can enter the system and divert the increased production of producer biomass into herbivore flesh. Part B of Fig. 4 shows the result: higher PPP yields an increase in herbivore biomass while producer biomass remains unchanged. This continues until herbivore biomass is sufficiently abundant to support predators (Fig. 4, part C). The introduction of predators to the system diverts increased herbivore biomass into predator biomass, freeing producer biomass from herbivore control and allowing it to increase with PPP. When a fourth trophic level enters the system at high PPP, it diverts predator biomass and allows herbivore biomass to increase at the expense of further increases in producer biomass (Fig. 4, part D).

Aquatic versus Terrestrial Ecosystems

Ecologists have long speculated that differences between aquatic and terrestrial ecosystems might affect trophic structure. Early researchers suggested that factors like producer size (predominantly small and short generation times in aquatic systems, predominantly large and long generation times in terrestrial systems) might explain the inverted biomass pyramids found in aquatic systems. Limiting nutrients like nitrogen and phosphorus are relatively more abundant in aquatic food webs; other terrestrial–aquatic differences include the fact that aquatic herbivores consume a larger fraction of available producer biomass, their herbivore–producer transfer efficiencies are higher, and aquatic herbivores are more abundant than their terrestrial counterparts.

Differences in food chain length

One hypothesis for the relative abundance of herbivores and scarcity of producers in aquatic versus terrestrial systems involves inherent between-system differences in the number of `effective' trophic levels (i.e., levels that contribute substantially to top-down control of trophic structure). This argument suggests that terrestrial systems possess three trophic levels (Fig. 2, a) while aquatic systems possess four. Four-level aquatic systems occur via the addition of top predators, for example, piscivorous fish that eat planktivorous fish. In such an example, planktivorous fish are thus predation-limited and cannot control increases in herbivorous

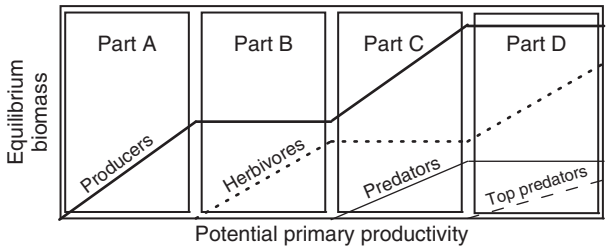

Fig. 4 The ecosystem exploitation hypothesis for trophic-level biomass accumulation as a function of potential primary productivity. Part A: As productivity increases, producer biomass increases. Part B: When producer abundance is sufficiently high to support a second trophic level, consumers enter the system and turn excess producer biomass into herbivore biomass. Part C: When herbivore abundance is sufficiently high to support a third trophic level, predators enter the system and turn excess herbivore biomass into predator biomass. This releases producers from herbivore control and allows producer biomass to increase. Part D: As in part C, but with a fourth trophic level (top predators) entering the system.

zooplankton that suppress phytoplankton biomass (Fig. 2, b). As a result, terrestrial systems have relatively few herbivores and appear `green,' while many (but not all) aquatic systems have abundant herbivores and relatively little in the way of producer biomass.

Differences in herbivore–producer linkage strength

While research supports the contention that aquatic producers experience greater grazing intensity than their terrestrial counterparts, there is less evidence that the apparent abundance of terrestrial producer biomass is due to predator suppression of herbivores. Studies manipulating top predator communities in aquatic versus terrestrial systems demonstrate that the resulting trophic cascades greatly affect producer biomass in aquatic systems. In contrast, the effect of predator addition on terrestrial producers is seen most strongly in reduced producer damage and less in increased producer biomass. Abundant research has shown, however, that manipulating the abundance of top and intermediate predators can strongly affect the biomass of both aquatic and terrestrial herbivores; this implies that system-specific variation in the top-down effect of herbivores on producers may be responsible for the observed differences between aquatic and terrestrial systems.

There are several suggestions for why aquatic versus terrestrial herbivores might have a greater impact on their resources. Phytoplankton, the primary producers in many aquatic systems, need to remain buoyant and absorb limiting nutrients across their cell walls; these requirements constrain them from reaching large sizes and may, in turn, preclude large investments in structural compounds while selecting for faster generation times. Terrestrial producers, in contrast, compete for light by investing in structural compounds that allow them to outgrow their neighbors. System-specific forces should thus select for small size (and rapid generation times) in aquatic producers and large size (and slower generation times) in terrestrial producers. These varying selective pressures may also mean that long-lived terrestrial producers are more apparent to herbivores and invest more heavily in defensive compounds that reduce the impact of herbivory. Ecological modeling has also shown that herbivore control over producer biomass is greatest when herbivores are larger than their resources; this is often the case in aquatic systems but rarely true in terrestrial food webs.

Trophic Position

The Menge–Sutherland hypothesis suggests how the trophic level of organisms within a food web may itself influence the factors that control biomass accumulation. In systems with multiple predator and prey species, herbivorous organisms are often preyed upon by many predators. In such systems, predation thus may play a more important role than resource competition in controlling the biomass accumulated by low-trophic-level organisms (Fig. 5). Although organisms at higher trophic levels are preyed upon by few (if any) predators, they compete fiercely with other members of their trophic level for relatively scarce prey resources. As a result, resource competition should be more influential than predation in determining high-trophic-level biomass. This hypothesis was developed in the context of marine inertial systems, and support for its general applicability has been mixed. A review of experimental literature found that predator effects were strongest on the lowest trophic levels in a food web, supporting the above argument; however, there is less evidence for the corollary that herbivore–herbivore competition is generally weak.

Heterogeneity Within Trophic Levels

Categorizing organisms within a community into discrete trophic levels can conceal a wide range of ecologically relevant differences between and among species. There are several ways in which the species-specific traits of organisms within a trophic level can affect biomass accumulation.

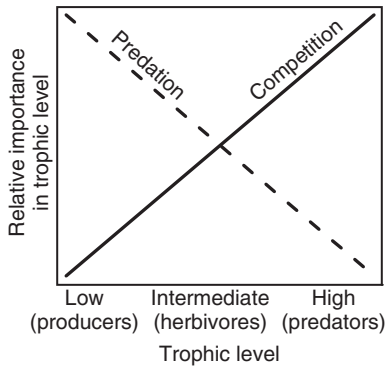

Fig. 5 The Menge–Sutherland hypothesis for within-community dynamics describing the relative importance of competition versus predation in structuring basal (producers) vs. higher trophic levels. Low trophic levels tend to be structured by predation, while higher trophic levels are increasingly structured by competition for resources.

Antiherbivore defenses

An early challenge to HSS came from the argument that the apparent abundance of `green' in terrestrial systems ignores the fact that terrestrial plants possess an array of chemical and physical defenses against herbivory. As such defenses become more effective, an increasing fraction of terrestrial plant biomass becomes effectively invulnerable to herbivory. In the midst of a `green world,' herbivores may thus in fact be forced to compete for access to a limited pool of edible resources. The array of plant defenses found in nature suggests that they are at least somewhat effective in suppressing herbivory; a counterargument points to the fact that even the best-defended plants have at least one herbivore species capable of devastating it in the absence of predators. Moreover, even if plant defenses reduce the overall impact of herbivory, digestibility-reducing compounds like tannins may force herbivores to develop more slowly and remain vulnerable to predators for a longer period of time, while herbivore-induced plant volatiles may attract predators to feeding herbivores. In both of these scenarios, plant defenses may actually serve to increase the efficacy of top-down control.

Heterogeneity in resource edibility

Several models address how interspecific variation in edibility within the basal trophic level might affect trophic structure. These models assume a tradeoff between defense (reduced edibility) and growth, with fast-growing species investing little in defense while slower-growing species are heavily defended and relatively invulnerable to consumption. In low-productivity environments with few consumers, species excelling in resource acquisition will predominate. As productivity and consumer abundance increases, however, the high-growth species will suffer disproportionately from consumption and the slow-growing but highly defended species will become increasingly abundant.

Edible–inedible resource model

The edible–inedible resource model (**Fig. 6**) posits EEH-type control over trophic biomass and predicts that low-productivity environments are initially inhabited only by rapidly growing edible producer species that competitively exclude inedible producers (**Fig. 6**, part A). Its predictions parallel those of EEH for the addition of a second trophic level (**Fig. 6**, part B). It diverges from EEH with the addition of a third trophic level that keeps herbivores from regulating producer biomass; in the edible–inedible resource model, the subsequent absence of herbivore control allows inedible producer species to invade the environment (**Fig. 6**, part C). Since inedible producers cannot be controlled by predation; further increases in PPP yields an increasingly large inedible fraction of total producer biomass.

Keystone predation model

A modification of the edible–inedible prey model, Liebold's keystone-predation model (**Fig. 7**) views resources as varying continuously rather than categorically in their degree of edibility; it predicts a series of species replacements of less- by more-defended resource species as consumer abundance increases. While it generates some of the same predictions as the edible–inedible resource model, it differs in that both consumer and resource biomass increase at a decreasing rate as PPP increases (**Fig. 7**, top panel). This is due to top-down control decreasing as better-and better-defended resource species come to dominate at high PPP (**Fig. 7**, bottom panel). While no resource species is completely invulnerable, consumers gain less and less biomass from preying upon marginally edible species and the system becomes increasingly bottom-up controlled.

Antipredator behavior

Most ecologists have traditionally seen the effect of predators on their prey in terms of the number of prey consumed by predators. A mounting array of evidence suggests that prey are far from helpless victims, however, and that they employ a wide array of defensive strategies. The costs of these strategies can include reduced energy income, lower mating success, or increased vulnerability to other predators. Predators can thus reduce prey density both through direct consumption as well as through the costs arising from antipredator strategies. The `nonlethal' consequences of altered and/or reduced prey foraging in the presence of

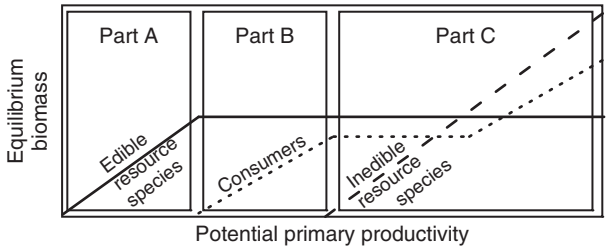

Fig. 6 The edible–inedible resource model showing the trophic-level effect of tradeoffs between species that are either fast growing and edible or slow growing but invulnerable to consumption. Part A: At low productivities, edible resource species outcompete inedible species and increase their biomass linearly with productivity. Part B: When edible resource abundance is sufficiently high to support a second trophic level, consumers enter the system and turn excess resource biomass into consumer biomass. Part C: When consumer biomass is sufficiently abundant to allow the entry of a third trophic level, predators enter (line not shown in figure) and turn excess consumer biomass into predator biomass. This allows inedible resource species to enter the system and increase linearly with productivity while edible species' biomass remains unchanged.

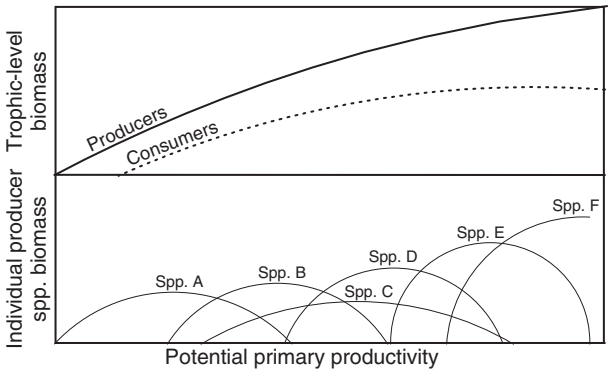

Fig. 7 The keystone predation model showing the trophic-level effect of species replacements by resource species that vary continuously in their growth rate and edibility. At low productivities, communities tend to be dominated by edible resource species with high growth rates. As productivity increases, communities come to be increasingly dominated by mostly inedible resource species with low growth rates. Bottom-up control thus increases as a function of productivity.

predators can profoundly affect the biomass of prey resources. For prey capable of antipredator behavior, predator-induced trophic cascades affecting the prey's resources may thus occur despite minimal prey mortality.

Generalist versus specialist predators

Species identity at the secondary consumer trophic level may also influence trophic structure. Effective top-down control in diverse ecological communities requires that predators consume a wide variety of prey species. As a consequence, generalist predators feeding on an array of species may be most effective at controlling trophic-level biomass accumulation. In contrast, specialist predators affect only a restricted subset of all prey. Any reduction in the biomass of prey targeted by specialist predators may simply release nontargeted species from competition and allow them to increase in abundance; in such a situation, even high densities of specialist predators should produce little change in overall trophic-level biomass. Differences in trophic structure due to predator identity should be most apparent when contrasting communities dominated by large generalist predators (strong top-down control) with communities characterized by small specialist predators (strong bottom-up control).

Omnivory and intraguild predation

Intraguild predators (organisms capable of eating their competitors) and omnivores (organisms that eat both autotrophs and primary producers) pose a major challenge to simple views of trophic structure; even their trophic classification is questionable. While omnivory and intraguild predation have traditionally been considered rare, there is an emerging consensus that both feeding modes occur in (and sometimes dominate) many food webs.

Abundant omnivory and intraguild predation in an ecological community can alter the strength of top-down control. Both feeding modes may act to reduce the strength of top-down control; this occurs because (1) the top-down effect of feeding is diluted across multiple trophic levels; (2) eating other predators may decrease the total predator impact on lower trophic levels; and (3) changes in abundance and feeding rates affect different trophic levels similarly. For example, increased abundance of an omnivorous crayfish should decrease the abundance of both snails (herbivores) and algae (producers). By feeding on the basal trophic level during periods when animal prey are scarce, however, omnivores may sustain high population densities capable of suppressing any future increases in prey biomass. Omnivory in such systems may thus actually serve to increase the strength of top-down control.

Species/trophic diversity

There are several arguments for how high `diversity' (a combined function of the number of trophic levels, species per level, and within-trophic-level foraging strategies) in food webs should alter the relative importance of competition versus predation in controlling trophic-level biomass. One argument suggests that low-diversity communities will tend to have fewer trophic levels, with the vast majority of species occupying the lower trophic levels; in such systems, the relative lack of predator pressure will mean that biomass accumulation will be determined primarily by resource competition (**Fig. 8**). As food web diversity increases, both the number and importance of higher trophic levels increase. This leads to an increased number of predator–prey interactions, and a corresponding rise in the relative importance of predation in structuring the community. As a result, more-diverse communities are structured primarily by predation, while competition plays a predominant role in less-diverse food webs. Contrary to this, an array of empirical work seems to show that less-diverse communities (`food chains') are more likely to show strong top-down control, while more-diverse communities (`food webs') tend to diffuse top-down control and be more affected by bottom-up factors.

Ecological models of even simple food webs incorporating linked food chains and multiple species per trophic level show that such changes may alter the bottom-up importance of increased productivity. Bottom-up effects on predator biomass in a simple food chain can be reduced by predator–predator competition, well-defended herbivores, or herbivores with shared predators and

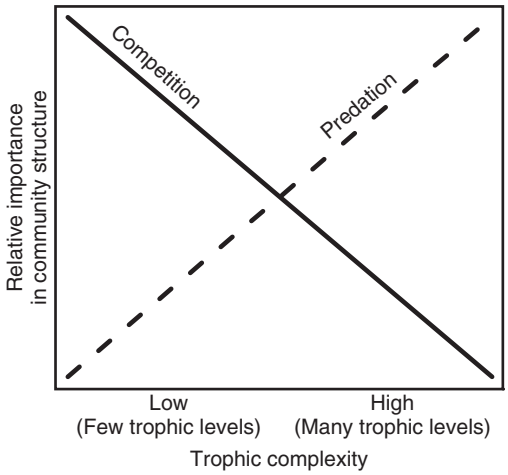

Fig. 8 The Menge–Sutherland hypothesis for between-community dynamics describing the relative importance of competition versus predation in structuring communities of low versus high complexity. Low-complexity communities tend to have few trophic levels and be structured primarily by competition, while high-complexity communities tend to have many trophic levels and are structured primarily by predation.

resources. As models grow more complex, outcomes ranging from strong top-down to strong bottom-up effects, and a range of intermediate conditions, are possible.

Temporal/Spatial Heterogeneity

Variation in both space and time can also affect the accumulation of biomass at different trophic levels. In the broadest sense, spatial and temporal variation in light, temperature, nutrients, and water availability sets the upper limit for ecosystem-level NPP. Systems characterized by wide seasonal variation often feature similarly wide swings in the strength of competitive interactions. Even when less-seasonal systems are included, temporal variation in competitive interactions appear to be the rule rather than the exception; as a result, food webs in a variety of systems may shift between top-down and bottom-up control over time.

Stressful environments

Trophic structure in harsh environments may be controlled by a different suite of factors than those operating in less-stressed systems. Models developed in the context of marine intertidal systems suggest that the effect of abiotic stress on trophic structure should occur because predators are, on average, more mobile than their prey. In relatively benign environments, predators should find it easy to search for and consume prey; higher trophic levels should be fully represented in such environments and be predominantly structured by predator–prey interactions. As abiotic stress increases, however, mobile predators can flee harsh environments while their sessile prey must remain. As a consequence, the importance of predator–prey interactions decreases sharply and competition, not predation, primarily determines trophic-level biomass accumulation.

Refuge habitats

Refuge habitats, areas where prey are free from the threat of predation, were at one time thought to play a major role in determining trophic structure. Since predators can only consume the fraction of prey that have lost in competition for refuge access, bottom-up control will dominate in refuge-rich areas. While such refuge-rich habitats are now generally considered to be the exception rather than the rule, they may explain systems where the changes in predator abundance have little overall impact on prey biomass.

Water Availability☆

Gage H Dayton, Moss Landing Marine Laboratories, Moss Landing, CA, United States

Introduction

Freshwater is a vital resource for all living organisms. Most organisms have a water content of 50%–90% and there is a critical threshold that they must maintain in order to survive and reproduce. In addition, water also serves as critical habitat for numerous organisms in a wide variety of environments, ranging from extremely arid deserts to tropical rainforests. Regardless of the environment, water availability is a driving force that shapes both aquatic and terrestrial species assemblages. Structure and function of freshwater environments varies across a wide gradient of aquatic environments ranging from small ephemeral pools to expansive permanent lakes. This gradient is controlled by both abiotic factors (e.g., rainfall, aquifer level, soil type, springs, and exposure to sun and wind) and biotic factors (e.g., shading from trees, vegetation, consumption, and biomodification). The hydroperiod (the period of time and area is covered by water) of a water body significantly influences the distribution and abundance of various species, and ultimately plays a significant role in influencing community structure.

Freshwater environments support a vast array of biological diversity, ranging from microbes to trees, and are often referred to as among the most significant and productive ecosystems on Earth. The distribution and abundance of species that occur in a particular freshwater habitat is shaped by a complex system of interactions between abiotic and biotic factors. Most of our knowledge regarding mechanisms that structure freshwater communities comes from studies conducted in the eastern United States and tropical forests of Central and South America. High rainfall over large areas in these regions results in a heterogeneous environment of pools that persist for variable lengths of times, and allow organisms with differing developmental rates to successfully reproduce.

Permanent water bodies are maintained by springs, shallow aquifers, glacial runoff, and snowmelt. Water input from these sources is predictable on an annual basis and results in permanent or long-lived sites. Seasonal rainfall and snowmelt raises aquifers, which in turn influences surface water availability, recharges lakes, and causes streams and rivers to swell. In contrast to permanent water sources, temporary aquatic habitats rely largely upon input from seasonal rains and persist only during wet periods of the year. After a rain event, water is retained for varying durations depending upon subsequent rainfall, runoff, evaporation, biotic uptake, and infiltration. Temporary aquatic environments are usually physically isolated from other seasonal and permanent water bodies (with the exception of flood events) and persist in patchy distributions across the landscape. In temperate and tropical regions where humidity is relatively high, the ground is saturated, and dense vegetation results in shading, temporary aquatic environments tend to persist for many months. However, in arid regions where temperatures are hot, vegetation is sparse, and soils are often course (which results in rapid water infiltration), hydroperiods are characteristically very short. Ultimately, these abiotic factors that regulate water input and output are responsible for influencing water availability and, consequently, the persistence of various organisms across the landscape. Thus, when examining the influence of water availability on the ecology of living organisms, it is important to realize that abiotic factors serve as an initial filter that influence which species can utilize a particular water body. However, as will be explained in more detail later on, biological factors such as resource competition and predation play an important role in influencing which species can persist in a particular water body. These biological factors can be interpreted as secondary filters influencing species assemblages in particular aquatic habitats.

☆*Change History:* March 2018. Irene Martins made minor changes to the text and references.

Aquatic Organisms

The ecology of freshwater organisms can be generalized as a gradient between temporary and permanent pools that is largely influenced by competition and predation. Small highly ephemeral pools often have low species richness due to rapid drying that results in short duration of the site. The short hydroperiod of highly ephemeral pools restricts which organisms can successfully use a particular site. For example, pools that persist for <3 weeks cannot be successfully utilized by organisms that require permanent water (e.g., fish), nor can they be utilized by organisms that require the presence of water for >3 weeks for part of their life cycle (e.g., most amphibians and aquatic insects). In temporary water bodies there is a positive relationship between hydroperiod and species richness of both aquatic invertebrates and amphibians. However, as pools transition from temporary to permanent sites there is a decrease in species richness of many taxa (Fig. 1). This decrease in richness is largely attributed to the presence of fish and other predators that are dependent upon long-lived or permanent water. Thus, hydroperiod is a driving abiotic factor that regulates which species can successfully use a site, and ultimately influences community composition of aquatic environments.

Temporary Aquatic Environments

Aquatic organisms inhabiting temporary water bodies require life cycles that enable them to survive during dry periods. Of the many species adapted to live in temporary water bodies, each has its own threshold for the minimum time period in which a site must be inundated in order for members of that species to successfully complete the aquatic component of their life cycle. Although there are a wide variety of adaptations that enable organisms to persist in temporary ponds, the limiting factor is that, prior to the site drying up, individuals must reach a critical life stage that enables them to survive outside of an aquatic environment. Most species that inhabit temporary aquatic environments must either metamorphose into a terrestrial form (as seen in most amphibians and many insects) or lay eggs that are capable of withstanding dry phases (exemplified in fairy shrimp, mayflies, and cladocera). For example, in North America the larval stage of most amphibians is at least 2 months. Thus, the lower temporal threshold of pond hydroperiod for the majority of amphibians that occur in North America is 2 months. If pools dry up prior to this time period, larvae are unable to complete metamorphosis and subsequently there are no adult recruits. In the case of many aquatic invertebrates, such as fairy shrimp, the entire life cycle is completed in the temporary pool. Eggs remain dormant in the dirt until the following wet season, whereupon eggs hatch and the cycle repeats itself.

Species that inhabit short-lived pools are generally superior resource competitors to species that have relatively long larval periods. Competitive ability enables organisms living in short-lived pools to grow quickly and obtain resources necessary for metamorphosis and/or reproduction. However, there is often a fitness cost to being competitively dominant. Aquatic organisms that inhabit temporary pools are typically very active foragers that exhibit high activity rates; this high activity rate makes them susceptible to a wide variety of predators. These species are more vulnerable to predation due to the fact that activity is correlated with predator encounter rates through both enhanced detection by visual predators as well as increased probability of encountering a "sit and wait" predator through spatial movement. Thus, aquatic organisms associated with highly ephemeral ponds are often restricted to these types of environments due to their inability to coexist with predators that are abundant in longer-lived and permanent sites. The unique adaptations required to successfully persist in highly ephemeral pools results in a disproportionately

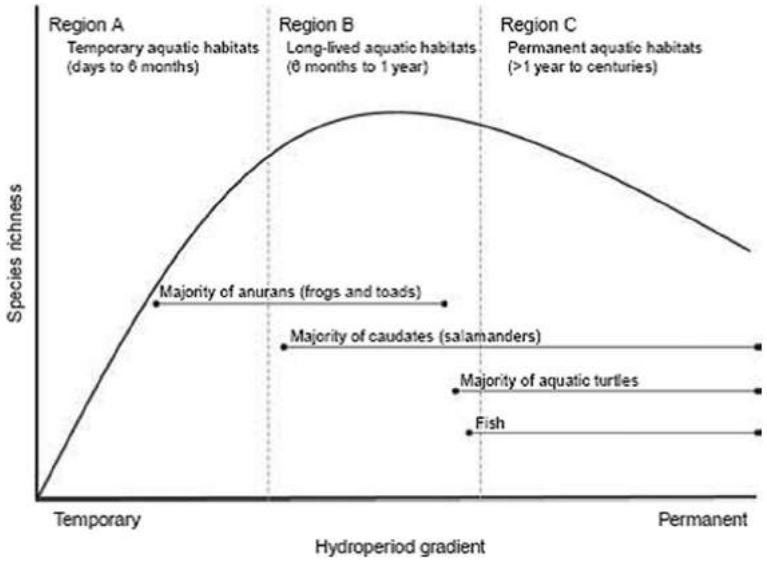

Fig. 1 Water permanency and species richness of several vertebrate groups that utilize aquatic habitats. Adapted from Wellborn, G. A., Skelly, D. K. and Werner, E. E. (1996) Mechanisms creating community structure across a freshwater habitat gradient. *Annual Review of Ecology and Systematics* **27**, 337–363.

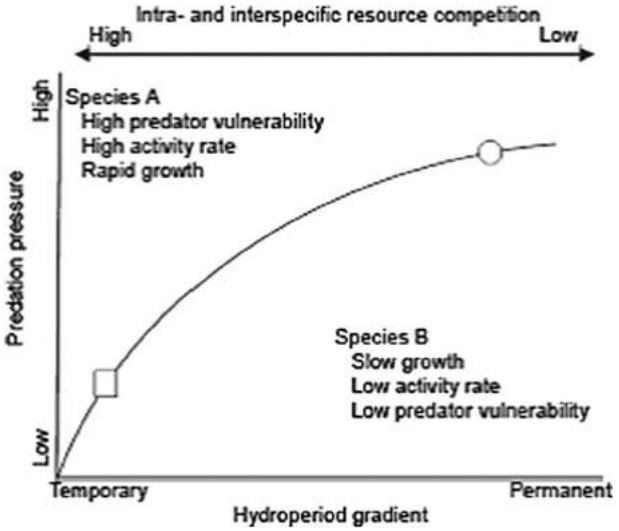

Fig. 2 Conceptual model that depicts the relationship of predation pressure, competitive environment, and hydroperiod gradient with predictions of prey characteristics along the gradient. Species A is likely to be susceptible to predation and show few defensive traits in the presence of predators because the cost of altering behavior and growth in delaying developmental time are too great in sites where desiccation is the primary cause of death. As a consequence of high susceptibility to predation, species A should be excluded from sites with long hydroperiods and high predator loads. Species B exhibits predator-induced defenses in the presence of predators. As a result, developmental times are longer, and species B is excluded from short-lived pools.

high number of endemic species associated with ephemeral water bodies, especially those that occur in dry environments where temporary pools are often very patchily distributed across both space and time.

As hydroperiod lengthens, there is a positive correlation with species richness. Many of the species that inhabit longer-lived pools are predators. As predation pressure increases in longer-lived pools, species composition shifts from an assemblage adapted to rapid growth and short life cycles, to an assemblage dominated by relatively slow-growing species adapted to coexisting with predators (Fig. 2). Organisms that inhabit aquatic environments where predators are common exhibit a wide array of defense strategies. Primary defense mechanisms include cryptic coloration, reduced activity, chemical compounds, and morphological adaptations. All of these defense strategies have a cost to the organism in that resources are either allocated toward producing defensive structures, or energy intake is decreased due to reduced feeding and lower activity rates. Consequently, the time required to reach critical developmental stages necessary for metamorphosis, or to produce gametes, is increased.

Permanent Aquatic Environments

Although temporary and permanent water bodies vary tremendously, competition, and predation are also important mechanisms affecting species assemblages in permanent aquatic habitats. In permanent aquatic habitats that lack predators, resource competition among organisms is believed to be important in structuring the composition of zooplankton communities. When few or no fish are present, zooplankton assemblages tend to consist of different species that are typically much larger in size than those that occur in lakes where fish are present. These relatively large zooplankton are believed to be superior resource competitors over smaller zooplankton; however, as discussed above for temporary pools, with competitive ability comes the cost of susceptibility to predation. In lakes where fish occur naturally, large zooplankton species are absent and assemblages are dominated by small species that are capable of withstanding predation pressure. Clear evidence for the impact of top predators on the structure of zooplankton, as well as amphibian, assemblages in permanent water bodies has been observed in alpine lakes of the Sierra Nevada Mountains in California. Many of the lakebeds in the Sierra Nevada Mountains were formed by glaciers carving out bedrock basins, which were later filled by annual snowmelt. As a result, these lakes are often very isolated and occur at high elevation and subsequently were never colonized by fish. However, beginning in the late 1800s, pioneers and sheepherders began stocking many alpine lakes with fish. The introduction of a top predator into these lakes eliminated many of the invertebrate and vertebrate species that naturally inhabited these sites. Thus, even though water availability remains constant among permanent sites (e.g., it is by definition always present), the presence of fish and other predators play an important role in structuring the species assemblages of permanent water bodies.

The Temporary/Permanent Aquatic Boundary

The potential fitness benefit for aquatic organisms that can utilize both temporary and permanent water bodies is very high. However, there are very few species that exhibit a generalist strategy that enables them to use both types of aquatic environments. This suggests that the selective pressures, and ultimately the costs, associated with being specialized for either fast growth (able to

Fig. 3 Couch's Spadefoot toad (*Scaphiopus couchii*). This individual recently emerged from estivating beneath the surface (notice mud on top of its head). Spadefoot toads remain underground for the majority of the year, emerging during heavy seasonal rains to breed and feed. Tadpoles will complete their life cycle in 7–10 days.

persist in temporary pools) or the ability to withstand predators (able to persist in permanent lakes and rivers) are high. However, there are many species that exhibit plasticity (ability to alter or change) in behavior, morphology, and or developmental rates. The ability to alter behavior or morphology, and thus developmental rates, by increasing feeding or portioning resources for defense mechanisms, enables some organisms to live in environments where competition and predation pressures vary from year to year. Plasticity is common in many organisms that experience fluctuating temporary aquatic environments that last for several months. Some of the best examples of phenotypic plasticity in aquatic organisms can be highlighted by examining behavior and morphological modifications that occur in tadpoles that inhabit long-lived temporary to permanent water bodies in the northeastern United States. In this region, permanent water bodies are abundant and temporary water bodies typically last for several months and exhibit a relatively linear increase in tadpole predators as hydroperiod increases. As predator density increases, many amphibian species reduce their activity rates, thus reducing the detection probability of predators. In addition, they will exhibit morphological changes in body shape that enable them to swim faster and evade predators. For example, when Gray Treefrog tadpoles inhabit waters with predators they reduce their activity rates and grow large tails that are tinted orange. The large colored tails are believed to help them evade predators by focusing attacks to regions of their tails that will rip easily and allow them to escape predation events. Because water is either permanent or present for a relatively long period of time, these plastic responses to shifting predatory regimes is an adaptation that likely increases the fitness of the species (e.g., time is not the limiting factor influencing tadpole survivorship, rather being eaten by a predator is the most likely cause of death).

Conversely, in very short-lived desert pools in the Chihuahuan Desert where Couch's Spadefoot (*Scaphiopus couchii*) breed (Fig. 3), desiccation is the most important factor influencing tadpole survivorship. Couch's Spadefoot tadpoles are very active foragers and can metamorphose in only 7–10 days after eggs are deposited (this is the shortest larval period for all North American amphibians). High densities of predators are very uncommon in temporary desert pools and the limiting factor for successful metamorphosis of Spadefoot tadpoles is time (rv75% of all breeding pools dry up prior to any metamorphosis occurring). Couch's Spadefoot tadpoles are very active foragers as they need to meet energy requirements for metamorphosis prior to ponds drying up. These high activity rates in turn make them susceptible to predators; thus, they are not capable of persisting in pools with high predator loads. The evidence that Couch's Spadefoot larvae are not adapted to coexisting with predators is further supported by studies that have exposed tadpoles to predators in controlled experimental settings and found that they do not exhibit plasticity in behavior or morphology. Together, these traits suggest that selective forces on rapid growth for Couch's Spadefoot tadpoles outweigh the costs of potential behavioral or morphological responses to predators.

Thus, while very few species can persist in both temporary and permanent water bodies, many organisms that inhabit intermediate sites tend to exhibit plasticity in behavior and/or morphology that enables them to adapt to varying competitive and predatory environments. However, in very short-lived aquatic environments, desiccation drives selection for rapid growth rather than antipredator responses. Finally, in permanent environments, predation fuels selection of behavioral and morphological traits that enable species to coexist with predators.

Water Availability and Terrestrial Organisms in Desert Environments

In addition to water availability being critical for all life, it is perhaps the single most important factor influencing the distribution of organisms that inhabit desert environments. Water availability for terrestrial organisms is important at both the surface and subsurface level. Surface water is an essential resource for terrestrial vertebrates and invertebrates (imagine a mountain lion lapping out of a pool or bees buzzing around your dogs water bowl). Subsurface water is critical for the persistence of most plants, benthic

invertebrates, and a wide diversity of fungi. Once water enters the soil (via precipitation, ground water, snowmelt, or runoff from surrounding water bodies), its availability to plants and other organisms depends upon the water potential of the soil. Water potential is the tendency of any system (e.g., soil, plant, and animal) to transfer water to its surroundings. Water always moves down the gradient from a system with high water potential to one with lower water potential.

The transfer of water from soil to roots is mediated by soil properties (e.g., pore space and texture). Fine texture soils, such as clay, are capable of holding more water than course sediments. However, because of the tight binding of water molecules in clay soils, it takes a much higher difference in water potential between soil and roots for plants to utilize the water. The capacity of plants to utilize water from the soil is determined by variation in water potential across the soil–root interface. If the water potential of roots is lower than the water potential of the soil, water moves from the soil to the plant and the plant grows. Plants in turn are the primary producers that are the basis of all trophic levels, produce oxygen, act as carbon sink, and provide essential habitat for numerous organisms.

Seasonal Vegetation as a Food Source

Desert habitats are defined as regions of the Earth's surface that receive less than 50 cm $year^{-1}$. Throughout desert environments much of the landscape is covered by open soil with sparse patches of vegetation. However, these areas are also dotted with springs where surface water is available throughout the year, as well as sites where water is captured during rain events, or runs at the surface, for several months at a time. The density of these water sources across the landscape varies depending upon the underlying geology of the area as well as the location of aquifers. Throughout much of the desert, vegetation is largely driven by seasonal rain events that bring patchy but predictable amounts of plant growth to the area. As water begins to dry up and become less available, vegetation begins to die off. The ebb and flow of vegetation in desert habitats has dramatic impacts on food availability for numerous species. Mammals are a conspicuous group of organisms that are significantly impacted by water availability in desert region. For example, as vegetation dries up, jackrabbit decline as individuals die of dehydration and malnutrition. However, populations are replenished by copious reproduction after seasonal rains when vegetation is once again abundant. Some species of kangaroo rats are highly adapted to living in desert areas and do not drink surface water, rather they get their water from seeds as well as feeding upon green vegetation during wet periods. It is believed that the water kangaroo rats get from eating green foliage plays a large role in supporting energetic costs of reproduction. Thus, in the case of the kangaroo rat, subsurface water availability provides both food and water requirements via plant growth.

As water availability decreases, due to factors such as reduced input and/or lowering of the aquifers through ground pumping, the impacts on vegetation are significant and have cascading effects on assemblages of species throughout the ecosystem. A classic example of this effect is the reduction in avian reproduction during drought years. Over a 2 year period in coastal California, avian reproduction output has been shown to drop from 2.37 fledglings per pair the first year to 0.07 fledglings per pair the second year. The low levels of nesting success may have been partially due to physiological constraints of not having enough water to utilize for egg production. However, the drop in reproductive success was likely due to the fact that arthropod abundance (food source for birds) was significantly impacted because plant growth was hindered as well. This illustrates an example of how water availability plays a fundamental role in shaping the community structure of organisms in an arid environment.

Influence of Spatial Heterogeneity of Water

The spatial distribution of water across the landscape is an important factor influencing the movement of organisms and, ultimately, the connectivity of populations. For example, many species of mammals cannot go without water for more than a few days; thus, their home ranges are limited by distances between reliable water sources. When water is abundant, home ranges of many organisms are significantly larger and there is more connectivity among populations as animals are able to move great distances.

Reduced water availability across the landscape can act as an isolating mechanism by separating populations. As populations become isolated, they are less likely to be recolonized or supplemented by immigration. In many arid regions, springs provide the only reliable year-round water sources. As spring habitats exhibit cycles of increase and decrease over the years, so do the populations of organisms that depend upon them. The temporal variation in the presence and absence of springs can impact species by spatially connecting or isolating disparate populations that are restricted to a particular range due to limited water availability. When springs go dry, due to natural or anthropogenic effects, the metapopulation structure of various species is altered. Thus, the spatial distribution of water bodies plays a critical role in the distribution and abundance of organisms across the landscape.

Conservation

Freshwater ecosystems are some of the most diverse environments in the world. Thus, the global loss of freshwater habitats poses a significant threat to plants, animals, and humans. In North America, 27% of freshwater fauna are considered threatened with extinction. In fact, United States Environmental Protection Agency reports that all watersheds analyzed in the continental United States have at least one species at risk. This fact is not hard to imagine when one considers that nearly half of all the wetlands in the United States are gone. In addition to playing a critical role in the survival of all living organisms, freshwater habitats serve as

biological filters, degrading contaminants through structural filtration, and chemical and photodegradation, as well as provide a significant increase in flood storage capacity, aquifer recharge, and surface water reuse. As water availability is reduced, community composition of organisms will shift to adapt to different conditions. The resulting shift in community structure will have significant impacts on species assemblages and will greatly alter the food web as well as the physical structure of freshwater habitats. In the coming century, climatic shifts and anthropogenic alterations of freshwater are likely to have profound effects on not only threatened and endangered species, but also ecosystem function. Preservation and restoration of freshwater ecosystems must be a top priority in order to maintain biodiversity as well as critical ecosystem processes.

Summary

The availability of water has numerous direct and indirect effects on the ecology of all living organisms. The presence and duration of water that is available for plant utilization has direct impacts on plant growth, which in turn regulates primary productivity and provides critical resources for numerous species. Freshwater habitats ranging from small temporary pools to permanent lakes support a tremendous amount of aquatic diversity. Community structure of freshwater habitats is largely determined by the duration a site remains inundated and frequency of desiccation. The pool of species that are able to exist in a particular site is determined by both abiotic and biotic factors. Abiotic factors control how long a site remains inundated, and biotic interactions play an important role in determining the species composition of each site.

Anthropospheric and Anthropogenic Impact on the Biosphere

S Pegov, Russian Academy of Sciences, Moscow, Russia

Introduction

Industrial growth proceeded at such a fast pace that in the second half of the eighteenth century it became globally important and resulted in what was called the industrial, or second technological, revolution. Approximately 100 years later, the use of new sources of raw materials and energy brought to life high-efficiency technologies of mass production to produce machine tools and consumption goods. In the later part of the twentieth century, scientific and technical progress stimulated development of high technologies and the advent of space, petrochemical, electronic, pharmaceutical, and other industries. Further progress has brought enormous achievements in the field of information technologies. The rates of dissemination of new technological achievements and economic growth were amazing. Unparalleled high rates of technological development led to a multifold increase in industrial production and consumption of energy resources. The gross world product increased from about US$ 60 million up to US$ 39.3 billion (more than 650 times) between 1900 and the end of the twentieth century. If it took several millennia for agriculture to win the world, then the industrial revolution became a global phenomenon within 1.5–2 centuries.

There were unprecedented rates achieved of burning fossil fuels that had been created by ancient biospheres during a long geological history. For the period from 1950 to 1998, the consumption of various kinds of fossil fuels, expressed in the oil equivalent, increased by 2.1 times for coal, 7.8 times for oil, and 11.8 times for natural gas. While per capita energy consumption was 4000 kcal d^{-1} in the Stone Age, it rose to 12 000 kcal d^{-1} during the era of agricultural technologies, and reached 23 000–250 000 kcal d^{-1} at present. Technogenic interventions in the environment began to compete with many natural processes. Extraction of solid minerals and, hence, the massive impact on the lithosphere sharply increased. About 100 billion tons of raw material is excavated from the Earth's crust annually, or 15 t per inhabitant of our planet.

Studies of ice cores taken from depths of glaciers in Antarctica and Greenland show that such rates of change in biogenic concentrations in the atmosphere did not happen for more than 150 000 years during the overall modern Holocene period.

Studies of carbon isotopes, C^{13} and C^{14}, show that the growth in CO_2 concentrations in the atmosphere for the recent decades is connected with combustion of mineral fuels (Fig. 1). Thus, a huge amount of carbon – up to 180 Gt – had been emitted in the atmosphere as a result of various forms of human land use since its establishment as a planetary phenomenon before 1980, while industrial emissions from the period of industrial revolution to 1980 contributed only 160 Gt of carbon. Thus, a share of land use in CO_2 concentration changes in the atmosphere exceeds 50%.

However, if one compares anthropogenic contribution to the basic biogeochemical cycles, which constitute `biosphera machina' (see more about it below), they do not appear to be too great. At the same time, we feel that there is something odd in our human environment, which leads; us to be concerned about a potential ecological crisis. What is the impact of a dominant anthroposphere on the ecosphere? Is harmonious coexistence of the anthroposphere and the ecosphere possible?

Let us note that unlike such biosphere components as the atmosphere, biota, soils, hydrosphere, and stratosphere, each of which has had more or less clear spatial localization, the anthroposphere has lacked it and has always permeated the above media, even penetrating in the Earth's crust.

World Human Population, Energy Food Demand, and Energy Consumption

It is natural that the intensity of anthropogenic impact on the ecosphere depends (not usually in a linear way) on the size of human population, which grows as shown in Fig. 2.

Two thousand years ago, there were a quarter of a billion people living on the planet. This had doubled to about half a billion by the sixteenth to seventeenth centuries. The next doubling required two centuries (from the middle of the seventeenth century to 1800), the following doubling occurred over only 100 years, while the last one took only 39 years.

Homo sapiens belongs to both the biosphere and anthroposphere. If we consider humans as animals, then all human energy requirements are satisfied through food, and the annual energy food demand per individual is 4×10^9 J. Thus, in the year 2000, the annual energy food demand that determines the annual trophic flow to species *H. sapiens* in the world ecosystem must be 2.4×10^9 J.

The Earth receives 3.5×10^{24} J of solar energy annually, providing the work of the `green cover' with net primary production (NPP) equal to 5.5×10^{21} J yr^{-1} of new biomass. This energy flow also provides a steady state for 1.84×10^{18} g of living

 doi:10.1016/B978-0-444-63768-0.09800-0

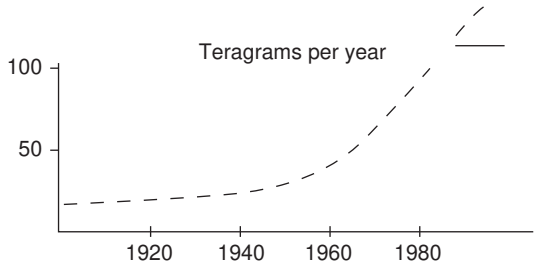

Fig. 1 Natural (solid line) and anthropogenic (dashed line) nitrogen fluxes in the twentieth century. From Vitousek, P.M., 1994. Beyond global warming: Ecology and global change. Ecology 75 (7), 1861–187.

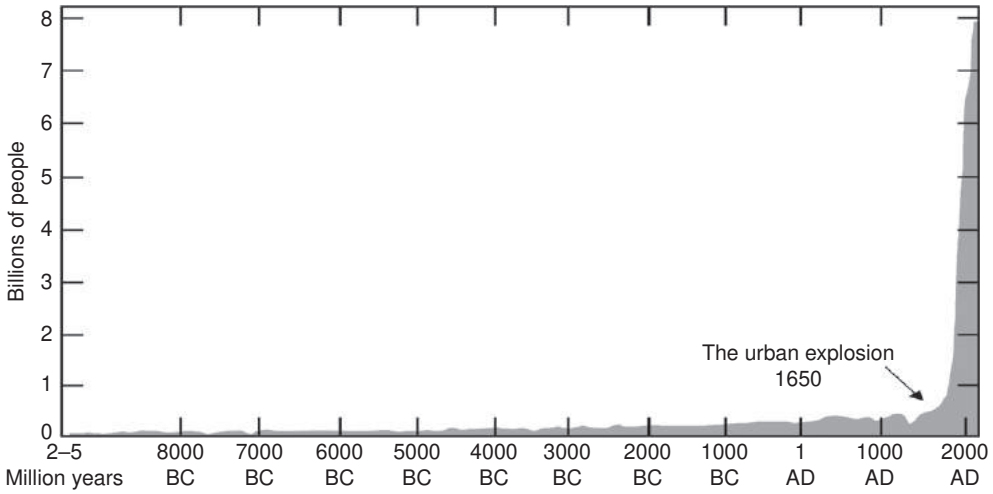

Fig. 2 Dynamics of the world population. From Heinke, G.W., 1997. The challenge of urban growth and sustainable development for Asian cities in the 21st century. AMBIO 8, 130–143.

biomass (or 3.5×10^{22} J), and animal biomass constitutes only 0.8% of it, that is, 1.46×10^{16} g. Animals consume only 3% of the NPP (7.35×10^{19} J yr^{-1}). *Homo sapiens* is one of the animal species with biomass 4.2×10^{14} g (in the year 2000), constituting 2.8% of the total biomass of animals. Therefore, humans can use only $2.8 \times 3 = 0.084\%$ of the NPP, that is, 2×10^{18} J. Thus, the food demand of mankind is more by almost 1 order of magnitude than the trophic flow, that is, the trophic chains including *H. sapiens* are very strained. It may bring in turn either global starvation or destruction of this chain, elimination of many species from the chain (or its elimination in the whole from the global ecosystem).

In 1650, human population was approximately 600 million, that is, an order of magnitude less than today (Fig. 2). From this, it follows that that the trophic flow was equal to food demand, and the corresponding trophic chain was not strained. In other words, humans were still one of many species, coexisting within the biosphere.

On the other hand, if we consider the fate of *H. sapiens* from the point of view of physical theory of fluctuations, the probability of fluctuation, which could cause the elimination of *H. sapiens*, is equal to

$$\mathrm{Pr} = \exp\left[-\frac{\text{energy demand for human population}}{\text{energy supply for all animals}}\right].$$

At the time of the Neolithic revolution, the human population consisted of around 4×10^6 individuals, and required an energy supply of 1.6×10^{16} J yr^{-1}, then $\mathrm{Pr} = \exp[-1.6 \times 10^{16}/7.35 \times 10^{19}] \approx 99.98\%$. If we estimate this probability for the year 2000, we get $\mathrm{Pr}' = \exp[-2.4 \times 10^{19}/7.35 \times 10^{19}] \approx 72.2\%$. Looking at these numbers one can say that *H. sapiens* as a biological species was very fortunate that it has not been eliminated before the anthroposphere arose. Namely, the industrial and accompanying agricultural revolution could mask the consequences of growing strain in the trophic chain.

One of the main characteristics of the anthroposhere is the use of fossil fuels (traces of the past biospheres), and (at present) such `nonbiosphere' energy as nuclear, with an accelerating rate (see Fig. 3).

At the present time, the anthroposphere spends about 3×10^{20} J yr^{-1} to provide for its functioning. This is mainly energy of fossil fuels and nuclear energy (fraction of the `pure' biosphere energy – hydropower station and firewood – in this balance is $\sim 5\%$), and it constitutes about 13% of the global NPP, 2.3×10^{21} J yr^{-1}. Nevertheless, this percentage is enough for the biosphere and anthroposphere to strongly compete for common resources, such as land area and freshwater. Contamination of the environment and reduction of biotic diversity are typical consequences of the competition.

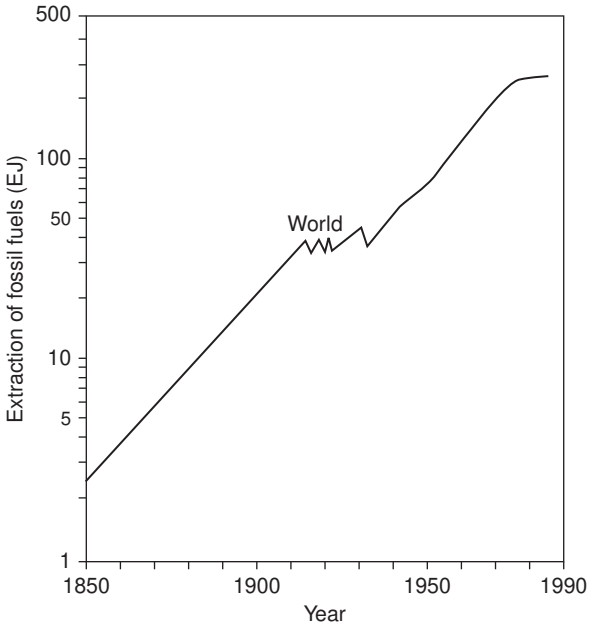

Fig. 3 Accelerating rate of use of fossil fuels and nuclear energy.

Since the biosphere (considered as an open thermodynamic system) is at a dynamic equilibrium, all entropy flows have to be balanced as well. Therefore, the entropy excess, which is created by the anthroposphere, has to be compensated by means of two processes: (1) degradation of the biosphere, and (2) changes in the work of the Earth's climate machine (in particular, through increases in the Earth's average temperature).

The energy of dissipation, corresponding to the full destruction of biota (equivalent to its complete combustion), is equal to 3.5×10^{22} J, while the energy dissipated by the anthroposphere is 3×10^{20} J. Even if the rate of the energy consumption in the anthroposphere does not increase, then this `anti-entropy storage' of biota can make up for the entropy, produced by the anthroposphere, in the next 120 years. If this `technogeneric' entropy could be compensated by soil destruction, then the agony would continue in the course of 300–400 years, since the storage of organic matter in soil is three- to fourfold larger than in biota.

Anthropogenic Impact on the Global Biogeochemical Cycles

It is known that all biogeochemical work of the biosphere is performed by the global biogeochemical cycles. The principal ones, which are, in particular, responsible for the contemporary global climate change, are the global carbon, nitrogen, and sulfur cycles.

Carbon. Gaseous carbon compounds of the global cycle include carbon oxides (CO_2, CO), methane (CH_4), and a great amount of different volatile hydrocarbons that are released as a result of vegetation metabolism and fuel combustion. The main problem here is to estimate flows of the main `greenhouse gases', such as carbon dioxide and methane, into the atmosphere, and their anthropogenic components.

The CO_2 flow into the atmosphere from anthropogenic sources results mainly (75%) from organic fuel combustion (coal, oil, gas) and also from other kinds of economic activities (cement production, flue gas burning), making 20 billion tons yr^{-1}. One should add about 7 billion tons of CO_2 due to annual destruction of forests and loss of vegetative cover. The overall CO_2 anthropogenic flow into the atmosphere reaches about 27 billion tons yr^{-1}, that is, less than 0.01% from the CO_2 total amount in the atmosphere. According to earlier data, the CO_2 anthropogenic emission into the air amounted to 21.3 billion tons yr^{-1} in 1990. Thus, estimating the proportion of anthropogenic and natural components in the CO_2 flux into the atmosphere, one should note that the natural component is approximately 25–30 times more than the human-made one.

Methane inflows to the atmosphere are subdivided into two groups:

- natural biogenic and abiogenic;
- anthropogenic that consists of two subgroups: sources relating to human activity as a biological species and technogenic sources.

An analysis of different data by Adushkin *et al.* in 1998 allows us to conclude that:

1. natural biogenic sources are responsible for an annual average flow of methane equal to about 540 million tons yr^{-1};
2. abiogenic natural sources from lithosphere and hydrosphere make up *c.* 1360 million tons of methane annually (therefore, a ratio between biogenic and abiogenic methane is 1:2.5 in natural sources);
3. anthropogenic sources, including methane resulting from human agricultural activity, losses of methane during extraction of fossil fuels, and its industrial emissions produce an average annual flow of methane equal to about 1100 million tons yr^{-1}.

Table 1 Global gas fluxes in the atmosphere from biosphere and anthroposphere

Source	*CO (bln. t yr^{-1})*	*CH_4 (10^6 t yr^{-1})*	*SO_2 (10^6 t yr^{-1})*	*NO_2 (10^6 t yr^{-1})*	*Total fluxes (bln. t yr^{-1})*
Natural	700	1900	200–300	310–1090	707.41–708.29
Anthropogenic	21.3–27	1100	130–210	30–110	22.92–29.12
Common	721.3–727	3000	330–510	340–1200	730.33–737.41

Therefore, the natural component of methane in the atmosphere estimated at 1900 million tons yr^{-1} is 1.7 times larger than its anthropogenic component.

Nitrogen. There are three kinds of nitrogen oxides – nitrous oxide (N_2O), nitrogen oxide (NO), nitrogen dioxide (NO_2) – and some ammonia. Nitrous oxide has the greatest concentration in the atmosphere (=270–280 ppbv).

Nitrogen oxides reach the atmosphere from different natural sources, such as decomposition of nitrogen-based compounds in the ground by anaerobic bacteria, forest and peat fires, hydrolysis, and sedimentation of nitrates. Nitrogen oxides give rise to aerosols of nitric acid, which is one of the basic components of acid deposits. Total emissions of nitrogen oxides from natural sources are estimated to be 310 million tons yr^{-1}, 540 million tons yr^{-1}, or 1090 million tons yr^{-1} depending on the source.

Sources of the anthropogenic flux of nitrogen oxides are industrial emissions of thermal power stations, chemical and iron and steel industry enterprises, waste dumps of coal and sulfur mines, motor transport, burning of biomass, etc. Total emissions of nitrogen oxides from anthropogenic sources are estimated to be from 30–55 million to 100–110 million tons yr^{-1}.

Therefore, a ratio of anthropogenic and natural components in a flux of nitrogen oxides is 1:10, that is, the anthropogenic flux is 10 times less than the natural one.

Sulfur. In nature, sulfurous gas, hydrogen sulfide, and other gaseous compounds containing sulfur are formed in large quantities as a result of processes of biological decomposition, decomposition of sulfur-containing ores, volcanic activity, and geothermal sources. Hydrogen sulfide getting in the atmosphere is quickly oxidized to make sulfurous gas; therefore, it can be considered one of the significant sources of SO_2.

A wide spectrum of gaseous sulfur compounds is released in the atmosphere after eruptions of volcanoes. Over a 25-year period, annual SO_2 emissions by subareal volcanoes changed from 10 to 30 million tons yr^{-1}. Volcanoes are responsible for approximately 7% of sulfur compounds getting to the atmosphere.

Thus, a total flux of gaseous sulfur compounds from natural sources (mainly gaseous sulfur dioxide) is estimated at 200–300 million tons yr^{-1}.

Anthropogenic sources of gaseous sulfur compounds are metallurgical enterprises, thermal power stations, cheminasescal and coke plants, oxidated landfills of collieries and sulfidic ores, transport, and explosive works. In addition, anthropogenic hydrogen sulfide is formed at factories manufacturing kraft pulp, mineral oil and natural gas treatment facilities, and enterprises making artificial silk and nylon. Global emissions of anthropogenic sulfur dioxide increased during 1950–90 from 20 to 160 million tons yr^{-1}.

The total emissions of anthropogenic sulfur oxides in the world are estimated at 130–200 million tons yr^{-1}. As a result, we observe that the anthropogenic flux of sulfur oxides is practically same, as its natural counterpart. Hence, an impact of anthropogenic sulfur oxide emissions on the environment, in particular, as regards atmospheric pollution, is comparable to the one from natural sources (**Table 1**).

Anthropogenic Impact on Chemical Composition of the Biosphere

The biosphere represents an immense equilibrium system of chemical reactions. Perturbation of the equilibrium at one site may provoke uncontrolled change in the whole system, in spite of the fact that there are different compensating mechanisms (Le Chatelier's principle). We can say that chemical activity of mankind is almost compared now with the chemical work of all living matter. For instance, about 10^{17} g of minerals are excavated annually from the Earth; this value already constitutes 5.5% in relation to 1.84×10^{18} g of all living biomass.

This is in regard to the so-called `gross' characteristics; if we look at `information' ones, in particular atomic composition of excavated matter, then one can see that its composition significantly differs from the compositions of living matter, soil, and oceanic waters. Note that all these minerals are dispersed finally over the Earth surface. The impact on the metal cycles is most significant (**Table 2**).

Our technocivilization is a civilization of iron. About 10% of iron used is destroyed as a result of corrosion, friction, etc. If the amount of lost iron increases by a factor of 2, then, in accordance with our table, soil concentrations of lead increase more than tenfold, and mercury concentrations by 100 times, with toxic contamination of these substances.

Global Land Use: Agriculture and Urbanization

One of the main spatial factors of anthropogenic impact on the biosphere is the rapid growth of agricultural lands, with accompanying change in their land use. Human activity to produce food leads to the reduction of areas of habitat for natural organisms and to a sharp increase in the area of marginal ecosystems. Improvement of agricultural technologies and wide application of fertilizers led to a fourfold rise in land productivity and sixfold rise of agricultural yield in the twentieth century.

Table 2 Relation of metals in soil, ocean, living matter, and world economy with respect to iron concentration

Element	*Soil*	*Ocean*	*Living matter*	*World economy*
Fe	1	1	1	1
Al	1.8	1	0.5	1.5×10^{-2}
Be	1.5×10^{-4}	6×10^{-5}	Traces	2×10^{-5}
Cr	5×10^{-3}	2×10^{-3}	1×10^{-2}	2×10^{-2}
Mn	2.1×10^{-2}	2×10^{-1}	1×10^{-1}	4×10^{-3}
Co	2.5×10^{-4}	5×10^{-2}	2×10^{-3}	3×10^{-4}
Ni	1×10^{-3}	2×10^{-1}	5×10^{-3}	4.5×10^{-4}
Cu	5×10^{-4}	3×10^{-1}	2×10^{-2}	1×10^{-2}
Zn	1×10^{-3}	1	5×10^{-2}	5×10^{-3}
Mo	5×10^{-5}	1	1×10^{-3}	3×10^{-5}
Ag	2.5×10^{-6}	3×10^{-2}	Traces	1.7×10^{-4}

Hg	2.5×10^{-5}	3×10^{-3}	1×10^{-5}	1×10^{-5}
Au		4×10^{-4}	Traces	3×10^{-6}
Pb	2.5×10^{-4}	3×10^{-3}	5×10^{-3}	4.5×10^{-3}

Vinogradov, A.P., 1959. Chemical Evolution of the Earth. Moscow: USSR Academy Scientific Publisher.

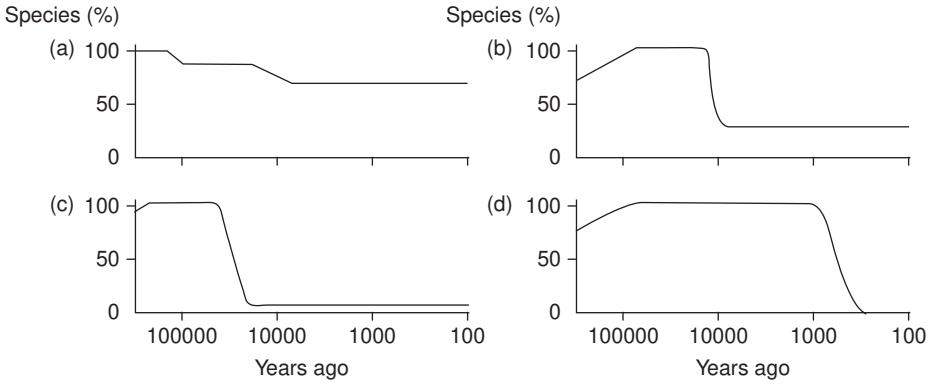

Fig. 4 Loss of large animal species in Africa (a), North America (b), Australia (c), Madagascar and New Zeeland (d) (The World Environment, 1992).

However, this was accomplished by reducing populations of organisms and biodiversity of natural ecosystems (Fig. 4). The biomass of agrocenoses never reaches the biomass of forests, while agrocenosis productivity is lower than that of natural ecosystems. Replacement of natural ecosystems by agrocenoses results in an 11.7% loss of the net primary product, while about 27% of NPP is lost in all human-degraded ecosystems.

About 23% of all usable lands in the world are subject to degradation, which leads to a reduction in its productivity. Agricultural technologies also lead to the destruction of a mid-term reservoir of biogenes, that is, soils. Significant amounts of soil are washed away. As a result of desertification, about 3% of NPP is lost, but soil organisms essentially suffer since they perish due to soil erosion and compression by agricultural implements, plowing, and application of fertilizers. For example, administration of nitrogen in the ground amounting to 3 g m^{-2} a year, with an unchanging amount of other fertilizers, would reduce the population of species by 20%–50% (Fig. 5).

Cities exert a spatially concentrated impact on the environment. While the world population has grown, since 1976, by 1.7% a year on average, population of cities increased by 4% annually. Accelerated urban growth leads to pollution of water, soil, and the air, making their inhabitants live in an unfavorable ecological and social environment. In addition, urbanization is accompanied by a sharp decrease in resistance of urban area territories to technogenic and technonatural hazards. This raises risks of urban dwellers and requires huge efforts of municipal authorities to maintain viability of urban infrastructure.

Industrial Revolution, Anthropocentrism, and the Biosphere Degradation

Industrial revolution unequivocally established an anthropocentric ideology in the human–nature relations. Humans placed themselves at the center of the biosphere, giving it a role of a huge pantry from which it is possible to extract resources beyond all

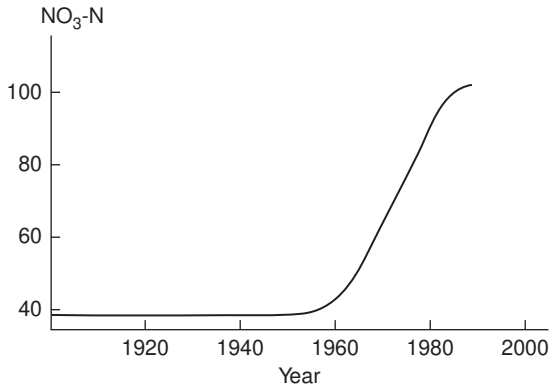

Fig. 5 Change in concentration of nitrogen compounds in estuary of the Mississippi River since the beginning of the twentieth century. From Vitousek, P.M., 1994. Beyond global warming: Ecology and global change. Ecology 75 (7), 1861–1876.

Table 3 Human-disturbed terrestrial ecosystems (not including glaciers and bare lands)

Land area	*Undisturbed area*	*Partly undisturbed areas*	*Totally disturbed area*
134 904 471 km^2	27%	36.7%	36.3%

bounds and, in return, store resulting waste. From the point of view of preservation of the global ecosystem, such relations are unpromising. Calculations show that the twenty-first century will see the exhaustion of many kinds of natural resources of our planet with perhaps unrealistic expectations that further technological advances and economic growth will open up new vistas for solving environmental problems.

Environmental degradation in the latter part of the twentieth century reached global scales. Notwithstanding that about US$ 1.2 billion was spent over the 20 years between the UN conferences in Stockholm (1972) and Rio de Janeiro (1992) on environmental protection, the state of the Earth's environment was worsening. Industrial development that should have strengthened economic advances went into contradiction with the environment since it failed to take into account real limits to biosphere sustainability. Two opposite trends prevail in the global economy: gross world income is growing while the global wealth (first of all, life-supporting resources) is shrinking.

Industrial revolution has led to further pressure of technically and technologically equipped humans on the environment and has created conditions for a new ecological crisis. The consequences of such processes are hard to predict. It is clear that the coming crisis will essentially differ from the previous crises.

Data on disturbed ecosystems is also given in **Table 3**.

Conclusion: Philosophy of the Biosphere

A concern over an imminent catastrophe is growing in the enlightened sectors of society. One of the first among the outstanding thinkers who have realized all the gravity of consequences of industrial revolution was Vernadsky, who developed a scientific concept about the biosphere as a synthesis of knowledge about humans, biology, and sciences about nature, closely connected historically. Dominant in this doctrine is belief in an indestructible power of scientific ideas as a planetary phenomenon capable to reconstruct the biosphere in a noosphere – the sphere of reason.

Many scientists and public and political leaders have understood this idea as a philosophical doctrine of the future development of the world. At the same time, the doctrine about a noosphere remains hardly worked out even at the conceptual level. At the world summit in Rio de Janeiro (1992), an attempt was made to suggest a global program of development of civilization. The document accepted at the conference was named as a concept of sustainable development.

The biosphere as a self-developing system for all its history has gone through a large number of local and global crises, every time reviving and continuing its development at a new evolutionary level. Humans as any biological species are temporary inhabitants on the Earth. Studies of biologists show that mechanisms of constant change of species incorporated in evolution of fauna provide existence in the biosphere of one species during about 3.5 million years on average. Therefore the modern human – Cro-Magnon man – that appeared 60 000–30 000 years ago as a biological species is at its initial stage of development. However, his activity for rather a short term placed him against the biosphere and he created conditions for an anthropogenic crisis.

Considering prospects of the postindustrial development of society, it is necessary to return to ecological understanding of sustainable development. Development can be considered sustainable if it remains within the limits of economic capacity of the biosphere, and maintains its functions as a self-organized and self-adjusted system.

Biogeocoenosis as an Elementary Unit of Biogeochemical Work in the Biosphere

J Puzachenko, Russian Academy of Sciences, Moscow, Russia

Introduction

Biogeocoenosis belongs to a class of ecological concepts such as phytocoenosis, landscape, units, and sites based on the ideas of spatial uniform units that are distinguished in a given area and separated by visible boundaries. The concept originated by realizing the necessity to study and display the interactions among soil-forming rocks, soil (edaphotope), atmosphere (climatope) with vegetation (phytocoenosis), animal population (biocoenosis), and microorganisms (microbocoenosis). The author of this concept is a Russian geobotanist and paleogeographer V. N. Sukachev.

Biogeocoenosis

The ideas of Sukachev as a geobotanist were close to those of Clements, although Sukachev never recognized phytocoenosis as an organism motivated by the fact that, unlike an organism, elements and parts of phytocoenosis and biogeocoenosis can exist out of the whole. However, he also did not accept the individualistic concept of Glizon-Ramenskii concerning the plant cover organization. According to the author's definition, on a specific area of the Earth's surface, biogeocoenosis is a combination of homogenous natural phenomena (atmosphere, rocks, vegetation, animal and microorganisms, and soil and water conditions). These components possess specific types of interactions and a definite type of interchange of matter and energy occurs between them and with other natural phenomena, thus representing an internally contradictory dialectical unity, being in constant movement and development. N.V. Timofeev-Resovskii determined biogeocoenosis as a biochorological unit, within which there exist no biocoenotical, geomorphological, hydrological, climatic, or pedological–geochemical boundaries. Biogeocoenosis is implied as an integral discrete elementary natural cell of the biosphere that realizes the function of matter and energy transformation. Although the boundaries of each biogeocoenosis may be distinguished according to any of its components, practically it is better to accomplish it using boundaries of the best-observed component, namely vegetation, that is, according to the boundaries of phytocoenosis. Different biogeocoenoses interact with one another in space forming the biogeocoenotic cover. Sukachev did not consider specially the spatial dimension of the biogeocoenotic cover, but as it follows from the context, it corresponds to a rather vast territory commensurable with a floristic district or area. Sukachev discussed in detail the correlation of his concept with Tansley's concept of an ecosystem, different variants of its definition, and the concept of landscape and its morphological units, mainly in the interpretation of the adherents of the Russian school. He paid attention rightly to the fact that an ecosystem is considered (according to Tansley) as an abstract physical system uniting organisms with their environment. It is worthwhile to recall that Tansley actively objected to Clements's holistic concept of organism and considered ecosystem as a set of relations within different spatial–temporal intervals and at different hierarchical levels rather than a reality. Later on, this methodological content of the ecosystem concept disappeared almost completely, and ecosystem has been considered as a natural unit representing a totality of biotic and abiotic elements and as a functional system. Nevertheless, the concept of ecosystem maintains its general meaning along with its traditional interpretation as a chorological unit. Sukachev insisted that the concept of biogeocoenosis as a strictly territorial unit was more definite than the uncertain concept of ecosystem. One can accept this to be true to some extent, but the history of development of science showed that precisely some uncertainty inherent to the concept of ecosystem ensured its viability and incorporation into the general scientific basis. In the light of general system concepts, biogeocoenosis may be considered as a kind of ecosystem which possesses relatively spatially homogenous or stable (random or specific quasi-regular variation) properties in terms of its components within the framework of their observed boundaries. At the same time, the reality and commonness of the distinguished boundaries are not proved specially, but accepted *a priori*, assuming that these boundaries are relatively gradual.

Comparing the concept of biogeocoenosis with the modern concepts of landscape, it is worthwhile to note that the latter are interpreted differently. The concept of biogeocoenosis is most likely to be close to that of units accepted in the Canadian and Australian schools. However, a unit in landscape science is a functional unit rather than an operational one. In American forest science, the notion of biogeocoenosis is comparable territorially with that of stand.

Sukachev, who fully accepted the concept of the biosphere proposed by Vernadsky, regarded biogeocoenosis as an elementary cell of the biosphere.

Researchers who accepted the concept of biogeocoenosis differentiated between the spatial structural elements of biogeocoenosis: vertical layers and horizontal occasionally or quasi-regularly alternating parcels (parts), which are usually distinguished by the shrub, grass, and moss layers commensurable with microassociations. The genesis of parcels was mainly related to the heterogeneity of the tree layer, and they may be associated with gaps. Different parcels are often related to different pedons of soil. Sometimes, parcels are determined by the initial pattern of the nanorelief and soil-forming rocks.

Biogeocoenotic Process

Sukachev considered studies of biogeocoenoses as an independent science – biogeocoenology, which studies the biogeocoenotic process. The idea of the biogeocoenotic process proper, being formed after the definition of the notion `biogeocoenosis', is the content of the concept and supplements the Vernadskii ideas for the local level of the biosphere organization. In addition, the elaboration of the concept of biogeocoenotic process was based on the ideas of materialistic dialectics (in this aspect, Sukachev was close to Tansley), kibernetics, and systems theory affecting greatly the development of science in the 1960s. The abundant experience of Sukachev himself as a paleobotanist, geobotanist, geographer, and naturalist was also of great importance.

The dialectic law of the unity and conflict of opposites is postulated as the basis of self-development of biogeocoenosis, with its existing discontinuities or disruptions, destruction of the old, and initiation of the new. Although a biogeocoenosis is an open system, all of its components together still form a certain integral dialectical unity characterized by internal contradictory interactions, which never produce a state of equilibrium within that unity (system). Climatope, edaphotope, phytocoenosis, zoocoenosis, and microbocoenosis are considered as components of biogeocoenoses.

The action of these interior forces leads to self-development, whereas the effect of the external ones leads to some variation and disturbance of the developmental process proper. It is practically useful to consider the mechanisms of nonequilibrium thermodynamics discussed by I. Prigogene, and the dynamics of nonlinear dissipative systems with positive and negative feedbacks capable of innovations discussed by G. Hacken.

The biogeocoenotic process is understood as a change in the matter and energy exchange due to the interaction of organisms with each other and with the environment, as well as between components of biogeocoenosis. The biogeocoenotic process includes not only interactions and exchange of matter and energy between biogeocoenose components, but also interactions and exchange of matter and energy between biogeocoenoses and their surroundings – the environment, in which they exist, and other biogeocoenoses (both adjacent and more remote ones). Since the process of interaction of a biogeocoenosis with its environment is partly expressed in terms of the incessant outflow of energy into space, it has, as it were, an entropic character. But, at the same time, new matter and energy are constantly entering the biogeocoenosis. A biogeocoenosis is considered as an elementary cell, and the biogeocoenotic process in each biogeocoenosis is typical due to specific relations between the biogeocoenosis components and the interaction with their environment. Under similar environmental conditions, biogeocoenoses with similar composition and structure also realize similar biogeocoenotic processes. Evidently, this model is the basis for the development of spatial hierarchical organization of biogeocoenosis, and the author of the concept suggests that the biogeocoenotic cover is a set of interacting biogeocoenoses over a rather vast territory.

The biogeocoenotic process unites four relatively independent processes:

1. The interactions of biogeocoenosis components and elements among themselves, which do not remain constant, but change in time and alter the course of the biogeocoenotic process. This process is a purely internal one and may be called `endocoaction'.
2. The introduction of microorganism germs, plants or new species of organisms by wind and water, and of some organisms from outside, which can change somewhat the biogeocoenotic process. This process was proposed to be called `inspermation'.
3. The introduction of mineral and partly organic matter with dust, surface, and intrasoil runoff. This process is called `inpulverization'.
4. The removal of mineral and organic matter by water and other organisms. This process is called `expulverization'.

The process of internal interactions never ceases; it slows down or accelerates to some extent. The slowing down is determined by a gradual increase in the resilience of biogeocoenosis, but the acceleration is determined by the disturbance of this stability via both settling of new species and changes in the structure of the interactions in the course of self-development. The second and third processes change at the level of the biogeocoenotic cover resulting from climatic and geodynamic fluctuations and asynchronous self-development of neighboring biogeocoenoses as well. The fourth process may be considered as an irreversible one to a considerable degree, and if it is not compensated for the third process, the changes in biogeocoenosis are determined by slow but permanent removal of mineral and organic substances from it. Finally, within the biogeocoenotic cover, the process of formation related to the origin of new phenotypes, genotypes, and morphofunctional forms of organisms is also realized.

A rather strict definition of the biogeocoenotic process as a change of states determined by different mechanisms allowed Sukachev to construct a harmonious classification of the dynamics of biogeocoenoses and biogeocoenotic cover on the following basis: equilibrium process with natural reversibility; nonequilibrium irreversible process; self-development (autogenous or endogenous processes), processes under the influence of external forces (exogenous); according to variation in time and space.

The classification of types of dynamics of the forest biogeocoenoses elaborated by Sukachev is given below:

A. Cyclic (periodic) dynamics of forest biogeocoenoses (reversible changes in forest biogeocoenoses).
   (1) Daily changes in biocoenoses.
   (2) Seasonal changes in biocoenoses.
   (3) Annual (weather) changes in biocoenoses.
   (4) Changes in biocoenoses due to the process of regeneration and growth of woody and other vegetation:
      (a) regular regeneration of woody plants;
      (b) irregular (wave) regeneration of tree stands;

(c) synusial dynamics, especially parcel dynamics (these variants of the dynamics were likely to be associated with a gap dynamics model; models of these types of relationships reproduce usually restricted quasi-cyclic fluctuations of productivity, biomass, and species composition).

B. Dynamics of the forest biogeocoenotic cover of the earth, or successions of forest biogeocoenoses.
   I. Autogenous (irreversible) successions of biogeocoenoses (developments of the forest phytogeosphere, of forest biogeocoenogenesis).
      (1) Syngenetic succession of biogeocoenoses.
      (2) Endogenous (endodynamic) successions of biogeocoenoses.
      (3) Phylocoenogenetic successions of biogeocoenoses:
         (a) phytophylocoenogenetic successions of biogeocoenoses;
         (b) zoophylocoenogenetic successions of biogeocoenoses.

(*Note*. Syngenetic processes are irreversible ones that proceed only due to alterations in the species structure without irreversible environmental changes (typical processes are the development of high bogs, progressive development of eluvial and illuvial horizons of soils). Phylogenetic successions imply processes determined by the origin of new forms. Probably, such processes are useful to be included into the dynamics determined by phylocoenogenesis of viruses and bacteria, including also the saprophytic microorganisms).

   II. Exogenous (reversible and irreversible) successions of biogeocoenoses.
      1. Hologenetic (irreversible) successions of biogeocoenoses:
         (1) climatogenic successions of biogeocoenoses;
         (2) geomorphogenic successions of biogeocoenoses;
         (3) selectocoenogenetic or areogenic successions of biogeocoenoses;
            (a) phytoareogenic successions of biogeocoenoses;
            (b) zooareogenic successions of biogeocoenoses.

(*Note*. Hologenetic processes are realizable at the regional level of the biogeocoenotic cover organization. It is worth noting that Sukachev did not extend the principle of actualism and reversibility to climatogenic, that is, paleoclimatic successions. Selectocoenogenetic successions may appear due to the invasions of alien species. Changes determined by invasions of agents of feral herd diseases of plants, animals, and saprophytic microorganisms are expedient to be included into this type of dynamics. A typical example is the mass and, most likely, irreversible death of American chestnut (*Castanea dentata* (Marsh.) Borkh.) in the Appalachians. If species change their properties in the process of settling, selectocoenogenetic successions are indistinguishable from phylocoenogenetic ones).

      2. Local (reversible and irreversible) catastrophic successions of biogeocoenoses.
         (a) anthropogenic successions of biogeocoenoses;
         (b) zoogenic successions of biogeocoenoses;
         (c) pyrogenic successions of biogeocoenoses;
         (d) windfall successions of biogeocoenoses;
         (e) successions of biogeocoenoses produced by mud streams, landslides, sudden inundations, and other causes.

Probably, this classification of the dynamics may be recognized as the most complete. For the modern ecology, it contains all the bases for particular and integrating models of dynamics and research programs (e.g., programs directed to the accumulation of data on the irreversibility of self-development processes). However, in order that the concept of biogeocoenosis might create the necessary bases for studies and simulation of biogeochemical cycles, it should contain some concrete system definition and refinement of ideas of the spatial–temporal hierarchy and elimination or weakening of contradictions between individualistic and organism concepts of spatial organization of the biosphere and its components.

Biogeocoenosis and the Biosphere

The system that specifies the biogeocoenosis concept is rigorously introduced in works by Vernadsky, who was not only a naturalist, but also a physicist and chemist; he possessed knowledge in thermodynamics and thermostatics. In complete accordance with concepts of thermostatics, he determined an object and its elements in the following way: ``I will call a set of organisms participating in geochemical processes living matter. Organisms composing this set will be elements of living matter. With all this going on, we will pay attention not to all the properties of the living matter, but only to those which are related to its mass (weight), chemical composition, and energy. In such a comprehension, living matter is a new scientific notion''. Later, Vernadsky directly associates individuals with molecules of gases and suggests to consider living matter as a statistical ensemble of elements. Thus determining the concept of the biosphere, he states that laws of equilibrium (equilibrium process) in general mathematical form as revealed by J. Gibbs (1884–87) (who reduced them to relationships between independent variables, such as temperature, pressure, physical state, and chemical composition, which characterize the chemical and physical processes and participate in system processes) could be applied to a living system of bodies. According to this statement, one can distinguish ``thermodynamic spheres as areas of equilibrium of thermodynamic variables that are determined by values of temperature and pressure; phase

spheres that are characterized by the physical state (solid, liquid, etc.) of bodies in their composition, chemical spheres different in the chemical composition. Only one sphere distinguished by E. Suess – the biosphere – remained aside. Undoubtedly, all the reactions of the biosphere follow the laws of equilibrium, but they include a new characteristic, new independent variable which was not taken into account by J. Gibbs and is very important in other equilibrium forms (in the context of thermodynamics). A special reaction is the phenomenon of photosynthesis, with radiant light energy as an independent variable. Therefore, ``living organisms, introducing the radiant light energy to physicochemical processes of the earth crust, drastically differ from other independent variables of the biosphere. Like these variables, living organisms change the course of equilibrium, but unlike them, they represent specific autonomous formations as specific secondary systems of dynamic equilibrium in the primary thermodynamic field of the biosphere. The autonomy of living organisms reflects the fact that the thermodynamic field, which inherently has quite other parameters than those observed in the biosphere. Therefore, organisms retain their own temperature (many organisms do so strongly) within the medium at another temperature and have their interior pressure. They are isolated in the biosphere, and its thermodynamic field is important for these organisms only due to the fact that it determines the area of existence of these autonomous systems, but not their interior field. From the chemical standpoint, their autonomy is expressed in the fact that chemical compounds produced in these systems cannot be synthesized beyond them under usual inanimate conditions of the biosphere. Being fallen into the conditions of this medium, they turned out to be unstable, are decomposed, transformed to other bodies, and in that way, they become disturbers of the equilibrium and represent a source of free energy in the biosphere''. Vernadsky discusses in detail all the properties of living matter known by that time, including basic mechanisms of its evolution. Generalizing his writings and using the modern terminology, one can define living matter as a stationary dissipative system of organism elements, which is far from thermodynamic equilibrium with free energy and exergy. The stationary state of this system is supported by the absorption of solar energy, which is responsible for the permanent conversion of the chemical element flux into a new organic form, realizing the cycle with a release of free energy to the environment, and transforming the latter as a result of useful work (exergy). The simplest example of this work is the intensification of the water cycle in the biosphere with appropriate contribution to climate control, that is, changes of equilibrium correspond to thermodynamic variables that change climate. So, when combining the concept of biogeocoenosis with the concept of `living matter', we obtain rather strict thermodynamic bases for the characterization of the biogeocoenotic process, as well as all the necessary fundamentals for consideration of their autochthonous (endogenous) dynamics and self-development of biogeocoenoses and biogeocoenotic cover as a nonequilibrium, stationary thermodynamic dissipative system. However, all this is insufficient to consider biogeocoenosis as an elementary cell of the biosphere, within which nonliving matter is converted to living one and, conversely, incomplete transformation of the former to mobile chemical compounds occurs with a release of free energy and changes in the environment (thermodynamic variables of the atmosphere, hydrosphere, and lithosphere).

Reductionism and Holism

According to the Gleason–Ramenskii continuum individualistic concept (reductionism), there are no necessary bases for the initiation of spatial cells as relatively discrete formations without any additional conditions. The existence of such cells is the basis of Clements's organism concept (holism). It is worthwhile to note that, strictly speaking, Clements may not be its original author. Even at the dawn of the development of geography, in 1811, Butte stated that none of the scientists had any doubts regarding the existence of earth organisms. Within any specific field, a combination of all the phenomena is not a simple set; they represent a holon. Butte assumed individual countries and districts (including humans), as `organisms', which, as any organism, may be considered both in terms of their physical and psychical aspects. He wrote that ``areas as a holon assimilate the human population'', and ``population assimilates these areas not less constantly''. At the same time, opponents of the hyperholon paid attention to the fact that it was difficult to find districts the boundaries of which could be determined as the basis of all the phenomena. The most complete criticism of this integral concept was given by A. L. Bucher in 1827. As a result, he concluded that there was no necessity to study boundaries, and regions might be distinguished in any arbitrary manner. He proved that geography should study relations between particular phenomena in any area of the earth's surface. Even now the same contradictions exist: on the one hand, the individualistic concept has been fully recognized; on the other, Gaia's superorganism concept is very popular. The criticism of this concept rests on traditional bases and factually repeats the discussion that has been continued for almost 200 years. If to leave aside these disputes, we can state that the two models of living matter – individualistic (reductionism) and organism (holism) – may be considered as those reflected in real natural phenomena. Developing these models up to possible logical limits, in both cases we obtain incompatible constructions. In the first variant, it is a construction similar to Dawkins's selfish gene; in the second one, it is a superorganism with its own purposeful development and superstability similar to Gaia's model. The individualistic model has been well substantiated theoretically and realized in microcosm and perfusion cultures. For the simplest linear variant, a theorem has been proved asserting that, in the homogenous environment, the number of stable coexisting populations is equal to the number of resources or, in general, to the number of any operating factors. The relations following this model were obtained by the methods of ordination for a wide diversity of plants and animals in direct terrain investigations. Particularly, such relations between different layers of a forest community and main tree species were shown for the Eurasian forest zone.

To prove the integrity of biogeocoenosis, ecosystem or plant community and their emergent properties should be understood more completely. Raised bogs may be referred to the formations of this type, the progressive growth of which is

supported by the positive feedback between the groundwater table at the territory adjacent to the bog and development of sphagnum mosses. The accumulation of dead parts of mosses raises the groundwater table, and this process promotes the further moss growth and peat accumulation. Raised bogs form their own dynamic spatial structure, and minimization of moisture evaporation in hot summer months may be accepted as its emergent feature. Such a raised bog in fact resembles a superorganism, which occupies slowly (up to 10 cm per year) the neighboring territories displacing forest communities. True, this superorganism exists primarily due to the almost complete cessation of the cycle of matter, representing an essential deceleration of the water cycle at the exergy lowest for the forest zone. Such organism features are difficult to find for many typical cases. If not to ignore the traditional experience to distinguish phytocoenoses as relatively homogenous spatial formations that indicate biogeocoenosis, their integrity may be accepted as an empirical fact. At the same time, it is admitted that the corresponding mechanisms are poorly known.

From the standpoint of postmodern science, there is no necessity to create a single eternal theory. The most topical concept is one that initiates research and provides foundations for verification of competitive hypotheses, as well as stimulates their diversification and does not eliminate their joint acceptability. From these positions, *a priori* denial of these two models is identical to a nonacceptance of liberal or social views in the organization of human society. It is evident that the individualistic concept is mainly close to the thermodynamic model of the world in its movement to equilibrium and higher entropy. The basis of the individualistic model is maximization of independency of each component and its resilience within the holon that is a rather satisfactory strategy for its survival. But at states far from equilibrium, positive correlation and effects of self-organization and relatively discrete spatial structures arise in the thermodynamic system in accordance to the theory of nonequilibrium thermodynamics. This is a good hypothesis, which is useful to be verified for the biosphere. If to lean upon the theory of dynamic systems, the entire biosphere and its patches may be considered with certainty as nonlinear oscillators of high dimension. From these positions, the efficiency of the fractal model for characterizing the diverse natural processes is well explained. Formally, a fractal set is continuous but undifferentiated, and displays a cascade of bifurcations in the spatial–temporal dynamics of nonlinear oscillators. In nature, it manifests itself in the possibility to distinguish between different-scaled and hierarchically subordinate relatively homogenous formations, boundaries of which may also be divided into such structures. The formal fractal model assumes a self-similar division into indefinitely small units. Real natural objects do not possess this specific feature – their fractality has a finite range of dimensions. Taking into account this property, the model is sufficient for the theoretical definition of a biogeocoenosis as a spatial–temporal cell commensurable with linear dimensions of dominant plant species in it, that is, including some minimal population stable at least in one generation. Direct measurements of the fractal landscape cover the structure using data of remotely sensed investigations and three-dimensional models of relief show that, almost everywhere, a fractal spectrum connecting the amplitude of spatial variation of the variables measured with the spatial wave number reveals quasi-harmonic fluctuations, but describes only some percentage of the spatial variation. However, the relative peaks of the spectrum, corresponding to definite linear sizes, allow correcting a choice of scale for different hierarchical levels. The nature of local spatial homogenous structures may be determined by the organization of relief, soil-forming rocks, soil, dynamics of vegetation, effects of animals, tree windfalls, fires, and so on. The spatial–temporal dynamics of each of these components are stipulated by both their own fluctuations and those originated due to their interactions. As a result, the spatial structure is fractal, and distinguishing the relatively even territories is possible and strictly realizable on the basis of classification of multispectral images, in particular. In the framework of the model of a nonlinear oscillator, the individualistic concept does not contradict the different-scale discontinuity, and although nonlinear oscillators produce effects of self-organization under definite conditions, these models do not contain mechanisms of structural stability. On the basis of these models, a holistic model is impossible to construct. On the other hand, using the multifractal model, the proportion between total energy, free energy, and entropy is deduced resulting in the natural generalization of two models of reality. Following this method, the concept of biogeocoenosis as an elementary cell of the biosphere may be of constructive importance in both the organization of terrain investigations for assessment of biogeocoenotic and biosphere processes and the elaboration of corresponding models. The fractal scheme of organization of the biogeocoenotic cover gives prerequisites for the recalculation of parameters obtained in large-scale studies to those corresponding to the high level of organization. In order to obtain the behavior similar to that of an organism, it is necessary to add contours of positive feedback providing relationships between components of the system and supporting system resilience under conditions far from the thermodynamic equilibrium in the environment to the model of nonlinear dynamics. The fact that such relations are realizable in organizing the components of the biosphere was shown from the example of the bog. A similar type of relation holds for a tropical forest that evaporates moisture intensely. The same is true for boreal spruce forest that evaporates more moisture than a deciduous forest and supports low temperatures favorable for spruce due to expenditures of heat for evaporation. The positive feedback is characteristic of mycorrhizae fungi and their hosts. There are many examples of positive feedbacks in a plant community (mutualism). However, the conditions under which they determine holistic features of biogeocoenosis and those of higher levels of its organizations are not evident and need special investigation. At the same time, their potentially significant role in the maintenance of homeostasis in an aggressive medium is evident, as is the nature of spasmodic and catastrophic transformations at small disturbances, primarily in the margin areas of the system tolerance.

Summary

A discussion of the general concepts of ecology and attempting to specify their physical sense are *a priori* ungrateful tasks. In ecology, as in any natural science, notions or definitions had a quite uncertain content at the time of their introduction and they determine an approach to studies rather than their object. Later, these notions and definitions were redetermined many times and differently by different researchers. The multidimensional subject of ecology stipulates such an uncertainty. The uncertainty causes periodically renewed discussions of the theoretical bases of science that are inevitable in formulating the concept of biogeocoenosis. The latter may be considered as a specific one in relation to a more general concept of an ecosystem. In the framework of the modern theory of thermodynamics and nonlinear dynamical systems, accepting the existence of self-similar quasi-discrete territorial units, the concept of biogeocoenosis is interpreted via living matter as a thermodynamic variable. On the other hand, the ideas of the dynamics of biogeocoenosis elaborated by Sukachev represent good bases to formulate verifiable hypotheses. They allow combining the concepts of reductionism and holism as interconnected (but not contradictory) models, the contribution of which to the spatial–temporal dynamics depends on geographic conditions, the current status, and the time of self-development.

Biosphere: Vernadsky's Concept☆

Yuri M Svirezhev and Anastasia Svirejeva-Hopkins, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Glossary

Biosphere Earth's crust and lower levers of Atmosphere, where living matter is present (see text for detailed definition).

Biogeocenosis An interrelated complex of living and inert components associated with each other by material and energy exchange; one of the most complex systems in nature.

Vladimir Ivanovich Vernadsky (1863–1945) Russian mineralogist and geochemist, one of the founders of biogeochemistry.

Introduction

Vladimir Ivanovich Vernadsky (1863–1945) (Fig. 1. V.I. Vernadsky, Paris 1889), the great Russian scientist and thinker, the founder of modern concept of the biosphere has shown that during all geological epochs on Earth, the life was developing as interconnected group of organisms (as he calls it "living matter") that provided and provides the continuous flow of elements in biogenic turnover of matter and energy on the surface of our planet. This could easily be called scientific revolution at that time. Indeed, as Thomas Kuhl points out, scientific revolutions occur when someone creates a new perspective, a model used for understanding reality. Only after introduction of such an idea, great progress, that was previously impossible, could be made, opening new ways of thinking. In recent years it becomes even clearer that all the works of Vernadsky were devoted to the further development of scientific thought as a planetary phenomenon. The significance of his ideas could be compared to the teachings of great philosophers of Ancient Greece, Roman Empire and Eastern world, of the Renaissance; the developers of the basics of mathematics and physics, such as I. Newton; the creators of system thinking about the origin and functioning of life on Earth, C. Linnaeus, G. Buffon, J.-B. Lamarck, C. Darwin, A. Humbolt, G. Mendel, etc.; as well as famous Russian scientists, M. V. Lomonosov, D. I. Mendeleev, I. M. Sechenov, I. N. Mechnikov, V. V. Dokuchaev, and others. As A. E. Fersman, Vernadsky's devoted pupil and successor in the area of geochemistry wrote about his Teacher: "His general ideas will be studied and elaborated during centuries and one will discover new pages in his works which will serve as the source for new searches. Many scientists will learn his creative thought, which is acute, stubborn and articulated, always genial, but sometimes poorly understood. As for young generations, he always will be a Teacher in science and a striking example of a fruitfully lived life."

Fundamental Idea

In Vernadsky's book *Biosfera*, first published in 1926, Biosphere is simply the surface or the outer domain of the planet, separating it from its cosmic surroundings. The author calls it the "Face of the Earth."

But what is crucially new, that in accordance with dialectic principle, the process of cosmogonic evolution of the Earth is considered in the light of dynamics of the environment, which includes the system of many different forms of matter turnover; while its highest form, life itself, is determining other planetary processes, the latter being the very central idea in Vernadsky's teachings. Namely this concept served as a necessary and desired base for the development of modern ecology.

Living and Nonliving Matter, Their Interaction and Cosmogonic View

The first step toward changing the world's picture, as natural scientists see it now, was the introduction of the concept of living matter by Vernadsky, and the second step was considering it as a cosmoplanetary phenomenon. Vernadsky has defined the living matter as "the existing at present time unity of organisms with the mass, chemical composition and energy" connected with its environment by constant processes such as breathing, feeding, and procreation, but we shall further address it sometimes as organic matter. Verndsky often mentioned that life propagates and dissipated non-living matter in a gas-like manner, very fast and thorough. Vasily Dokuchaev, regarded as the "Father of Soil science" had played a big role in a formation of Vernadsky as a scientist. Studying mineralogy and crystallography during his student years, Vernadsky later has classified the dead organic matter

☆*Change History*: March 2018. Yuri M Svirezhev. Changed Fig. 1 to another photo. Some additional thoughts and details that are described in the newly published translation and collected works are interweaved in the text. Some minor text editing were done.

This is an update of Y.M. Svirezhev and A. Svirejva–Hopkins, Biosphere: Vernadsky's Concept, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 467–471.

 doi:10.1016/B978-0-12-409548-9.11154-6

Fig. 1 V.I. Vernadsky, Paris 1889.

of soils and sediments as "bio-generic matter" or bio-inert bodies (the natural structures, consisting of inert and living bodies). One can call it "the remnants of the past biospheres."

The processes of interaction between the living (organic) and nonliving (inorganic) matter, considered as the most important initial stage of cosmoplanetary evolution, could be observed since the very first stages of planet's existence. As an example, proving Vernadsky's generalizations, the recent determination of time of the beginning of formation of primary sedimentary rocks (the *Stratispehere*, as Vernadsky named it) is 3.7 billions years ago, while slightly younger age (3.4–3.5 billions years ago) is determined for the formation of first organic compounds, that is, "islands of living matter." The origin of life on our planet is directly connected to the origin of the biosphere; and evolution, as we perceive it, always takes place inside the biosphere, involving exclusively living matter. However, Vernadsky has expressed the fundamental importance of eternal interconnection between the living and nonliving matter, in the following very significant paragraph: "The Earth cover, Biosphere, while fully embracing the globe, has limits that are strictly determined by the existence of living matter in it—it is populated by it. Between its inorganic "lifeless" and living parts, inhabiting it, continuous exchange of matter and energy exists, expressed by atomic movement caused by living matter. With the time course, this exchange is expressed by constantly changing and tending to steady-state equilibrium. This equilibrium threads through the entire biosphere and this biogenic atomic flux to a large extent creates and maintains it. Hence, in this manner and during all geological epochs, biosphere is connected with the living matter that populates it. And namely by this biogenic flux of atoms and energy, the strong planetary cosmic significance of living matter is determined." This view through the "cosmic prism," so to speak, radically changes our understanding of dialectical interconnection of living and nonliving matter, that originally differ in their composition of elements. As one can add, nowadays there is certainly more data and hypotheses about the influence of solar and other cosmic radiation on the living organisms at different levels of their structural development.

As Vernadsky writes in his Essays on Geochemistry: "Radiations of immaterial substance (pure energy) embrace not only biosphere but all space, with wavelengths ranging from millionth part to a millimeter up to several km. Cosmic radiations received by our planet creating the biosphere extend over only 4,5 of the forty known octaves of frequencies. In the most familiar cosmic radiations those from the Sun we distinguish one octave of light, three octaves of heat (infrared) and half an octave of ultraviolet radiation, the last one being a small remnant that passed through the stratosphere. It seems improbable that the other octaves should be missing in cosmic space. We see their absence as an illusion caused by the absorption of the rays by the rarefied material of the upper layers of the atmosphere."

Indeed, quite a lot of data have been accumulated on the influence of weak electromagnetic fields on the information exchange between living cells. Cosmic rays could in certain way influence the information exchange that is conducted by means of weak electromagnetic fields between cells of a living organism, and therefore alter functioning of the multi-cell structures. "When the substance of the biosphere is penetrated by energy it becomes active, gathers and distributes the energy and turns it, in terrestrial organisms, into free energy capable of performing work. Therefore biosphere is not just a domain of sheer substance, but of energy, the site of transformation of the planet by external cosmic forces. The history of the biosphere is sharply distinguished from that of

the rest of the planet. The larger part of the biosphere is of non-terrestrial origin, since this substance from outside—cosmic dust and meteorites—is of the same structure as terrestrial substance. It is not limited to biosphere, it is the same for the whole crust of the Earth—for the kilometers of lithosphere of which the upper part is the biosphere. Lithosphere and biosphere gradually and inseparably merge with each other. The substance of the deeper parts of the planet is different, it hardly penetrates the biosphere in larger amounts during short periods of time, therefore can be ignored." Vernadsky believes that it is impossible to explain the definite composition of the Earth's crust and the whole planet by the different atomic masses of the elements comprising it. The difference in composition between Earth core and crust is due to the similarity between the composition of meteorites and of deeper layers of the planet. Relatively light elements prevail in Earth's crust but it is also rather heavy in iron, which is related to cosmic history and perhaps to the structure of chemical elements. Vernadsky also stresses the similarities in atomic structure between the surfaces of the Sun, the Earth, and the stars.

"By the way of radiation the elements exert a reciprocal effect on one another." Vernadsky begins to see them not entirely as purely terrestrial phenomena but related to the structure of atoms though their location in the cosmos, and to their evolution in the history of the cosmos. "The biosphere is the place for us for search not only for the reflections of accidental unique geological facts, but also for manifestations of the structure of the cosmos related to the structure and history of chemical atoms.

The mechanism of chemical action of living matter is unknown to us but it is obviously becoming clear that from the standpoint of energy phenomena in living matter, photosynthesis takes place not only in some chemical surrounding but also in a special thermodynamic field of the biosphere where they prove unstable and serve as sources of free energy (the thermodynamical field of living matter) is thermodynamically and chemically different from that of the biosphere".

Two Main Principles of Interactions Between Living and Nonliving Matter

It is necessary also to say a few words here about the two main principles of interactions between living and nonliving matter that Vernadsky has formulated, namely two biogeochemical principles that describe the nature of energy fluxes in the biosphere:

1. Geochemical biogenic energy of the biosphere tends to maximum.
2. During the evolution of species, only the organisms that increase this biogenic geochemical energy in a process of their life, will survive.

Vernadsky also writes about the irreversibility of life's processes and the increase in life's free energy, expressed in dissymmetry of composition of living matter.

In connection to the first biogeochemical principle, it becomes important to mention the similar work of Russian theoretical biologist, E. Bauer, who has formulated the fundamental principle of the permanent inequilibrium of living matter and the principle of maximum effect of external work. These principles, describing thermodynamics of evolution and organization of living matter, are called "the law of Bauer-Vernadsky."

Concept of the Biosphere, Definition of Term, and Method of Analysis

At the beginning of the nineteenth century J.-B. Lamarck had introduced the term "biosphere." He considered it as the "scope of life" and some sort of external cover for the Earth. In 1875 the same term was introduced in geology by E. Suss, who distinguished the biosphere as one of the Earth's covers. But V. Vernadsky was the first person who created the modern concept of the biosphere. This concept was first introduced in his two lectures in Paris, published in 1926. In a sequel it was further developed by Vernadsky himself, and by V. Kostitzin, V. Sukhachev, N. Timofeev—Resovsky, and other Russian scientists.

Biosphere includes all the hydrosphere, troposphere to the height of 30 km, and the upper part of the Earth's crust down to a depth of 2–3 km, for living bacteria still may be found at this depth in the underground waters and in the soil. It is an open thermodynamic system that exists with a permanent flow of solar energy (1.2×10^{22} kcal year^{-1}) since the very beginning of the Earth's history.

According to Vernadsky, the biosphere is an external Earth cover, the "scope of life" (as Lamarck named it). He also notes that this definition (as just the "scope of life") is not complete. Vernadsky's biosphere includes.

1. living matter;
2. "biogeneric matter," that is, organic and mineral substances, created by living matter (for instance, coal, peat, litter, humus, etc.); and
3. "bioinert matter," created by living organisms together with inorganic nature (water, atmosphere, sediment rocks).

Empirical Generalization Method

Two components constitute Vernadsky's concept of the biosphere. The first is the actual biosphere concept, which can be called a verbal model of the biosphere. The second component is the method of study of such a complex system as the biosphere, which he called "empirical generalization method" (EGM). Vernadsky opposes the reliance on mere hypotheses, repeatedly insisting that the

better suited method for a scientist is the Baconian system of accumulation of facts, as generalizations are becoming apparent from the data. That is essentially an inductive method and it indeed lies at the heart of the modern science. A perfect example of this method is Mendeleev Periodic Table of the elements. Certainly, the EGM is essentially wider than simply a method for the study of biosphere processes; it is the general scientific method. Let us remember Descartes' principle that "Science is a method." Speaking in modern terms, the EGM is a typical method of systems analysis.

How the IGM Works

The empirical generalization is based on real facts collected in an inductive way, but always keeping in mind to not leave the domain of these facts. At this first stage all possible scientifically established facts about studied phenomenon must be collected. The next stage is the aggregation of collected facts into some more general categories, called proper empirical generalizations. Basically, it gives us the possibility to pass from a huge number of accumulated facts to a considerably lesser number of statements that, in turn, allows us to truly speak about the possibility to describe the studied large (complex) system quantitatively. This stage does not allow for formulating of any kind of hypothesis, on which there is inevitably a mapping not only of scientific ideas, but also of nonscientific ones. Really an empirical generalization is a system of axioms, reflecting our level of empirical knowledge, which could be used as a basis for any formal theory developed in the future. Hence, having the system of empirical generalizations, we can follow either of two ways to construct models. Either we remain within the framework of this system, constructing so-called "phenomenological" models; or complementing some hypotheses relating to the existing empirical generalizations, we shall get some new models. In accordance with Vernadsky's opinion, in order to choose on the type of these models, one must produce hypotheses, based on coincidence of predicted and newly observed facts. If this coincidence takes place, then the hypothesis becomes an empirical generalization of a higher level. From this point of view, for example, the practical astronomy of Ancient World was a typical empirical generalization, and ancient astronomers were successfully using the phenomenological model created on its basis. The same underlying empirical generalization is the basis of two principally different cosmogonic hypotheses of Ptolemee and Copernicus. If and only if new facts had appeared, the Copernicus cosmogony would have become a new empirical generalization. Therefore, the same empirical generalization can be a basis of different models.

However, the reciprocal picture is possible, when an empirical generalization exists separately, without some kind of hypotheses and explanation from the viewpoint of contemporary science. For example, the radioactivity phenomenon could not have been explained by the state of the nineteenth century physics.

The System of Axioms

Which empirical generalizations constitute the base of Vernadsky's biosphere? In this case we will call this system of axioms "Vernadsky's biosphere;" however, these axioms will be presented in slightly more formal way than in Vernadsky's original work.

1. *During all geological periods on Earth, living organisms have never been created directly from inorganic matter*. This is the homogeneity axiom. Note that in mathematics, the operators that transform a zero into zero are called homogeneous, too. There is also an analog of this axiom in biology, called the Redi's law ("life comes only from life").
2. *The presently known facts cannot answer the question about the origin of life on Earth*. To get an answer, we must go beyond the framework of the EGM and use different speculations. There is only one way to resolve this contradiction, namely, to postulate the following: whatever the pre-biosphere history of the Earth was, the evolution of the biosphere during all geological periods must have produced the contemporary biosphere as a result. This is the ergodicity axiom. It postulates that to a large degree the process of the biosphere's evolution is deterministic and stable in respect to the initial periods of its history.
3. *There were no lifeless geological epochs*. This means that the contemporary living matter is genetically connected with living matter of all the previous epochs. It is natural to call this axiom the continuity axiom.

   The following empirical generalizations are, actually, a form of the conservation law. On the other hand, since they generalize some equilibrium properties of the biosphere, it is logical to call them: the axioms of stationary state.
4. The chemical composition of living matter was always, on average, the same as it is now.
5. *The amount of living matter, on average, was the same for all geological time*.

   These two above generalizations of Vernadsky cause a lot of objections at the present time. However, there are not enough new facts to formulate new empirical generalizations. Therefore, it is quite possible to consider the changes of the total amount of living matter, observed during different geological epochs, as fluctuations around some constant average level. (The same can be also said about the chemical composition of living matter in the terrestrial crust.)

   And, lastly, below are generalizations that determine the principles of functioning of the biosphere mechanisms.
6. *The energy which is being stored and emitted by living organisms is the solar energy*. With the help of organisms this energy is controlling the chemical processes on the Earth (in particular, the global biogeochemical cycles).
7. *Vegetation plays the main role in the assimilation and allocation of the solar energy*. If we agree with the axiom about the constancy of the total amount of living matter during the whole lifetime of the biosphere, then we have to assume that its evolution only followed the path of the structural complication of living matter, either by increasing the number of species (there are 3106 species on Earth), or by making the structure of biological communities more complex.

The Future of the Concept: Noosphere and Modern Perspective

Biogeocoenosis

While Vernadsky's concept can be considered as maximally aggregated (i.e., like a view on the biosphere from the outside), the concept of the biogeocoenosis (BGC) first suggested by V. Sukhachev in 1945 and later developed by N. Timofeev-Resovsky, relates to the elementary units of the biosphere, and is one that is basically atomistic in nature. In accordance with the definition by Timofeev-Resovsky's, the BGC is the part (area) of the biosphere, which has no essential ecological, geomorphological, hydrological, microclimatic, or any other boundary inside itself. Hence, the biosphere is divided into elementary systems, naturally separated from one another. According to Vernadsky, the biogeocenosis have appeared immediately upon the beginning of existence of the biosphere.

Noosphere

In his last years of life, Vernadsky's works were directed toward the future development of scientific thought as a planetary phenomenon. He perceived civilization as a form of a new geological force—scientific force performance. Vernadsky wrote:

"In the 20th century man for the first time in history of the Earth knew and embraced the whole Biosphere… That mineralogical rarity, native (pure) iron, is now being produced by billions of tons. Native aluminum, which never before existed on our planet, is now produced in any quantity. The same is true with regard to the countless number of artificial chemical combinations newly created on our planet. Chemically, the face of our planet, the biosphere, is being sharply changed by man… New species of animals and plants are being created by man."

The biosphere is a powerful geological force that has transformed this planet and its geochemistry in a most spectacular way. Toward the end of his life, Vernadsky planned to consider the Noosphere—the supremacy of scientific thought that always existed (term introduced in 1922 by a French philosopher and mathematician Edouard Le Roy) in more detail, but sadly could not finish developing this in his lifetime.

Vernadsky's ideas act on the contrary to doomsday scenarios since he views our civilization as a form of a new geological force—scientific thought, and therefore it cannot destroy itself. Indeed, we observe now the World's population growth stagnation, contrary to the predictions and calculations from the mid 20th century. This could be an example of the influence induced by intelligent thought and man's growing ability to forecast. Again, it is important to stress, that Noosphere is far from being Utopia, but rather the next stage of biosphere's development and these forecasting scenarios could change its future. It seems that we already live in Noosphere, even though most changes are subtle and happen slowly even with new technologies introduced.

Indeed, at present, despite its growing industrial power, our science and civilization will not yet be able to reconstruct the entire biosphere in the desirable way, if it comes near some critical conditions. It is practically impossible to predict the new quasi-stationary state, as no other possible states of the biosphere's equilibrium are known. The model of coevolution of "man" and the "biosphere" as the main principle of global coexistence was suggested by Yu. Svirezhev. And, indeed, Vernadsky has pointed out that humans and biosphere are not "enemies." The basic idea is to study the dynamics of the biosphere as an entity and its reactions to human impact. In the framework of this research the study of possible ways of development of human society as a natural component of the biosphere is of a special importance. The mechanism of coexistence of human society and the biosphere, which is actually the way of mutual coevolution and harmonic coupling of humans and their environment, is now becoming one of the most important scientific and social questions of the modern society. This problem, integrating natural dynamic processes operating within the biosphere, with human dynamics is of a multiscale and very complex.

Conclusions

In conclusion, we would like to stress again the great significance of Vermadsky's ideas for the future science and say that the concept of the biosphere and the next new state of it, Noosphere (from the Greek noó(s) (mind) and sphere), has shaped, and is continuing to do so, the global understanding of the origin and evolution of mankind, since as the Teacher himself points out: It "is a new geological phenomenon on our planet. In it for the first time man becomes a large-scale geological force… Wider and wider creative possibilities open before him. It may be that the generation of our grandchildren will approach their blossoming… Fairy-tale dreams appear possible in the future; man is striving to emerge beyond the boundaries of his planet into cosmic space. And he probably will do so."

Climate Change 2: Long-Term Dynamics☆

Werner von Bloh, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Glossary

Archean Geologic eon from 4000 to 2500 Myr ago.
Eucaryotes Organisms with cell nucleus and organelles.
Kerogen Reduced organic carbon in rocks.
Phanerozoic Current geologic eon from 542 Myr ago to present.
Procaryotes Unicellular organism lacking a nucleus.
Proterozoic Geologic eon before the onset of complex life from 2500 to 542 Myr ago.

Nomenclature

Symbol	Description (Unit)
C_{ker}	Carbon stored in kerogen pool (kg)
β	Biological enhancement factor of weathering (none)
$\delta^{13}C$	Isotopic signature ($^0/_{00}$)
F_{weath}	Normalized weathering flux (none)
Π	Biological productivity (kg/year)
P_{CO_2}	CO_2 partial pressure in atmosphere (bar)
P_{soil}	CO_2 partial pressure in soil (bar)
p_{O_2}	O_2 partial pressure (bar)
P_{min}	Minimum CO_2 partial pressure for photosynthesis (bar)
T_{max}	Upper temperature tolerance (°C)
T_{min}	Lower temperature tolerance (°C)

☆*Change History*: March 2018. Werner von Bloh. Sections "Continental Growth" and "Evolution of Climate" have been updated. Figs. 3 and 5 have been replaced by new figures. New Fig. 6 added. More up-to-date references have been added in the Further Reading section.

Introduction

The main component of the early Earth's atmosphere after the formation of the oceans was CO_2 as the second most abundant volatile in the accreting material. On planetary timescales the variation of the CO_2 content in the atmosphere is most important in investigating the relation between the evolution of the Sun as a main-sequence star and the stabilization of the Earth's surface temperature. During the history of the Earth the luminosity of the Sun has increased to the present level starting with a 30% lower value. There must be a mechanism that provides a feedback, generating a high concentration of atmospheric CO_2 in the past to prevent the Earth from freezing while solar luminosity was low. On the other hand a progressive lowering of CO_2 concentration is necessary for an increasing solar luminosity. Such a negative feedback mechanism is provided by the global carbon cycle among the surface reservoirs of carbon (atmosphere, ocean, crust) and the mantle reservoir. The overall chemical reactions for the weathering processes are

$$CO_2 + CaSiO_3 \leftrightarrow CaCO_3 + SiO_2$$
$$CO_2 + MgSiO_3 \leftrightarrow MgCO_3 + SiO_2$$

The main idea of this abiotic feedback is the interplay between weathering rate, surface temperature, and atmospheric CO_2 pressure. An increase of the luminosity leads to a higher mean global temperature causing an increase in weathering. Then more CO_2 is extracted from the atmosphere weakening the greenhouse effect. Overall the temperature is lowered and homeostasis, that is, self-stabilization of the global surface temperature is achieved. Plate tectonics is a necessary condition for closing the carbon cycle. Without spreading and subduction carbonates would be buried on the seafloor and not brought back to the atmosphere via regassing at mid-ocean ridges or andesitic/back-arc volcanism.

During the evolution of the Earth the global carbon cycle has been mediated by the biosphere. The occurrence of microfossils and stromatolites in rocks has shown that life had originated at least 3.5 Gyr ago. Isotopic signatures of $^{13}C/^{12}C$ suggest the presence of organic carbon in 3.8 Gyr rocks from Greenland. Photosynthetic fixation leads to buildup of organic material consuming CO_2 from the atmosphere. On the other hand, organic material is decomposed and CO_2 is remobilized:

$$CO_2 + H_2O \leftrightarrow CH_2O + O_2$$

Carbon isotopes imply that the enzyme Rubisco preferring the lighter isotope ^{12}C and therefore oxygenic photosynthesis controlled the global distribution of carbon in the atmosphere–ocean system for at least 3.5 Gyr and gave an imprint on the isotopic signature of the carbon reservoirs. Direct evidence of oxygenic photosynthesis is given by the steep rise of oxygen in the atmosphere 2.2 Gyr ago. Life is unable to influence Earth's carbon cycle in the absence of photosynthesis.

The biosphere can in principle be divided into three life forms that appeared on Earth in consecutive order (see Fig. 1). First Archaean and prokaryotic bacteria appeared, second eukaryotic life, and third complex multicellular life. In particular complex multicellular organisms have a strong influence on weathering by amplifying the weathering rates.

Global Carbon Cycle and the Biosphere

The global carbon cycle can be described by a box model of the surface reservoirs of carbon and the mantle reservoir. Fig. 2 denotes the most pertinent fluxes between the storage of carbon in the mantle, the combined reservoir consisting of ocean and atmosphere, the continental crust, the ocean crust and floor, the kerogen, and the three different biospheres. The efficiency of carbon transport between the reservoirs takes into account mantle de- and regassing, carbonate precipitation, carbonate accretion, hydrothermal reactions at mid-ocean ridges, decay of dead organic matter, and weathering processes. The Earth's crust contains the carbon storage of the continents, kerogen, and the ocean crust and seafloor. Biomass is accumulated from the atmosphere by photosynthesis. A fraction of the dead organic matter is buried in the kerogen pool. Additionally to these direct effects of the biosphere on the surface reservoirs of carbon there is an indirect effect due to the increase in weathering rates denoted by the dashed arrow in Fig. 2.

Continental Growth

The continental crust is especially diverse and heterogeneous, and its formation is less understood than that of the geologically relatively simple oceanic crust. In contrast to the seafloor which is primarily made of basalts it is granitic in composition. The onset of the granitic continents might have been triggered by the origin of life. Two different hypotheses have been suggested to explain the evolution of the continental crust. The first proposes that the present continental crust formed very early in the Earth's history and has been recycled through the mantle in steadily decreasing fashion such that new additions are balanced by losses, resulting in a steady-state system. The return of the continental material to the mantle and its replacement by new younger additions reduces its mean age, both of which keep the mass of the continents constant. The second hypothesis proposes crustal growth throughout geological time without recycling into the mantle.

Fig. 3 summarizes the different classes of continental growth scenarios. The continental area can be assumed to be fixed at its present value, can be grown linearly with a constant growth rate, or linearly with a delay. Geological investigations of the best-studied regions, North America and Europe, which formed a single land mass for most of the Proterozoic suggests that the

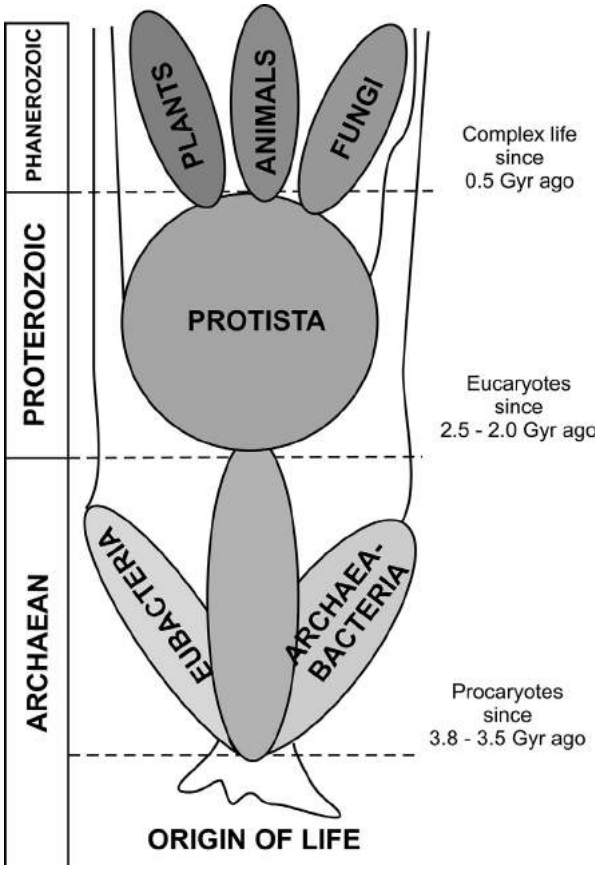

Fig. 1 Evolutionary path of life on Earth.

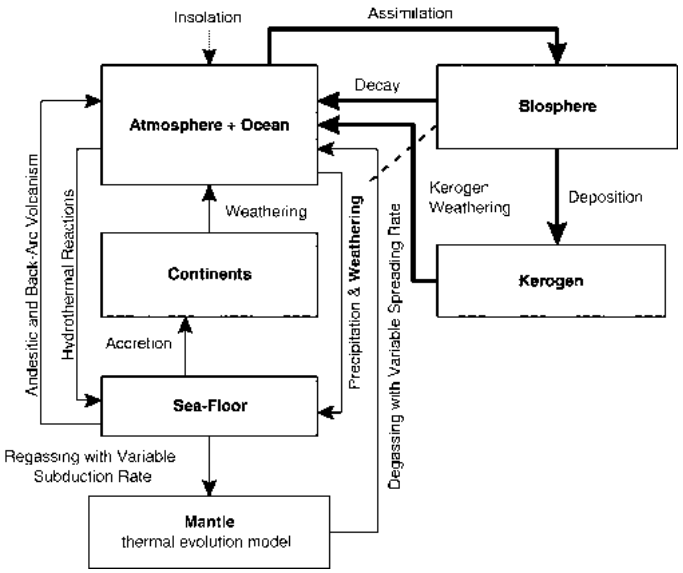

Fig. 2 Box diagram illustrating the basic mechanisms and interactions of the global carbon cycle. *Gray* boxes are the surface reservoirs of carbon. The fluxes from and to the different pools are indicated by *arrows*. *Bold arrows* denote fluxes affected by the biosphere.

continental crust grows episodically, and it is concluded that at least 60% of the crust has been replaced by the late Archaean. Furthermore, Thorium–Uranium–Niobium systematics of the depleted mantle can be used to derive the evolution of the continents. These data-based descriptions are clearly more realistic than the theoretical models. The continental area is directly related to the weathering process. A larger continental area leads to proportionally higher weathering rates.

Evolution of the continents and the atmosphere inferred from Th-U-Nb systematics of the depleted mantle *Science* **283**, 1519–1522 (*dashed line*).

Atmospheric Carbon Dioxide and Climate

The climate of the Earth is governed by the energy-balance equation between incoming and outgoing radiation and depends on the concentration of greenhouse gases and the solar luminosity. CO_2 and H_2O are the most abundant greenhouse gases in the atmosphere. The partial pressure of H_2O, p_{H_2O}, can be expressed as a function of temperature and relative humidity using the Clausius–Clapeyron equation. Therefore, the global mean temperature of the Earth depends primarily on the CO_2 concentration in the atmosphere and the solar luminosity. During the Earth's history the luminosity of the Sun has increased at a rate of about 10% per Gyr and will increase in the future (up to the next 5 Gyr) at approximately the same rate.

The efficiency of weathering processes and the biosphere productivity strongly depend on the partial pressure of atmospheric CO_2, p_{CO_2}. On geological timescales atmospheric carbon content is always in chemical equilibrium with the carbon content in the ocean and depends on the pH value of the ocean. A more acidic ocean lead to a an accumulation of CO_2 in atmosphere while an alkaline ocean results in lower atmospheric CO_2. In the case of a constant density profile of carbon dioxide in the atmosphere the distribution of carbon can be calculated from the condition of equal partial pressures of CO_2 at the interface between atmosphere and ocean.

Biotic Enhancement of Weathering

The rate of weathering is greatly amplified by a range of biological processes that respond to photosynthetic productivity. First, there is an increase of soil CO_2 partial pressure due to respiration of soil organisms and due to the respiration from the roots of vascular plants. Furthermore litter is decomposed by microorganisms, through providing organic matter for the formation of humic acids, and through mycorrhizal and fungal digestion. This can be expressed by a direct dependence of weathering on biological productivity by a factor β mediating the weathering rate, F_{weath}:

$$F_{\text{weath}} \propto \beta \cdot \left(\frac{a_{H^+,s}}{a^*_{H^+,s}}\right)^{0.5} \exp\left(\frac{T_s - 288\text{K}}{13\text{K}}\right),$$

where $a_{H^+,s}$ denotes the activity of fresh soil water $a^*_{H^+}$ is the corresponding present-day values. The activity $a_{H^+,s}$ itself is a function of the surface temperature and the CO_2 partial pressure in the soil, p_{soil}, where the equilibrium constants for the chemical activities of the carbon and sulfur systems have been taken into account. p_{soil} depends on the terrestrial biological productivity Π, the atmospheric CO_2 partial pressure, p_{CO_2}, and their corresponding (long-term mean pre-industrial) present values p^*_{soil}, Π^*, $p_{CO_2}{}^*$:

$$\frac{p_{\text{soil}}}{p^*_{\text{soil}}} = \frac{\Pi}{\Pi^*}\left(1 - \frac{p^*_{CO_2}}{p_{CO_2}}\right) + \frac{p_{CO_2}}{p^*_{\text{soil}}}$$

It is assumed that $p^*_{soil} = 10 p_{CO_2}{}^*$. The parameterization of weathering that considers only the variation of soil carbon dioxide levels gives a biotic amplification of weathering of 1.56 for the present state, which is a significant underestimate. Furthermore vascular land plants increasing the partial pressure of CO_2 in the soil appeared on Earth only 0.35 Gyr ago. The total weathering amplification due to land life is at least a factor of 10. This indicates that much of the observed biotic amplification of weathering is due to processes other than increased soil p_{CO_2}. This is considered by the prefactor β that reflects the biotic enhancement of weathering by the biosphere types, i:

$$\beta = \prod_{1=1}^{3} \left(\frac{1}{\beta_i} + \left(1 - \frac{1}{\beta_i} \right) \frac{\Pi_i}{\Pi_i^*} \right)$$

The factor β_i denotes the specific biotic amplification of weathering, Π_i the specific biological productivity, and Π_i^* the respective present-day value of biosphere type i. Biotic enhancement of weathering is only affected by complex multicellular life ($\beta_1 = \beta_2 = 1$, $\beta_3 > 1$). Complex multicellular life contributes about 10–100 times more to the biotic enhancement of weathering than primitive life.

Biological Productivity

The biological productivity Π is the amount of biomass that is produced by photosynthesis per unit time. In reality, Π is a function of various parameters as water supply, photosynthetically active radiation (PAR), nutrients (N, P, etc.), atmospheric CO_2 content and surface temperature:

$$\frac{\Pi_i}{\Pi_{\max,i}} = f_{T_s,i}(T_s) \cdot f_{CO_2,i}(p_{CO_2}) \cdot f(\mathrm{N}, \mathrm{P}, \mathrm{H_2O}, \mathrm{PAR}, \ldots)$$

where $\Pi_{max,\,i}$ is the maximum productivity of biosphere type i. For simplification biological productivity should depend only on the mean global surface temperature, T_s, and on the CO_2 partial pressure of the atmosphere, p_{CO_2}. Both variables are affected by the global carbon cycle. The qualitative dependence on CO_2 partial pressure and temperature is shown in Fig. 4. The function for the temperature dependence, $f_{T_{s,\,i}}$, can described by a parabola and the function for the p_{CO_2} dependence is an increasing function with a saturation level. A minimum CO_2 atmospheric partial pressure, $p_{min,I}$, allowing photosynthesis is necessary for all biosphere types. A biosphere based on C3 photosynthesis has a minimum value of 150×10^{-6} bar, while C4 photosynthesis results in a value of 10^{-5} bar. The interval $[T_{min,i} \ldots T_{max,i}]$ is the temperature tolerance window for the biosphere. If the global surface temperature is inside this window a global abundance of biosphere type i is possible. It must be emphasized that this window is related to the mean global surface temperature. Latitudinal differences in temperature decrease as global mean temperature increases and might vanish for $T > 30°C$. Table 1 contains estimated parameter ranges for the prokaryotic, eukaryotic, and complex multicellular biosphere, respectively.

Carbonate Precipitation

Weathering products are transported to the ocean and, depending on the solubility product, precipitated to the ocean floor. Because there exists a calcium carbonate compensation depth level in the present ocean, carbonates can precipitate only in the shallower regions such as around the mid-ocean ridges and the continental shelves. A total of 8% of the Earth's area is covered with ocean less shallow than 10^3 m. The change of equilibrium concentrations of Ca and Mg in water results in a change of solubility of carbonates in ocean water. Furthermore, oceanic photosynthesis provides an additional way to sequester carbon on the seafloor.

Hydrothermal Reactions

Due to hydrothermal reactions CO_2 dissolved in the oceans reacts with fresh mid-ocean basalts and precipitates in the form of carbonates to the ocean floor. Therefore it is an additional sink in the atmosphere-ocean reservoir. The hydrothermal flux is proportional to the production of fresh basalt at mid-ocean ridges, which in turn is proportional to the areal spreading rate. Assuming hydrothermal reactions to be dependent on the dissolved CO_2 content lead to a stronger sink for CO_2 in the atmosphere ocean system and can be an explanation for relatively low atmospheric CO_2 concentration and corresponding moderate temperatures in the Archean. The area around the spreading centers is likely to be one of the most habitable environments for a subsurface biosphere. It is porous and characterized by extensive hydrothermal circulation. Such hydrothermal systems provided a site for the rapid emergence of life through a sequence of abiotic synthesis.

Kerogen

Kerogen comprehends the dispersed, insoluble, organic carbon in rock including coal and mineral oil deposits. It is probably the least important reservoir from the point of view of carbon cycling because it is relatively inert. However, there are processes of kerogen weathering and kerogen formation. Kerogen is formed from ~0.1% of the dead biomass that is not returned to the atmosphere through litter decomposition. The present size of the kerogen reservoir of 10%–20% of the surface reservoirs is

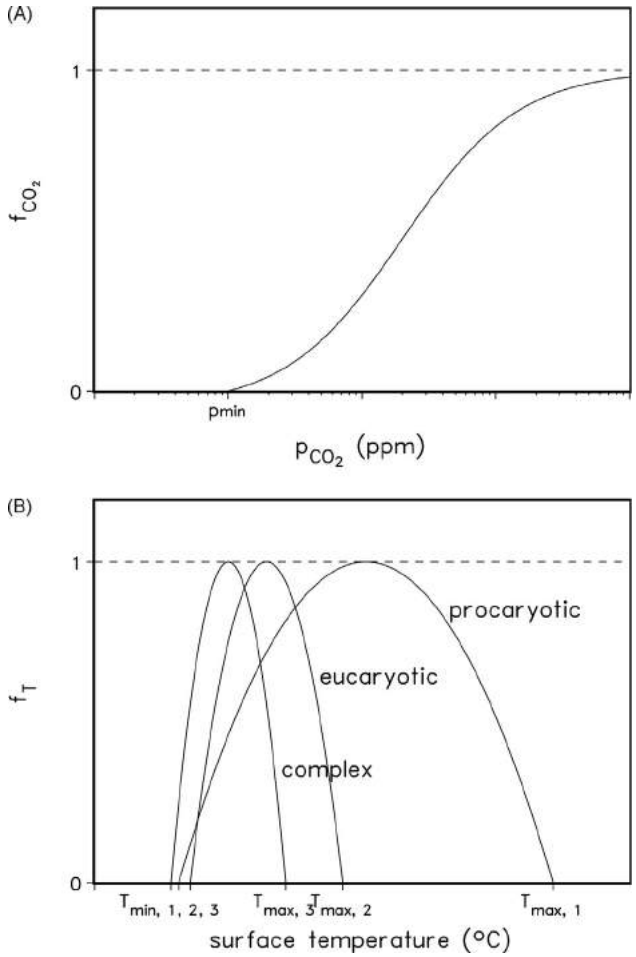

Fig. 4 (A) The dependence of biosphere productivity on CO_2 partial pressure in the atmosphere. (B) The dependence of biosphere productivity on global surface temperature for prokaryotes, eukaryotes, and complex multicellular life.

Table 1 Parameter estimates for the three different life forms (prokaryotes, eukaryotes, complex multicellular life)

Life form	*Prokaryotes*	*Eukaryotes*	*Complex multicellular*
T_{min} (°C)	2	5	0
T_{max} (°C)	100–130	45–60	30–45
P_{min} (10^{-6} bar)	10^a–150^b	10^a–150^b	10^a–150^b
β	1	1	4–20

[a]For C4 plants.
[b]For C3 plants.

obviously the net result of these processes. The main constraint for the reservoir size results from isotopic geochemistry. Since kerogen is isotopically light due to its biological origin it sequesters preferentially ^{12}C, while the continental carbon reservoir must get enriched in the heavier isotope ^{13}C. The isotopic signature is measured as a difference to a standard sample:

$$\delta^{13}C = \left[\frac{(^{13}C/^{12}C)\,\text{sample}}{(^{13}C/^{12}C)\,\text{standard}} - 1\right] \times 1000‰$$

The kerogen has a $\delta^{13}C$ value of $\sim -20‰$. The isotopic composition of the two carbon reservoirs kerogen and continental crust might have been constant over the last 3.5 Gyr. The ratio of kerogen carbon to continental carbon would also have been constant at a value of 1:4 taking into account the isotopic signature of the mantle carbon of $\delta^{13}C \sim -5‰$.

Atmospheric Oxygen

The evolution of the atmospheric partial pressure of oxygen, p_{O_2}, can be derived from the evolution of the kerogen pool C_{ker}, that is, the long-term deposition of reduced organic carbon. Between about 2.2 and 2.0 Gyr ago there was a global oxidation event in which atmospheric p_{O_2} rose from <0.0008 to >0.002 bar. Under the assumption that before 2.2 Gyr all oxygen had been chemically bound it is possible to make the following simple estimate:

$$p_{O_2}(t) = p^*_{O_2} \cdot \frac{C_{ker(t)} - C_{ker}(t = -2.2\,\mathrm{Gyr})}{C^*_{ker} - C_{ker}(t - 2.2\,\mathrm{Gyr})}$$

where $p_{O_2}{}^*$ is the present atmospheric O_2 level and C^*_{ker} is the size of the present kerogen pool.

Coevolution of the Biosphere–Geosphere System

The feedback between the biosphere and the surface reservoirs of carbon leads to several bifurcation points in Earth's history. In particular the evolution of the climate is affected by the change in CO_2 concentration in the atmosphere. Atmospheric CO_2 concentration is regulated by biologically mediated weathering processes and is driven by an increase in solar luminosity, continental growth, and lowering mantle temperatures. The decline of mantle temperature is causing a decrease in the spreading rate with lower outgassing at mid-ocean ridges.

Evolution of the Climate

Fig. 5A shows the results for the evolution of the mean global surface temperature (solid line). The figure has been derived from a coupled model of the global carbon cycle including the biosphere. The modeled surface temperature curve is in good agreement with the ^{18}O chert thermometer. According to these data, the ocean surface water has cooled from 70°C (±15°C) in the Archaean to the present value. There is, however, a recent debate of how strongly these isotope data reflect the ocean temperature. It might be that the Archean ocean temperatures were below 40°C. Such moderate Archean temperatures can be caused by more intensive hydrothermal reactions reducing the ocean/atmosphere CO_2 concentrations in combination with an acid ocean (see Fig. 6). The decrease of the global temperature from the Archean to the present time is caused by the growth of the continental area increasing the weathering processes and decreasing spreading rates lowering CO_2 outgassing at mid-ocean ridges. There was a drop in temperature 0.54 Gyr ago due to an increase in weathering rates caused by the first occurrence of complex life. After that event temperatures have roughly stabilized around the optimum growth temperatures for complex life. In the future the global surface temperature will rise because the increase in solar luminosity cannot be balanced by intensified weathering rates.

Evolution of the Biosphere

Fig. 5B shows the cumulative biomasses for the three life forms. From the Archaean to the future there always exists a prokaryotic biosphere. At 2 Gyr ago eukaryotic life first appears because the global surface temperature reaches the tolerance window for eukaryotes. This moment correlates with the onset of a temperature fall caused by an increasing continental area. The resulting enlargement in the weathering flux takes out CO_2 from the atmosphere. In contrast to the eukaryotes the first appearance of complex multicellular life starts with an explosive increase in biomass connected with a strong decrease in Cambrian global surface temperature at about 0.54 Gyr ago. The biological colonization of land surface by metaphyta and the consequent increase in silicate weathering rates caused a reduction in atmospheric CO_2 and planetary cooling. Protein sequence analysis has shown that a first appearance of land plants at this time was already possible. Metazoan fecal pellets supplied a new and important transport mechanism of organic carbon to the deep ocean. This provides an additional sink for CO_2 in the atmosphere–ocean system.

Cambrian Explosion

The Cambrian explosion is known as the Big Bang in biology. It began 542 million years ago and ended about 40 million years later. This period is characterized by the first appearance of abundant skeletonized metazoans, a sudden increase in biodiversity, and the emergence of most modern lines. In the Vendian (0.56–0.54 Gyr ago) first animals with soft bodies appeared announcing the Cambrian explosion. Before the Vendian period life was microscopic, vegetative, and mainly prokaryotic and eukaryotic.

There is still a lot of speculation about what caused the Cambrian explosion and why it happened when it did after 3 billion years of potential evolutionary time. The approaches that have been put forward to solve the puzzle of what triggered the explosion can be split into extrinsic (environmental) factors, intrinsic (biological) factors, or a mixture of both. Extrinsic factors are physical changes in the Precambrian environment. Among these changes are the breakup of the supercontinent Rodinia and the Neoproterozoic glaciations known as snowball Earth events. The snowball Earth events and the continental breakup are associated with genetic isolation but also with a reorganization of oceanic flow patterns causing upwelling, with increasing primary production, and with a consequently higher atmospheric oxygen level. Another cause is given by the rise of atmospheric oxygen as a trigger of the Cambrian explosion. This higher oxygen level can be caused by an intensified phosphorus flux into the ocean. The phosphorus is

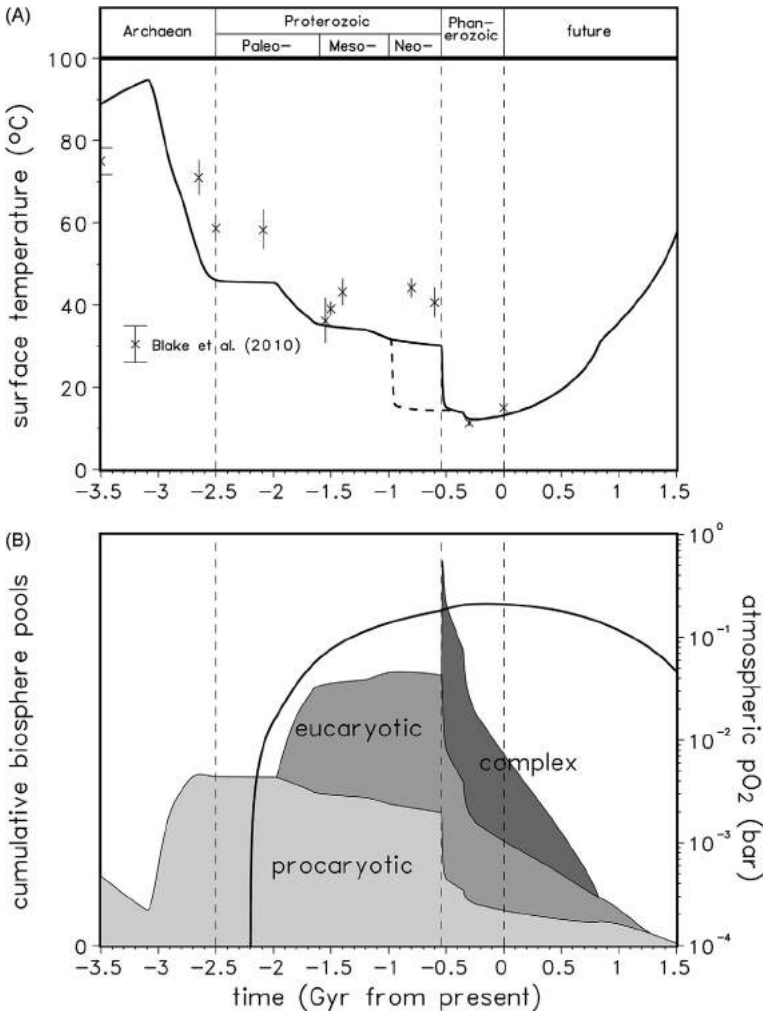

Fig. 5 (A) Evolution of global surface temperature (*solid line*). The *dashed line* denotes a second possible evolution path triggered by a temperature perturbation in the Neoproterozoic era. Vertical bars denote temperature estimates derived from cherts. (B) Evolution of the cumulative biosphere pools for prokaryotes, eukaryotes, and complex multicellular life. From Von Bloh, W., Bounama, C. and Franck, S. (2003). Cambrian explosion triggered by geosphere–biosphere feedbacks. *Geophysical Research Letters* **30**(*18*), 1963–1967.

released by weathering rates biotically enhanced by the first colonization of continents. Intrinsic causes involve some mechanisms within the Precambrian biosphere itself, which enabled evolution and diversification to start. An example is the finding in developmental genetics that the mutation of an ancestral metazoan could potentially initiate a large morphological change in the animal.

The dashed line in Fig. 5A shows a possible second evolutionary path. A cooling event can cause a premature rising of complex life. Up to 1.75 Gyr ago there is only a unique evolutionary path. After that time more than one stable state of the Earth system exists (bistability). It depends on the environmental conditions which state (with or without complex life forms) is realized.

Phanerozoic Time

After the Cambrian explosion, there was a continuous decrease of biomass in all pools. At 0.35 Gyr ago there was a slight drop in the global temperature connected with the rise of vascular plants. At this time weathering rates were increased due the elevated partial pressure of CO_2 in the soil by root respiration. The continuous decrease in biomass of primitive life forms (prokaryotes and eukaryotes) since the Cambrian explosion is related to the fact that Phanerozoic surface temperatures are below the optimum for these life forms. The decrease in biomass of complex life forms is due to the fact that there is a continuous decrease in Phanerozoic atmospheric carbon content. At present the biomass is almost equally distributed between the three pools and the mean global surface temperature of about 15°C is near the optimum value for complex multicellular life.

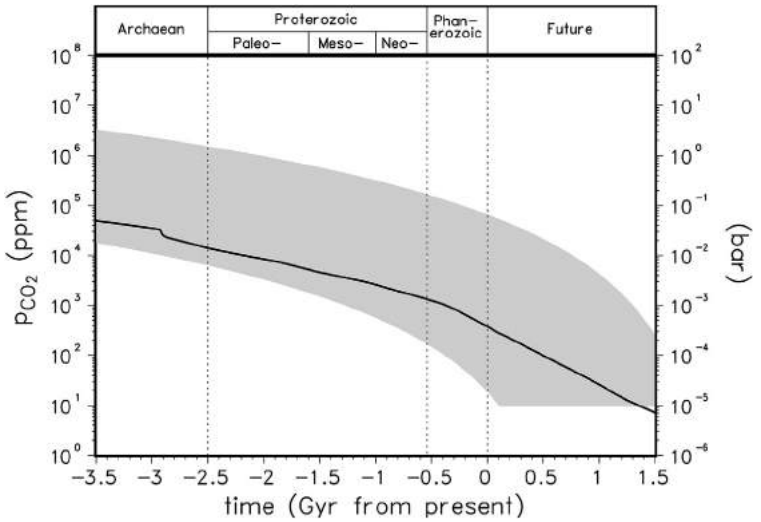

Fig. 6 Evolution of atmosphere CO_2 for strong hydrothermal reactions and acid ocean pH in the Archean. The *gray shaded* area denotes corresponding climate conditions with global surface temperatures $0°C < T < 100°C$.

Future Evolution

In the future we can observe a further continuous decrease of biomass with the strongest decrease in complex multicellular life. The life spans of complex multicellular life and of eukaryotes end at about 0.8 Gyr and 1.3 Gyr from present, respectively. In both cases the extinction will be caused by reaching the upper limit of the temperature tolerance window. In contrast to the first appearance of complex multicellular life via the Cambrian explosion, its extinction proceeds more or less continuously. In the future there will be no bistability, that is, the extinction of complex multicellular life will not proceed as an implosion. Comparing these results with the life span for an Earth without biotic enhancement of weathering ($\sim$0.5 Gyr) the life spans are extended.

Summary

The global temperature on Earth is regulated by the global carbon cycle. The main negative feedback is provided by the weathering processes mediated by the biosphere. In the past the Earth system was characterized by lowering temperatures caused by continental growth and declining outgassing at mid-ocean ridges. In the future, however, temperatures will rise due to the increase in solar luminosity.

The Cambrian explosion can be explained by extrinsic environmental causes, that is, a gradual cooling of the Earth. The Cambrian explosion was so rapid because of a positive feedback between the spread of biosphere, increased silicate weathering, and a consequent cooling of the climate. The environment itself has been actively changed by the biosphere maintaining the temperature conditions for its existence. Therefore, this explanation of the Cambrian explosion is in line with the Gaia theory of the Earth as a self-regulating system.

Prokaryotes, eukaryotes, and complex multicellular life forms will become extinct in reverse sequence of their appearance. Nonlinear interactions in the biosphere–geosphere system caused bistability during the Neo- and Mesoproterozoic era. There is no bistability in the future solutions for complex life. Therefore, complex organisms will not become extinct by an implosion (in comparison to the Cambrian explosion). Eukaryotes and complex life become extinct because of too high surface temperatures in the future. The time of extinction is mainly determined by the upper temperature tolerance limit of these life forms. The ultimate life span of the biosphere is defined by the extinction of prokaryotes in about 1.6 Gyr because of CO_2 starvation. Only in a small fraction (1.3–1.7 Gyr) of its habitability time (6.2 Gyr) can our home planet harbor advanced life forms.

Deforestation

A Shvidenko, International Institute for Applied Systems Analysis, Laxenburg, Austria

Introduction

Conversion of forest to other land-use is an inherent feature in the history of human civilization. During the last 8000 years, the planet has lost ~40% of its original forest cover. By estimates, mature primary tropical forests once occupied 1600×10^6 ha; today their area is about 900×10^6 ha. Latin America and Asia have already lost 40% of their original forest cover, and Africa almost 50%. Most of this loss has occurred during the last two to three centuries. By the beginning of the third millennium, forests have completely disappeared in 25 countries, and forest of 57 countries covers less than 10% of their total land area. Historically, converting forest land to agricultural, infrastructural, industrial, and urban uses was ubiquitous process for development and progress. However, human interactions with forests have often resulted in conversion to unsustainable land uses that led to substantial environmental, social, and economic losses. During the last decades, deforestation and degradation of forests, mostly in the Tropics, have been continuing at an alarming rate. Increasing forest plantations do not change this trend – they account for less than 5% of the world's forest area. Between 1980 and 2005, the Tropics experienced much more intensive forest-cover loss than other regions, with the largest concentration of deforestation occurring in the Amazon Basin, Southeast Asia, and the Congo Basin.

Deforestation and other processes of impoverishment of the world's forests are one of the major drivers of undesirable transformation of the planet. It causes substantial losses of different nature (ecological, economic, social, etc.), dramatically accelerates global biogeochemical cycling, and negatively impacts the Earth system.

Major Definitions

Forest Cover

The global Forest Resource Assessment (FRA), which is provided regularly by the United Nations Food and Agricultural Organization (UN FAO), uses three major terms related to tree cover. Forest is defined as a land class with tree cover more than 10%, and the trees should be able to reach a minimum height of 5 m. Other wooded land (OWL) has either a tree canopy cover of 5–10%, or is presented by a combined cover of shrubs, bushes, and trees above 10%. Other land with tree cover (OLTC) should meet the above criteria for forest but is related to land classified as `other land' (e.g., groups of trees on agricultural land, parks, gardens, etc.). All three definitions require a minimum area of 0.5 ha. The last FRA (2005) estimated the world's forest area as 3952×10^6 ha of which the Tropics (~46%) and the boreal domain (~29%) are major forest biomes. About 30% of land surface is covered by forest. In addition, 1376×10^6 ha was classified as OWL. Global data on OLTC are incomplete – the area of this land-cover category was estimated at 76×10^6 ha in 61 countries out of 229. These estimates are mostly based on national forest statistics and individual country's reports. Another information source on the world's forests is observation of the Earth from satellites. Four different global remote sensing (RS) land-cover products, which have been reported during the two last decades, indicated the area of the world's forests on average as ~20% smaller than the FAO estimate. Reasons for this inconsistency stem from coarse resolution of the imagery used (1 km), not completely compatible definitions of forest, differences in classification, fragmentation of forests in many regions, long-period cloudiness in some (particularly tropical) regions, and lack of satisfactory ground truth data for proper validation of RS imagery. On the other side, national forest inventories are neither complete nor reliable for many developing countries.

Deforestation

Trends in dynamics of global forest cover are defined by two groups of processes. A major driver of decreasing the world forest area is deforestation. Two definitions of deforestation are widely used in their respective international frameworks. By the definition accepted by the UN Framework Convention for Climate Change (UNFCCC) this is an anthropogenic process: deforestation is defined as the direct human-induced conversion of forest to nonforest land. The FRA did not distinguish natural loss of forest from that caused by human impacts: deforestation was defined as the conversion of forest to another land-use or the long-term reduction of the tree canopy cover below the minimum 10% threshold. Both definitions refer to long-term or permanent change from forest to nonforest. Major alternative processes to deforestation are afforestation (establishment of forest on previously nonforest land), reforestation (natural or artificial development of forest on recently forest land), and natural expansion of forests into previously nonforest land. A superimposition of these four major processes results in net change of forest areas.

Here we apply the FAO definition which is used in most assessments and inventories: deforestation includes areas of forest converted to agriculture, natural nonforests such as shrubs and savannas due to anthropogenic impacts or natural disasters,

nonvegetative land (e.g., water reservoirs and urban territories), etc. The term does not include areas where the trees have been removed as a result of forest management activities (e.g., logging) or due to natural disturbances (fire, insects), and where forest is expected to regenerate in a natural way or by silviculture activities. Deforestation also includes areas where some permanently impacted drivers (e.g., disturbance, overutilization, pollution, or other changing environmental conditions) do not allow for maintaining the tree cover above the 10% threshold during a long period of time.

Some other processes like degradation and fragmentation also contribute to the impoverishment of the world's forests and impact global biogeochemical cycling. Three mostly used definitions of degradation (of FRA, International Timber Trade Organization (ITTO), and UN Convention to Combat Desertification (UNCCD)) are comparable with respect to the main clusters. Forest degradation means a process leading to a temporary or permanent decline in the density or structure of forest cover or its species composition, and thus leading to a lower capacity of forest to supply products and/or services, and finally to reduction or loss of the biological productivity of the land. Many reasons can contribute to forest degradation, including diverse human-induced disturbances; unsustainable, excessive forest exploitation; insufficient logging; short rotation periods; etc. In many regions of the world, particularly where forest ecosystems are impacted by accelerated regimes of natural and human-induced disturbances, deforestation and degradation are usually closely interconnected. Fragmentation of forests often leads to decreasing vitality of remaining pieces of forest cover, acceleration of disturbance regimes, and, under the lack of integrated land management, can be a component of structural degradation of forest cover, impoverishment of ecosystem structure, and decline of productivity. Only 22% of the world's forests are classified now as `intact' forests; 82 of 148 countries lying within the forest zone have lost all their intact forest landscapes.

Desertification

The process of (forest) desertification is a specific type of combining deforestation and degradation. The UNCCD defines desertification as land degradation in the arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities. Current drylands occupy 5.4×10^9 ha ($\sim$40% of the world land's area) of which $3.5–4.0 \times 10^9$ ha (57–65%) is either desertified or prone to desertification. Recently, a term of `green desertification' was introduced for the boreal biome, meaning a long-term (more than the life span of major forest-forming tree species) replacement of forests by grass-, shrub-, and wetlands, mostly due to disturbances (e.g., fire), the extent, frequency, and severity of which exceed the restoration capacity of forest ecosystems.

Major Drivers of Deforestation and Degradation

Tropical deforestation is driven by a sophisticated combination of direct and indirect drivers of different nature (social, ecological, economic, environmental, biophysical), which interact with each other, often synergistically; the specific combinations of drivers vary within a region of the globe, by countries, and across localities within countries.

Direct drivers are basically human activities at the local level and can be broadly categorized into those related to agricultural expansion, wood extraction, and infrastructure extension. Agriculture expansion is the most important direct driver of deforestation in practically all tropical regions and includes shifting cultivation, permanent agriculture, pasture creation, and resettlement programs, following converting the forest to other land uses. Wood extraction includes commercial logging, fuelwood harvesting, and charcoal production. A substantial negative effect is provided by illegal harvest: over 70 countries have problems with illegal logging that leads to dramatic ecological and economic losses. Commercial logging is an important direct driver in Asia and Latin America while fuelwood gathering is one of the most important drivers in Africa. Infrastructure extension includes construction of transport ways; development of new industrial enterprises; settlement expansion; and a variety of other activities (oil exploration and extraction, mining, construction of hydropower stations, pipeline and electric grids). The construction or paving of roads in forested areas is among the principal causes of deforestation. For example, in the Brazilian Amazon, above 80% of deforestation occurs in a 100 km band along major roads. During recent decades, wildfires have been recognized as a new actor of deforestation and degradation in the Tropics, as a rule following land-use change and fragmentation of forest cover. Exceptional fires took place in east South Asia and the Amazon in 1997–98, provoked by the severe droughts due to the El Niño event. In Indonesia alone, these fires enveloped 2.4 million ha of forest and peatland. Other drivers can be important in different regions of the globe, such as insect damage, drainage or other forms of alteration of wetlands, permafrost destruction in high latitudes, etc.

Indirect drivers of deforestation are caused by fundamental social processes which are usually revealed as a sophisticated interplay of factors of different nature. Economic factors (e.g., rapid market growth and incorporation into the global economy, commercialization, urbanization and industrialization, growth of demand for forest-related consumer goods, poverty, etc.) are crucial across many tropical regions. Institutional factors (taxation, subsidies, corruption, property rights, etc.) are frequently tied to economic drivers. Cultural and sociopolitical factors like lack of public support for forest protection and sustainable use, low educational level, and low perception of public responsibilities also play a substantial role. Population growth, density, and spatial distribution are usually not a primary driver of deforestation: these are always combined with other factors. Nevertheless, in a number of studies, population density has been shown to be highly correlated with the determination of certain land-use patterns often connected to deforestation. Impacts of some of the above factors are often difficult to separate.

Ecological Consequences of Deforestation

The primary ecological consequences of deforestation are decline in biodiversity, invasion of exotic species, destruction of hydrological cycle, increase in water runoff and decrease in water quality, and acceleration of soil erosion. Tropical forests contain between 70% and 90% of all of the world species, and as a result of deforestation the planet is losing between 50 and 130 animal and plant species each day. Deforestation dramatically impacts runoff and hydrological regime, which threatens, for example, about 2000 known species in the waters of the Amazon Basin – 10 times the number found in Europe. Clearing of tropical forests substantially impacts fertility of soil. About 80% of soil in the humid Tropics is acid and infertile. Once the soil temperature exceeds 25 °C, volatile nutrient ingredients like nitrogen can be lost. Due to intensive rainfalls and soil specifics in the Tropics, a single storm can remove up to 100–150 t topsoil per hectare after deforestation. Deforestation can also decrease the social, esthetic, and spiritual values of forested landscapes. The extent and magnitude of these impacts are influenced by the size, connectivity, shape, context, and heterogeneity of the forest patch remnants. A critical point of negative change in landscape functionality – when fragmentation increased rapidly – on average occurs when mature forest declined to 30–35% of the landscape area.

Forest-cover decline alters regional and potentially global climate system by affecting surface energy, water, and greenhouse gas (GHG) fluxes. Deforestation of temperate and boreal forests has a cooling effect on near-surface climate by increasing surface albedo because cultivated fields generally have a higher surface albedo than natural forests. In tropical regions, deforestation generally leads to the opposite response where the prevailing effect is a decrease of evapotranspiration due to lower surface roughness and a shallower rooting zone. The associated decrease in the latent heat flux suggests a warming trend. Change of evapotranspiration and sensible heat flux impacts the low-level atmosphere, regional, and, potentially, global-scale atmospheric circulation. For instance, higher rainfall and warmer temperature are already observed due to recent large-scale deforestation in the Amazon Basin. However, the length of the dry season increases due to deforestation-induced rainfall inhibition, which can be accelerated by rainfall reduction in future due to global warming. The changes in forest cover have consequences far beyond the Amazon Basin. Regional-scale deforestation in the Tropics has been observed in a number of modeling results to lead to remote temperature and precipitation changes. Simulations for the twenty-first century give regional anomalies (due to human-induced land-cover change) as ± 2 K in magnitude.

There are already recognized impacts of current climate change on tropical forests. Biomass and production of pristine tropical forests is increasing but it expected to be reversed. Climate change and fragmentation substantially increased vulnerability of tropical forests to fire. The species composition is changing even in remote areas. Strong negative relationship is recognized between changes of precipitation regime and net primary productivity (NPP) in the humid Tropics.

Global simulations show a clear decline of vegetation productivity with increasing values of its fraction that is appropriated to human use. This decline is the consequence of two effects: reduction of biomass and climatic differences associated with a reduced vegetation cover. An important biospheric feedback of decreasing biomass is changes in the strengths of dissipative processes in terrestrial ecosystems.

Territories prone to deforestation, degradation, and desertification contain a huge amount of organic carbon: world tropical forests contain 220–270 Pg C in vegetation and 220 Pg C in soil (down to a depth of 1 m); drylands and boreal forests contain, respectively, *c.* 240 Pg C and 470 Pg C in soil. Human-induced land-use–land-cover change (LULCC) destroys the equilibrium state of these carbon pools and eventually impacts stability of the Earth system due to large emissions of major GHGs to the atmosphere because the biomass stock per hectare in standing forest is much higher than in any replacement use, including tree crops and silviculture, and as a result of substantial decrease of soil carbon after the conversion.

Understanding the Extent of Deforestation and Degradation of Forests

Lengths of retrospective periods of documented LULCC, as well as reliability of data, vary by continents and countries. Relatively reliable `reconstructions' of global land-use dynamics have been done since the 1850s. According to these estimates, between 1850 and 1990, the area of cultivated lands, worldwide, has been estimated to have increased by more than a factor of 4, from 320×10^6 ha in 1850 to 1360×10^6 in 1990. The most rapid increase occurred in tropical regions after the 1940s – about half of the increase of $\sim 1000 \times 10^6$ ha occurred during this period. About 730×10^6 ha of agricultural lands was cleared from forests and woodlands that reduced the area of the world forests by 17% since 1850. The total net flux of carbon to the atmosphere from changes in land use was estimated to be 124 Pg C over the period 1850–1990. Changes in the forest area accounted for almost 90% of the net long-term carbon flux.

Currently, there are two major sources for monitoring LULCC including deforestation and degradation: RS and data of national forest inventories. RS was provided either at global or biome scale using imagery of coarse spatial resolution, or by statistical sampling of fine resolution. The basic tradeoff between these two groups of RS instruments is between spatial and temporal resolution. For example, Landsat's revisit time is 16 days – for satellites of coarse resolution, near-daily. Due to the high probability of cloud cover in many regions and the presence of smoke from vegetation fires, instruments of fine resolution cannot provide a satisfactory complete coverage. However, fine-resolution sensors cannot be avoided due to patchy structure of tropical deforestation with many small plots. Currently, a number of different satellites (optical bands) are used: SPOT (20 m resolution), IRS-2 (6–56 m), Landsat 5 and 7 (30 m), Terra (250–1000 m), ENVISAT (300 m), some others. Use of radars, which can penetrate the cloud cover, is one of the alternatives for estimating deforestation by satellites. Applications of radars from new satellites (e.g., SAR

Table 1 Annual average rates of tropical deforestation (10^6 ha yr^{-1})

Region	Average annual rates of deforestation			Net loss of forest area	
	1980s[a]	1990s[a]	2000–05[b]	1990–2000[c]	2000–05[c]
America	4.4–7.4	4.0–5.2	4.6	−4.5	−4.6
Asia	2.2–3.9	2.7–5.9	3.8	−0.8	+1.0
Africa	1.5–4.0	1.3–5.6	4.1	−4.4	−4.0
Total	8.1–15.3	8.0–16.7	12.5	−10.3	−7.6

[a]Range due to available publications and results of surveys.
[b]FAO (2005) data estimated as the total area for countries with net loss of forest area; data for Asia additionally include 0.4 × 10^6 ha for Oceania.
[c]FAO (2005) Global Resources Assessment 2005. Progress towards sustainable forest management. *FAO Forestry 147*, 350pp. Rome: Food and Agriculture Organization of the United Nations; the area of net change of forest area for USA and Canada are deducted from the total area for the American continent.

from ENVISAT, 75 m resolution, or ALOS, 50 m) show promising results. However, identification of small patches of deforested land, distinguishing degraded forests, and indicating regrowth can still not reliably be done from space for large areas. Thus, available estimates of global deforestation are not consistent and reliable enough yet.

Reported areas of deforestation in the Tropics vary substantially (**Table 1**). Several subsequent estimates of dynamics of the global forest cover were provided by FAO FRA, mostly using country surveys which are based on compilation and standardization of data of national statistics. Recently, FRA-2005 presented revised estimates for 1990–2000 and new results for 2000–05. As a total conclusion for 1990–05, the global deforestation rate was estimated at 13 × 10^6 ha per year, almost completely in the Tropics. Taking into account increased areas of forest plantations and natural expansion of forests, particularly in temperate and boreal zones, the global net change of forest area was estimated at −8.9 × 10^6 ha in 1990–2000 (equivalent to loss of 0.22% to remaining area annually) and −7.3 × 10^6 ha in 2000–05 (−0.18%). The largest net loss of forests in 2000–05 was estimated at 4.6 × 10^6 ha yr^{-1} for Central and Southern America followed by Africa, which lost 4.0 × 10^6 ha annually. During the last 5 years, the previously negative trend in Asia has reversed due to large-scale plantations established mostly in China and India. Other estimates of tropical deforestation for the last two decades of the twenty-first century vary from 8 × 10^6 to >16 × 10^6 ha yr^{-1}. RS estimates report that over 20 years (from the 1970s to the 1990s) the area of global forest decreased by 6%. On average, the RS estimates report lesser areas of tropical deforestation than FAO estimates. Likely, the above estimates of deforestation rate are slightly overestimated due to the fact that national inventories and RS data do not adequately record the regrowth. However, from another side, small deforested patches and selective logging, as a rule, are not included in the reported area. Probably, an aggregated conclusion on the current level of deforestation in the Tropics of *c.* 10 × 10^6 ha yr^{-1} can be considered as `the best' conservative estimate of this process.

Considering the regional aspect, Brazil reported 21% of the net global loss for 1990–2000 and 24% for 2000–05, but this country has probably the best national RS system of deforestation monitoring: since 1997, the Brazilian National Institute of Space Research (INPE) has been monitoring deforestation down to 6.25 ha. Estimated areas for the three years 2002–05 (August to August) were on average 2.37 × 10^6 ha yr^{-1} with reported error ±4%. Overall, during the last 25 years, the Brazilian Amazon lost an area of forest greater than the size of Germany. For ten countries of Southeast Asia, about 2.3 × 10^6 ha of forests was cleared every year between 1990 and 2000 and transferred to other forms of land use. Annual deforestation in Indonesia was estimated some 1.7 × 10^6 ha in 1987–97 with the increase to 2.1 × 10^6 ha in 2003.

Estimation of Carbon Emissions

Major results for assessing emissions due to land-use change were received using inventory-based approaches or models of different type. Inventory-based models consider all or some of the basic processes: (1) the immediate release of carbon to the atmosphere from organic matter burned at the time of clearing, (2) postdisturbance flux of carbon from decay of slash, (3) accumulation of carbon during regrowth, and (4) changes in soil carbon.

Table 2 contains data on carbon emissions caused by deforestation in the Tropics. The estimates differ substantially: the average annual carbon emissions for 1990–2005 are estimated in the range 0.8–2.2 Pg C yr^{-1} (15–35% of the annual global emissions from fossil fuels approximately during this period) with the overall average at about 1.5 Pg C yr^{-1}. This estimate corresponds well to the estimate of the third IPCC assessment of 1.6 ± 0.8 Pg C yr^{-1} for the period 1987–98 and to recent estimates for 2000–06. Simulations done with the model IMAGE 2.1 estimated C emissions from deforestation from 0.83 Pg C yr^{-1} in 1995, 1.04 in 2000, 1.58 in 2005, to 2.16 Pg C yr^{-1} in 2015. Several estimates of aggregated carbon fluxes from tropical land given by inverse modeling vary from 1.2 to1.5 Pg C yr^{-1}, if both fluxes to the atmosphere and hydrosphere are accounted for.

These estimates do not include carbon emissions from wildfire which could be very high, particularly during years of severe droughts. For instance, recent estimates put global carbon emissions from fires during 1997–98 El Niño event at 2.1 ± 0.8 Pg C, particularly in Indonesia.

The carbon stocks in forests may change without a change in forest area (e.g., selective harvest, forest fragmentation, non-stand-replacing disturbances, shifting cultivation, browsing, and grazing) and accumulation of biomass in growing and recovering

Table 2 Annual carbon emissions from tropical deforestation

Region	Carbon emissions due to deforestation (Pg C yr^{-1})		Total emissions in 1990–2005 (Pg C)
	1990s[a]	2000–05[b]	
America	0.55 (0.35–0.75)	0.55	8.3
Asia	0.72 (0.35–1.09)	0.64	10.4
Africa	0.24 (0.12–0.35)	0.29	3.8
Total	1.5 (0.8–2.2)	1.5	22.5

[a]Range due to available estimates.
[b]Emissions are calculated based on the average estimate for 1990–2000.

forests. During the last two decades, the area of primary natural forests decreased or modified through human intervention by 6×10^6 ha yr^{-1}. Due to FAO estimates, degraded and secondary forests in Africa, America, and Asia covered about 850×10^6 ha in 2002. While deforestation can be measured from space with relatively high accuracy, this is not the case for degradation and secondary regrowth; usually regrowth is spectrally indistinguishable from mature forests as early as after 15–20 years. Forest inventories, as a rule, do not contain any specific data on forest degradation. FAO (2000) estimated the area of disturbances that can be labeled as forest degradation at 24×10^6 ha yr^{-1} in the period 1990–2000; another recent estimate is at 10×10^6 ha yr^{-1}. Estimates of carbon emissions from the degradation of forests (expressed as a percentage of the emission from deforestation) vary greatly – from 5% for the world's humid Tropics to 25–42% for tropical Asia and above 100% for tropical Africa. Another study reports the global net emissions from land-use change in the Tropics including emissions from conversion of forest to other land use (71%) and loss of soil carbon after deforestation (20%), emissions from forest degradation (4.4%), emissions from the 1997–98 fires (8.3%), and sinks from regrowth (–3.7%).

Uncertainties of the above data are high. A number of reasons impact reliability of carbon emissions from deforestation and forest degradation: (1) accuracy of recognizing the areas of tropical deforestation and degradation; (2) weak knowledge of the amount of biomass and soil carbon on areas impacted by the land-use change; (3) fate of deforested land, that is, how much is reverting to secondary forests; (4) how much forests are burnt; and (5) how forest disturbance is affecting soil and forest floor carbon stores. In a number of studies, uncertainties on the amount of CO_2 released are estimated to be 25–50%. For the Brazilian Amazon, for example, a range of 150–280 Mt C yr^{-1} was reported.

The greenhouse impact of deforestation is greater than the difference in carbon stock between the forested and replacement landscapes due to releases of other GHGs, basically methane (CH_4) and nitrous oxide (N_2O) (ozone, carbon monoxide, and some other gases which are produced by deforestation are not direct GHGs; nevertheless, they impact concentrations of CO_2 and CH_4 in the atmosphere). The emissions of these gases do not occur directly with deforestation, but basically with the following land use such as rice cultivation, cattle breeding, application of fertilizers, etc. IPCC-2001 assesses the following contribution of the major GHGs to the enhanced greenhouse effect in 1750–2000: CO_2 – 60%, CH_4 – 20%, and N_2O – 6% (the other 14% are caused by halocarbons which are not produced by the biosphere). The contribution of deforestation to the global greenhouse effect is estimated in the range of 25–35%. Of this total, the contribution of CO_2 is about 15% (or about one-fourth of the global CO_2 emissions), CH_4 9–11% (40–50% of the global methane emissions), and N_2O 2% (from one-fifth to one-third of the global nitrous oxide emissions). Available regional estimates are of a similar magnitude. In the case of Brazilian Amazonia, for example, gases other than CO_2 increase the greenhouse effect by about 35%.

For decades, deforestation and degradation were considered as an almost exceptional phenomenon of the Tropics and arid lands. However, recent years have brought much evidence of possible damage to forests due to ongoing and expected global change in the boreal biome. Forest degradation and deforestation here mostly relate to the increase in frequency and severity of large-scale disturbances, change of hydrological regimes mostly related to permafrost destruction, industrial pressure on landscapes, pollution, and unsustainable logging. For instance, wild vegetation fires enveloped 23×10^6 ha (of which 17×10^6 ha on forest land) in Russia in 2003; during the first years of this century, outbreaks of dangerous insects in boreal forests exceeded 20×10^6 ha in the circumpolar boreal zone, of about the same area in American and Asian continents. The increase in the area of `green desertification' in the Russian taiga zone is estimated to be about 5×10^6 ha during the last two decades. The direct carbon emissions due to a fire in 2003 are estimated to be about 200 Tg C yr^{-1}. Very likely, the expected dramatic warming in high latitudes (up to 6–10 °C) will substantially accelerate processes of northern deforestation and degradation.

Conclusion: Managing Deforestation

While many governments try to provide a legislative basis and to realize measures to slow deforestation, the most recent and thorough deforestation studies offer no suggestion that deforestation is decreasing, either of its own accord or in consequence of policy interventions. On the contrary, increasing global integration of markets and growing demand for agricultural commodities and fuelwood in many regions of the developing world appear to be driving substantial increases in deforestation rates that will result in unsustainable forest management and further declining diverse forest services.

Some models and scenarios predict a substantial `baseline' deforestation, for example, for 2005–2015 ($\times$ 10^6 ha yr^{-1}): South America 3.9, Central America 1.2, Southeast Asia 2.6, Africa 5.2, and the total 12.9, with the average annual carbon efflux at the level of 1.2–2.0 Pg C yr^{-1} during the next two decades. The Special Report of IPCC on LULCC (2001) predicts the average annual accounted carbon stock change due to deforestation at –1.8 Pg C yr^{-1} of which –1.6 Pg C yr^{-1} is expected in the Tropics, and the global result of ARD activities between –1.2 and –1.6 Pg C yr^{-1}. The ongoing climatic change will accelerate negative consequences of the human-induced deforestation: the expected significant warming by the end of the century suggests dangerous implications for forests and human welfare. Studies report that the warming turns more and more tropical rainforest into steppe, and will transform up to 60% of this forest into dry land, dramatically impacting the region's richest biodiversity. Very likely, a similar process will be accelerated in the forest–steppe ecotone of the Northern Hemisphere, with substantial (up to 30%) increase in the area of the desertified steppe.

Tropical countries can reduce deforestation through adequate funding or programs designed to enforce environmental legislation; support for economic alternatives to extensive forest clearing, including carbon crediting; building institutional capacity in remote forest regions; and increase in areas of protective forests. Planted forests provide an opportunity to sequester carbon in vegetation and soils: afforestation and reforestation potentially could achieve annual carbon sequestration rates in live biomass in tropical regions 4–8 versus 0.4–1.2 t C ha^{-1} yr^{-1} in boreal regions, and 1.5–4.5 t C ha^{-1} yr^{-1} in temperate regions. An IPCC scenario (2000) predicts that the maximal amount of carbon that can be sequestered by global afforestation and reforestation activities is 60–87 Pg C on 344 $\times$ 10^6 ha during the first half of the twenty-first century with 70% in tropical, 25% in temperate, and 5% in boreal forests, provided the average annual carbon uptake is at 1.1–1.6 Pg C yr^{-1}. Of course, vast areas of forests converted to agriculture use, particularly to pastures, cannot be expected to recover forests of the original type on a timescale relevant to human planning: secondary forests differ in structure, composition, and productivity from their predecessors.

Reducing the rate of deforestation is another major way to decrease GHG emissions. However, neither the UNFCCC nor the Kyoto Protocol has introduced a satisfactory mechanism reducing GHG emissions from deforestation. Avoided deforestation was excluded from the Clean Development Mechanism, and the current international climate policy regime does not provide incentives for developing countries to reduce carbon emissions from tropical deforestation. This problem is under intensive international debates. One of the relevant ways how to curb emissions from deforestation is a so-called compensated reduction of tropical deforestation – the idea that tropical countries might reduce national deforestation under a historical baseline and be allowed internationally tradable carbon offsets having demonstrated reductions. Recent estimates assume that net deforestation would continue until the price of 1 t of sequestered carbon will be less than \$100 t^{-1} C. Such a price could give a possible decrease of carbon fluxes due to avoided deforestation at 300–650 Tg C yr^{-1}.

Tropical deforestation may be decisive in global efforts to stabilize GHG concentrations at levels that avoid dangerous interference in the Earth system. However, it will require substantial international and national efforts in many aspects, for many nations, at all times.

The Earth System and Climate Science: Understanding a Very Complex Entity

Hans Joachim Schellnhuber and Maria A Martin, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Glossary

2° guardrail Upper limit of global warming that is considered to most likely avoid catastrophic changes.

Anthroposphere Manifestation of human presence within the Earth System.

Ecosphere Biosphere-geosphere complex.

Paris agreement International political agreement from 2015, adopting the 2° guardrail.

Tipping element Element of the climate system that can undergo rapid and potentially irreversible, qualitative changes under global warming.

Ecosphere, Anthroposphere and Earth System Science

What is the "ecosphere"? Most of us will nowadays quickly type an unknown term into their search engine. In this case we would be confronted with an advertisement for a little world under glass, an aquatic system containing algea, bacteria, and even small shrimps (**Fig. 1**).

It is fascinating to observe a little world like this on its own, from a god-like perspective—but shatter the glass and you will destroy it. The real ecosphere on planet Earth is so much more robust, of course … or is it?

The history of the ecosphere began about 4 billion years ago, when the conditions on planet Earth finally became habitable for the first simple organisms. The interactions between them and their environment started with the development of basic forms of metabolic engines, life forms which drew on chemical compounds from their environment, and later recycled the waste products of other life forms as their food. In turn, the environment was changed by living things early on, the composition of the atmosphere being altered by the output of organisms, aiding with its oxidation. There has been a vivid partnership where life on Earth and the environment jointly developed, climbing up the *coevolution ladder*. This concept has been described over a decade ago by Lenton *et al.* (2004) (**Fig. 2**).

The authors extend it from its application to the early development of life to the major stages of human history—from the appearance of the hunter-gatherer *Homo sapiens*, via the *hydraulic societies* in the valleys of the Nile, Euphrates, Tigris and Indus, to our current state as a modern technical civilization in the trap of our own productivity; namely in a state of global industrialization. The degree to which we are currently interacting with the environment is unprecedented: The global metabolism revolving vast amounts of carbon, nitrogen, phosphorus and sulfur has been shifted markedly, land use alters the face of the Earth, and ocean acidification threatens marine life.

The study of the ecosphere, that is, the biosphere-geosphere complex, therefore needs to be complemented by consideration of its most recent offspring, the anthroposphere. This is indispensable in order to fully understand the design of the most recent bars of the coevolution ladder. The (inter)discipline aiming at achieving this completion is *Earth System Science*. Embracing this new scientific endeavor brings along a veritable shift in understanding, which has been called the *Second Copernican Revolution* (Schellnhuber, 1999). While the first Copernican Revolution was based on the desire to understand stellar phenomena and thereby place Earth in its proper astrophysical context, this one is directed at our planet itself with its seemingly endless complexity, weaving together the interacting physical, chemical, biological and not the least human components (**Fig. 3**).

It is revolutionary indeed because it again places us, humanity, in a new context: our presence and our activities on Earth have shifted, altered and even destroyed multiple elements of the system or interaction pathways. We are on the verge of triggering large-scale regime shifts, of which climate change is undoubtedly the most dangerous one. In other words: The anthroposphere is now dominating the ecosphere. Welcome to the *Anthropocene* (Crutzen, 2002)!

In order to direct this domination into a sustainable regime, we need to identify a safe operating space for humanity, respecting certain *Planetary Boundaries*. The principle was first introduced as a feature in *Nature* as part of the *Road to Copenhagen* program (Rockström *et al.*, 2009). It is based on the identification of crucial biophysical subsystems or processes in the Earth System like biochemical flows, land-use or climate change and their corresponding control variables, like flows of phosphorus to the ocean and biological nitrogen fixation, the percentage of forested land or atmospheric CO_2 concentration. A recent update on the state of the system (Steffen *et al.*, 2015) quantifies the control variables for seven of these planetary boundaries, several of which have been already transgressed. Climate change must be placed in the "zone of uncertainty," where thresholds might have been crossed, moving the climate system into a fundamentally different regime (**Fig. 4**).

Those thresholds play a vital role in a powerful paradigm of sustainability, epitomized by the concept of tipping elements in the climate system, which will be discussed in some detail in the following.

Fig. 1 A search-engine result for the term *Ecosphere*. From Flickr with CC-BY: https://www.flickr.com/photos/wicker-furniture/14808673001.

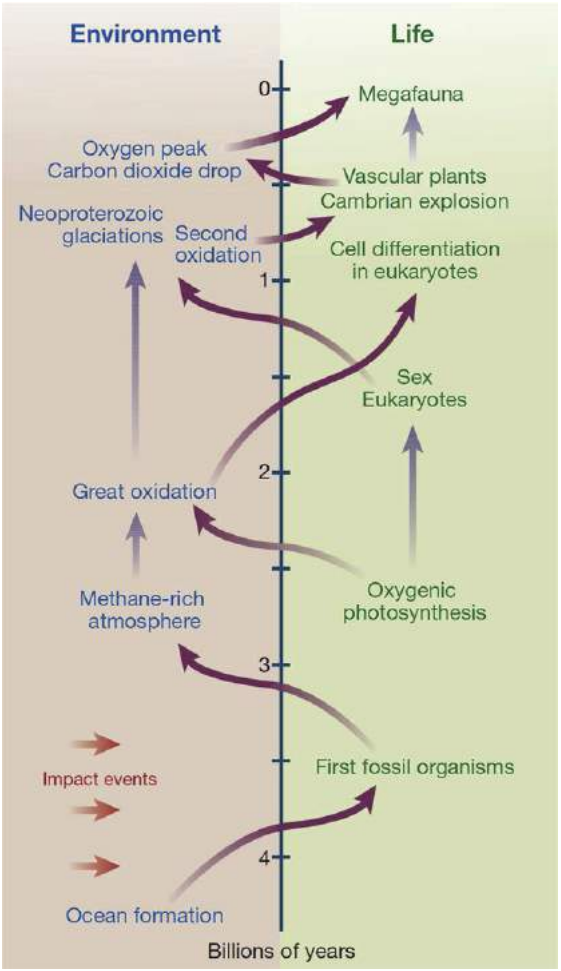

Fig. 2 The Coevolution ladder (Lenton *et al.*, 2004).

Tipping Elements

In the year 2003, a Dahlem Workshop was held in Berlin, Germany, bringing together pioneers at the new scientific frontier of Earth System science. The discussion covered long-term geosphere-biosphere interactions, the mode of operation of the Earth System during the Quaternary, its current state in the age of the Anthropocene and the potential transition towards sustainability. The freely available introductory chapter of the resulting book *Earth System Science for Sustainability* (Schellnhuber *et al.*, 2004) covers these topics and gives an excellent overview of the prospects for this new field of science (Clark *et al.*, 2005). It also

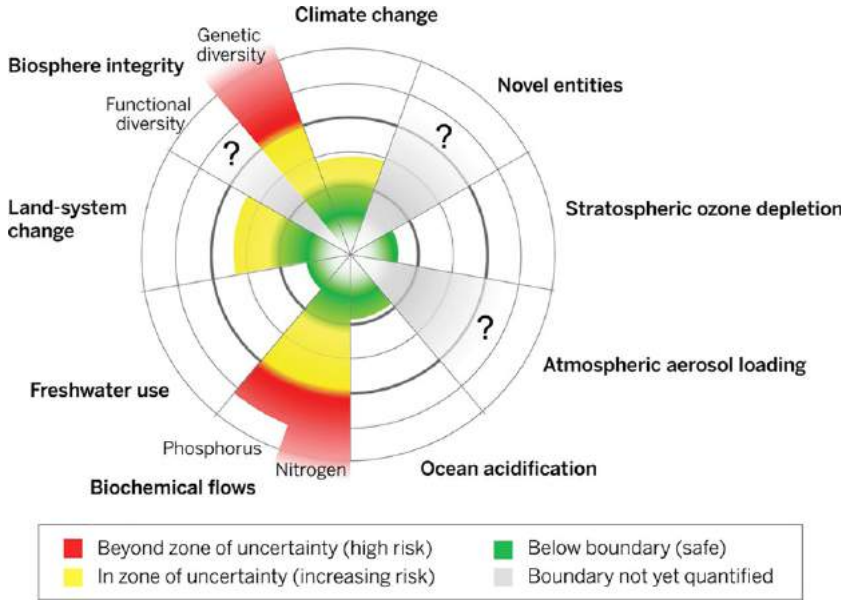

Fig. 4 Planetary Boundaries. From Steffen, W., Richardson, K., Rockström, J., Cornell, S., Fetzer, I., Bennett, E.M., Biggs, R., Carpenter, S.R., de Wit, C.A., Folke, C., Mace, G.M., Persson, L.M., Veerabhadran, R., Reyers, B., Sörlin, S., Cornell, E., Fetzer, I., Bennett, E.M., Biggs, R., Stephen, R., De Vries, W., De Wit, C.A., Folke, C., Gerten, D., Heinke, J., Mace, G.M., Linn, M., 2015. Planetary Boundaries: Guiding human development on a changing planet. Science 347 (6223), 1259855. https://doi.org/10.1126/science.1259855. Reprinted with permission from AAAS.

elaborates on the fact that Earth System science cannot rely on the valuable knowledge generated by natural sciences alone, but has to from an alliance with the social sciences in order to truly promote sustainability and not again step into the old pitfall of underestimating the human dimensions.

Although published around 12 years ago, these thoughts and concepts are still up to date. For instance, the early notion of tipping elements, at the time still called "switch and choke elements," is described and visualized in a manner largely resembling today's iconic graph (**Fig. 5**).

In 2008, a systematic revision of the concept, giving a formal definition along with an extensive literature review resulting in a short list of policy-relevant tipping elements, was published in PNAS (Lenton *et al.*, 2008) and one year later integrated into a special feature of the same journal (Schellnhuber, 2009).

In short, a tipping element denotes a component of the Earth System that is of at least subcontinental scale and enters a qualitative different state if a certain control parameter exceeds a critical value. This change of state might be irreversible, even if the control parameter (which could be the global mean temperature, for example) turns around to resume its original value. The pace at which the state of the tipping element changes after being triggered, however, differs greatly, depending on the nature of the system. Some examples may shed more light on the actual meaning of these general statements.

The Atlantic overturning circulation is responsible for the transport of vast amounts of warm surface water from equatorial regions towards northern latitudes near Greenland and the Labrador coast, where this water cools down and sinks. The resulting

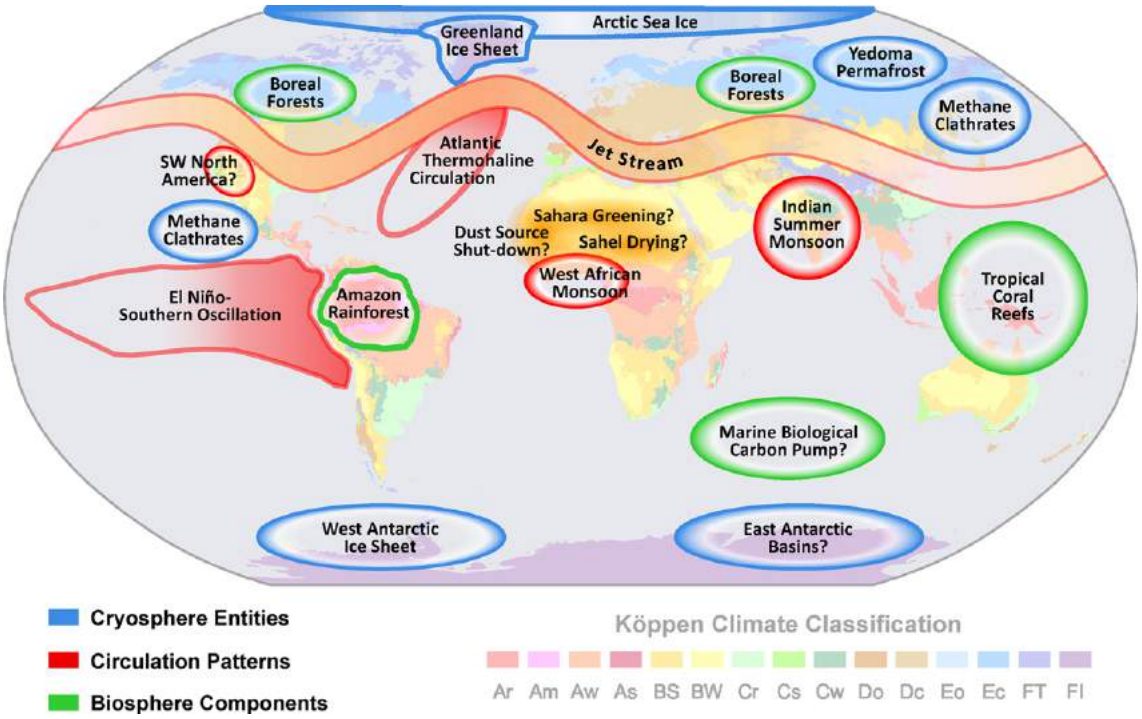

Fig. 5 Tipping Elements in the Earth System. Potsdam Institute for Climate Impact Research. (2017). Website: https://www.pik-potsdam.de/services/infodesk/tipping-elements/kippelemente.

cold, salty masses then flow southwards along the ocean floor. The cooling and sinking acts as a motor for the circulation system, which includes the Gulf Stream. Actually, the fuel for this motor is the very same northward stream of salty water from southern regions with high evaporation rates. This interplay constitutes a self-sustaining cycle, which cannot necessarily re-start once it is interrupted. Such an interruption could be brought about by a freshwater influx from melting polar ice, reducing the density of the water and thereby hindering downwelling—the motor begins to stutter or even shuts down. There is evidence that an exceptional weakening of the thermohaline circulation is currently underway (Rahmstorf *et al.*, 2015). The impacts of such a weakening range from disturbances of marine ecosystems, via cooling of the North Atlantic region to regional sea-level rise on the US-Atlantic coast.

There are more examples for circulation systems within the global environment that can be considered tipping elements. They include the tropical Pacific climate oscillation giving rise to the El Niño phenomenon or the planetary waves of the Jet Stream, which can give rise to extreme weather events in the mid-latitudes when blocking events occur and the waves lock into a certain position, thereby isolating cold polar and warm equatorial air for weeks. Monsoon systems are also prone to disturbance as they are based on a self-reinforcing feedback involving latent heat release during rainfall events.

In West Antarctica, there is enough ice stored to raise global sea level by around three meters. A special topographic situation, with kilometer-thick ice resting on bedrock deep below sea level at the center of the ice sheet, causes an unstable flow regime: Once too much ice is lost at the thinner borders of the ice sheet due to ocean warming or the reduction of buttressing by the floating ice shelves, the outflow keeps growing in line with the ice retreating inland (Joughin and Alley, 2011). The ice sheet may already have crossed a tipping point (see for example Mouginot *et al.*, 2014), leading to unstoppable sea-level rise in the centuries to come. In Greenland, on the other hand, the interplay between warming, melting and lowering of the surface leads to a self-reinforcing feedback (surface-elevation feedback), because the sinking ice surface is exposed to warmer masses of air, inducing further melt. A threshold might be crossed at a global warming level as "low" as 1.6°C (Robinson *et al.*, 2012).

But it is not only the inanimate parts of the Earth System that can undergo disruptive transitions. The unique terrestrial biodiversity of the Amazon rainforest, for example, depends on its own capacity to capture and store rainfall and to evaporate the water again, which will be eventually transported further inland by horizontal advection. If the abundant vegetation is destroyed or replaced with plantations in too many places, the "flying river" carrier of rain, conveying water from the oceans to the core of the continent, might be intercepted. Also, it has become painfully clear in recent years that coral reefs, the beautiful homes of thousands of types of marine life and the sources of nourishment for many more, are in acute danger because of warmer waters and less light received due to sea-level rise. Even if the 2°C guardrail agreed on in the Paris is respected, a breakdown of this marine sphere—a unique world of its own—has to be expected. Ocean acidification also plays a decisive role in the loss of corals, because the build-up of calcium carbonate structures requires waters of relatively mild acidity only. And ocean acidification plays the main part in one of the most exciting recent insights of Earth System science.

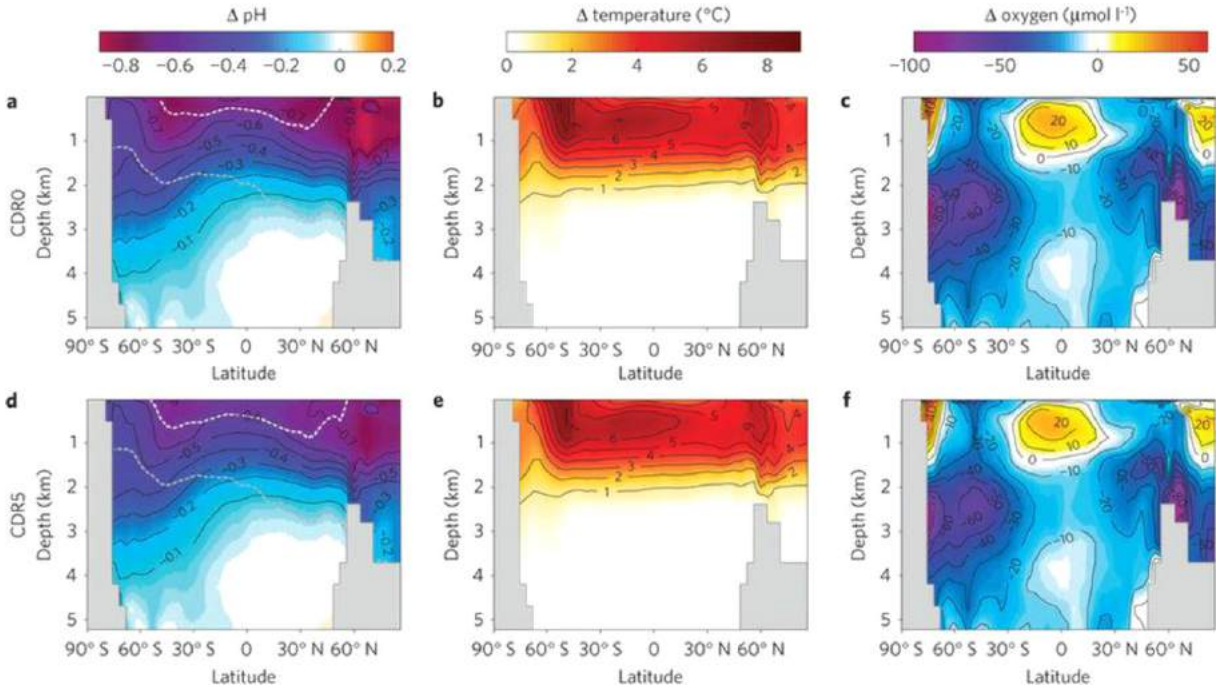

Fig. 6 The virtually nonexistent effect of massive carbon dioxide extraction from the atmosphere on the ocean (Mathesius *et al.*, 2015).

Topical Results of Earth System Science

It is well known that high atmospheric carbon dioxide levels due to anthropogenic emissions indirectly disturb the Earth System by enhancing the greenhouse effect, basically hindering long-wave radiation escaping into space. But there is also a very direct effect: CO_2 dissolves into the oceans, thereby altering the chemical composition of sea water and leading to acidification. This means that even if—by the improper means of climate manipulation (euphemistically called geoengineering) through solar radiation management—global mean temperature was kept stable, the acidification process would keep going and increase in severity. Humanity might feel safe to continue emitting CO_2, because the impacts on land would be stalled—marine life, however, would be subject to major disruptions. But what if we extracted CO_2 directly from the atmosphere? Would ocean acidification then disappear? This question has been answered with a big *NO* by a study involving scientists from the Carnegie Institution for Science in Stanford and the Potsdam Institute for Climate Impact Research (Mathesius *et al.*, 2015). If—in a dire scenario—humanity initially follows a business-as-usual scenario and in a late attempt to repair things starts reducing the net CO_2 content of the atmosphere around 2250, not even the utterly challenging scenario of extracting 18 billion tons of CO_2 each year would be a remedy. Even if extraction then continued for centuries, ocean chemistry would remain basically unimpressed by this effort (second row in **Fig. 6**, compared to the upper row without CO_2 extraction).

Another example of the dimension of the ongoing human interference with the Earth System concerns the natural cycle of ice ages, triggered by delicate changes in the way our planet orbits the sun (*Milankovic cycles*). The distribution of solar radiation impinging on Earth changes according to quasi-periods, for example due to axis precession (26,000 years period) or reflecting eccentricity changes of the elliptical trajectory of the planet (100,000 years period). The interplay of these periods with the nonsymmetric distribution of land on Earth is the underlying cause of drastic effects: ice ages and warm periods (*interglacials*) have now dominated the state of the Earth System and shaped the planet for 2.6 million years (*Quaternary glaciation*). But another player also has a key role here: atmospheric carbon dioxide concentration. Subtle differences in CO_2 levels can make all the difference!

On the basis of careful analysis of the conditions during past glaciations, a critical relationship between summer insolation at 65°N and CO_2 concentration has been derived (Ganopolski *et al.*, 2016). Based on this relationship it can be inferred that the next glaciation, which—without human interference—would be scheduled in about 50,000 years from now, will be canceled assuming even relatively moderate emission scenarios! (**Fig. 7**)

Understanding the Earth System, as has been discussed in this article, is both a tremendous scientific challenge and an absolute necessity. After decades of research and infinite struggles to make the significance of this research apparent to both the public and decision makers worldwide, an international agreement has been reached in 2015 in Paris to keep global warming below the threshold of 2°C, and possibly even below 1.5°C. The contours of this so-called Paris range have not been the result of political negotiations, but were ultimately derived from our best knowledge about the complex system constituting our environment. Recently, an analysis of an extensive body of literature on tipping points in the climate system has been condensed in one single graphic (**Fig. 8**). There are a number of tipping elements that might possibly be switched even within the Paris range, and several

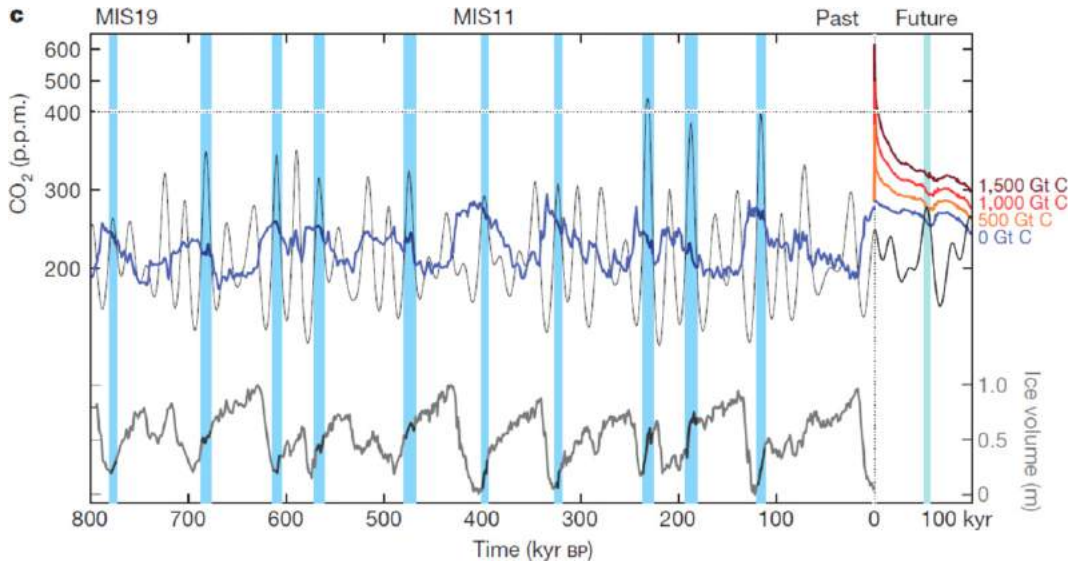

Fig. 7 Past glacial inceptions (*vertical blue bars*) as derived from the empirical relationship between maximum summer insolation at 65°N and CO_2 concentration. The next glacial inception—in 50,000 years from now (*vertical green bar*)—will be missed if either the red or dark red scenarios for anthropogenic carbon emission become reality (Ganopolski *et al.*, 2016).

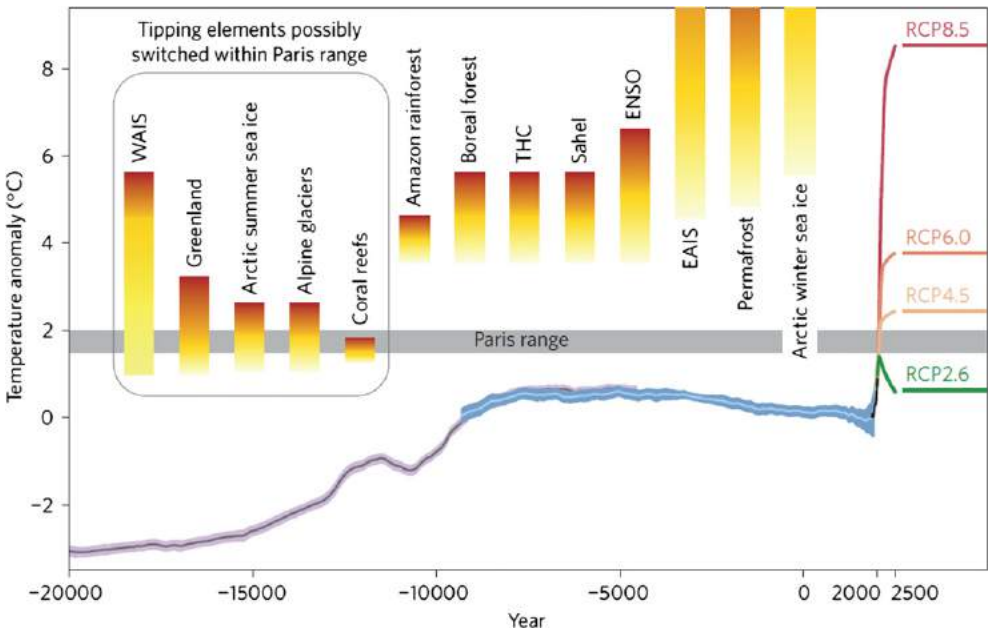

Fig. 8 Tipping elements in the context of 20,000 years of global mean temperature evolution and possible scenarios for the future (Schellnhuber *et al.*, 2016).

more looming not far above. This should make clear, without ambiguity, why the right climate target was agreed on in Paris (Schellnhuber *et al.*, 2016).

Emergence of Climate Change Ecology

Sergey Venevsky, Tsinghua University, Beijing, China

Introduction

The term "climate change ecology" is rather recent. Scopus search for this term results in only 42 articles with the term firstly mentioned in 2004 (Forchhammer and Post, 2004). Meanwhile, the leading scientific journal like Nature and Science are publishing Special Issues or sections with the title "Climate Change Ecology" (e.g. "Science" from August 2, 2013). Here, I discuss a subject of this newly appeared branch of ecology, its methods and current state.

What Is Climate Change Ecology

It can be defined that climate change ecology is a part of ecology dealing with climate change impacts upon terrestrial and marine ecosystems.

Climate Change

External and internal forces of climate

Climate at a certain location is a feature of Earth described by a sequence of long period (decadal, or century) averaged climate variables with temperature, precipitation, wind speed and direction, short wave radiation and relative humidity most important variables for the atmosphere (for the oceans the most important climate variable is sea surface temperature). Climatic variables can be considered at different time scale (larger than daily, i.e., 5-days, weekly, monthly, annually or for decades). Climate is different around the globe it may be polar, temperate, tropical (or has other subdivision) depending on temperature or may be arid or humid (depending on precipitation). Classification of Earth climates was suggested by Koppen (Wladimir and Alfred, 2005) and refined by Geiger in 1961 (see **Fig. 1**).

Climate of the Earth is controlled by external and internal forces. External driving forces for the Earth's climate are gravitation of nearest space bodies, which determine position of the planet to the Sun, and Solar irradiation. Climate internal driving forces are more numerous. They include gas and particle composition of the atmosphere, distribution of land and ocean masses, topography of land surface and bottom of the ocean. Especially important for providing climate suitable for life is gas content of the atmosphere. Greenhouse gases like water vapor, carbon dioxide, methane and nitrogen oxides are absorbing outgoing long wave radiation from the planet surface into outer space and, thus keep the average temperature of the Earth being 14°C. Humans by actively exploring Earth natural resources changing gas composition of the atmosphere. Exponentially increasing anthropogenic greenhouse gases emissions are responsible for additional warming of the atmosphere to almost 1°C since preindustrial period. The observed and projected increase of average global temperature induced by humans has differential regional manifestations, including not only seasonal warming, but cooling, as well as extreme climate events like prolonged droughts or floods, hurricanes etc. Projected climate change to the next century will substantially reshape Koppen-Geiger climate zones (see **Fig. 2**). Impact of climate change upon ecosystems and humans at different spatial scales at recent or at geological time steps is a subject of climate change ecology.

Climate change: Natural and man-made

Quantitatively climate change is determined as long-term (decadal to millions of years) change in statistical parameters of regional or global weather patterns. Mean and spread are major statistical parameters of climate change. For instance, annual average global temperature is a main statistical parameter used in description of global climate change. It was shown that annual average global temperature had significant variation (3–8°C) during history of the Earth. Evidence of climate change at decadal to geological time scales is confirmed by different observation sources. Temperature direct measurements from surface meteorological stations or radio balloons in troposphere allows direct record of climate change on decadal scale. Recent satellite observations allow conduction of observations of climate variables with fine spatial resolution using different proxies. Glaciers considered the best indicators of climate change in the past. Analysis of ice cores from glaciers revealed that since 3 million years glacial and interglacial cycles caused by orbital forcing were major regulators of climate change. However, data from ice cores drilled in central Greenland demonstrated that abrupt climate change during glaciation may persist without orbital forcing due to fast inner restructuring of climate system. Dendrochronology, which is focusing on width of tree rings as an indicator of dry and wet and warm and cold years is demonstrating evidence of climate change at century time scale. Palynology looks in distribution of fossil pollens reflecting pattern of past vegetation zones which were constrained by past climates.

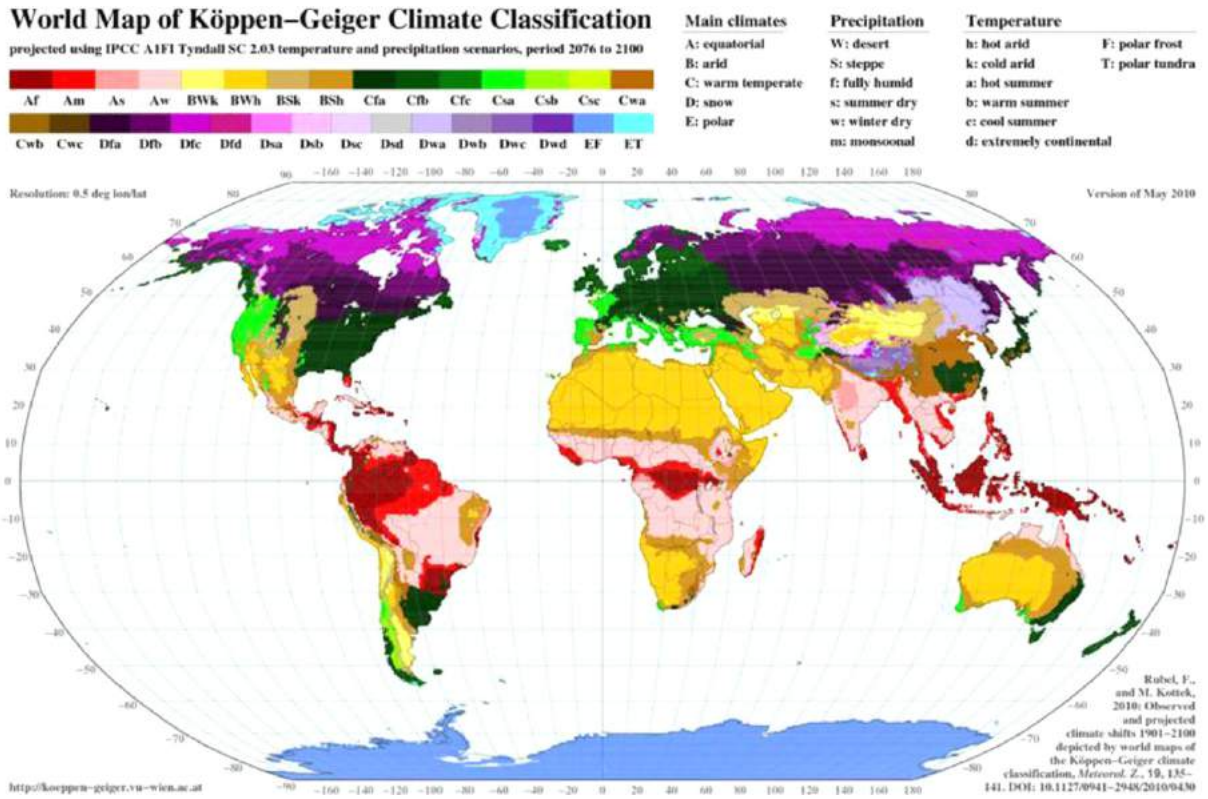

Fig. 2 Koppen-Geiger classification of climate zones 2076–2100 (Rubel and Kottek, 2010).

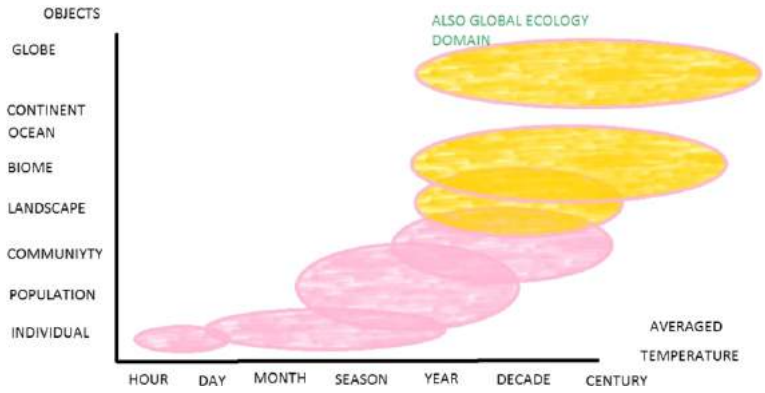

Fig. 3 Variety of objects of climate change ecology. Objects are shown in a space of one from averaged over long period climatic variables. Golden color depicts objects for which consideration of biophysical changes are considered in line with ecological changes. Intersection of objects assume consideration of intrainfluence of objects with different level of organization. Globe is an object not only of "climate change ecology," but as well an object of "global change ecology."

Climatic system consists of several elements: atmosphere, ocean, biosphere and cryosphere. Interaction of atmosphere and ocean due to transfer of heat, distributed differentially in space, creates inner climate variation. Biosphere is another important regulator of inner climate variability because of its role in global carbon and water cycle. Humans actively exploiting carbon stored in former biospheres as fossil fuel are changing gas content of the atmosphere and its radiative transfer abilities. Excessive amounts of greenhouse gases, first of all of carbon dioxide, may the reason of recent increase in global temperature named by general public as global warming, The so named "global warming," associated with change of global surface temperature, in regional realization can be seen as drying, wetting or cooling, as well as change in frequency of extreme weather events like hurricanes, because of complexity of interactions of elements of climate system and its highly nonlinear dynamics (Shepherd, 2014).

In course of time anthropogenic and natural forcing mechanisms may change each other even at decadal time scale. This can be seen for instance in XX century, where in the beginning of century increasing trend in global surface temperature is attributed to variation of solar irradiance, while relatively quick rise in global surface temperature in the last decades of the century is associated with rapid rise in anthropogenic greenhouse emissions (Stott *et al.*, 2000). The climate change caused by humans in the last few decades is a subject of great concern of society as consequences of climate change are already observed everywhere in biosphere and anthroposphere.

Ecological Response to Recent Climate Change

Impacts of recent climate change are observed almost everywhere, despite value of global surface temperature changed only to several percent to absolute value in last decades. We can divide conditionally these impacts to (a) biophysical changes which related to change in chemical fluxes and stores in ecosystems of different scales from the global to local both natural and human-dominated (urban and agricultural); (b) ecological changes, which include changes of abundance ranges and interactions between biological objects (organisms, populations, biomes). Accordingly climate change ecology studies impacts of climate change upon as living so nonliving objects of different temporal and spatial scales (see simplified scheme at **Fig. 3**). We figure further an overview of (a) most cited and (b) most recent findings of climate change ecology for different scales and objects.

Biophysical changes

Studying of global warming induced biophysical changes (changes of energy, information and matter fluxes and pools) at different spatial and temporal scales are most popular topics in climate change ecology. Research of alterations of biogeochemical cycles in terrestrial and marine ecosystems are central in studying of climate driven biophysical changes.

Climate change and global biogeochemical cycles

Climate change and water cycle

Global water cycle is significantly influenced by climate. There is a general agreement in projections that global water cycle accelerates with increase of global surface temperature. However, despite of amount of fresh water available for humankind is suggested to increase, regional distribution of water is supposed to has a great disparities in space (Oki and Kanae, 2006). This can increase vulnerability of water-stressed areas where according to several estimates leaves almost one third of human population of the Earth. Change of terrestrial water cycle is the key research focus in climate change ecology, as it determines future of humankind. Unfortunately, recent studies confirm that aridity over the land is being accelerated in course of climate change due to the land-atmospheric feedback, provides by soil moisture, and reaction of vegetation to CO_2 enhancement in the atmosphere (Berg *et al.*, 2016).

Climate change and carbon cycle

Alterations of global carbon cycle are closely related to climate change. Study of such alterations constitutes a core of climate change ecology equally to research in water cycle alterations. Anthropogenic carbon dioxide emissions are affecting climate due to greenhouse effect. Around half of these emissions are absorbed by oceans and marine and land ecosystems currently, while second half is gradually accumulated in the atmosphere. The absorbing ability of the ocean and the ecosystems are climate sensitive, so that increase of global surface temperature may decrease global absorption of carbon from the atmosphere and accelerate climate change even in the nearest future (year 2050 see Cox *et al.*, 2000)). Recent findings for Arctic underline close interconnection between marine and terrestrial part of carbon cycle in course of global warming. It appeared that sea-ice melt, permafrost thaw and release of fresh water in the Polar Ocean regulate carbon storage and release as from terrestrial so for marine ecosystems (Parmentier *et al.*, 2017).

Climate change and nitrogen cycle

Humankind accelerates global nitrogen cycle by industrial production of fertilizers to solve food problem. This acceleration, however, has significant direct effect on global carbon cycle, especially to absorbing abilities of the biosphere. Question of mitigation of climate change by artificial controlling of nitrogen cycle, however, is open due to counterbalancing negative effects of euthropication and global acidification of terrestrial and aquatic ecosystems (Gruber and Galloway, 2008). Recent manipulation mesocosm experiments over Tibetan alpine wetlands demonstrated that lowering of water table observed here due to climate change now days in combination with nitrogen deposition from human land use synergistically influence emissions of greenhouse gases from the area because of reactions of microbial communities in soil (Wang *et al.*, 2017).

Climate change and terrestrial ecosystems

Impact of climate change to ecosystems as terrestrial ones so marine ones has principal difference with the impact upon biogeochemical cycles. Indeed, climate driven alterations of biogeochemical cycles described by a set of rather similar (although rather complicated) chemical reactions in living and nonliving objects. Climate control of ecosystems is more subtle as living objects with their unique climate response are interacting within an ecosystem at individual, population and community levels. This interaction is a consequence of evolutionary history, sharpened by climate at different time scale and unequally distributed in geographical domains. Thus, a question of location and timing will be defining when studying climate change impact upon ecosystems. Besides, marine ecosystems, living in environment strikingly different by chemical and physical features from terrestrial environment have their own peculiar features of climate control over them.

Climate change and natural terrestrial ecosystems

Research of impact of climate change to terrestrial ecosystems is not new. Simultaneous observation records for weather and changes in phenologies, life cycles and ranges for birds, animals, herbs and trees are coming back to 1700 in Northern Europe. Especially, charismatic taxons like butterflies or birds have well documented responses of body size, reproductive functions and ranges to climate variation.

Now days, the number of published studies, observational or experimental or modeling, relating climate change to terrestrial ecosystems is increasing exponentially since 2003 (see Parmesan, 2006).

Mostly these studies orient to phenological responses to climate change. Plants as primary producers in terrestrial ecosystems are in major focus of phenological observations. So, it was observed using remote sensing that normalized difference vegetation index (NDVI), which describes summer photosynthetic activity, was increasing in the Northern Hemisphere during 1981–1991 in line with increase of the hemisphere average surface temperature (Myneni *et al.*, 1997). On-ground observations in the network of European Phenological Botanical Gardens revealed lengthening of growing season to 10.8 days in the period 1953–1993 (Menzel, 2000) as a response to global warming. However, recent research revealed that systematic identifying of climate windows, which include number and type of variable (if it is temperature, rain, air humidity, wind e. t. c.) and critical timing for physiological, behavioral, life-history, demographic, population and community traits is lacking (van de Pol *et al.*, 2016). More rigorous identification of climate windows at each spatial and temporal levels of living objects is necessary.

Climate change and agricultural ecosystems

Projected climate change can significantly influence crop production mainly due to availability of water. Combination with rapid growth of population in some areas makes climate change a major threat for food security. So, an analysis of climate risks to food security conducted on scenarios for 20 global circulation models till year 2030 confirmed that regions of South Africa and South Asia will most likely suffer from climate induced drop for important crop yields, which will lead to food insecurity for their fast growing populations (Lobell *et al.*, 2008). Using of cover crops (legumes, clover, mustard etc.) which are historically aimed for nitrogen fixation or reduction of soil erosion for mitigating of climate change is a new and blooming idea relating climate change and agricultural ecosystems (Kaye and Quemada, 2017).

Climate change and aquatic ecosystems

Climate change and marine ecosystems

Although there is a clear bias toward study climate change impact to terrestrial ecosystems, phenological response of marine species also got attention recently. For example, Arctic seabird *Uria lomvia*, has advanced its egg-laying date few days at its southern

boundary (Hudson Bay). The change of date is closely correlated to change in sea-ice cover (Gaston *et al.*, 2005). However, recent analysis of research of response to climate change of living marine resources is still rather poor and faces significant modeling and observational challenges (Tommasi *et al.*, 2017).

Climate change and freshwater ecosystems

Freshwater ecosystems demonstrate phenological response for climate change similar to terrestrial ecosystems. So, phytoplankton bloom, moved gradually by 19 days earlier in the period 1962–2002 in a lake in North-Western USA, while zooplankton development showed more erratic behavior (Winder and Schindler, 2004). Fresh study of rivers across a continent of Australia highlighted that climate change case a significant turnover and extinction of riverine fauna species additionally to a main threat coming from anthropogenic land use and water use (James *et al.*, 2017).

Ecological changes per se

Climate change and biogeography

The coherent signals of climate change on broad scale plant and animal communities are seen now days almost everywhere. One can expect poleward and upward shifts in warming regions and opposite direction development in cooling regions with restructuring of communities. Such studies at communities level are however rather rare. The theoretical models as a generalization of communities use biome concept or plant functional type concept related to it (Sitch *et al.*, 2003). However, observations confirming broad scale redistribution of biomes are rather rare. Here, observations of tree line change play major supporting tool for climate driven biogeography impacts. So, northward migration of tree line in warm decades of 1990s are seen in Scandinavia (Kullman, 2001) eastern Canada (Lescop-Sinclair and Payette, 1995) and in Europe (Meshinev *et al.*, 2000). It is found in recent study, however, that Alpine vegetation community has little control of multilevel hierarchical organization of species composition, but rather controlled by climate variables, which are different at different spatial scales (Malanson *et al.*, 2017). This means that this "biome" is either supporting "neutral" theory of biogeography (stochastic composition of species) or system in disequilibrium.

Climate change and spatial distribution of species

There are numerous confirmations to climate change related species ranges. Shifts in species abundance ranges are seen recently at polar latitudes, in Northern Hemisphere temperate species, in tropical species, mountain species and marine species (see review of Parmesan, 2006). It should be noted, however, that whole species range/climate change studies are rather rare. Such studies focus at the moment to plants, mammals and amphibian. The difficulty in research of climate change and spatial distribution of species are arising from patchiness of habitats with different size populations of a species. It was found recently from experimental manipulations and modeling that increases in climatic variance may as decrease, so increase a certain population growth making predictions rather uncertain (Lawson *et al.*, 2015).

Climate change and interaction between species

Species involved in trophic networks have different climate tolerances, variety of phenological responses to climate change. This may influence their interactions in prey–predator relationships. Climate change related asynchronies in timing of appearance/senescing of species of related trophic interactions may bring some species to the verge of extinctions or benefit them. Studies focusing on impact of climate change to interactions of species are, however, still rare and related mainly to plants–insects or plants–birds interactions. So, range contractions or expansions of common butterfly *Enphydra editha* were documented in relation with the time of blooming or senescing of nectar flowers (Thomas *et al.*, 1996). Flower life events in its turn were shown to be related to droughts or low snow pack years (Thomas *et al.*, 1996). Species–species tolerances determined by climate suitability may serve as a predictor tool for management and eradication of future invasive species as it was demonstrated on example of Australian Alps region recently (Harris *et al.*, 2017).

Methods of Climate Change Ecology

Climate change ecology by definition should focus on living and nonliving objects at different spatial scales, which function at different time steps. This requires combination of all available in ecology methods from traditional (as observations) to most recent (like large scale terrestrial ecosystem modeling).

Observations

Field observations

Analysis of climate change impact upon ecosystems requires systematic laborious monitoring. It is now widely accepted that so named research observatories networks are suitable for these purposes. Typically, such research networks are focusing on some rather large scientific questions (like status of carbon in an ecosystem, or status of biodiversity in an area). Most famous like Carbo-North, LTER and FLUXNET are building international networks based on predefined principles. Such principle can be, for

example, using watersheds of different level if we concentrating on soil moisture alterations due to climate change (Bogena *et al.*, 2006). Important global conclusions were found recently at FLUXNET observations: it was found that enhanced aerosol loading increase water use efficiency for all plant types due to diffuse radiation (Lu *et al.*, 2017).

Set experiments across climate gradients: FACE

Rising level of CO_2 in the atmosphere, which comes alone with climate change, may heavily influence plant physiology and accelerate or decelerate further global warming. Free-air CO_2 experiment (FACE) allows study of carbon dioxide enrichment on plant and ecosystem growth in natural conditions. The experiment is going already more than 20 years in different ecosystems types around the world. It was confirmed in the course of the experiment that above-ground production of plants is increasing in conditions of elevated CO_2, thus, making negative feedback to climate change. The effect, however, depends on functional type of ecosystem. Trees are reacting to carbon dioxide increase more than herbaceous vegetation (Ainsworth and Long, 2005). Now days FACE experiment also looks at the intercanopy structure and position of leaf for a control of possible response to elevated CO_2 (see example of Duke Forest FACE experiment (Paschalis *et al.*, 2017)).

Remote Sensing

Satellite remote sensing measuring entering and leaving flux of radiation from top of the atmosphere is one of the most powerful tools in climate change ecology. NASA at the moment uses 14 satellites of different types of orbits (sun-synchronous and geo-synchronous) with different type of sensors (passive sensors, which record naturally occurring electromagnetic radiation at top of the atmosphere and active sensors which emit electromagnetic radiation toward the Earth and measure its scattering/reflection (http:/earthobservatory.nasa.gov). Satellite remote sensing allowed to study large scale areas and make findings which cannot be done by modeling or field observations. An example is consequence of global sea-rise, which cannot be detected by the models at the moment (Yang *et al.*, 2013).

Geo-Spatial and Statistical Analysis

Statistical analysis of time series plays key role in quantitative climate change ecology. So, two thirds of all studies related to climate change impacts to marine ecosystems are studying statistical relationships between climate drivers and quantitative indicators of the ecosystems (Brown *et al.*, 2011). Visualization using geo-information systems is another important tool in climate change studies. Analysis of 30 visualizations for climate change impacts in Australia with stakeholders reveals high effectiveness of these tools for understanding of climate change.

Process-Based Modeling

Landscape scale modeling

Recent development of computer technics and systematic field observations made it possible to describe certain features of functioning of terrestrial and marine ecosystems at landscape scale as a set of related processes described by physical (e.g., mass conservation), chemical (e.g., kinetic) and biological equations (e.g., Lotka–Volterra). Outcome of response to climate change can be simulated using system of these equations (Allen *et al.*, 2010). Examples of such models are forest gap models which explicitly simulate process of tree growth for focused species, competition for light, water and space with favorite outcome for some trees and dying of other trees and opening the gap in the canopy. Processes of growth, competition and mortality are all climate specific. Thus, impact of climate change in form of composition of forest stand, above ground and underground biomass can be directly estimated by these simulation models. Recent experimental studies strongly support approach of forest gap models demonstrating that local interactions within stand and edaphic factors play almost no role in long-term vegetation dynamics (Murphy and McCarthy, 2017).

Continental scale and global modeling

The most important goal of climate change ecology is an understanding of functioning of Earth as a separate ecosystem, where interaction of biosphere, atmosphere, hydrosphere and oceans is considered. This requires using of modeling living objects of continental or global scale. It should be noted that continental/global scale objects of climate change ecology are potential vegetation types, while global change ecology considers actual vegetation cover and focuses on global change as synergy between climate change and land use/land cover change. An example of modeling object of climate change ecology at continental scale is a grid cell of dynamic global vegetation models (Sitch *et al.*, 2003), which is seen in these models as a separate ecosystem situated in terrestrial rectangle size of 1 to 1 km or 50 by 50 km. Grid cell is described as a set of percentage cover of certain functional types of vegetation (like boreal evergreen or grassland or tropical evergreen) with related carbon and water pools and fluxes. Listed grid cell ecosystem indicators are all climate sensitive. Thus, global or continental scale vegetation distribution with associated pools and fluxes can be simulated as an outcome of global or continental climate change scenarios. Recent studies of continental scale potential vegetation are concentrating on boosting of their performance (Khvostikov *et al.*, 2015).

Conclusion: Current State and Possible Future Trends in Climate Change Ecology

Climate change ecology appeared to become research field well established in recent decades. Future trends in climate change ecology will emerge as more close fusion of field and remote sensing observations as well as statistical and process-based models at fine spatial and temporal resolution. This will be secured by use of recently developed supercomputers and micro computational technologies. In the nearest future climate change ecology is going to focus on interecological disciplines like combining approaches of marine science and plant science, or climate envelop approach with invasive species theory and so on.

Energy Balance☆

Axel Kleidon, Max Planck Institute for Biogeochemistry, Jena, Germany

Nomenclature

a_p	Planetary albedo
E	Evaporation rate (mm d^{-1})
H	Sensible heat flux (W m^{-2})
J	Ground heat flux (land) or horizontal heat transport (ocean) (W m^{-2})
L	Latent heat of vaporization ($\approx 2.5 \times 10^6$ J kg^{-1})
L_0	Solar luminosity (3.9×10^{26} W)
LE	Latent heat flux, composed of the latent heat of vaporization L and the evaporation rate (E) (W m^{-2})
R_0	Solar constant (1367 W m^{-2})
$R_{l,d}$	Downwelling flux of terrestrial radiation at the surface (greenhouse effect) (W m^{-2})
$R_{s,d}$	Downwelling flux of solar radiation at the surface (W m^{-2})
$R_{s,toa}$	Incoming flux of solar radiation at the top of the atmosphere (W m^{-2})
S	Entropy of a system (J K^{-1})
T_r	Radiative temperature (K)
T_s	Surface temperature (K)
λ	Wavelength of radiation (m)
σ	Stefan-Boltzmann constant (5.67×10^{-8} W m^{-2} K^{-4})
$\sigma_{process}$	Entropy production of a process (W m^{-2} K^{-1})

Glossary

Albedo The albedo describes the reflectivity of the atmosphere or surface. A high value of the albedo is associated with a highly reflecting object, such as snow or clouds.

Entropy production Entropy production refers to the general characteristic of Earth system processes to increasingly disperse energy at the scale of atoms, electrons, and molecules. It reflects that a system is far from thermodynamic equilibrium with its dynamics proceeding in the direction imposed by the second law of thermodynamics.

Feedback A feedback refers to a chain of functional relationships that modulate the response of a system to an externally caused change. A positive feedback refers to a chain of relationships which enhances the response of a system to the initial change, while a negative feedback stabilizes and dampens the response. Important feedbacks for the energy balance are the ice-albedo feedback and the water-vapor feedback.

Gaia hypothesis The Gaia hypothesis states that the state of the Earth system is regulated for and by the biosphere to maintain habitable conditions. It originated from the notion that organisms as well as the whole Earth system are complex thermodynamic systems that are maintained far from equilibrium.

Greenhouse effect The greenhouse effect refers to the absorption and subsequent re-emission of radiation within the atmosphere, which enhances the downward flux of radiation to the surface. The greenhouse effect is mostly caused by clouds, water vapor, and other greenhouse gases such as carbon dioxide, methane, and nitrous oxide.

Radiative temperature The radiative temperature is derived from a radiative flux using the Stefan-Boltzmann law. It thus refers to the equivalent temperature at which emission takes place to cause a certain flux of radiation.

Solar radiation The radiation emitted by the Sun is referred to as solar radiation. Its wavelength composition has a peak at visible light. It is also referred to as shortwave radiation.

Terrestrial radiation Terrestrial radiation, or longwave radiation, refers to radiation that is emitted by the Earth's surface or by the atmosphere. It is emitted at much lower temperatures of the Earth (when compared to the Sun) so that its wavelength composition is shifted to longer wavelengths with a peak in the infrared range.

Turbulent fluxes Turbulent fluxes refer to heat and mass fluxes associated with turbulent motion near the surface. These fluxes consist of the sensible heat flux and the latent heat flux which is associated with evaporation. These fluxes typically cool the surface and represent major components of the surface energy balance.

Introduction

All ecosystems are affected by and interact with their physical environment. At the global scale, the Earth's environment is characterized by the global energy balance, the balance of all heating and cooling terms that shape the climatological variations in

☆*Change History*: March 2018. Axel Kleidon updated all sections. Figures 1, 4, and 5 were updated with more recent data. The section on the global entropy balance was moved to a later section and was revised. The text was shortened to reduce overall length and also feedback diagram in Fig. 7(D) was updated. This is an update of A. Kleidon, Energy Balance, In Reference Module in Earth Systems and Environmental Sciences, Elsevier, 2013.

 doi:10.1016/B978-0-12-409548-9.00927-1

space and time, especially with respect to surface temperature, precipitation, and the availability of light. From an energy balance viewpoint, the interrelationships between ecosystems and their environment are threefold: (1) ecosystems utilize energy sources from their environment, and thereby are a part—though small—of the energy balance; (2) ecosystem processes are affected by environmental conditions that are directly or indirectly connected to the energy balance (e.g., precipitation affects the levels of water limitation of terrestrial productivity); and (3) the form and functioning of ecosystems affect energy balance terms. This article reviews the basics of the global energy balance, how it is reflected in the geographic distribution of mean climatological properties, and how it interacts with life through ecosystem functioning.

Global Energy Balance

At the planetary scale, the energy balance is driven by the absorption of sunlight and the emission of radiation to space. Planetary properties and the global energy balance give a first impression of the relevant processes that shape the environmental conditions at the surface and how habitable these are to life.

Planetary Energy Balance

The planetary energy balance is driven by the absorption of solar radiation of about 240 W m^{-2} in the global mean, which is then re-emitted into space at longer wavelengths as terrestrial radiation. The planetary energy balance is approximately at a steady state when the amount of absorbed radiation is balanced by the emission of radiation. In this case, the planetary energy balance is:

$$R_{s,\,toa}\left(1-a_p\right)=\sigma T_r^4$$

where the amount of absorbed solar radiation is expressed by the mean incident solar radiation at the Earth's orbit $R_{s,\,toa}$ = 340 W m^{-2} and the Earth's planetary albedo (or reflectivity) a_p = 0.29, which combined yield about 240 W m^{-2}. Emitted radiation is expressed by the Stefan–Boltzmann radiation law as σT_r^4, with σ = 5.67 10^{-8} W m^{-2} K^{-4} and T_r being the so-called radiative temperature. These numbers yield a value of T_r = 255 K for present-day Earth. The cooling of the Earth's interior adds <0.1 W m^{-2}, which is very small in comparison to the amount of absorbed solar radiation, and can therefore be neglected in the Earth's energy balance.

The observed global mean surface temperature of T_s = 288 K is notably higher by 33 K than the radiative temperature. This additional warming of the surface is due to the atmospheric greenhouse effect. It results from the absorption of long-wave radiation by greenhouse gases in the atmosphere that was emitted from the surface (Fig. 1). The absorbed radiation is re-emitted to space, but also back to the surface, thereby providing an additional radiative flux incident at the surface. The comparison of Earth's planetary characteristics to those of the planetary neighbors shows the importance of a well-balanced greenhouse effect in providing a habitable environment, with the hot surface temperatures of Venus explained by a very strong greenhouse effect while the greenhouse effect is absent on Mars (Table 1).

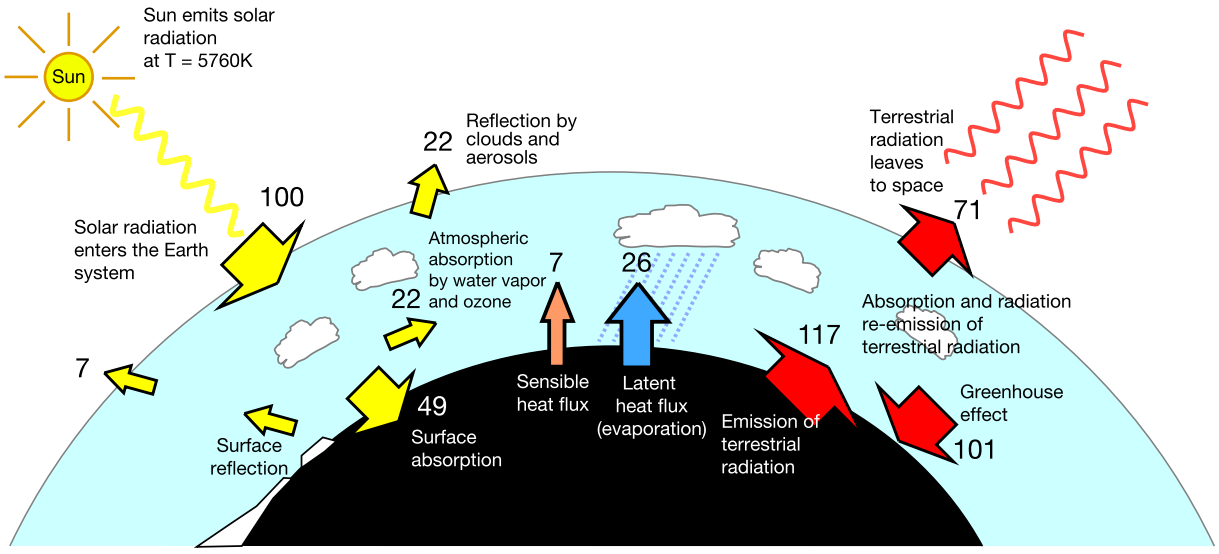

Fig. 1 Earth's global energy balance in terms of its dominant energy fluxes, their brief description, and their magnitudes, expressed as percentage of the average amount of incoming solar radiation of 340 W m^{-2}. The numbers are derived from the climatological mean of the years 2000–10 based on Stephens et al. (2012).

Table 1 The Earth in comparison to its planetary neighbors

	Earth	*Venus*	*Mars*	*Moon*
Orbital characteristics				
Distance to Sun	150×10^6 km	108×10^6 km	228×10^6 km	[b]
Obliquity	23.45°	<3°[a]	25.2°	6.7°
Eccentricity	0.017	0.007	0.094	0.055
Length of day	24 h	2802 h	24.7 h	708.7 h
Length of year	365.2 days	224.7 days	687 days	27.3 days
Atmospheric composition				
Surface pressure	101.3 kPa	9.2 MPa	640 Pa	3×10^{-10} Pa
Carbon dioxide (CO_2)	360 ppm	96.5%	95%	
Nitrogen (N_2)	78%	3.5%	2.7%	
Oxygen (O_2)	21%	0%	0.13%	
Climate parameters				
Planetary albedo	0.30	0.71	0.16	0.11
Absorbed solar radiation	239 W m^{-2}	190 W m^{-2}	124 W m^{-2}	304 W m^{-2}
Radiative temperature	255 K	233 K	210 K	275 K
Surface temperature	288 K	737 K	210 K	100–400 K
Greenhouse effect	+33 K	+504 K	+0 K	

[a]Venus rotates in the opposite sense than Earth.

[b]Distance Moon–Earth is 0.378×10^6 km.

Orbital characteristics, atmospheric composition, albedo, absorbed radiation, radiative temperature, surface temperature, and the strength of the atmospheric greenhouse effect are given for selected inner planets and the Earth's moon.

Surface Energy Balance

In addition to the absorption of solar radiation and the emission of terrestrial radiation, the surface energy balance needs to account for additional terms that heat and cool the surface:

$$R_{s,d}\,(1 - a_s) + R_{l,d} = R_{l,u} + H + LE + J$$

where the terms on the left hand side express the two radiative fluxes that heat the surface: the downwelling flux of solar radiation, $R_{s,d}$, modulated by the surface albedo a_s that describes its reflectivity, so that the product $R_{s,d}\,(1 - a_s)$ describes the absorption of solar radiation at the surface, and the downwelling flux of longwave radiation, $R_{l,d}$, that is emitted by the atmosphere (the greenhouse effect). The right hand side contains terms that generally cool the surface: The emission of radiation from the surface, $R_{l,u}$, which is directly linked to surface temperature by the Stefan-Boltzmann radiation law (as mentioned above), but also the turbulent fluxes of sensible and latent heat, H and LE, where the latent heat flux is written as the product of the latent heat of vaporization, $L \approx 2.5 \times 10^6$ J kg^{-1} K^{-1} and E is the evaporation rate. In addition, J is a term that either describes heat storage changes in the soil or the surface ocean and/or the horizontal transport of heat (relevant for oceans, but not for land).

Note that photosynthesis utilizes a fraction of the absorbed solar radiation and thus, in principle, also represents a term of the surface energy balance. However, photosynthesis utilizes <3% of the absorbed solar radiation, so that it represents a minor, often neglected term in the surface energy balance.

Global Energy Balance Components

In the global climatological mean, heat storage and transport terms in the surface energy balance average out to zero (i.e., $J \approx 0$). The estimates of each of the energy balance terms are shown in **Fig. 1**. Of the incoming 340 W m^{-2} of solar radiation at the top of the atmosphere, $R_{s,toa}$, 22% is reflected by clouds and aerosols in the atmosphere and another 7% by the surface. These two numbers add up to the planetary albedo of about $a_p = 0.29$. The remaining radiation is absorbed in the atmosphere (22% of $R_{s,toa}$, by ozone in the stratosphere and by water vapor) and at the surface (49% of $R_{s,toa}$). Additional surface heating is provided by the atmospheric greenhouse effect (*red arrow* in **Fig. 1**), which adds twice as much energy to the surface than solar radiation. These heating terms are balanced by cooling through emission of terrestrial radiation and the turbulent fluxes of sensible and latent heat. The atmosphere is heated by the absorption of solar radiation (22% of $R_{s,toa}$), absorption of terrestrial radiation emitted by the surface (117% of $R_{s,toa}$), turbulent fluxes (33% of $R_{s,toa}$), and cooled by the emission of terrestrial radiation to space (71% of $R_{s,toa}$) and to the surface (101% of $R_{s,toa}$, the greenhouse effect).

Radiation

Absorption, reflection, and emission of radiation are the dominant processes that shape the global energy balance and its regional variations. To understand these variations, the nature of radiation, the processes that reflect and absorb it, as well as the resulting latitudinal variation of radiative fluxes for the present-day climate are explained in the following.

Electromagnetic Radiation

Electromagnetic radiation is characterized by its wavelength λ, or alternatively by its frequency v. The two variables are related by $\lambda v = c$, with c being the speed of light ($c = 3 \times 10^8$ m s^{-1} in vacuum). Radiation with shorter wavelengths is referred to as more energetic. Relevant for climate are mainly the following wavelength ranges: (1) ultraviolet radiation, corresponding to wavelengths of <400 nm, is highly energetic and harmful for life. It plays a central role in the production and destruction of ozone in the stratosphere; (2) visible light, ranging from 400 nm (blue light) to 750 nm (red light), which is the energy source for photosynthesis; and (3) infrared radiation, referring to wavelengths longer than 750 nm that are associated with absorption and emission processes within the atmosphere that result in the atmospheric greenhouse effect.

Solar radiation is composed of a range of wavelengths centered around 550 nm (green light), while the Earth with its much lower emission temperature emits radiation around 11 μm (infrared). The peak in the wavelength composition of radiation is described by Wien's law in terms of the radiative temperature ($\lambda_{peak} = 0.2898 \times 10^{-3}$ m K/T_r). Since these peak wavelengths and the associated distributions are well separated, electromagnetic radiation in climatology is generally classified into two types: solar (or shortwave) radiation that is emitted by the Sun, and terrestrial (or longwave) radiation associated with emission of radiation within the Earth system.

Solar Radiation

Variations in the surface energy balance, and therefore temperature, relate mostly to variations in solar radiation. The main factors that cause variability in solar radiation are:

1. *The amount of emitted radiation by the Sun (solar luminosity L_0).* The typical value of the solar luminosity is $L_0 = 3.9 \times 10^{26}$ W, corresponding to a surface emission temperature of about 5760 K. The actual value of L_0 varies, for instance, on decadal timescales through the sunspot cycle (11 years, by <1.5 W m^{-2} at the Earth's orbit), and has increased over geologic time (4.5 billion years ago, L_0 was about 70% of the present-day value).
2. *The distance d_{Earth} of the Earth to the Sun.* The flux of solar energy remains constant through any surface around the Sun, so that the flux density decreases quadratically with distance. At the mean distance of the Earth's orbit of about $d_{Earth} = 150 \times 10^6$ km, an average amount of $R_0 = L_0/4\pi\, d_{Earth}^2 = 1367$ W m^{-2} illuminates the Earth. The value of R_0 is referred to as the solar constant. Considering that the Sun illuminates the Earth's cross section of size πr_{Earth}^2 (with the radius of the Earth denoted by r_{Earth}), but the surface area of the Earth is $4\pi r_{Earth}^2$, the mean solar radiation used above is obtained by $R_{s,toa} = R_0/4 = 340$ W m^{-2}. The mean distance of the Earth varies between 147×10^6 and 152×10^6 km throughout the year, due to Earth's slightly eccentric orbit (Fig. 2). The location of the Earth's orbit that is closest (farthest) to the Sun is called the perihelion (aphelion). The perihelion

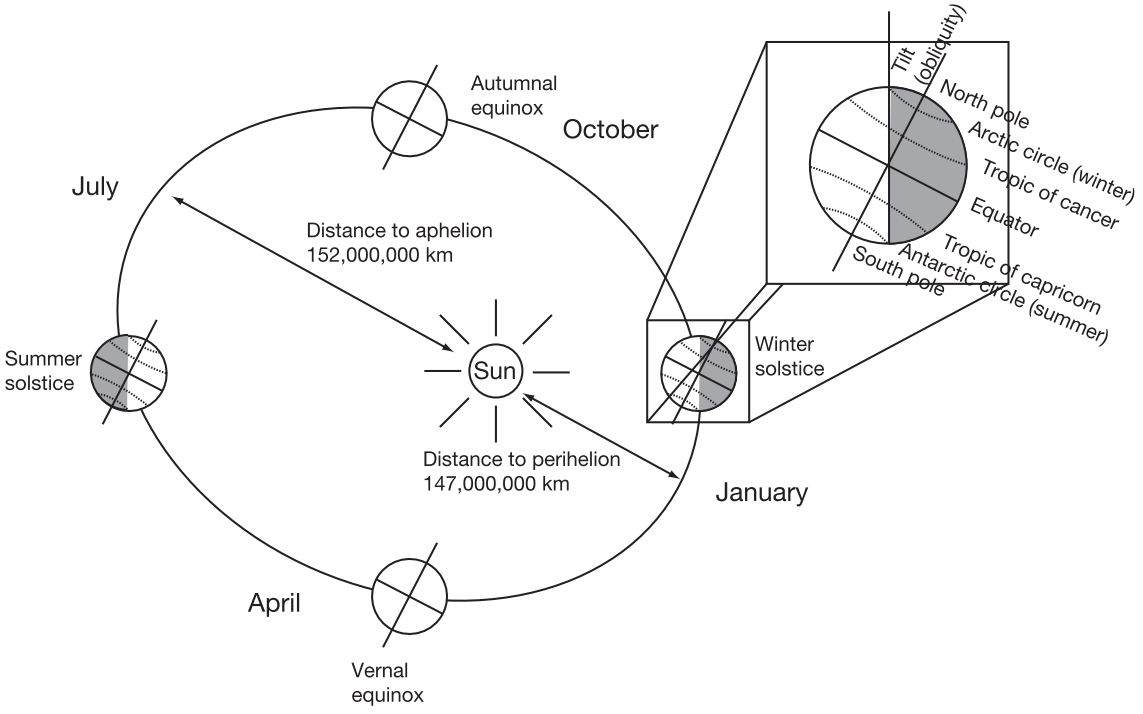

Fig. 2 The orbit of the Earth around the Sun and its relation to seasons. The orbit of the tilted Earth around the Sun results in the seasons, as indicated for the Northern Hemisphere (NH). In the NH winter, the Earth's axis of rotation is pointed away from the Sun, resulting in less incident solar radiation and the polar night at latitudes above the Arctic Circle. This situation is reversed in the summer.

currently occurs in early January. At this time, the Earth in total receives about 7% more sunlight than it does in July. These orbital parameters—perihelion, eccentricity, and tilt (or obliquity)—vary on longer timescales and relate to the timing of ice ages. The direct impacts of solar radiation and its variations are well understood, yet the indirect effects and feedbacks that amplify the Earth system response to these changes are not yet fully understood.

3. *The orientation of the surface toward the Sun*. The orientation of the surface to the incident solar radiation is characterized by two angles, the solar zenith angle and the declination angle. The incident solar radiation for a given location at the surface depends on latitude and time within the year. It is calculated from the zenith angle θ, which measures the position of the Sun to the vertical, and the declination angle δ, which characterizes the relation of the Earth's tilt to the direction of sunlight (**Fig. 3**). Integration yields a global mean solar radiation $R_{s,toa} = R_0/4$.

Reflection of Radiation

Reflection of radiation applies mostly to solar radiation and is mainly due to scattering. The size of the scattering particle plays an important role and affects the amount of radiation of a certain wavelength λ that is scattered, resulting in three types of scattering:

1. *Rayleigh scattering* applies to very small particles, such as electrons of air molecules. The intensity of scattering varies with λ^{-4}, therefore affecting primarily radiation of short wavelength. This form of scattering results in blue skies since blue light has a short wavelength and is therefore scattered much more strongly than red light.
2. *Mie scattering* involves particles of intermediate sizes, such as aerosols. The intensity of scattering varies with λ^{-1}, so that scattering is more evenly spread across wavelengths. This form of scattering results, for example, in hazy skies at a windy day at the beach due to sea spray, or over cities with air pollution due to aerosols from traffic.
3. *Geometric scattering* applies to large particles such as cloud droplets. The intensity of scattering does not vary with wavelength. This form of scattering makes clouds appear white.

The overall fraction of scattered radiation is described by the albedo (or reflectivity). Typical values of albedo of different surfaces are summarized in **Table 2**, with greater values of the albedo meaning greater reflectivity. The albedo also depends on other factors, such as the zenith angle, and wavelength. For instance, vegetated surfaces are generally much more reflective

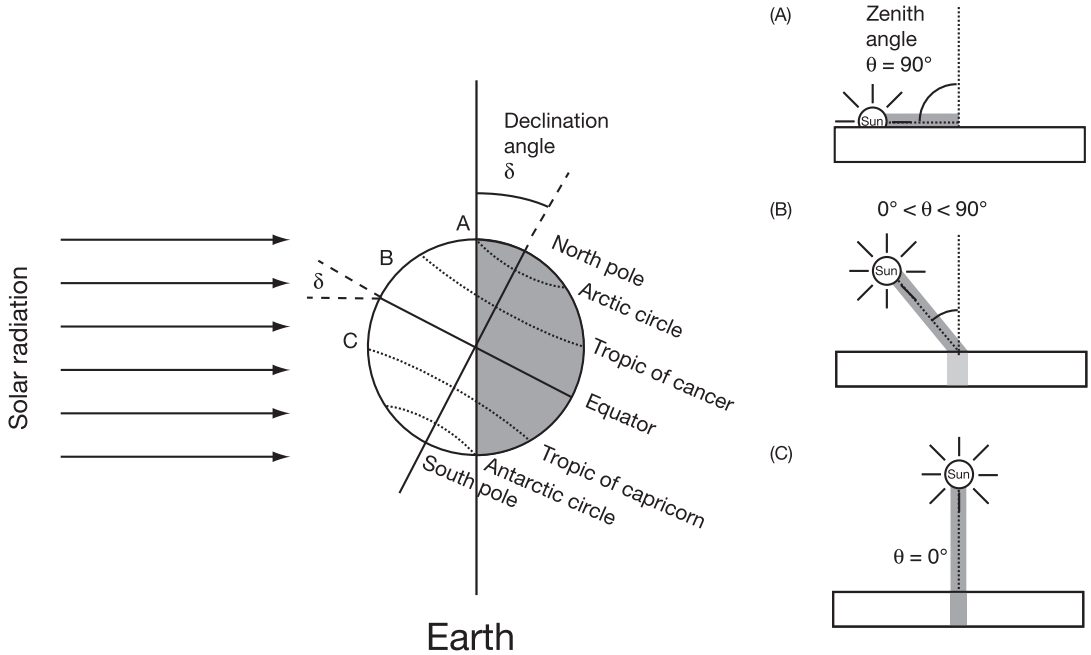

Fig. 3 Effects of the orientation of the Earth's surfaces toward the Sun on the amount of incident solar radiation at different locations labeled by A, B, and C. Left: The amount of solar radiation that reaches the surface at a given latitude depends on the declination angle δ. The declination angle measures the angle between the Earth's axis of rotation and the vertical plane of the orbit, or, alternatively, the angle between the direction of solar radiation and the Earth's equator. The declination angle defines Earth's major regions: the tropics (latitudes $-\delta$ to δ) and the polar regions ($90^\circ - \delta$ to 90°). Earth's declination angle is currently at 23.45°. Right: At a given location on Earth, the zenith angle θ measures the angle between the vertical and the Sun. It depends on hour, latitude, and time of year. In the situation shown on the left (Northern Hemisphere winter solstice), the zenith angle at location A at noon is 90°, that is, the Sun does not rise above the horizon and no solar radiation is incident at the surface. At location B, the zenith angle is in between 0° and 90°. At location C at the tropic of Capricorn, the zenith angle is 0° at noon, and the incoming solar radiation is vertical to the surface. In sloped terrain, a correction needs to be applied for the calculation of incident radiation to correct for the slope.

Table 2 Typical values and ranges for albedo for different surfaces and clouds

	Range (%)	*Typical (%)*
Atmosphere		
Cirrus clouds		21
Cumulus clouds		48
Stratus clouds		69
Ice, snow, and water		
Deep water (small zenith angle)	3–10	7
Deep water (large zenith angle)	10–100	
Sea ice	30–45	30
Snow (fresh)	70–95	80
Snow (old)	35–65	50
Snow (with forest)	11–35	25
Bare land		
Sand (wet)	20–30	25
Sand (dry)	30–45	35
Clay (wet)	10–20	15
Clay (dry)	20–40	30
Humus (moist)	5–15	10
Desert	20–45	30
Concrete	15–35	20
Asphalt	5–10	7
Vegetation		
Tundra	18–25	15
Grassland	16–26	19
Coniferous forest	5–15	12
Deciduous forest	10–20	17
Evergreen forest	12–25	13
Cropland		18

(30%–50%) in the near infrared (at wavelengths of 0.8–1.0 μm) but absorbent in the red part of the spectrum at about 0.6 μm, with a low reflectivity of around 5%. This difference in absorptive characteristics is used for the remote sensing of vegetation greenness.

Absorption of Radiation

Radiation is absorbed by different processes and at different intensities, depending on material characteristics and the wavelength of the radiation:

1. *Photoionization* refers to a process in which highly energetic radiation with wavelengths of <100 nm is absorbed by removing electrons from atoms, resulting in ionized atoms. This process can be found in the higher atmosphere at heights of 100 km and above in the so-called ionosphere.
2. *Photodissociation* is a process which also absorbs highly energetic radiation by breaking up molecular bonds. This process occurs in the atmosphere mainly for wavelengths shorter than visible light. An example is the absorption of ultraviolet radiation by molecular oxygen and ozone in the stratosphere.
3. *Electronic absorption* is associated with the absorption of visible light. Radiation is absorbed by raising electrons into excited states. While this form of absorption has little relevance in atmospheric absorption, it is essential for photosynthesis, where electronic absorption is used to separate hydrogen ions from the water molecule.
4. *Absorption by rotational and vibrational modes of molecules* takes place with radiation of low energy and long wavelengths (near infrared and longer) and causes molecules to rotate or vibrate. This form of absorption requires molecules with an uneven distribution of electrons, so that these molecules have a dipole moment. In the atmosphere, water vapor (H_2O) absorbs very well by its rotational and vibrational modes due to the architecture of the molecule, where the oxygen atom attracts the electrons more than the two hydrogen atoms. Other relevant gases that absorb by this mechanism are carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O).

Because the Earth's surface emits radiation mainly in the infrared, gases that absorb in these wavelengths are called greenhouse gases. Water vapor and clouds are by far the most important contributors to the strength of the present-day greenhouse effect. The special role of carbon dioxide as a greenhouse gas originates from two facts: (1) water vapor absorbs poorly at the peak of the Earth's surface emission at about 11 μm at which the CO_2 molecule has a dominant absorption peak nearby at 15 μm and therefore absorbs very well; and (2) the concentration of water vapor in the atmosphere is constrained by its saturation level, which in turn depends on the ambient air temperature. Hence, the concentration of water vapor reacts to other prevailing

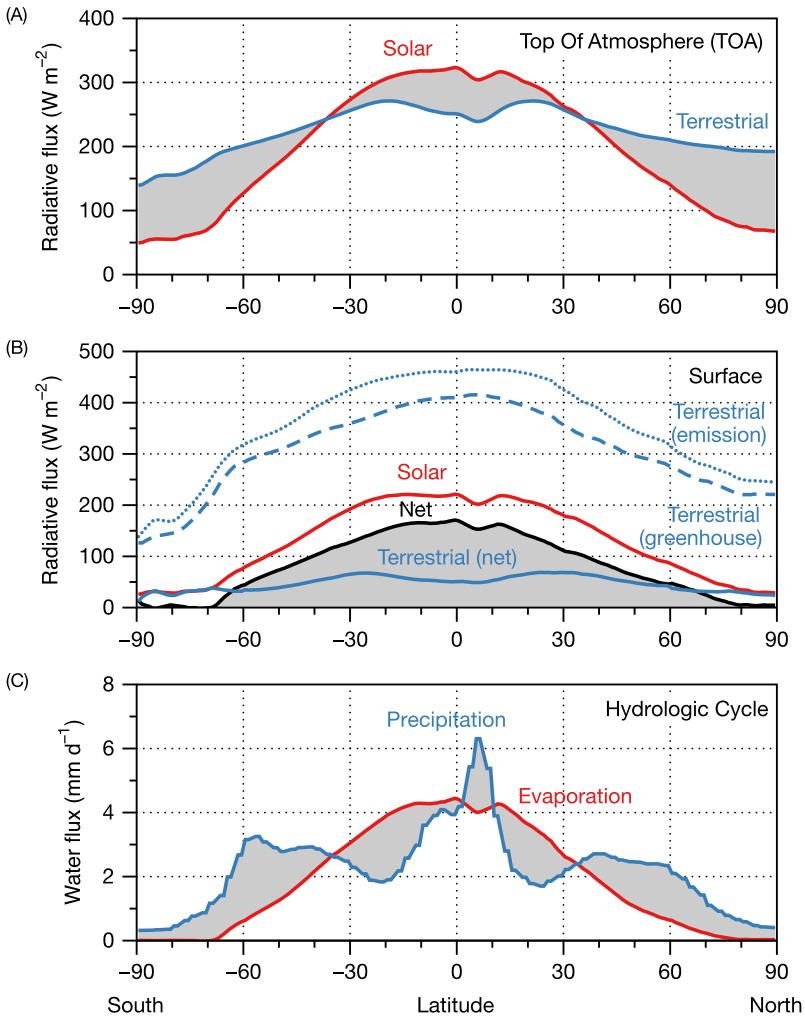

Fig. 4 Annual mean components of the energy and water balance along latitudinal zones at the top of the atmosphere and the surface for the time period 2001 to 2015. (A) The graph shows the fluxes of net solar radiation (incoming minus reflected, red line, "Solar") and terrestrial radiation (outgoing long-wave radiation, blue line, "Terrestrial") at the top of the atmosphere. The positive values of net radiation in the Tropics (i.e., more solar radiation is absorbed than terrestrial radiation emitted to space) indicates that heat is transported by the atmosphere and ocean systems toward the polar regions, where emission of terrestrial radiation exceeds absorption of solar radiation. This effect of heat transport is marked by the *gray shading*. (B) Radiative fluxes at the Earth's surface: absorbed solar radiation (*red line*, "Solar"), emission of terrestrial radiation (*blue dotted line*, "Terrestrial (emission)"), downward flux of terrestrial radiation (the greenhouse effect, *blue dashed line*, "Terrestrial (greenhouse)"), net flux of terrestrial radiation at the surface (*blue solid line*, "Terrestrial (net)") and net radiation (*black solid line*, "Net"). Net radiation is mostly balanced by the turbulent fluxes of sensible and latent heat and thus atmospheric motion (shaded *gray*), although ocean heat transport also contributes a minor part to this component. (C) The fluxes of precipitation (*blue line*) and evaporation (*red line*) that remove and add moisture to the atmosphere. Regions where evaporation exceeds precipitation are regions where the atmosphere gains moisture, which is transported by the atmospheric circulation to regions where precipitation exceeds evaporation. This effect of atmospheric transport is indicated by the *gray shading*. The plots were created using the CERES radiation datasets for the radiative fluxes, the GCPC precipitation data set for precipitation, and evaporation estimated from net radiation and temperature.

conditions and by itself does not act as an independent driver for change. For instance, cold air is unable to hold large amounts of water vapor, and consequently water vapor plays a less important role, for example, in cold regions of the atmosphere, and in winter seasons in polar regions.

Emission of Radiation

Emission of radiation is described by the Stefan-Boltzmann radiation law which relates the temperature to the rate of emission. Emission also depends on the emissivity of the emitting mass. While surfaces generally emit with emissivities near one, emission within the atmosphere typically takes place at lower emissivities, depending on the concentration of greenhouse gases and clouds, which vary with height, location and time.

Energy Balance and Climate

The mean variation in solar radiation shapes the climatological variations of the surface energy balance, atmospheric dynamics and the hydrologic cycle. These variations are described here in terms of the latitudinal variations of the annual means and is shown in Fig. 4.

Radiative Forcing

Solar radiation varies mostly due to the orientation of surfaces across latitudes, with slight variations in reflectivity due to cloudiness and ice cover, particularly at latitudes 70°S poleward. The flux of terrestrial radiation to space shows a less pronounced latitudinal variation. The imbalance at the top of the atmosphere between the net fluxes of solar and terrestrial radiation reflect the overall heat transport within the climate system. The surplus of heat from greater absorption of solar radiation than emission of terrestrial radiation in the tropical regions is transported toward the extratropics where it maintains a greater flux of terrestrial radiation compared to the absorption of solar radiation. This heat transport is accomplished by the large-scale circulation of the atmosphere and ocean.

Surface Fluxes

The components of the surface energy balance are also strongly shaped by the zonal variation of absorbed solar radiation. Fig. 4b shows the zonal variation of the radiative fluxes at the surface and the net radiation, the sum of all radiative fluxes at the surface. Net radiation is balanced by the heat transported by turbulent fluxes and by oceanic heat transport (which is comparatively small when averaged over a latitudinal band). Note how the downward flux of terrestrial radiation (the greenhouse effect) is considerably larger than the absorption of solar radiation, yet as emission of radiation is also a large flux, the net cooling of the surface by terrestrial radiation is comparatively small across latitudes. Much more relevant for the cooling of the surface are the turbulent fluxes of sensible and latent heat. As solar radiation is absorbed mostly at the surface and the atmosphere aloft cools by emitting terrestrial radiation to space, a difference in density is generated that drives vertical convection which transports sensible and latent heat from the surface to the atmosphere. The sensible heat flux directly relates to dry convection, that is, the upward transport of heat by motion generated by the heating of near-surface air from the surface, which gains a lower density and thus becomes buoyant. The latent heat flux links directly to evaporation, which acts as a moisture source for the atmosphere. It thus plays a central part for the hydrologic cycle (see also below). When the moisture condenses within the atmosphere, it creates another heating source that creates lower density and drives moist convective motion.

Large-Scale Motion

The zonal variation in solar radiation causes heating differences that drive the large-scale atmospheric circulation. Heating differences cause differences in temperature and density that result in large-scale pressure differences within the atmosphere that then generate planetary-scale motion. This motion redistributes heat, water, and mass at the hemispheric scale, and overall aims to deplete the differences in heating caused by the zonal variation in solar radiation. The ocean is maintained in motion due to the wind stress at the ocean surface, and by differences in density caused by temperature variations and the removal or addition of freshwater by evaporation and precipitation which affects the density of seawater by affecting its salinity. The effects of large-scale motion are then noticeable in the imbalance in radiative fluxes at the top of the atmosphere (as marked by the gray shading in Fig. 4a). Most of this imbalance results from the heat transported by the atmosphere, with a comparatively smaller contribution by the oceanic circulation.

Hydrologic Cycling

The latent heat flux within the surface energy balance directly relates to evaporation, which moistens the atmosphere. The drying of the atmosphere is accomplished by precipitation, which releases the latent heat into the atmosphere, causing a strong heating source and moist convection. The zonal variation in evaporation follows strongly the zonal variation of solar radiation, but precipitation occurs more concentrated in the tropics and mid-latitude regions (Fig. 4c). The difference between evaporation and precipitation indicates that moisture is transported by the atmospheric circulation (indicated by the *gray shading* in Fig. 4c). In the tropics, precipitation exceeds evaporation because the atmosphere imports moisture from the subtropics and condenses it in a relatively narrow band of the tropics within the innertropical convergence zone. The large-scale atmospheric circulation also transports moisture from the subtropics into the mid-latitudes, resulting in precipitation exceeding evaporation in those latitudes as well. Hence, hydrologic cycling directly follows from the latent heat term of the energy balance, yet with a strong imprint of the atmospheric circulation.

Feedbacks

Changes in climate affect the energy balance, and these effects are often modulated by a chain of processes resulting in feedbacks. Examples for important feedbacks that affect the energy balance are given in Fig. 5. Feedbacks characterize the response of the energy balance to a perturbation in the external forcing. They formalize the nonlinearities and interactions among the processes

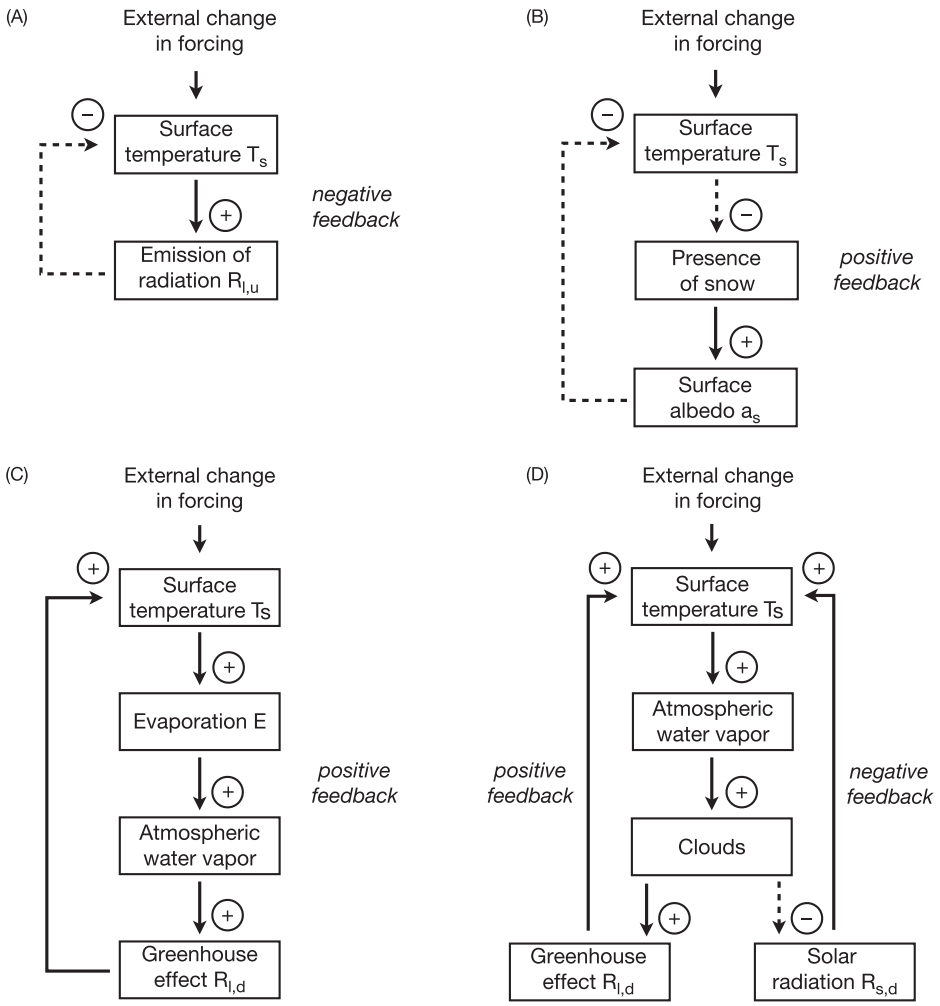

Fig. 5 Dominant feedback processes that shape the response of the global energy balance and surface temperature to external change. The diagrams show the variables involved in four important feedback loops. The (+/−) signs at the arrows indicate positive/negative influences. (A) The thermal radiation feedback. An external change in forcing that would increase surface temperature would also increase the emission of terrestrial radiation (a "+" influence). An increased emission would result in a lower surface temperature (a "−" influence). The enhanced emission of terrestrial radiation therefore counteracts the initial change, resulting in a negative feedback loop. The same line of reasoning also applies for an external change that would reduce surface temperature. (B) The snow (or ice) albedo feedback. An external change that warms the surface reduces the presence of snow, lowers the surface albedo, thereby amplifying the warming (a positive feedback). (C) The water vapor feedback. An external change that warms the surface heats the lower atmosphere. Since warmer air can hold more moisture, this enhances surface evaporation and the amount of water vapor in the atmosphere. More water vapor results in a stronger atmospheric greenhouse effect, thereby amplifying the initial change (a positive feedback). (D) Two types of cloud feedbacks. Continuing from the water vapor feedback, more water vapor in the atmosphere can result in more clouds. Depending on the balance of increased cloud cover on increased greenhouse forcing (left loop) or shortwave reflection (right loop), cloud feedbacks can form both positive and negative feedback loops on surface temperature.

within the climate system. Feedbacks are classified into positive and negative feedbacks. Positive feedbacks enhance the response of a chosen variable (mostly temperature) to the external forcing, while negative feedbacks stabilize the system, making it less responsive. In other words, a positive feedback makes a positive (negative) external change more positive (negative).

Thermodynamics and the Energy Balance

The general direction into which processes take place within the energy balance is described by thermodynamics, particularly the second law. This law states that the entropy, a measure for how well energy is dispersed at the microscopic scale of photons (carriers of radiative energy), electrons and molecules, can only increase in an isolated system. This implies that energy tends to become increasingly dispersed, a direction that is irreversible, meaning that it cannot be undone. An example for this dispersal is that heat fluxes are directed from hot to cold, thereby aiming to deplete temperature differences. The associated increase in entropy

is a general characteristic of any process and thus sets a basis to compare processes of different kinds in terms of how they follow the second law.

This direction applies to the processes involved in the energy balance and the Earth system in general. In addition, entropy sets an important constraint on how much physical work can be done, which, for example, is needed to accelerate the atmosphere and sustain the large-scale circulation against friction or to maintain hydrologic cycling.

Entropy Budget of the Earth System

By exchanging radiation with space, the Earth system is not an isolated system. The second law of thermodynamics then needs to be evaluated in the context of the entropy budget. The entropy budget relates the change of entropy within the system, dS/dt, to the entropy production of processes, $\sigma_{process}$, within the system, and to the net entropy exchange across the system boundary ($J_{s,in} - J_{s,out}$):

$$dS/dt = \sigma_{process} + J_{s,in} - J_{s,\,out}$$

The entropy S relates to the extent of thermodynamic disequilibrium within the system, with thermodynamic equilibrium achieved when S reaches its maximum value. A steady state of the entropy budget is defined by $dS/dt = 0$, and this state can be maintained in thermodynamic disequilibrium as long as the entropy production within the system is balanced by the net entropy exchange. Note that this is a different, less common definition of the climatological steady state as it relates to the disequilibrium within the Earth system.

The entropy budget of the Earth can be estimated from this steady-state condition by the difference of entropy fluxes across the Earth–space boundary. The entropy flux associated with a heat flux is described by the heat flux divided by its temperature. Planetary entropy production results from various irreversible processes and is maintained by entropy exchange associated with the radiative fluxes of solar and terrestrial radiation. Solar radiation has a very low entropy due to the high temperature at which emission takes place at the Sun's surface. In contrast, terrestrial radiation has much higher entropy due to the comparatively low emission temperature of the Earth. Among the processes that produce entropy within the Earth system, radiative processes are by far the dominant contributors. They produce entropy by scattering the direct, focused beam of solar radiation to diffuse radiation and by the absorption and re-emission of radiation at different temperatures. Entropy production by planetary motion results from the heat redistribution and mixing that depletes temperature gradients that are generated by solar radiation. Dry convection is driven by the sensible heat flux which depletes the temperature difference between the surface and the atmosphere, thereby producing entropy. Large-scale motion of the atmosphere produces entropy by transporting heat from the warm tropics toward the cold poles. Hydrologic cycling includes several processes that produce entropy, including the evaporation of water vapor into unsaturated air, the generation of motion and subsequent frictional dissipation by latent heating in moist convection, and the dissipation of kinetic energy of falling raindrops. Biotic activity uses a fraction of low entropy solar radiation, converts it into chemical energy in form of organic carbon compounds, and produces entropy by the respiration of these compounds into heat. There are various other processes that produce entropy, such as seasonal freeze–thaw associated with sea ice and snow cover, seasonal storage and release of heat, wetting and drying of soils, geochemical reactions and metabolisms.

Thermodynamic Limits

The entropy balance sets an important constraint on how dissipative the Earth system can be, and, more specifically, how much physical work can be generated. This work is needed to maintain motion, hydrologic cycling and other processes in states of thermodynamic disequilibrium.

The limit to work is set by the Carnot limit, which describes how much work can maximally be generated (at a rate G) out of a heat flux J between two heat reservoirs at temperatures T_w and T_c with $T_w > T_c$:

$$G = J\,(T_w - T_c)/T_w$$

where the temperature ratio term is referred to as the Carnot efficiency. This limit is a direct consequence of the first and second law of thermodynamics.

This limit constrains the large-scale atmospheric circulation. The work needed to drive the atmospheric circulation is derived from the heat flux from the tropics to the poles. Yet, the more heat is transported toward the poles, the lower the temperature difference between the tropics and the poles. This effect is shown in the three plots in **Fig. 6**, which illustrate three cases of heat transport and their effect on top-of-atmosphere radiative fluxes. By reducing temperature differences, heat transport thus reduces the Carnot efficiency, and thereby sets a maximum power limit at an intermediate value of heat transport and temperature differences. This limit yields about 2 W m^{-2} of power to accelerate the large-scale circulation, which is much less than the total influx of solar radiation of 340 W m^{-2}. Comparison to observations and modeling studies suggest that the atmosphere operates near this limit.

The work done balances frictional dissipation in steady state, which produces entropy. The maximum power limit therefore closely relates to the hypothesis of Maximum Entropy Production (MEP), which states that complex systems with sufficient degrees of freedom maintain states at which entropy production is at a maximum. However, this hypothesis is not widely accepted within climatology.

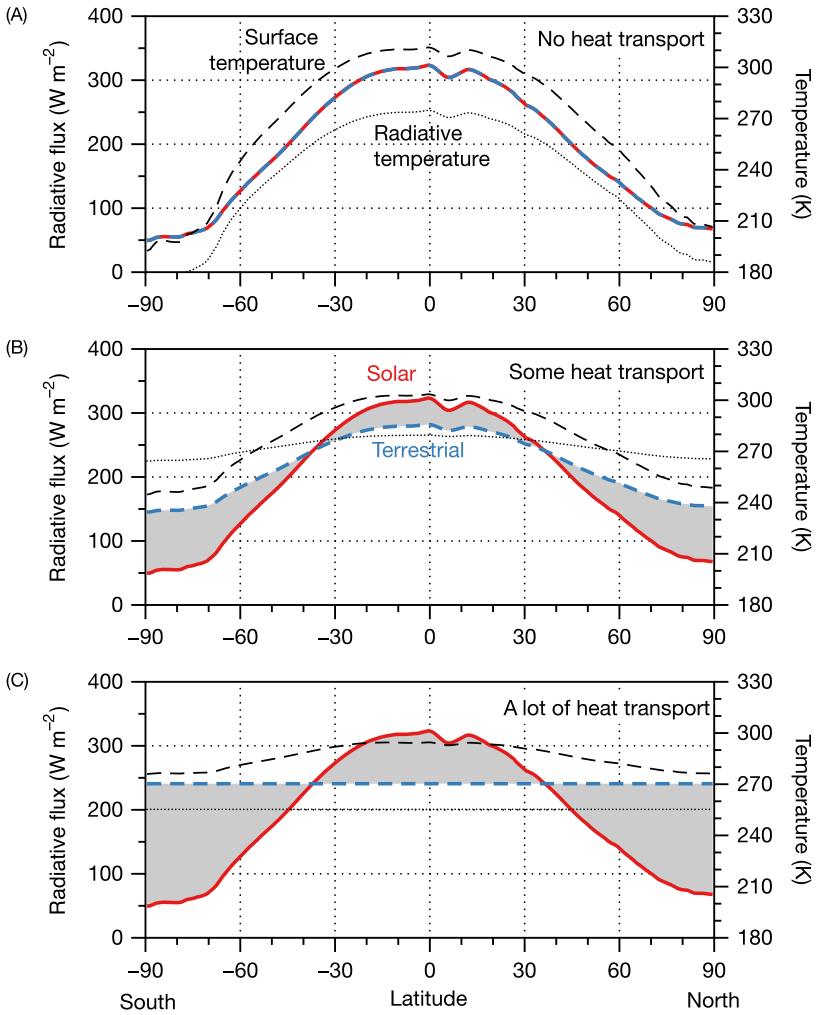

Fig. 6 The effect of poleward heat transport on radiative fluxes at the top of the atmosphere (net solar flux $R_{s,toa}$, *red lines*; net terrestrial flux, $R_{l,toa}$, *blue dashed lines*) and temperatures (*black lines*). The three panels show the cases of differing heat transport (A: no heat transport, B: some heat transport, and C: a lot of heat transport) which result in a different latitudinal distribution of terrestrial radiation to space and affect temperatures. Estimates for surface temperature, T_s, (*black dashed line*) and radiative temperature, T_r (*black dotted line*) are also shown. The reduction of the temperature difference by heat transport sets a thermodynamic limit on how much work the global atmosphere can maximally perform to maintain motion. Of the three cases shown here, the intermediate case (B) has greatest power and is closest to observations (cf. Fig. 4).

Energy Balance and Ecosystems

Ecosystems affect the energy balance directly by utilizing solar radiation by photosynthesis, and indirectly by altering the surface energy balance components, for instance by changing the surface albedo and evapotranspiration rates, and by affecting biogeochemical fluxes and atmospheric composition, which alters radiative transfer, for example, by scattering by aerosols or by changing the magnitude of the greenhouse effect.

Direct Biotic Effects

Photosynthesis utilizes $<3\%$ of the absorbed solar radiation. Since most of the carbohydrates are respired within relatively short time at the same location, most of the energy is released as heat by respiration. Hence, the energy fluxes associated with photosynthesis and respiration are generally neglected in considerations of the surface energy balance.

Indirect Biotic Effects and Feedbacks

Ecosystems interact with their physical and geochemical environment. The effect of ecosystems on the energy balance are categorized into two types of effects:

1. *Biogeophysical effects* modify components of the surface energy balance and the physical functioning of the climate system. These effects are strongest for terrestrial vegetation, which affects the energy balance over land in various ways: (a) the surface albedo of vegetated surfaces is generally darker than bare surfaces (**Table 2**), thereby enhancing absorption of solar radiation; (b) vegetation root systems enhance the ability to recycle soil moisture through transpiration, thereby affecting the latent heat flux; and (c) vegetated surfaces modulate the partitioning of sensible and latent heat through stomatal functioning. These effects have considerable effects on the surface energy and water balance on land and the overlying atmosphere, particularly on evaporation, (**Fig. 7**) and can result in two biogeophysical feedback processes that enhance productivity (**Fig. 8**).
2. *Biogeochemical effects* modify geochemical cycling of elements and the atmospheric composition (**Table 1**). Some of these have important consequences for the global energy balance and atmospheric dynamics, such as (a) carbon cycling affects the

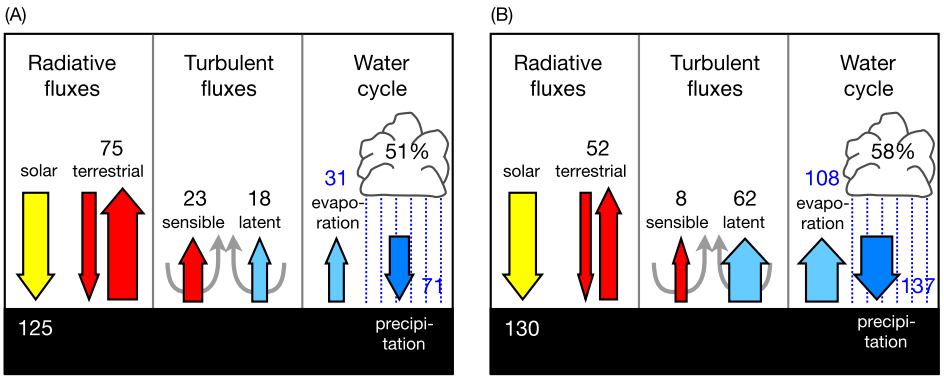

Fig. 7 Estimates of vegetation effects on the energy- and water balances on land in the climatological mean. The diagrams show results from climate model simulations of (A) a "desert world" void of terrestrial vegetation and (B) a "green planet" where all land regions acts like a rainforest. Radiative and turbulent fluxes are given in W m^{-2} and water fluxes in 1000 km^3 per year. These climatological differences result mostly from the effect of vegetation on surface albedo and the depth of the rooting zone.

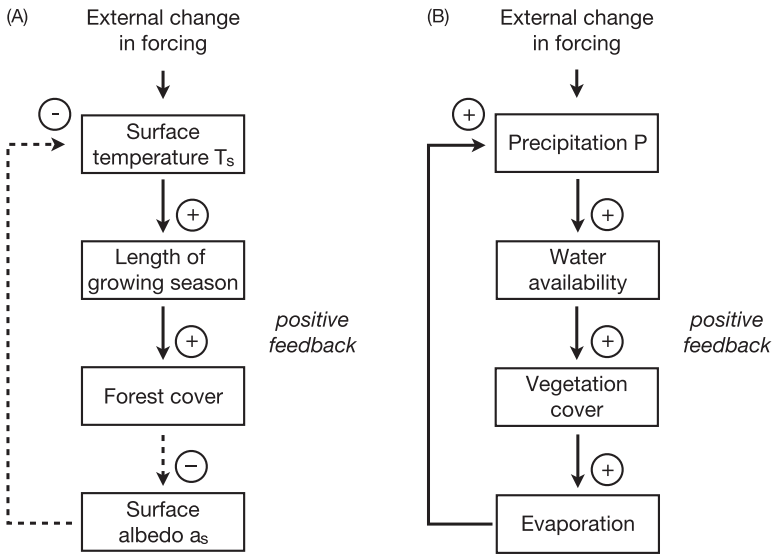

Fig. 8 Vegetation feedbacks on the surface energy balance. The diagrams show the two major feedback loops by which vegetation affects the surface energy balance. (A) The snow masking feedback. An external change in forcing that would increase surface temperature in regions where temperature limits terrestrial productivity (such as the Arctic) increases the length of the growing season. A longer growing season would result in higher productivity, which extends the boreal forest cover in temperature-limited regions. Enhanced boreal forest cover masks the presence of snow at the surface, thereby lowering the surface albedo. This results in enhanced absorption of solar radiation and a warmer temperature, which amplifies the initial change, resulting in a positive feedback loop. (B) The water cycling feedback. An external change that results in enhanced precipitation in regions where water limits productivity (such as the semiarid regions) increases the productivity. This can sustain a greater vegetation cover and thereby evaporation, which can enhance precipitation further. The initial change is hence amplified, resulting in a positive feedback.

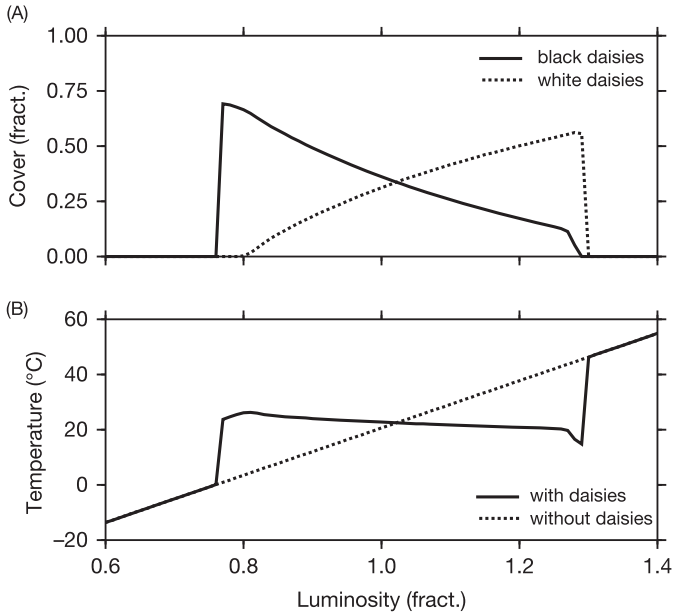

Fig. 9 Emergence of temperature regulation in the conceptual "Daisyworld" model. The "Daisyworld" model represents a virtual world in which the planetary albedo is regulated by the population dynamics of *black* and *white* daisies. (A) The fractional cover of *black* and *white* daisies for different values of solar luminosity, expressed as the fraction of its present-day value. (B) The different proportions of daisies result in an overall planetary albedo that results in constant temperature conditions over a wide range of solar luminosity values.

strength of the greenhouse effect caused by carbon dioxide, (b) oxygen concentrations affect the ozone layer and stratospheric absorption of solar radiation, and (c) the production of some compounds, such as dimethyl sulfide by marine algae or volatile organic compounds (VOC) by terrestrial vegetation, act as cloud condensation nuclei, thereby modifying cloud cover.

Gaia Hypothesis

In the extreme form, strong negative biotic feedbacks on temperature can regulate the global energy balance into a state of homeostasis (i.e., no temperature sensitivity to changes in external forcing). This has been suggested by the Gaia hypothesis of James Lovelock, stating that the atmosphere is regulated for and by the biosphere. This notion was originally motivated by the observation that the Earth's atmospheric composition is far from thermodynamic equilibrium, and that this state of dis-equilibrium is maintained by the biota.

The conceptual "Daisyworld" model was developed to demonstrate the possibility of global homeostasis. This model describes a world where the planetary albedo is determined by the fractions of *black* and *white* daisies, and of bare ground. Using equations of population dynamics and a temperature-dependent growth, "Daisyworld" demonstrates that homeostasis is a possible outcome of population dynamics interacting with the global energy balance (**Fig. 9**).

However, the notions of Gaia and Daisyworld remain controversial. Surface temperatures in Earth's history have been far from constant, and the representation of biospheric dynamics in Daisyworld is highly simplistic. Yet the challenge to find and apply general organizing principles, such as the maximum power limit of the previous section, that can explain the interactions of the biosphere with the global energy balance remains an active research topic.

Energy Flows in the Biosphere

YM Svirezhev, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Introduction

Life on Earth is a product of so-called 'photon's mill', which has started to function when our solar system was in the form of matter's 'clots' embedded into the ocean of 'cold' photons with temperature $T=2.7$ K. Evolution and self-organization of planets (including life on our planet) is a result of this mill's functioning, which is happening due to the fact that Sun's surface irradiates the 'hot photons' at $T=5800$ K, and these photons reach the cold planet's surfaces. Then they cool down to the temperature of the surface and irradiate back into the space. For the Earth, this temperature is equal to 253 K; it is the temperature, which could be measured by an observer at the top of atmosphere. Formally, the photon's mill is a typical 'heat machine' that is functioning by Carnot cycle, but its working body is the photon gas.

Incoming and Outgoing Radiations and the Planetary Energy Balance

A parallel flow of solar radiation at the Earth's mean distance from the Sun is equal to 1368 W m^{-2}; this is an irradiation of blackbody with $T=5800$ K (see Fig. 1). Since the Sun's flow is parallel its effective section is πr_{Erth}^2, where r_{Erth} is the Earth's radius. An area of the Earth's surface is $4\pi r_{\text{Erth}}^2$, that is, four times larger than the section's area; therefore, only one-fourth of the total flow, 342 W m^{-2}, is coming to the area unit of the upper boundary of the 'Earth + atmosphere system' (EAS). It is obvious that specific flow is varying from point to point on the globe and in time within 1-year interval, so that these and other local values connected with energy flows are averaged over the globe and the year.

Incoming radiation is described by the energy spectrum $E^{\text{in}}(\lambda, x, y, t)$, where λ is a wavelength, x and y are geographic coordinates, and t is a time. By interacting with a surface, it is transformed onto the energy spectrum of outgoing radiation, $E^{\text{out}}(\lambda, x, y, t)$:

$$E^{\text{in}}(\lambda, x, y, t) \overset{F(\lambda,x,y,t)}{\Rightarrow} E^{\text{out}}(\lambda, x, y, t) \qquad [1]$$

where $F(\lambda,x,y,t)$ is the transition operator. The spectrum of outgoing radiation is close to the blackbody spectrum with $T=253$ K.

Really, we have information only about these two spectra measured sufficiently frequently, sufficiently densely, in sufficiently big number of spectral bands (today up to 120), in the course of sufficiently long time. Outside of the EAS, satellites are carrying out these measurements today. At the level of the Earth's surface (the ground), it is performed also by satellites, and when they are corrected by data of the ground measurements. Note that outgoing radiation contains a lot of information about a surface, interacting with incoming radiation. Spectra of incoming and outgoing radiations are shown in Fig. 1.

The simplest form of $F(\lambda, x, y, t)$ is a shift operator $R(\lambda, x, y, t) = E^{\text{in}}(\lambda, x, y, t) - E^{\text{out}}(\lambda, x, y, t)$; a convolution $\overline{R}(x, y, t) = \int_\Omega R(\lambda, x, y, t)\mathrm{d}\lambda$ over all wavelengths is named a local 'radiative (radiation) balance'. Convolutions $\overline{E}^{\text{in}}(x, y, t) = \int_\Omega E^{\text{in}}(\lambda, x, y, t)\mathrm{d}\lambda$ and $\overline{E}^{\text{out}}(x, y, t) = \int_\Omega E^{\text{out}}(\lambda, x, y, t)\mathrm{d}\lambda$ are the total energy of incoming and outgoing radiation at the given point and in the given moment. If we average $\overline{R}(x, y, t)$ over the EAS surface, S_{EAS}, and 1-year interval, t_1, we get the 'annual planetary radiative balance'

$$\hat{R} = \frac{1}{S_{\text{EAS}} \cdot t_1} \int_G \int_T R(x, y, t)\mathrm{d}x\, \mathrm{d}y\, \mathrm{d}t \qquad [2]$$

is equal to zero. This is a typical 'empirical generalization'.

The wavelengths λ is usually measured in the band Ω: (0.2, 50 μm), which contains almost 100% of the total energy of incoming and outgoing radiations. Its most part (~99%) is a shortwave radiation (SWR) with wavelengths λ lying within the spectral band S: (0.2, 5.0 μm), where 53.5% constitutes a radiation with $\lambda \in (0.4, 0.7\ \mu\text{m})$, so-called photosynthetically active radiation (PAR). This spectral band is called 'visible'. The radiation with $\lambda \in L(5, 50\ \mu\text{m})$, the long-wave radiation, LWR, constitutes only 0.45% of the total radiation. About 0.5% constitutes an ultraviolet radiation, $\lambda < 0.2$ μm, that is, fortunately, almost completely detained by ozone layer. Note that other divisions of the total spectral band are often used, for instance, S: (0.3, 3.0 μm), etc.

Later on we shall operate with values of energy integrated over these two spectral bands and averaged on the total EAS' surface and 1-year interval: $\hat{E}_S^{\text{in}}, \hat{E}_L^{\text{in}}$ and $\hat{E}_S^{\text{out}}, \hat{E}_L^{\text{out}}$. In accordance with observed data we have with sufficient accuracy that for the EAS: $\left(\hat{E}_S^{\text{in}}\right)_{\text{EAS}} = 340$ W m^{-2}, $\left(\hat{E}_L^{\text{in}}\right)_{\text{EAS}} = 0$, and $\left(\hat{E}_S^{\text{out}}\right)_{\text{EAS}} = 102$ W m^{-2}, $\left(\hat{E}_L^{\text{out}}\right)_{\text{EAS}} = 238$ W m^{-2}, so that $\left(\hat{E}^{\text{in}}\right)_{\text{EAS}} = \left(\hat{E}^{\text{out}}\right)_{\text{EAS}}$. Earth on the whole gets 238 W m$^{-2} \times 5 \times 10^{14}$ m$^2 = 1.2 \times 10^{17}$ W of the SWR, and irradiates as much LWR again.

 doi:10.1016/B978-0-444-63768-0.00604-1

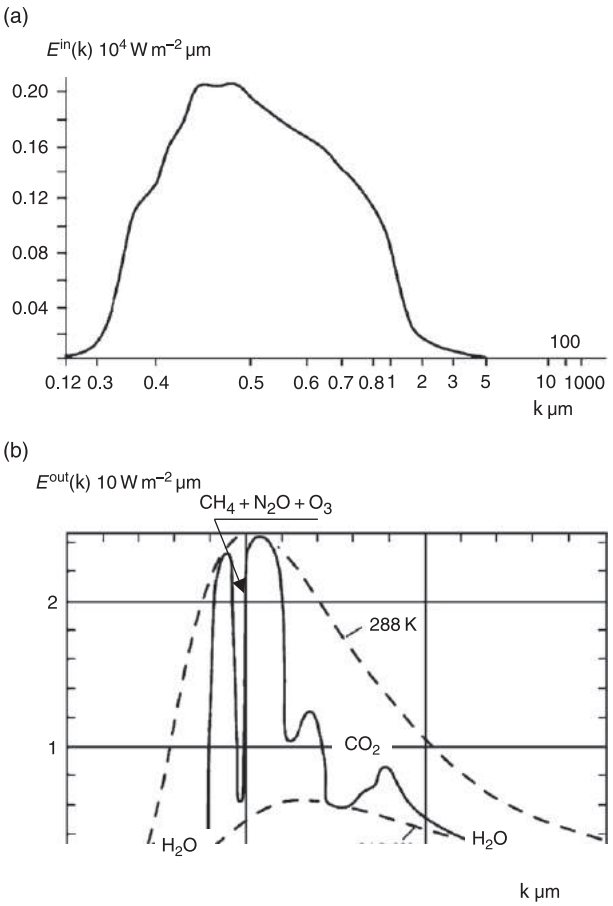

Fig. 1 Spectra of incoming and outgoing solar radiation. (a) Standard spectrum of solar radiation at the top of the atmosphere. (b) Typical spectrum of the Earth's thermal radiation.

The relation between these values can also be presented as

$$\hat{R}_{EAS} = \left(\hat{E}_S^{in}\right)_{EAS}(1 - \alpha_{EAS}) - \left(\hat{E}_L^{out}\right)_{EAS} \quad [3]$$

where $\alpha_{EAS} = \left(\hat{E}_S^{out}\right)_{EAS} \Big/ \left(\hat{E}_S^{in}\right)_{EAS} = 0.3$ is so-called planetary 'albedo' (from Latin 'whiteness'), that is, a coefficient of reflectance of the EAS with respect to incoming radiation.

Transformation of Solar Energy Inside the EAS

What is the fate of 340 W m^{-2} of SWR coming into the top of the atmosphere? Clouds reflect about 68 W m^{-2} of the total incoming radiation. Molecules of atmospheric gases and aerosols still scatter 16 W m^{-2} by forming so-called diffuse radiation, half of which finally goes out to the space, and other half reaches the ground. The 26 W m^{-2} of SWR is reflected by the ground. So, the $68 + 8 + 26 = 102$ J m^{-2} of energy in the form of SWR leaves our planet every second. The rest, 238 W m^{-2}, is consumed and used by the EAS to maintain the work of the Earth's climate machine: evaporation and 'precipitation', 'oceanic currents', atmospheric circulation, etc.

About 78 W m^{-2} is absorbed by the atmosphere and then used in different phase transitions: clouds formation, precipitation, formation of dew, etc. Another part, 160 W m^{-2}, is absorbed by the ground. The measurements show that the spectrum of radiation coming into the Earth's surface is a mixture of SWR, $\left(\hat{E}_S^{in}\right)_G = 186$ W m^{-2}, and LWR (a counter-radiation from the warmed atmosphere), $\left(\hat{E}_L^{in}\right)_G = 102$ W m^{-2}. The ground irradiates into the atmosphere $\left(\hat{E}_S^{out}\right)_G = 26$ W m^{-2} of SWR that corresponds to the mean albedo $\alpha_G = \left(\hat{E}_S^{out}\right)_G \Big/ \left(\hat{E}_S^{in}\right)_G \approx 0.14$ and $\left(\hat{E}_L^{out}\right)_G = 160$ W m^{-2} of LWR. The radiation absorbed by the ground, 160 W m^{-2}, is transformed to heat. The depth of heat penetration depends on the properties of underlying surface. For the land, the depth depends on the properties of soil (for instance, soil moisture) and equals a few meters. As to the ocean, oceanic waves intermix effectively the surface layer, so that the depth is about 100–200 m. If we take into account that the mean depth of

the ocean is 3800 m, then the depth of heat penetration is negligibly small in comparison with the mean depth. Therefore, the warmed body is a very thin film, which is not able to warm the 'lithosphere' (their masses are not commensurable), but it is warming up the atmosphere. Seasonal and diurnal oscillations of the temperature at the levels lying below the film stopped. The film is considered as a low boundary (basement) for the EAS, and it is namely identified with the Earth's surface. A heat flow across the low boundary is negligibly small. For instance, the thermal flow from the Earth's upper mantle is maximally 0.2 W m^{-2}. So, one can say that the EAS consists of the atmosphere and the upper layers of the 'hydrosphere and lithosphere'.

Greenhouse Effect

If Earth would not have the atmosphere, then all absorbed 160 W m^{-2} has to be irradiated into space in the form of LWR, since the temperature of the Earth's surface does not change. However, different atmospheric gases, transparent for SWR, may be weakly transparent for the LWR. For instance, the water vapor strongly absorbs LWR (in the cloudless atmosphere) in the spectral band (5–7.5 μm) and the carbon dioxide in the band (13–17 μm); absorption in the band (9–12 μm) is relatively small (see Fig. 1). As a result, a part of the ground infrared radiation is detained, the atmosphere is warmed, and becomes in turn a source of LWR. Appearing here as a 'counter-radiation', $E_{\text{count}} = \left(\hat{E}_L^{\text{in}}\right)_G = 102$ W m^{-2}, it compensates a significant part of the ground LWR. A difference between the ground LWR and the counter-radiation is called an 'effective radiation' of the Earth's surface, $E_{\text{eff}} = \left(\hat{E}_L^{\text{out}}\right)_G - \left(\hat{E}_L^{\text{in}}\right)_G = 58$ W m^{-2}. Its spectrum is close to the blackbody one with $T = 288$ K, and namely this amount of LWR is irradiated by the Earth's surface into the space, the rest 180 W m^{-2} is irradiated by the atmosphere. This is an essence of the 'greenhouse effect'.

Albedo

Theoretically, the albedo's value may change from 0 of a blackbody until 1 of a 'white body' completely reflecting the solar radiation. It is natural that an albedo depends on spectrum of the radiation, since different surfaces reflect differently in different spectral bands.

Albedos of typical underlying surfaces in visible light range from 0.04 for charcoal, one of the darkest substances, up to 0.90–0.95 for fresh snow. Albedo of salt and sand deserts are 0.45–0.5, while the albedo of coniferous forest is 0.1. Note that the maximal albedo of a surface, covered by vegetation (meadow), is 0.25. Albedo of wet soils is usually less than the albedo of dry ones, for instance, the albedo of chernozem (~ 0.15) is reduced to 0.05 under moistening conditions.

The classic examples of albedo's effect are the snow–, vegetation–, and moisture–temperature feedbacks. If a snow-covered area warms and the snow melts, the albedo decreases down to 0.4–0.5, more sunlight is absorbed, and the temperature tends to increase. If a desert is covered by vegetation, then the albedo decreases, and the temperature has to increase. While the increase in plant biomass tends to slow down in the carbon dioxide concentration in the atmosphere that, in turn, tends to decrease the temperature, so that the balance of these feedbacks may become very complex. Similar considerations are valid also for 'soil moisture– temperature' feedback.

Albedo of water bodies differs from albedo of land surfaces, since the reflection of SWR from water depends on the angle of incidence. At small angles, most part of radiation is reflected from the surface, not penetrating deeply into water body. As a result the albedo increases up by a few tenths, while the albedo at the great angles, that is, when the Sun elevation is high, is equal to a few hundredths. For instance, if the angle of incidence $\beta < 10^\circ$, then $\alpha > 0.22$; if $\beta > 45^\circ$, then $\alpha < 0.05$. Albedo of scattered radiation does not really depend on the angle of incidence, and it is almost constant, about 0.10.

The significant part of incoming radiation is reflected by clouds; their albedo, depending on the thickness of cloudiness, is equal on average to 0.4–0.5, so that the mean albedo of the Earth is about 0.29. This is far higher than for the ocean primarily.

The Earth's surface albedo is regularly estimated via 'Earth observation satellite sensors' such as NASA's MODIS instruments onboard the Terra and Aqua satellites.

Equations of Radiative Balance

Due to the greenhouse effect, the Earth's surface gets the 102 W m^{-2} of radiative heat additionally. An amount of 80 W m^{-2} of this heat is used in the process of evaporation and transpiration of water by plants, evapotranspiration, and 20 W m^{-2} are transported into the atmosphere by a turbulent (sensible) heat flow, E_{turb}, caused by a difference in the temperatures of the ground and the atmosphere. The first term is named a 'latent' flow; it is equal to $L \cdot Q$, where $L = 2453$ J g^{-1} is the specific enthalpy of evaporation (heat content) and Q is the flux of water, evaporated from the surface of water-bodies, soils, and plants, and also water, condensed on these surfaces. To close the balance, we add the value of $E_{\text{mech}} = 2$ W m^{-2} that is a dissipated mechanical energy (friction). The corresponding equation of radiative balance for the Earth's surface is

$$\hat{R}_G = \left(\hat{E}_S^{\text{in}}\right)_G (1 - \alpha_G) - E_{\text{eff}} \qquad [4]$$

which is positive, $\hat{R}_G = 102$ W m^{-2}.

Since the radiative balance of the EAS is equal to zero, the radiative balance of the atmosphere

$$\hat{R}_a = \hat{R}_{EAS} - \hat{R}_G = \left(\hat{E}_S^{in}\right)_{EAS}(1-\alpha_{EAS}) - \left(\hat{E}_S^{in}\right)_G(1-\alpha_G) - \left[\left(\hat{E}_L^{out}\right)_{EAS} - E_{eff}\right] \quad [5]$$

has to be negative. The negativeness is compensated by the latent and turbulent heat flows.

The main carriers of heat between the ground and the atmosphere are precipitation and water vapor. Then the radiative balance for the EAS can be represented as

$$\hat{R}_{EAS} = F_s + L(Q-P) \quad [6]$$

where the term F_s is the sum of the heat inflows and outflows across the vertical walls of the EAS column with unit basement, the term $L(Q-P)$ is a difference between the flows of latent heat $L \cdot Q$ and heat brought by precipitation, $L \cdot P$, where P is the sum of all precipitations. Since for the globe and 1-year interval $Q=P$ and $F_s=0$, then the equation of energy (heat) balance for the EAS has a simple form:

$$\hat{R}_G = 0 \quad [7]$$

The balance equations for the atmosphere and the Earth's surface are

$$\begin{aligned} \hat{R}_a &= -L \cdot P - E_{turb} - E_{mech}(\text{atmosphere}) \\ \hat{R}_G &= L \cdot Q + E_{turb} + E_{mech}(\text{Earth's surface}) \end{aligned} \quad [8]$$

A generalized scheme of energy flows and their transformation is shown in Fig. 2.

At least, we can estimate the internal energy of the atmosphere, which is equal to 8.6×10^{23} J (1.7×10^9 J m^{-2}), the storage of latent heat 3×10^{22} J (6×10^7 J m^{-2}), and the storage of mechanical energy 2.5×10^{15} (5×10^5 J m^{-2}). About 40% of the total atmospheric internal energy constitutes a potential energy (0.7×10^9 J m^{-2}), but only 4 W m^{-2} is necessary to maintain turbulent flows.

Parallel to the vertical redistribution of solar energy, there are powerful energy flows redistributing it over the Earth's surface. All of them form the complex system of atmospheric circulation and oceanic currents that provides to transport heat from the low latitudes to the high latitudes by 'softening' the Earth's climate.

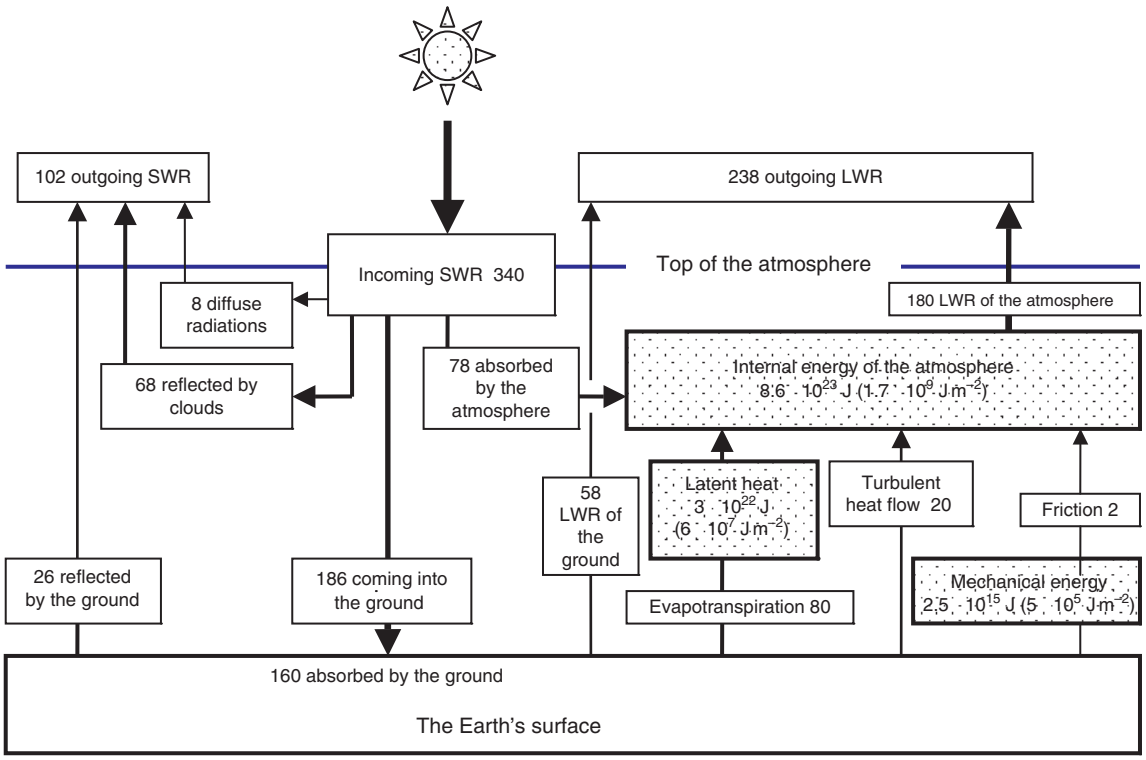

Fig. 2 Energy flows in the system 'the Earth's surface + atmosphere'.

Energetics of Photosynthesis and Vegetation

We described above the main processes of the transformation of solar energy, which are the principal components of the global energy balance, forming in essence the thermostat for the biosphere. However, there are other processes, which do not really influence the energy balance. Their heat flows are very small (mentioned above as the dissipation of mechanical energy, dew condensation, etc.). Some of them, nevertheless, play the principal role in the biosphere, for instance, photosynthesis.

Green plants (autotrophs) convert solar energy into the chemical energy of new living biomass in the process of photosynthesis. The process uses energy of visible light, which is absorbed by the chlorophyll molecules of plants to convert carbon dioxide and water into carbohydrates and oxygen. Note that the presence of oxygen in the Earth's atmosphere is a result of photosynthesis. Proteins, fats, nucleic acids, and other compounds are also synthesized during the process, as long as elements such as nitrogen, sulfur, and phosphorus are available.

Then the stored chemical energy flows into herbivores, carnivores (predators), parasites, decomposers, and all other forms of life. Photosynthesis produces the living biomass of vegetation, constituting more than 95% of the global biomass and being a main agent in the 'global biogeochemical cycle of carbon'.

Photosynthesis

The basic equation of photosynthesis is

$$CO_2 + H_2O + h\nu \rightarrow (CH_2O) + O_2 + 470\ \text{kJ mol}^{-1}$$

where $h\nu$ is a photon energy and (CH_2O) is a fragment of carbohydrate molecule, releasing 470 kJ mol^{-1} of energy (that equals an increase in enthalpy, ΔH). Since the change of free energy is equal to $\Delta G = 504$ kJ mol^{-1}, and $G\Delta = \Delta H - T\Delta S$, the change of entropy, ΔS, is equal to $(470 - 504)/273 = 116$ J K^{-1} mol^{-1} ($T = 293$ K), that is, photosynthesis is an antientropic process.

Efficiency of photosynthesis is defined in different ways. Its theoretically maximal value is the ratio of ΔG to the total energy of eight photons ($E_{ph} = 1470$ kJ mol^{-1}), which are necessary to get one molecule of O_2, $\eta_{max} = 504/1470 = 34\%$. On the other hand, since the 'useful' work, which can be performed by photosynthesis, is 'exergy', $Ex = -T\Delta S = 34$ kJ mol^{-1}, then efficiency is defined as $\eta_{ex} = Ex/E_{ph} = 34/1470 = 2.3\%$.

Efficiency of Vegetation

If the working process creating a new biomass is photosynthesis, then the working machine is plant. Therefore, it is natural to say about efficiency of plant (efficiency of vegetation) or 'green leaf' than about efficiency of photosynthesis. The rate of photosynthesis depends on the amount of light reaching the leaves, the temperature of surrounding air, and the availability of water and other nutrients such as nitrogen and phosphorus. One of these factors ('limiting factors') already limits the rate, so that the real efficiency of vegetation is lower than its theoretical value, 34%, and what is more, this efficiency should not exceed the 'exergic' efficiency, 2.3%.

From the thermodynamic point of view, a 'green leaf' is a heat machine with photosynthesis as the working process, and molecules of chlorophyll, adenosine triphosphate (ATP) etc., transferring energy of photons into leaves as the working body. Efficiency of the heat machine is $\eta_{leaf} = (T_{leaf} - T_{air})/T_{leaf}$, where T_{leaf} and T_{air} are the mean daily temperatures of leaves and surrounding air; since the reaction of photosynthesis is exogenous, the leaf is warmed, $T_{leaf} > T_{air}$. Under summer conditions in temperate forest, $T \sim 5\ ^\circ$C and $T_{air} \sim 20\ ^\circ$C on average; therefore, $\eta_{leaf} = 5/298 = 1.7\%$.

It is known that about 98–99% of solar energy, reaching the Earth's surface, is reflected from leaves and other surfaces and absorbed by other molecules, which convert it to heat. Thus, vegetation is available to catch about 1–2% of incident solar energy, that is, these numbers constitute its efficiency.

The rate at which plants convert PAR (or inorganic chemical energy) to the chemical energy of organic matter is named gross primary production (productivity) (GPP). This value (as well as biomass) is often reported in grams or metric tons of either dry weight or carbon (the latter is about one-half of the first). Since enthalpy of 1 of carbon is equal to ~ 42 kJ g^{-1}, then production and biomass can be also reported in joules.

Fifteen to sixty percent of the energy assimilated by plants immediately is spent in cellular respiration, when carbohydrates, proteins, and fats are broken down, or oxidized, to provide energy (in the form of ATP) for the cell's metabolic needs. The residual (40–85%) is stored in biomass as net primary production (NPP). The highest annual NPP, 2000 gC m^{-2} yr^{-1}, occurs in swamps, marshes, and tropical rainforests; the lowest, 20 gC m^{-2} yr^{-1}, occurs in deserts. The mean NPP for terrestrial ecosystem is about 400 gC m^{-2} yr^{-1}. Among aquatic ecosystems, the highest NPP, 2000 gC m^{-2} yr^{-1}, occurs in estuaries; the mean NPP in the ocean is 75 gC m^{-2} yr^{-1}, so that the ocean is a desert (see **Table 1**).

Efficiency of solar energy utilization by vegetation can be defined as the ratio of enthalpy, contained in the NPP, to the solar radiation, reaching to the Earth's surface and integrated over the vegetation period. The corresponding values for continents and for land overall are shown in **Table 1**.

Table 1 The NPP and the efficiency of utilization

Continents	*NPP* ($gC\ m^{-2}\ yr^{-1}$)	*Efficiency (%)*
Europe	365	0.54
Asia	421	0.38
North America	353	0.40
South America	899	0.49
Africa	443	0.25
Australia with Oceania	370	0.19
Land on average	408	0.37

One square meter of the terrestrial vegetation on average utilizes in the course of 1 year about 17 million joules of solar energy, but this gigantic number constitutes only 0.37% of the total solar energy that comes into the Earth's surface.

The total annual production of terrestrial vegetation is about 60 gigatons (Gt, 1 Gt $= 10^9$ t) of carbon, while for the ocean this value is estimated as 25 Gt with NPP $= 75$ gC m^{-2} yr^{-1}. Thus, the mean global NPP is 186 gC m^{-2} yr^{-1}, and the mean efficiency of global vegetation is about 0.1%. However, it is necessary to take into account that much energy is consumed in the process of forming and maintaining of the thermostat for vegetation. It is very similar to the situation with greenhouse, where the most part of energy is used for its heating.

Energy Transfers, Trophic Chains, and Trophic Networks

If we look at a global pattern of pathways on which the solar energy stored in biomass is flowing within the gigantic (and unique) ecosystem (often associated with the biosphere), we see the network entangling the Globe. It is named a 'trophic network or a food web', and as a rule subdivided on local networks. The trophic network is described by an oriented graph with vertices corresponding to species that constitute the ecosystem, and links indicating trophic interaction between them (their directions show the energy flowing, for instance, prey → predator). In the network structure the 'trophic levels' are naturally distinguished, that is, groups of species having no direct trophic interactions; however, species of one level usually either compete for life resource or cooperate in its utilization. It is natural that some part of energy is spent (and later on dissipated as heat) in such kind of interactions – this is a payment by means of energy for stability of the network structure. Another significant part of consumed energy (from 30% to 70%) is spent for maintaining life in the process of 'metabolism' (respiration).

In any trophic network a structure, in which every two adjacent species form a prey–predator pair and which is described by a linear graph, can be distinguished. It is called a 'trophic (food) chain'; their interlacing and branching form a trophic network. Since the energy dissipation along the chains is very high they are usually short (their length measured in the number of links is about 4–6).

The basic trophic species of chain usually are 'producers' (plants, autotrophic organisms that accumulate the solar energy and 'nutrients' – carbon, nitrogen, phosphorus, etc.); the next species are 'primary consumers' (herbivorous, heterotrophic organisms), and 'secondary consumers' (carnivores, predators, preying on herbivorous). Really, the chain may be longer. It is not necessary that the chain be originated by an autotroph: it may be any species considered as a resource for consequent ones. For instance, if a resource is 'detritus' (faeces, dead organic matter) then a special 'detritus chain' can be considered. At last, trophic chains could be 'open' and 'closed'; as a rule they are open in relation to the energy flowing through an ecosystem and carbon that is accumulated in the process of photosynthesis and spent in the respiration, and closed in relation to nutrients turning in the ecosystem.

In order to start a 'biogeochemical machine' we have to 'close' the chain by species named 'decomposers' (protozoa, bacteria, fungi, scavengers, and carrion eaters), which in the course of their vital activity split complex organic compounds into simpler mineral substrates (nutrients) for autotrophs. A principal scheme of such kind of 'biogeochemical machine' is shown in **Fig. 3**.

Really, the closure is not complete: about 1% of dead organic matter is deposited in the deep ground ('kerogen'), and has accumulated over long periods of geologic time (oil and coal repositories).

A small amount of the energy passes from one trophic level to another; for instance, only from 5% to 25% of plant biomass is consumed by herbivores, the rest falls out and becomes a resource for decomposers (detritophages). Efficiency of this passing is called 'ecological efficiency'; on average, it equals 10%. The rate at which these consumers use the chemical energy of their food for growth and reproduction is called 'assimilation efficiency'. For instance, assimilation efficiency of herbivores lies in the interval from 15% to 80%, while the interval for carnivores is from 60% to 90%.

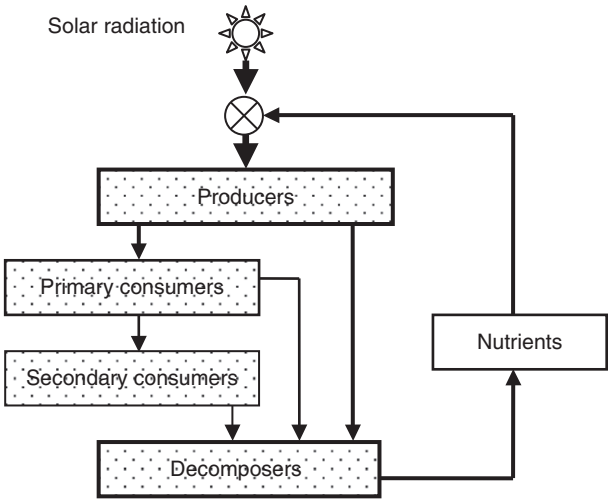

Fig. 3 Flows of mass and energy in an elementary biogeochemical machine.

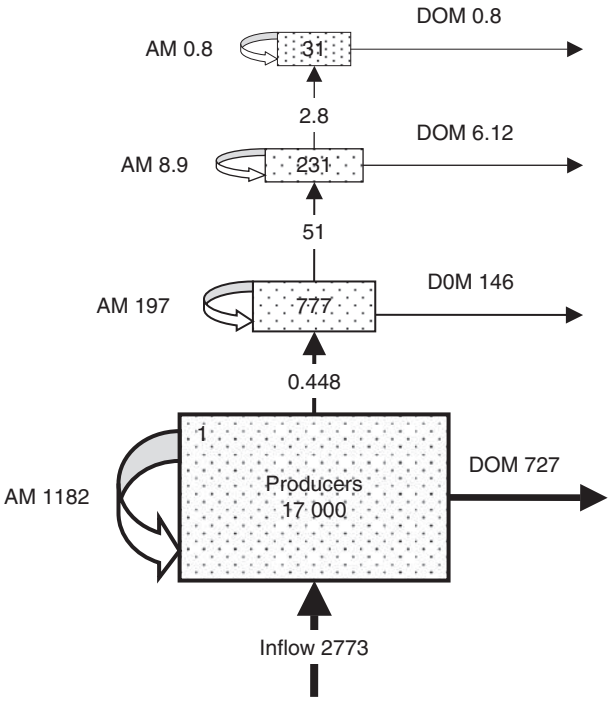

Fig. 4 Trophic chain of the ecosystem of Silver Springs. Energy flows and biomasses are measured in mW m^{-2} and kJ m^{-2}, respectively. DOM, dead organic matter; AM, assimilation and metabolism.

It is easy to estimate that such a predator as *Homo sapiens* (the third trophic level) gets only 1% of solar energy stored by plants. Unfortunately, the situation has not improved; if he would be a vegetarian, by winning in the ecological efficiency, he would lose in the assimilation efficiency.

The result of such kind of consequent energetic transitions is a pyramid of energy, with most energy concentrated by autotrophs at the bottom of trophic chain and less energy at each higher trophic level. As an example the trophic chain and the pyramid of biomass of the concrete ecosystem of warm Silver Springs in Florida are presented in **Fig. 4**. Note that it is a classic object that has been studied by H. T. Odum. The ecosystem has four trophic levels: (1) producers (phytoplankton), (2) herbivores (zooplankton), (3) carnivores (fish), (4) higher predators (predacious fish), and one special level, decomposers, with biomass equal to 105 kJ m^{-2}. Since the system is through-flowing, that is, described in the terms of energy flows, therefore the chain may be considered open, without decomposers.

Conclusion

As described above biosphere machines from the anthropocentric point of view are badly made, with very low efficiency. They dissipate the solar energy by heating the environment more than perform some useful work. Nevertheless, they are significantly reliable. Since it is necessary to pay for their reliability and stability, they pay by high dissipation of energy that in turn decreases their efficiency.

Entropy and Entropy Flows in the Biosphere

YM Svirezhev, Potsdam Institute for Climate Impact Research, Potsdam, Germany

Introduction

From the thermodynamic point of view, Earth is a closed system, which gets 1.2×10^{17} J of energy from the Sun every second in the form of a short-wave radiation, which corresponds to the density of energy flow in 238 W m^{-2}. The same amount of energy is irradiated into the space in the form of a long-wave (infrared) radiation. We assume that the Earth's total mass and its mean temperature (more precisely, the temperature of the Earth–Atmosphere System (EAS)) are not changing in the course of rather long time ($\sim 10^3$ years). The latter means that the planetary radiative balance is constant. These are plausible hypotheses, which can be considered as 'empirical generalizations'.

Carriers of energy are 'hot' photons with temperature $T_S = 5800$ K of the Sun's surface, and the energy is carried away by 'cooled' photons at $T_E = 253$ K. This is the so-called 'photon mill'; evolution and self-organization of planets (including life on Earth) is a result of its work.

Formally, the photon mill is a typical 'heat machine' functioning as a Carnot cycle, but its working body is the photon gas, whose 'molecules' have no mass, so that in this case it becomes slightly incorrect to talk about a heat machine (although Gibbs has indicated it). Later on, Prigogine stated that such a classic thermodynamic concept as the heat machine is also applicable to the photon gas. Note that this 'roughness' is not necessarily present, if the concept of 'exergy' is used.

Let $d_i\sigma/dt$ be the internal production of entropy by the EAS, and $d_e\sigma/dt$ be the exchange flow of entropy between the Sun and the EAS, then the change in the total entropy of the EAS is

$$\frac{d\sigma}{dt} = \frac{d_e\sigma}{dt} + \frac{d_i\sigma}{dt} \qquad [1]$$

The value of $d_e\sigma/dt$ can be estimated as the algebraic sum of the entropy flow from Sun to Earth, $q_{SE} = (4/3)\ (238\ \mathrm{W\ m^{-2}})\ (1/T_S)$, and the entropy flow from the EAS to space, $q_{ES} = -(4/3)\ (238\ \mathrm{W\ m^{-2}})\ (1/T_E)$:

$$\frac{d_e\sigma}{dt} = \frac{4}{3}\left(238\mathrm{W}\,m^{-2}\right)\left(\frac{1}{5800} - \frac{1}{253}\right) \approx -1.2\mathrm{W\,K^{-1}m^{-2}} \qquad [2]$$

where factor 4/3 is the so-called Planck's form factor. The annual entropic balance for the globe overall is equal to -2×10^{22} J K^{-1} yr^{-1}.

We assume here implicitly that the irradiation of the EAS is the blackbody irradiation with $T_A = T_E = 253$ K. Indeed, the irradiation is a sum of the blackbody irradiations with the temperatures from 215 to 288 K, so that this estimation is a zero approximation.

In accordance with Prigogine's theorem, at the dynamic equilibrium the system's entropy must be constant, that is, $d\sigma/dt = 0$; whence

$$-\frac{d_e\sigma}{dt} = \frac{d_i\sigma}{dt} \qquad [3]$$

The value of $d_e\sigma/dt$ is known; if we could estimate the value of $d_i\sigma/dt$, and if equality [3] holds, or, in other words, if the internal production of entropy is balanced by its export into the environment, we would prove one important statement: the EAS is at the dynamic equilibrium with its environment, the space. Note that equality [3] has to hold overall for the EAS, but each of its subsystems may be in nonequilibrium, so that the main statement of Prigogine's theorem (equality [3]) in relation to each subsystem does not necessarily hold.

Entropy Flows in the EAS

Let us look at the simplified scheme of the energy flows in the EAS shown in **Fig. 1**.

Using **Fig. 1** we can write equations of entropic balance for the EAS (atmosphere + ground) in a more detailed way:

$$\begin{aligned}\frac{d\sigma_G}{dt} &= \frac{4}{3}\frac{q(SG)}{T_S} - \frac{q_1(GA)}{T_G} - \frac{q_2(GA)}{T_G} - \frac{4}{3}\frac{q(GS)}{T_G} + \frac{d_i\sigma_G}{dt} \\ &\approx -0.586\,\mathrm{W\,K^{-1}\,m^{-2}} + \frac{d_i\sigma_G}{dt}\end{aligned} \qquad [4]$$

 doi:10.1016/B978-0-444-63768-0.00888-X

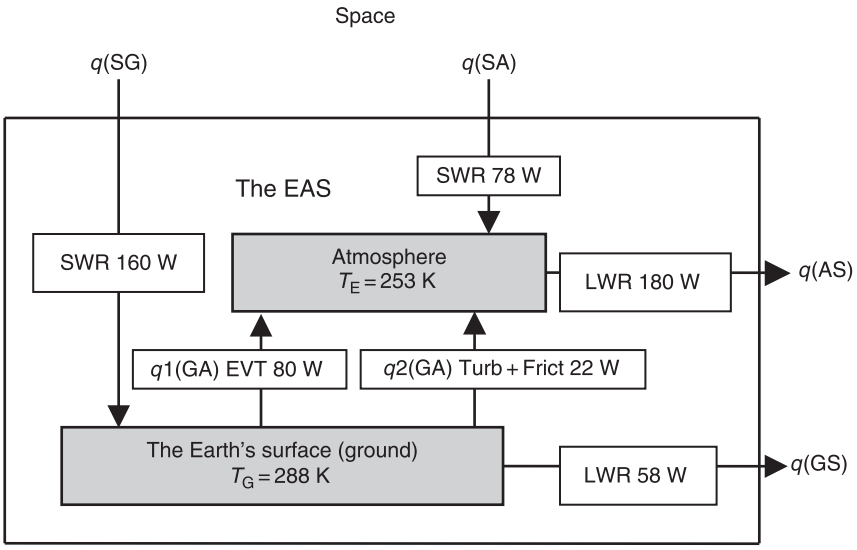

Fig. 1 Energy flows in the EAS. SWR is the flow of short-wave radiation with $T_S = 5800$ K, LWR is the flow of long-wave radiation with the temperatures of the Earth's surface (ground), $T_G = 288$ K, or the atmosphere $T_E = 253$ K; EVT is the flow of latent heat (evapotranspiration), and Turb + Frict is the flow of turbulent heat (sensible flow) + the flow of heat discharged in mechanical movements (friction).

$$\begin{aligned}\frac{d\sigma_A}{dt} &= \frac{4}{3}\frac{q(SA)}{T_S} + \frac{q_1(GA)}{T_G} + \frac{q_2(GA)}{T_G} - \frac{4}{3}\frac{q(AS)}{T_E} + \frac{d_i\sigma_A}{dt} \\ &\approx -0.576\,W\,K^{-1}\,m^{-2} + \frac{d_i\sigma_A}{dt}\end{aligned} \quad [5]$$

It is interesting that the exchange entropic flows, $d_e\sigma_G/dt \approx -0.586\,W\,K^{-1}\,m^{-2}$ for the ground and $d_e\sigma_A/dt \approx -0.576\,W\,K^{-1}\,m^{-2}$ for the atmosphere, are almost equal, and their sum is equal to $d_e\sigma/dt \approx -1.16\,W\,K^{-1}\,m^{-2}$, that almost coincides with the value given by eqn [2]. In accordance with Prigogine's theorem,

$$-\frac{d_e\sigma}{dt} = \frac{d_i\sigma}{dt} = \frac{d_i\sigma_A}{dt} + \frac{d_i\sigma_B}{dt} \approx 1.16\,W\,K^{-1}\,m^{-2} \quad [6]$$

Entropy Storage of the Biota

The EAS is divided into four subsystems: atmosphere (A), hydrosphere (H), pedosphere (P), and biota (B). The atmosphere is a mixture of different gases: mainly nitrogen and oxygen; in lesser concentrations, carbon dioxide, water vapour, argon, etc., which determine the thermal regime of our planet. The hydrosphere's mass is a mass of all water (including salt dilutions and excluding polar ice and glaciers). The pedosphere is soils. All these are exchanging energy and matter with each other, and in turn the EAS is exchanging, however, only energy with space. In particular, the matter exchange is realized by means of the global biogeochemical cycles.

The atmosphere, hydrosphere, and pedosphere have stored gigantic amounts of entropy. For instance, the entropy storage of atmosphere is $3.5 \times 10^{22}\,J\,K^{-1}$ that in general is close to the global entropy balance; the storages of other subsystems are significantly larger. The exchange entropy flows that bound them with the biota are relatively weak with respect to their entropy storages, and do not really change their state, but they are able to change the state of biota. Thus, the latter is important for us.

Since the atmospheric CO_2 is one of the 'life-forming' gases, it is interesting to estimate its entropy, which is equal to $1 \times 10^{19}\,J\,K^{-1}$.

The biota is defined as all of the Earth's living matter. Apparently, this is one of the reasons why the term 'biosphere' is often used (especially in Anglo-Saxon literature) in the sense of 'biota'. The present bulk of living organisms are confined to land, and their mass (on dry basis) amounts to 1.88×10^{18} g. For instance, the oceanic biomass is about 0.5% of that in land. Since the terrestrial vegetation constitutes the most part of biota, mainly contributing to its dynamics, the biota is identified with the terrestrial vegetation.

So, biota is the terrestrial phytomass, put into a thermostat with the mean annual temperature of the Earth's surface, $T_B = 15\,^{\circ}C$. The total phytomass is known; hence, if only the specific entropy of living matter is also known, there is no problem in calculating the total entropy of biota. However, here we deal with a strongly nonequilibrium system, and it is unknown how to define the entropy in this case. What can be done here is to calculate the entropy of dead organic matter (DOM; in dry weight), $s(DOM) = h(DOM)/T_B$, where $h(DOM) = (16.4 - 18.4)\,kJ\,g^{-1}$ is its specific enthalpy. Therefore, $s(DOM) = 60.4\,J\,K^{-1}\,g^{-1}$, and the total entropy of 'dead biota' is $S(DOM) \approx 1.1 \times 10^{20}\,J\,K^{-1}$, which is less by two orders of magnitude than the atmosphere entropy.

Change of Entropy in the Terrestrial Biota

Let $d_iS_B/dt = \dot{S}_B^i$ be the annual internal production of entropy by the global biota, and $d_eS_{jB}/dt = \dot{S}_{jB}$, j=S, P, H, A be the flows of entropy from jth subsystem into biota, then the rate of its entropy change is

$$dS_B/dt = (\dot{S}_{SB} + \dot{S}_{PB} + \dot{S}_{HB} + \dot{S}_{AB}) + \dot{S}_B^i \quad [7]$$

Here we make a very important assumption: although we do not know what the specific entropy of living matter is, we can still speak about the change of entropy. For instance, the value of $(-T_B \cdot \Delta S)$ can be interpreted as an ability of a living system to perform the work, which in turn can be measured. This ability is named 'exergy'.

For the Earth's surface, using the data given above, $d_e\sigma_G/dt \approx -0.586\ W\ K^{-1}\ m^{-2}$. Since the area of globe is $5.1 \times 10^{14}\ m^2$, $d_eS_G/dt \approx (-0.586\ W\ K^{-1}\ m^{-2})(5.1 \times 10^{14})\ (3.15 \times 10^7) = -9.41 \times 10^{21}\ J\ K^{-1}\ yr^{-1}$.

Exchange between Space and Biota

We assume that plants use only the solar short-wave radiation, absorbed by the Earth's surface, $160\ W\ m^{-2}$. Since plants absorb only 53.5% of this energy (photosynthetically active radiation), $85.6\ W\ m^{-2}$, and vegetation covers 72.5% of land area, $A_{veg} \approx 1.1 \times 10^{14}\ m^2$, the biota gets annually

$$\begin{aligned} \dot{S}_{SB} &= \frac{4}{3}(85.6\ W\ K^{-1}\ m^{-2})\frac{A_{veg}}{T_S}(3.15 \times 10^7) \\ &= 0.53 \times 10^{20}\ J\ K^{-1}\ yr^{-1} \end{aligned} \quad [8]$$

Here T_S=5800 K.

Exchange between Pedosphere and Biota

This flow is mainly determined by the flow of DOM from terrestrial biota into pedosphere q_{DOM}. Assume that annual flow of DOM is equal to the net primary production (NPP), 140 Gt of dry matter, then $q_{DOM} = -1.4 \times 10^{17}$ g d.w. of DOM per year. Since a living biomass contains about 65% (on average) of water, then it is natural to assume that standing dead vegetation contains the same percentage of water, and the flow of dry DOM, -1.4×10^{17} g, has to be accompanied by the water flow, -2.6×10^{17} g H_2O. By taking into account that specific entropy of H_2O is $3.89\ J\ K^{-1}\ g^{-1}$, the total entropy flow $\dot{S}_{PB} = -(60.4 \times 1.4 + 3.89 \times 2.6) \times 10^{17} = -0.947 \times 10^{19}\ J\ K^{-1}\ yr^{-1}$.

There is also a reversible flow of minerals (the nutrients: nitrogen, phosphorus, potassium, etc.), which are used in the process of creation of new biomass. All these substances come into the biota in the form of water solutions, entropy of which is the sum of the water entropy and exactly these elements. Note that their contribution constitutes less than 1% of the contribution of water.

Exchange between Hydrosphere and Biota

This flow is defined as $\dot{S}_{HB} = s(H_2O) \cdot q_{HB}(H_2O)$, where $q_{HB}(H_2O)$ is the annual flow of water consumed by biota, and $s(H_2O) = 3.89\ J\ K^{-1}\ g^{-1}$ is the specific entropy of liquid water at T=288 K. We assume that $q_{HB}(H_2O)$ is equal to the annual transpiration of global vegetation, 4.8×10^{19} g H_2O. Then $\dot{S}_{HB} = 3.89 \times 4.8 \times 10^{19} = 1.87 \times 10^{20}\ J\ K^{-1}\ yr^{-1}$.

Exchange between Atmosphere and Biota

This flow, $\dot{S}_{AB}$, is a sum of the following flows:

1. entropy flow caused by diffusion of CO_2 through stomata into leaves, $\dot{S}_{AB}(CO_2)$;
2. entropy flow caused by diffusion of O_2 through stomata into the atmosphere, $\dot{S}_{BA}(O_2)$; and
3. entropy flow caused by the transpiration of water, $\dot{S}_{BA}(H_2O)$.

The first and second flows are defined as $\dot{S}_{AB}(CO)_2) = s(CO_2)_{AB} \cdot q_{AB}(CO_2)$ and $\dot{S}_{BA}(O_2) = -s(O_2) \cdot q_{BA}(O_2)$, where $q_{AB}(CO_2) = NPP[gC] \cdot (44/12) = 6.6 \times 10^{16} gC(44/12) = 2.42 \times 10^{17} gCO_2\ yr^{-1}$ and $q_{BA}(O_2) = -(6.6 \times 10^{16} gC)(32/12) = -1.76 \times 10^{17} gO_2 yr^{-1}$ are the rates of consumption and release of carbon dioxide and oxygen by plants in the process of photosynthesis. The specific entropies are: $s(CO_2) = 4.86\ J\ K^{-1}\ g^{-1}$ and $s(O_2) = 6.41\ J\ K^{-1}\ g^{-1}$. Then $\dot{S}_{AB}(CO_2) = 1.18 \times 10^{18}\ J\ K^{-1}\ yr^{-1}$ and $\dot{S}_{BA}(O_2) = -1.13 \times 10^{18}\ JK^{-1}\ yr^{-1}$. The summation of these flows gives $\dot{S}_{AB}(CO_2) + \dot{S}_{BA}(O_2) = (1.18 - 1.13) \times 10^{18} = 5 \times 10^{16}\ J\ K^{-1}\ yr^{-1}$, that is, the exchange flows of entropy related to CO_2 and O_2 are almost balanced by each other, so that their sum is reduced by two orders of magnitude.

The entropy flow $\dot{S}_{BA}(H_2O) = s(WV) \cdot q_{BA}(H_2O)$, where $q_{BA}(H_2O) = -q_{HB}(H_2O) = -4.8 \times 10^{19} gH_2O\ yr^{-1}$ is the annual transpiration through stomata (we assume that all consumed water is transpired), and s(WV) is the specific entropy of water vapor at T_B=288 K and 1 atm. We see that maximal entropy flows are associated with water in liquid and vapor forms, that is, with the global water cycle. Their total balance $\dot{S}(H_2O) = \dot{S}_{HB} + \dot{S}_{BA}(H_2O) = q_{BA}(H_2O) \cdot (h_{ev}/T_B)$, where h_{ev}=2462 J per g H_2O is the

specific enthalpy of evaporation, and is equal to a jump of entropy caused by the phase transition 'liquid water→water vapor', $\dot{S}(H_2O) = -4.1 \times 10^{20}\,J\,K^{-1}\,yr^{-1}$.

The internal production of entropy, $\dot{S}_B^i$, can be represented as a sum of two terms: $\dot{S}_B^i = \dot{S}_B^{DOM} + \dot{S}_B^{Work}$. The first is mainly connected with chemical reactions forming structural molecules of biomass (cellulose, proteins, carbohydrates, lipids, etc.). Organic compounds containing phosphorus take an active part in such type of reactions. All these processes are associated mainly with the carbon, nitrogen, and phosphorus biochemical cycles, the entropy flows of which are less than in the water cycle approximately by two (and less) orders of magnitude. Certainly, knowing the chemical composition of living matter, we can calculate its chemical entropy as a sum of corresponding specific entropies weighted proportionally to their percentages. However, since the dead matter has the same composition, then the specific chemical entropies of living and dead matter do not differ from each other. Hence, we can assume that the processes of forming of the new biomass and falling off the DOM with respect to their chemical composition are mutually reversible, that is, $\dot{S}_B^{DOM} + \dot{S}_{PB} = 0$.

The second term, $\dot{S}_B^{Work}$, is the entropy produced by the biota during its working cycle (see details below).

By summing all these flows, we get

$$dS_B/dt \approx [(0.53 - 4.11) \times 10^{20} = -3.58 \times 10^{20}\,J\,K^{-1}\,yr^{-1}] + \dot{S}_B^{Work} \quad [9]$$

that is, from the thermodynamic point of view, biota is a strongly nonequilibrium system. The structure of the exchange entropic flows for the biota is shown in Fig. 2.

If we compare $d_eS_B/dt \approx -3.57 \times 10^{20}\,J\,K^{-1}\,yr^{-1}$ and $d_eS_G/dt \approx -9.41 \times 10^{21}\,J\,K^{-1}yr^{-1}$, then it is easy to see that these values differ by 26 times. Even if we take into account that in the case of biota we deal with the land area (covered by vegetation), which is less by almost fivefolds than the globe area, then we have almost five-multiple excess. Nevertheless, if we now compare the biota and the Earth's surface with respect to the energy obtained (the first obtains less than 1% in comparison with the second), then we can conclude that the biota is one of the main actors on the entropic scene.

Biota Performs the Work

We have an argument carrying the concept of self-organization of the biosphere: the very existence of the living biota is in necessary disequilibrium with the nonliving part of the biosphere. The main consequence of this disequilibrium is that the biota is able to perform some useful work, and a measure of this work is 'exergy'. By performing work, the biota produces additional entropy; namely, this entropy 'closes' its balance. This in turn allows us to say that the biota is in dynamic equilibrium at least in the course of last millenaries. What is this work? This is mainly the chemical work of the biogeochemical cycles, the work forcing to move the matter flows, that is, forcing the 'wheels' of the 'biosphere machine' to be turned, and then to move evolution. In particular, all the work to produce and maintain the gigantic overproduction of offspring (namely this is one of the main ideas of Darwin, while the concept of natural selection dates back to antiquity) is the work of biota.

So, this work (more correctly the ability to perform the work, i.e., 'exergy') is equal to

$$Ex = -T_B(\text{change of entropy}) = -T_B(d_eS_B/dt) \approx 1 \times 10^{23}\,J\,yr^{-1} \quad [10]$$

Exergy is also defined as $Ex = \beta\, h_{DOM} \cdot NPP$, where $h_{DOM} = 17.4\,kJ\,g^{-1}$ is the specific enthalpy of DOM, $NPP = 1.4 \times 10^{17}$ g d.w. is the annual NPP, and the factor β is some specific genetic characteristic of a living organism defined by a number of nonrepetitive genes in its genome. For plants, this value lies in the range 29–87. In our case $\beta \approx 42$, which is close to the mean of this interval, $\hat{\beta} = 58$.

It is not a secret that all these estimations for the total biomass of vegetation, its annual production, the volume of water transpired by plants, etc., are rather conditional and strongly varying. Nevertheless, the corresponding values of β in most cases get into the interval from 29 to 87.

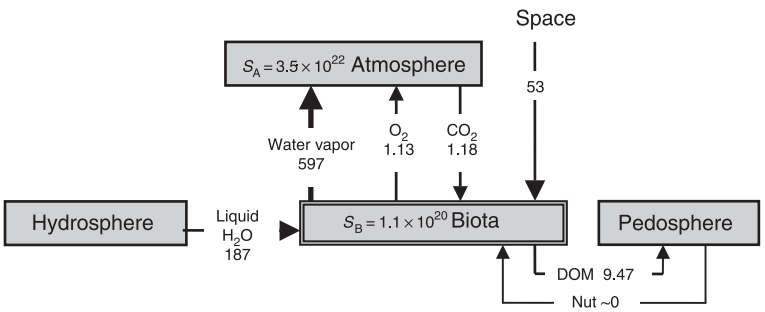

Fig. 2 Exchange entropic flows for the biota (all the flows are shown in $10^{18}\,J\,K^{-1}\,yr^{-1}$). DOM is the entropy flow determined by falling off the dead organic matter, Nut is the entropy flow of nutrients (nitrogen, phosphorus, potassium, etc.).

Humans and Biota

The annual production of artificial energy consumed by the anthroposphere constitutes about 3×10^{20} J yr^{-1}, which is $\sim$12% of the global terrestrial NPP. If all the energy is transformed into heat, then the annual production of entropy is $\dot{S}^{\mathrm{Art}} \approx 1 \times 10^{18}$ J K^{-1} yr^{-1}, which is comparable with some entropic flows in the biota (e.g., with flows caused by uptake of CO_2 and release of O_2).

Now the biosphere and anthroposphere are in the state of strong competition for common resources, such as land area and fresh water. Contamination of the environment and reduction of the biota diversity are the consequences of the competition.

Since the biosphere (considered as an open thermodynamic system) is in dynamic equilibrium, then all entropy flows have to be balanced too. Therefore, the entropy excess, which is created by the anthroposphere, has to be compensated by means of two processes: (1) reduction of the biota and degradation of the biosphere, and (2) change in the work of the Earth's climate machine (in particular, an increase in the Earth's mean temperature). Note that in any case it is desirable to include the entropic flow $\dot{S}^{\mathrm{Art}}$ into the total balance of entropy for both, the atmosphere and biota, but we shall assume that the anthropogenic impact concentrates only on the biota. Then $\dot{S}_{\mathrm{B}}^{\mathrm{i}} = \dot{S}_{\mathrm{B}}^{\mathrm{DOM}} + \dot{S}_{\mathrm{B}}^{\mathrm{Work}} + \dot{S}^{\mathrm{Art}}$. By assuming that equalities $\dot{S}_{\mathrm{AB}}(\mathrm{CO_2}) + \dot{S}_{\mathrm{BA}}(\mathrm{O_2}) \approx 0$ and $\dot{S}_{\mathrm{B}}^{\mathrm{DOM}} + \dot{S}_{\mathrm{PB}} = 0$ hold in this case also, we get the following simplified equation:

$$\mathrm{d}S_{\mathrm{B}}/\mathrm{d}t \approx \dot{S}(\mathrm{H_2O}) + \dot{S}_{\mathrm{B}}^{\mathrm{Work}} + \dot{S}^{\mathrm{Art}} \qquad [11]$$

The total flow of transpiration can be represented as $|q_{\mathrm{BA}}(\mathrm{H_2O})| = bB$, where B is the total mass of biota (in d.w. of DOM) and $b = |q_{\mathrm{BA}}(\mathrm{H_2O})|/B$ is the specific intensity of transpiration (in g H_2O g^{-1} d.w.), which is constant. We implicitly assume here that the power of transpiration 'pump' is proportional to the biomass of plant.

On the other hand, since this value of water is necessary to transpire in order to create P units of a new biomass (P=NPP in d.w.), then $|q_{\mathrm{BA}}(\mathrm{H_2O})| = pP$, where p is the amount of transpired water, which is necessary for creating 1 g of biomass. Therefore, the coefficient $P/B = b/p$. It is known that the P/B coefficient is a biome-specific value; apparently, we can let it be a constant. Since $|q_{\mathrm{BA}}(\mathrm{H_2O})| = 4.8 \times 10^{19}$ g H_2O yr^{-1}, $B = 1.86 \times 10^{18}$ g d.w. and $P = 1.4 \times 10^{17}$ g d.w. yr^{-1}, then b=25.8 g H_2O g^{-1} d.w. per year, p=343 g H_2O g^{-1} d.w., and P/B=0.075 yr^{-1}. So, $S\cdot(\mathrm{H_2O}) = -0.221 \times 10^3 B$ J K^{-1} yr^{-1} or $S\cdot(\mathrm{H_2O}) = -2.93 \times 10^3 P$ J K^{-1} yr^{-1}.

Let us consider the entropic flow $\dot{S}_{\mathrm{SB}}$, which is proportional to area A_{veg} covered by vegetation. Since vegetation covers the globe by a relatively thin layer, then the equality $\dot{S}_{\mathrm{SB}} = aB$ or $\dot{S}_{\mathrm{SB}} = [a/(P/B)]P$ are rather plausible hypotheses. The value of a is easily found from eqn [8]: a=28.5 J K^{-1} per g d.w. per year.

The entropic flow $S_{\mathrm{B}}^{\mathrm{Work}} = [\beta s(\mathrm{DOM})]P = [\beta s(\mathrm{DOM})(P/B)]B$, so that $S_{\mathrm{B}}^{\mathrm{Work}} = 60.4\beta P = 4.53\beta B$.

Finally, eqn [11] is rewritten as

$$\begin{aligned} \mathrm{d}S_{\mathrm{B}}/\mathrm{d}t &\approx (-192 + 4.53\beta)B + \dot{S}^{\mathrm{Art}} \\ &\approx (-25.5 + 0.604\beta) \times 10^2 P + \dot{S}^{\mathrm{Art}} \end{aligned} \qquad [12]$$

This equation allows us to estimate different critical bounds of the impact of humankind on the biosphere. The impact may be manifested through: (a) increase in energy, $E = T_{\mathrm{B}}\dot{S}^{\mathrm{Art}}$ leads to decrease in the total biomass, B; (b) increase in energy inhibits the NPP, that is, $B = B(E)$, $\partial B/\partial E \leq 0$ and $P = P(E)$, $\partial P/\partial E \leq 0$. The simplest form of these functions may be linear, $B = B_{\mathrm{nat}}\left(1 - E/E_{\mathrm{crit}}^{\mathrm{B}}\right)$ and $P = P_{\mathrm{nat}}\left(1 - E/E_{\mathrm{crit}}^{\mathrm{P}}\right)$, where $B_{\mathrm{nat}} = 1.86 \times 10^{18}$ g and $P_{\mathrm{nat}} = 1.4 \times 10^{17}$ g are natural (without anthropogenic impact) values of biomass and NPP, $E_{\mathrm{crit}}^{\mathrm{B}}$ and $E_{\mathrm{crit}}^{\mathrm{P}}$ are critical values of energy with respect to the biomass and NPP (they vanish at these values).

The biota is living if $\mathrm{d}S_{\mathrm{B}}/\mathrm{d}t < 0$; therefore, the upper bound for human energy production, E^* is

$$E^* = \frac{E_{\mathrm{crit}}^{\mathrm{B}}\xi^{\mathrm{B}}}{E_{\mathrm{crit}}^{\mathrm{B}} + \xi^{\mathrm{B}}} = \frac{E_{\mathrm{crit}}^{\mathrm{P}}\xi^{\mathrm{B}}}{E_{\mathrm{crit}}^{\mathrm{B}} + \xi^{\mathrm{B}}} \qquad [13]$$

where $\xi^{\mathrm{B}} = T_{\mathrm{B}}(192 - 4.53\beta)B_{\mathrm{nat}}$, $\xi^{\mathrm{P}} = T_{\mathrm{B}}(25.5 - 0.604\beta) \times 10^2\ P_{\mathrm{nat}}$. In the previous section, we gave some meaningful interpretation to the parameter β, but here β is regarded as a free parameter.

Let us consider two simple examples.

Example 1: *The lower bound of β is $\beta_* = 29$, which is equivalent to full disappearance of the biosphere of vascular plants. From eqn [13] we get, for $\beta = 29$: $\xi^B \approx 3.2 \times 10^{22}$ J yr^{-1}. In order to estimate $E_{\mathrm{crit}}^{\mathrm{B}}$ we assume that this value is equal to the full enthalpy of biota, that is, $E_{\mathrm{crit}}^{\mathrm{B}} \approx 3.2 \times 10^{22}$ J yr^{-1}, then $E^* \approx (1/2)E_{\mathrm{crit}}^{\mathrm{B}} = 1.62 \times 10^{22}$ J yr^{-1}. Today humans are consuming about 3.24×10^{20} J annually. If humans would be doubling their energy consumption by every decade, then they would reach and exceed this bound during the next 70 years.*

Example 2: *The work performed annually by the biota is $W_{\mathrm{B}} = T_{\mathrm{B}}\dot{S}_{\mathrm{B}}^{\mathrm{Work}} = T_{\mathrm{B}}h_{\mathrm{DOM}}\beta P$. Since $P = P_{\mathrm{nat}}\left(1 - E/E_{\mathrm{crit}}^{\mathrm{P}}\right)$ where $P_{nat} = 1.4 \times 10^{17}$ g, then $W_{\mathrm{B}} = W_{\mathrm{B}}^{\mathrm{nat}}\left(1 - E/E_{\mathrm{crit}}^{\mathrm{P}}\right)$, where $W_{\mathrm{B}}^{\mathrm{nat}} = h_{\mathrm{DOM}}\beta P_{\mathrm{nat}} \approx 1 \times 10^{23}$ J yr^{-1} is the work of the 'natural' biota. Therefore, the relative work corresponding to the bound E^* is $W_{\mathrm{B}}^*/W_{\mathrm{B}}^{\mathrm{nat}} = E_{\mathrm{crit}}^{\mathrm{P}}/(E_{\mathrm{crit}}^{\mathrm{P}} + \xi^{\mathrm{P}})$. One of the possible estimations of $W_{\mathrm{B}}^*/W_{\mathrm{B}}^{\mathrm{nat}} \approx 0.95$, that is, only 5% of the potential work of the biosphere can be used to maintain its structure (in particular, animals) and its evolution; the rest is spent to turn the 'wheels' of the global biogeochemical cycles, so that $\xi^{\mathrm{P}}(\beta) = 0.0526E_{\mathrm{crit}}^{\mathrm{P}}$. By substituting this value into eqn [13], we get $E^* = 0.05E_{\mathrm{crit}}^{\mathrm{P}}$. We assume that $E_{\mathrm{crit}}^{\mathrm{P}}$ is equal to the total enthalpy of the NPP $\sim 2.44 \times 10^{21}$ J yr^{-1}, then $\mathrm{E}^* = 1.22 \times 10^{20}$ J yr^{-1}. By comparing this value with the current energy uptake, 3×10^{20} J yr^{-1}, we see that we already have serious problems today.*

Entropy Balance in Elementary Ecosystems

From the thermodynamic point of view, any ecosystem is an open system. An ecosystem being in a 'climax' state corresponds to a dynamic equilibrium, in which the internal production of entropy is balanced by the entropic outflow to the environment.

An 'elementary ecosystem' is the area unit of land, covered by some type of vegetation, which is properly the main part of any terrestrial ecosystem, and upper layer of soil with litter, in which DOM is decomposed. We neglect horizontal exchange flows of matter, energy, and entropy between this and other ecosystems.

The equation of energy balance for this area is $R = h_{evp} q_W + Q_{turb} + h_{DOM}\mathrm{GPP}$. Here $h_{evp} = 2462\ \mathrm{J\ g^{-1}}$ H_2O is the specific enthalpy of evaporation, q_W is the flow of evapotranspiration, Q is the turbulent heat flow, transporting heat from the surface into the atmosphere, $h_{DOM} = 17.4\ \mathrm{kJ\ g^{-1}}$ is the specific enthalpy of DOM, and GPP is the gross primary production (in g d.w.). Oxidation of biomass (respiration and decomposition of DOM) gives an additional source of heat, therefore the left side of the balance equation has to be $R + (Q_{met} + Q_{dec})$, where Q_{met} is a metabolic heat and Q_{dec} is heat releasing in the process of decomposition.

Let us group items of the radiative balance into two classes (in square brackets), which differ by values of their elements: $[R - h_{ev} q_W - Q_{turb}] + [Q_{met} + Q_{dec} - \mathrm{GPP}] = 0$, where the difference may constitute a few orders. For instance, the energy acting in the process of evapotranspiration is higher by two orders of magnitude than the energy of photosynthesis. Then we can equate each of the brackets to zero (it is the so-called 'asymptotic splitting': $[R - h_{ev} q_W - Q_{turb}] = 0$ and $[Q_{met} + Q_{dec} - \mathrm{GPP}] = 0$.

We assume that the fulfilment of the first equality provides the existence of some 'thermostat', which should be called the 'environment'. Then the fulfilment of the second equality is determined by a consistency of the processes of production, on the one hand, and metabolism of plants and decomposition of DOM in litter and soil, on the other.

In accordance with a standard definition, the internal production of entropy is equal to $d_iS/dt \approx Q_{ox}/T$, where T is the system temperature, and Q_{ox} is the heat generated by the system. The total heat production is a result of two processes: metabolism or respiration (Q_{met}) and decomposition of DOM (Q_{dec}). Since these processes can be considered as a burning of corresponding amount of organic matter, then the values of Q_{met} and Q_{dec} can be also expressed in enthalpy's units. Thus, $d_iS/dt \approx (Q_{met} + Q_{dec})/T$. The mean annual temperature at the surface of given site is the system temperature.

Since the equality $[Q_{met} + Q_{dec} - \mathrm{GPP}] = 0$ must hold, then $d_iS/dt \approx \mathrm{GPP}/T$. At the dynamic equilibrium the internal entropy production must be compensated by the entropy export from the system, so that

$$\frac{d_iS}{dt} = \frac{d_eS}{dt} = \frac{\mathrm{GPP}}{T} \qquad [14]$$

where $|d_eS/dt|$ is so-called 'entropy pump', which 'sucks' the redundant entropy (that is existing in the system for a long time), out of the ecosystem. We assume the local climatic, hydrological, soil, and other environmental conditions are adjusted in such a way that only one natural ecosystem corresponding specifically to these conditions can exist at this site and be in dynamic equilibrium. This is a concept of 'entropy pump'.

Any natural ecosystem is in dynamic equilibrium if and only if the internal entropy production within the system is balanced by an entropic outflow from the system to its environment (the 'entropy pump' is working). Suppose that additional inflows of artificial energy (energy load, W_{ae}) and chemical substances (chemical load, W_{ch}) start entering into the system. This is a typical impact of industry (or, in a broader sense, technological civilization) and industrialized agriculture on the environment. The internal production of entropy by the 'disturbed' ecosystem is given by

$$\frac{d_iS}{dt} = \frac{1}{T}[W + \mathrm{GPP}(W)] \qquad [15]$$

where $W = W_{ae} + W_{ch}$ is the total anthropogenic impact. Since a certain part of the entropy is released by the 'entropy pump' with power $|d_eS/dt| = \mathrm{GPP}_0/T$, where GPP_0 is the gross primary production of undisturbed 'wild' ecosystem located at a given point, then the total entropy balance is given by

$$\frac{dS}{dt} = \sigma = \frac{1}{T}[W + \mathrm{GPP}(W) - \mathrm{GPP}_0] \qquad [16]$$

Under the anthropogenic pressure, the system moves toward a new state, gaining the ability to perform some work, then it returns to the initial state, performing the work and producing the entropy. This is a typical two-time working cycle of a thermodynamic machine called an 'elementary ecosystem'.

If this system tends to some stable dynamic equilibrium with respect to W ($W_{eq} = W^*$) and, in addition, satisfies to Prigogine's theorem, then $\mathrm{GPP}(W^*) + W^* = \mathrm{GPP}_0'$ and $\mathrm{GPP}(W) + (W) \to \min_W$ at $W^* \neq 0$. Here GPP_0' is a new value of the power of 'entropy pump', corresponding to a new equilibrium, which is established in the process of succession from natural to 'anthropogenic' ecosystem. Unfortunately, the proper time of this transition is rather long, and often the transition is not successfully finished (e.g., the 'old field' succession recovers a structure of pre-anthropogenic natural ecosystem, and does it very fast).

As a rule, the decrease in entropy, obtained at the first stage of the cycle, does not compensate its increase at the second stage. The further destiny of this 'superfluous' entropy could be different: (1) it is accumulated by the system, the system (in particular, its environment) degrades, and after a while, dies; (2) entropy may be exported from the system, the initial state is reestablished, and the system is again ready for the next cycle. The latter strategy may be realized by means of an import of additional low-entropy energy that could be used for the system restoration: soil reclamation, pollution control, or generally speaking, ecological

technologies, etc. In other words, this refers to the so-called 'ecological management'. Using such entropy calculation, we can estimate the necessary investments (in energy units).

Unfortunately, there is a 'third alternative' to restore the initial state: to divide the system on two parts – a proper biological community and its abiotic environment, pumping over the superfluous entropy from one to another. In other words, we try to resolve the problem at the expense of environmental degradation. Note that the value of entropy excess σ could be used as a measure of the latter, or, as the entropy fee which has to be paid by society (actually suffering from the degradation of environment) for modern industrial technologies.

From the thermodynamic point of view, the environmental degradation leading to a decrease in the GPP is a typical system's reaction tending the internal entropy production to decrease (Prigogine's theorem and Le Chatelier's principle), while it may be considered as a disaster from the anthropocentric position. Thus, in order to avoid the anthropogenic disaster, we have to compensate the positive increment of entropy at each working cycle of this machine.

All these concepts are visibly illustrated in the case of agroecosystems.

Agricultural (Agro-) Ecosystems

What concerns agroecosystems, which are typical representatives in the class of anthropogenic ecosystems exploited by *Homo sapiens*, it is obvious that by increasing the input of artificial energy we increase their (agricultural) production. Note that the increase does not have an upper boundary and can continue infinitely. However, this is not the case, and there are certain limits, determined by the second law of thermodynamics. In other words, we pay the cost for increasing of agricultural productivity, which is a degradation of the physical environment, in particular, soil degradation. As an example, we shall analyze, as a case study, the maize production in Hungary of 1980s.

To start with, we apply the previous results to the case of agroecosystems. By taking into account that only some fraction of the GPP, $(1-k)(1-r)$GPP, participates in the local production of entropy, another fraction, $\gamma = k(1-r)$GPP, is exported from the system as a crop yield. Here r is the respiration coefficient and k is the fraction of biomass corresponding to the crop yield γ. Note also that the latter and the flow of artificial energy is usually bounded by some linear relation, $\gamma = \eta W$, where η is the so-called Pimentel's coefficient. Then instead of eqn [16] we write

$$\begin{aligned} \frac{dS}{dt} &= \sigma = \frac{1}{T}\left[\gamma\left(\frac{1}{\eta}+\frac{1}{s}-1\right) - \mathrm{GPP}_0\right] \\ &= \frac{1}{T}\left[W\left(1-\eta+\frac{\eta}{s}\right) - \mathrm{GPP}_0\right],\ s = k(1-r) \end{aligned} \qquad [17]$$

The agroecosystem will exist for an infinitely long time without degradation if the annual overproduction of entropy will be equal to zero ($\sigma = 0$). This is a typical situation of the local sustainability.

Therefore, eqn [17] under the condition $\sigma = 0$ gives us the value of 'limit energy load':

$$W_{\mathrm{sust}} = W_{\mathrm{sust}} = \frac{\mathrm{GPP}_0}{1-\eta+\eta/s} \qquad [18a]$$

which provides sustainability of the agroecosystem, if $W \le W_{\mathrm{sust}}$. Using another form of eqn [18] we get

$$\gamma_{\mathrm{sust}} = \frac{\mathrm{GPP}_0}{1/s+1/\eta-1} \qquad [18b]$$

This is an evaluation of some sustainable yield, that is, the maximal crop production, which could be obtained without a degradation of agroecosystem, in other words, in a sustainable manner.

In our case $W = 27$ GJ ha^{-1}, $\gamma = 4.9$ ton d.m. per hectare $= 73.5$ GJ ha^{-1}, $\eta = 2.7$, $r = 0.4$, $k = 0.5$, $s = 0.3$. It is natural to take the Hungarian steppe as a reference natural ecosystem with $\mathrm{GPP}_0 = 118$ GJ ha^{-1}. By substituting these values into [17] we get $\sigma T = 81$ GJ ha^{-1}; therefore, to compensate for the environmental degradation we must increase the energy input by three times, when two thirds of it is used only for soil reclamation, pollution control, etc., with no increase in the crop production.

Using eqns [18a] and [18b] we get $W_{\mathrm{sust}} = 16$ GJ ha^{-1} and $\gamma_{\mathrm{sust}} = 2.9$ ton d. m. per hectare. It is interesting that the first value is very close to different estimations of the 'limit energy load', 14–15 GJ ha^{-1}, derived from economical considerations or empirically. It is the maximal value of the total anthropogenic impact (including tillage, fertilization, irrigation, pest control, harvesting, grain transportation and drying, etc.) on 1 ha of agricultural land; and if the anthropogenic impact exceeds this limit, an agroecosystem is destroyed (soil acidification and erosion, chemical contamination, etc.).

As to the second value, let us now keep in mind that the contemporary maize yield in the USA is equal to 3 ton; and also after 'black storms of 1930s', the modern agricultural technologies allow us to avoid the strong soil erosion.

Entropy (more correctly the dissipative function, $\sigma_{\mathrm{er}}T$) corresponding to the destruction of one ton of soil in the Hungarian case is $\sigma_{\mathrm{er}}T = 2.54$ Gt ha^{-1}; then the annual loss of soil per one hectare is $\sigma T/\sigma_{\mathrm{er}}T \approx 32$. Therefore, the high maize production would cost us 32 ton of soil loss annually. It is obvious that the value of 32 ton per hectare is an extreme value: the actual losses are less, approximately 13–15 ton. This means that also other degradation processes take place, such as environmental pollution, soil acidification (the latter is very significant for Hungary), etc.

Myth of Sustainable Development

Thanks to the Brundtland Commission book *Our Common Future. From One Earth to One World*, the concept of sustainability has become rather 'fashionable' today. Unfortunately, the sustainable development runs counter the second law of thermodynamics. What kind of arguments could be used to prove this thesis?

Our technological civilization: (a) uses nonbiospheric, nonrenewable sources of energy (fossil fuels and nuclear energy); (b) applies technological processes, which increase concentrations of chemical elements in comparison with their concentrations in the biosphere (metallurgy, chemical industry, etc.); (c) disperses chemical elements decreasing their concentrations in comparison with their biotic concentrations. All these processes produce redundant entropy, which is not sucked out by the biosphere's entropy pump, which is tuned in natural conditions. Thus, degradation of the environment is the only way to compensate for the entropy overproduction. Of course, we can avoid the degradation by applying ecological technologies, but they are rather expensive. Therefore, another way is often used by TNC. What is this way?

Since the overproduction is spatially heterogeneous, the redundant entropy naturally overflows from one site with high entropy to others with lower entropy, or it is artificially transported. If in the first case the process manifests as spreading of different pollutants by natural agents (wind, rivers, etc.), then in the second case this is either a purposeful export of industrial waste and polluting technologies to other regions, or import of low-entropy energy (e.g., fossil fuels) from other regions. Finally, we formulate the following thesis: sustainable development is possible only locally, in selective areas of the planet, and only at the expense of creating 'entropy dumps' elsewhere.

Note that in order to 'save' the sustainability concept, in the sustainability literature one talks about the so-called 'strong' sustainability, which is impossible due to the second law, and then 'weak' sustainability where losses are replaced by other gains. For instance, our technological civilization is generally using nonrenewable energy resources and materials that inevitably will lead to a loss of sustainability, but if we develop new technologies based on renewable sources of energy and materials, we are still doing well with respect to weak sustainability. However, in this case we shall deal with some slow movement of the biosphere from its contemporary equilibrium to some new unknown one. Certainly, the equilibrium might either be more suitable and comfortable for *Homo sapiens*, or might not be – that we do not know. There is one more rock in this slow movement: the small changes are accumulated without some visible effect, but sooner or later it could result in a disaster. This behavior is typical for nonlinear system such as the biosphere.

Conclusion

The author would like to complete the article by quoting the British physicist Robert Emden:

> When I have been a student, I have read with pleasure F. Wald's small book under the title "The Queen of the World and her Shadow". Energy and entropy were kept in mind. Now, when I understand these concepts deeper, I think that their positions should be interchanged. In the giant factory of natural processes, the entropy law is a director who controls and manages all the business, while the energy conservation law is only an accountant who is keeping a balance between debit and credit. (Emden, 1938).

Environmental and Biospheric Impacts of Nuclear War

Introduction

Apprehensions about uncontrolled thermonuclear fusion arose early in the Manhattan Project: Could explosion of a hydrogen bomb trigger a global physical catastrophe in starting chain reactions that seize the light elements and thus wipe out all life on Earth? It was not without grave anxiety that Emil Konopinski, Cloyd Marvin, Jr., and Gregory Breit ruled out this possibility. Since the end of World War II, public knowledge about `the unthinkable', the consequences of nuclear war, was largely shaped by the horrible direct health effects of the 1945 atomic bombing of Hiroshima and Nagasaki, by the devastations and disruptions of life and infrastructure due to heat, blast and electromagnetic waves, prompt ionizing radiation, and radioactive fallout.

Public awareness of worldwide fallout risks was triggered by the fatal outcome of the atmospheric test Bravo, the largest weapon exploded by the United States (Bikini atoll, 28 February 1954; 15 Mt TNT equivalent). Temporary geophysical effects of atmospheric tests, such as planetary pressure waves, magnetic field distortions, or ionospheric disruptions causing blackout in radio communication, were frequently recorded. A signature in worldwide weather was not found, however. The largest weapon ever tested, the `Tsar of Bombs', a more than 50 Mt `clean' bomb (with a nonfissionable mantle), was exploded on 30 October 1961, above the northern Soviet test site at Novaja Zemlya. Its pressure wave circled the Earth several times. The most obvious long-term, large-scale direct geophysical effect of nuclear explosions appears to have been caused by the Starfish Prime test on 9 July 1962 – a 1.4 Mt detonation some 400 km above the Johnston Island area in the tropical central North Pacific. An artificial (mini-van Allen radiation) belt of charged particles was trapped by the Earth's magnetic field and traced for a couple of years. High-altitude nuclear explosions may `blind' reconnaissance satellites, impair electronics over vast areas, and even inflict on a missile attack, by their electromagnetic pulse (EMP).

Radioactive tracers from the 539 atmospheric test explosions until 1980, with an aggregate yield of about 440 Mt, will remain identifiable worldwide for millennia. Hot spots at test sites and the unresolved issue of low-dose radiation effects notwithstanding, though, their health effects are far from endangering the species of man. In a nuclear war, the number of warheads and their total explosive yield might exceed these figures by an order of magnitude, and the period of 35 years would reduce to a couple of days, if not hours. Such a 10^5-fold `compaction' of interacting effects rules out extrapolation from the test series, as do consequences of a decisive distinction in targeting: The deadly logic of `mutual assured destruction' (MAD) bears attacks on large population centers. Cities would also not escape `countervalue' and `counterforce' strikes against the economic and military potential, notably the command, control, communication, and intelligence (C^3I) structures. Not only does this turn `warfare' into `exchange', it also gives birth to a new quality of risks – the long-term, worldwide indirect aftereffects that add to and interfere with the disastrous direct effects of nuclear explosions.

Studies on Indirect Effects of Nuclear War

Multiple upper-atmosphere nuclear bursts might be scheduled for a ballistic missile defense (BMD) system's `terminal phase defense' under the threat of a `decapitation' strike. This would endanger the Earth's `ozone screen' in generating high amounts of nitrogen oxides (NO_x). Rising fireballs of tropospheric bursts would have the same effect. The biologically active part of the solar ultraviolet radiation (UV-B), which causes structural change in amino acids and is normally absorbed by stratospheric ozone molecules, would then reach the surface. According to the US National Academy of Sciences (NAS; 1975), a 10 000 Mt exchange could cause a hemispheric ozone loss by 30–70% that would extend globally, with potentially grave impacts on terrestrial and aquatic ecosystems, and recovery over years. The amount of stratospheric dust, injected by megaton-yield near-surface explosions, may resemble the aerosol load due to the Krakatau eruption in 1883. NAS thus took a surface cooling of only a few tenths of a degree centigrade for plausible, but expressed another concern: ``It is not known whether climatic variables have stable equilibrium values and a tendency to relax after an impulse disturbance such as that generated by a nuclear exchange.'' This led the authors to conclude that irreversible climatic shifts cannot be ruled out.

Criticism by the Federation of American Scientists (FAS) for too `optimistic' NAS conclusions about potential impacts on remote, noncombatant countries became justified 7 years later. Invited to contribute on ozone impacts to a first international, comprehensive nuclear war risk study commissioned by the Royal Swedish Academy of Sciences and first published in its environmental journal *AMBIO* (1982), Paul Crutzen and John Birks were surprised to find unknown, severe effects due to the

†We are mournful about the loss of our friend and colleague Yuri Mikhailovich Svirezhev who passed away during the time of working on this paper. We dedicate our own contribution to his memory. (GS & PC)

 doi:10.1016/B978-0-444-63768-0.00611-9

smoke from `postnuclear' fires. A key mechanism like this was missing since the early speculations on changes of weather and climate due to nuclear war.

To grip consequences of the changing military policy away from `assured destruction', the US Office of Technology Assessment (OTA; 1979) had just analyzed a range of scenarios in an influential war risk study, from attacks on cities and oil refineries to one-sided counterforce and countervalue strikes. High-altitude bursts were mentioned as critical but not addressed, though doubts were cast on massive stratospheric ozone depletion. The chemical system was better known then, and high-yield weapons had given way to missiles with multiple warheads of lower yield each. Focusing on direct effects of nuclear attacks, civil defense, economic breakdown, recovery and societal impacts, OTA suggests that extreme uncertainties, and certainty about disastrous `minimum' consequences, both ``play a role in the deterrent effect of nuclear weapons''.

Other than OTA, the *AMBIO* study used a global reference exchange that comprises ground and tropospheric bursts with a total yield of about 5750 Mt. Crutzen and Birks confirmed both the NAS estimates of ozone depletion and the OTA doubts, that is, their advanced ozone model did not qualitatively alter the results, but the evolving strategic arsenals apparently did. In addition, they identified large-scale forest fires and intense urban and industrial conflagrations as sources of a long-lasting photochemical smog over large areas of the Northern Hemisphere. The sunlight needed for its formation, however, could be blocked by high amounts of smoke, notably when oil and gas fields or refineries were targeted. Smoke absorbs the short-wave solar flux and heats up, but interferes much less with the outgoing long-wave thermal radiation. The surface cools therefore, which would also suppress convection and reduce precipitation. Cold and darkness after a nuclear war would be severe for terrestrial ecosystems, but especially grave for oceanic food chains given the quick consumption of phytoplankton at the very base of the trophic web.

The anticipated climatic disruption triggered inquiry by Richard Turco, Owen Toon, Thomas Ackerman, James Pollack, and Carl Sagan (TTAPS), who were able to marshal the data for urban mass fires and fire storms not available in time to Crutzen and Birks, and to quantify the effect they coined `nuclear winter' for a broad range of scenarios (100 Mt `countercity', 5000 Mt `baseline', 10 000 Mt full-scale exchange, for example): a massive thermal inversion of the planetary atmosphere and its climatic consequences. A line of research which turned out to be essential addresses mass extinctions in Earth history, including hypotheses of extraterrestrial impacts and those that blame geological periods of enhanced volcanism or worldwide forest fires, maybe even all in combination. An authoritative circle of biologists and ecologists, led by a group including Paul Ehrlich, John Harte, Mark Harwell, Peter Raven, and George Woodwell, concluded that the extinction of man after a large nuclear war could no longer be ruled out. A public conference ``The World after Nuclear War'' (Washington, 31 October–1 November 1983) attracted unprecedented attention by communicating these findings, by the participation of scientists of both superpowers, and by a technique used on this occasion: a satellite TV bridge (Moscow–Washington) between both academies of sciences. Two research groups from either side of the globe exchanged their first `nuclear winter' results, based on global climate models, via this public `Moscow link:' Vladimir Aleksandrov and Georgiy Stenchikov, and Curt Covey, Steven Schneider and Starley Thompson.

Rethinking the Unthinkable

An unparalleled, open activity toward a worldwide process of research and education, which goes beyond the traditional understanding of scientific responsibility in terms of specialist's denial, the public action of the scientific elite, and the work in closed circles, was launched after delivery of the *AMBIO* study by the International Council of Scientific Unions (ICSU). Steered by the project ``Environmental Consequences of Nuclear War'' (ENUWAR) of the Scientific Committee on Problems of the Environment (SCOPE), resulted it by the end of 1985 in the two-volume report SCOPE-28. This study cannot offer an overall view on the complex entity `ecosphere' after nuclear war. None of the major physical control parameters (light, temperature, water) are expected to be disturbed that hard or weak at planetary scale so as to justify `simple' conclusions. A substantial impact on the stratospheric ozone budget, however, maintained by the US National Research Council (NRC; 1985), holds the more, since smoke-induced heating would change all chemical reaction rates.

Long-term problems due to radioactive exposure are borne in the selective vulnerability of forest communities. Nuclear war might change the biogeography of vast areas, notably where coniferous temperate forests dominate and the `radiation shock' combines with large-scale fire, climatic change, UV-B effects, etc. SCOPE-28 notes specific sensitivities: ``Temperature effects would be dominant for terrestrial ecosystems in the Northern Hemisphere and in the Tropics and subtropics; light reductions would be most important for oceanic ecosystems; precipitation effects would be more important to grasslands and to many Southern Hemisphere ecosystems.'' Such a `distributed vulnerability' structure and its more subtle patterns, the other side of the `biogeography' medal, reflects a range of stabilizing feedbacks against gradual or abrupt transitions in atmospheric or oceanic conditions and related compositional, thermal, meteorological, and hydrological regimes. The `acute' phase of nuclear winter would bear structural changes in the physical environment of a dimension that might transgress those stability limits, maybe at hemispheric scale. The crucial question is the one posed by the NAS 10 years before: Will new feedbacks take over to stabilize the system in a regime different from present day, or will it return? Latest, the transition to `chronic' response would be influenced by climate–biosphere feedbacks. The result of acute-phase environmental devastations, like the patchiness of surviving communities, may thus attain a structural role in shaping a postwar environment.

The vulnerability of the `noosphere' – taken as the complex entity of man's society and managed environment – against the direct effects of nuclear war is much higher than that of the (natural) ecosphere. Agricultural systems may only exist due to human maintenance. Worldwide disruption of functioning agriculture and food supply after nuclear war would expose the majority of

survivors to the risk of starvation. The OTA study suggests that this would even hold without severe environmental aftereffects. Climatic impacts that hit agriculture at vulnerable spots (length of the growing season, hydrological change, etc.) may bear just that sort of feedback, however, which keeps surviving humans stuck to marginal subsistence for any period relevant to societal restoration. The impact on the Southern Hemisphere of nuclear war in the north is a key issue in view of a postwar noosphere. Beyond the `import' of climatic effects due to interhemispheric smoke transport, with their ecological and agricultural consequences, a major disturbance would be caused by interruption of the lifeline of international trade, even if agricultural productivity could be maintained at a level of sufficiency. The risk consists in a large societal setback to which a modern society may not adapt without existential disturbance.

A convincing approach to environmental impacts addresses productivity limits and `convolves' this knowledge with a realistic range of stresses derived from climate model output. The resulting `response surfaces' to stress factors as expected after nuclear war (changes in temperature, light level, precipitation) are not of a simple shape for grassland ecosystems, notably when secondary productivity of herbivores is considered. Regulatory feedbacks act together, that is, stresses are not generally additive or even mutually enhancing (`synergistic'). The `nonsevere factor space' of functioning ecosystem response may have rather sharp boundaries, however, beyond which the `message' becomes simple: ecosystem productivity reduces almost abruptly to a level that would not support a human population. An important conclusion is on uncertainty again: a group of survivors who found an ecological niche in a postwar environment may be ``plunged into destruction by seemingly minor drift away from those conditions.'' Ecosystems become unpredictable when driven to marginal existence, in the vicinity of critical transition, by a changing climate.

In two authoritative assessments, the World Meteorological Organization (WMO) confirmed the risk of a severe smoke-induced climatic impact. Among the pertaining uncertainties, a potential modification of the hydrological cycle was emphasized. This concerns the `Hadley circulation' above all, a double-cell of upward and poleward circulation (in the zonal mean) flanking the meteorological equator, which is driven by the strongest heating there. As the season advances, the southern `Hadley cell' shifts northward and blows up to form the `monsoon cell' in boreal summer, with upward legs as far north as the Tibetan and Mexican plateaus. A smoke veil above would attenuate this structure, that is, weaken or disrupt the monsoons, but depending on season, injection heights, and location of the smoke source, the Hadley circulation may also become enhanced. The WMO assessments posed into doubt that climate models may reach the required realism and reliability soon, but confirmed both a potential monsoon disruption in boreal summer and smoke lofting as well as transport into the Southern Hemisphere.

A minimum demand, the realistic simulation of seasonally varying rainfall, is not easily met by global climate models. Even more challenging is the agriculturally important intraseasonal activity, notably the active–break cycles of the major monsoon branches and their dynamic interplay. Key knowledge about monsoon dynamics, and thus about the atmospheric hydrological cycle and its interactions, did just settle when the scientific consensus formed about major climatic effects of nuclear war. This bears potential for surprise, and the consensus may deserve further development just where it directly concerns half the world population. Abrupt onset and retreat of the boreal summer monsoon are known for decades, its oscillatory (interhemispheric) nature since the mid-1970s. These are features typical of a dynamic system that passes a critical transition. Long-term consequences for man and the biosphere of the climatic response to nuclear war may thus be borne in the potential for structural recovery of the present-day `monsoon climate' on Earth. This includes monsoon interactions with the El Niño–Southern Oscillation (ENSO) system. Both dynamic subsystems mediate climatic and environmental impacts on the Southern Hemisphere, beyond the more direct effects of interhemispheric smoke transport.

SCOPE successor studies to ENUWAR (1982–88) took another turn: the projects RADPATH (1988–93) and RADTEST (1993–99) addressed the pathways of radionuclides across the environment, exemplified by field studies into the consequences of the 1986 Chernobyl nuclear reactor accident and at selected nuclear test sites worldwide. These projects mounted a substantial database, improved the knowledge of processes, and identified gaps in understanding the biogeochemical dispersion of radionuclides. All three projects were led by Sir Frederick Warner. Their documented results, SCOPE report nos. 28, 50, and 59, are reference sources for the state of scientific knowledge toward the turn of the twentieth century about the gravest risk and challenge of its second half – the `doomsday' of man in an all-out nuclear conflict.

Behind and Beyond the Scenarios

The idea of a `doomsday machine' as an *ultima ratio* of deterrence is due to Herman Kahn. As a `terminal' retaliation should deterrence fail, such a hypothetical device was thought to automatically kill the majority of mankind, if not the species of man or all life on Earth. MAD was a sort of `homicide pact' indeed, settled by the Antiballistic Missile Treaty of 1972 (which allowed one BMD system at either side). Negotiations could give MAD a frame as long as it was accepted as a matter of fact and a relatively stable island was sought within the sea of inherent risks. In a severe crisis, however, a strategic exchange could have been initiated just by technical failure, misinterpretation, false information, or madness. Aimed to balance Soviet conventional forces, the US nuclear guarantee for Western Europe established the principal context of the doctrine of extended deterrence. The ability to control escalation, a prerequisite of this posture, was its dilemma as well. The myth, the adversaries in a nuclear war could climb a fictitious `escalation ladder' up and down at will, is not backed by any realistic view on the dynamics of escalation, be it only due to the vulnerability of the very means of control, the C^3I systems, which are primary targets in the earliest phase of war. Moreover, tactical nuclear weapons are an escalation-prone arming *per se*. Their massive deployment along the European front made an early,

uncontrolled use in any armed conflict nearly certain. Postures other than MAD were also delusionary due to the `third power problem': the nuclear forces of Britain and France, maintained in part in recognition of the US dilemma with extended deterrence, were `MAD forces' by intention, with a substantial destruction potential. `Escalation control' and `limited nuclear war' were sold by a `nuclear utilization theory' (NUT) as alternatives to MAD. Soviet strategic forces in `launch on warning' alert, however, and a doctrine of earliest possible, massive infliction of (not just response to) any nuclear attack would have left no space for bargaining after crossing the threshold to war. NUT did not replace MAD, but increased the risk of strategic instability.

When Herman Kahn died on 3 July 1983, a revision of his classic *Thinking about the Unthinkable* had been caught up with `nuclear winter'. In a comment, the editors admit strategic consequences, excepting the `war fighting' postures. A similar view was held in a brief report delivered by the US Secretary of Defense, Caspar Weinberger. It focuses on the early TTAPS study and uncertainties discussed there, cites with the same bias the reasoning of the NRC study, `massacres' Soviet contributions as `propaganda', and praises escalation control as one of the means to avoid nuclear winter. That resistance of the military bureaucracy to new knowledge drives the `overkill' arsenals beyond any justification shows also the example of the Pacific-Sierra Research Corporation, where smoke emissions and fire effects have been studied with a primary view on target planning for nuclear war: the `blast model' of casualty estimation survived any `fiery' challenge. For a 10 000 Mt war, the World Health Organization (WHO) estimated a short-term toll of 2.2–2.5 billion casualties, with a ratio of deaths to injured from 1.1 to 1.6. Lacking appropriate medical care, many of the injured would be doomed to die. Immediate casualty estimates of the Greater London Area War Risk Study (GLAWARS; 1986), the most comprehensive public assessment of the impact of nuclear war on a region, range from 1 to 6.2 millions (97%) of the London population. At a symposium at the NAS Institute of Medicine (IOM; September 1985) such estimates were challenged by a new model that takes `postnuclear' fires into account. Immediate fatalities had been underestimated by a factor of 2 or more when `only' prompt radiation, heat and blast waves, as well as local radioactive fallout were considered (blast model). The lower-edge figures for London increase substantially when using the `conflagration model'.

Difficulties in `translating' climatic into health effects are partly due to missing local information, neither provided by climate models nor easily derived: fog or haze, storminess, chemical and radioactive load of precipitation, etc. For the longer term, GLAWARS' gravest concern is food supply for survivors. Genuine medical aspects include enteric diseases and those spread by insects or due to poor sanitation and nutrition, all favored in victims who became `immunocompromised'. The key point here, also identified at the IOM symposium, is just the combined action of stresses in the nuclear aftermath to impair the immune system. Factors causing immune suppression include radioactive and UV-B radiation, malnutrition, burns and trauma, as well as psychosocial stress. Clinical evidence indicates that these factors all converge in their action on a single element of the immune system, the T-lymphocyte, of which also the `helper-to-suppressor ratio' is crucial. The Acquired Immune Deficiency Syndrome (AIDS) is characterized by deficiencies of the T-lymphocyte variety similar to those expected due to the combined stresses after nuclear war. The list of factors is certainly not exhaustive. The `clinical record' of today's monsoon and ENSO variability, from lasting hot-dry to torrential flooding, should bear medical implications of structural impacts on the tropic–subtropical climate. Coming to grips with these dynamic systems challenges climate modeling today, as did a smoky atmosphere in the 1980s.

`Nuclear Winter' Modeling – A Sketch

To follow solar and thermal radiations through a smoke- and dust-laden atmosphere, TTAPS had used a height-resolved (one-dimensional; 1-D) radiative–convective model (RCM) with annual mean insolation. An RCM describes these processes in greater detail than general circulation models (GCMs) do but misses their horizontal motions. Further 1-D and 2-D studies, at the Lawrence Livermore National Laboratory (LLNL), the US National Aeronautics and Space Administration (NASA), and the University of Maryland, helped clarifying basic effects and feedbacks including smoke uplift and changes in the snow-ice albedo, both of which may protract climatic effects. Like Covey, Schneider, and Thompson of the US National Center for Atmospheric Research (NCAR), who used a GCM of Australian origin with 7 atmospheric layers, Aleksandrov and Stenchikov of the Moscow Computing Center of the USSR Academy of Sciences (CCAS) confirmed TTAPS' major results. They used a coarse-resolution two-layer tropospheric GCM that had been adapted for different purposes in cooperation with Lawrence Gates of the Oregon State University (OSU), and equipped it with a simple ocean model. In addition to severe surface air temperature drops in continental interiors (mitigated near oceanic coasts) and large-scale thermal inversions of the atmosphere, clear signs of interhemispheric smoke transport due to a structural response of the Hadley circulation were noted by both groups.

These early 3-D `nuclear winter' studies were admittedly quick shots: their immobile smoke stayed uninfluenced by atmospheric motions, did not interact with the hydrological cycle to become washed out, and could not buoyantly rise by solar heating. Though state-of-the-art in the early 1980s, artificial model climates had also to be left behind for more realistic assessments. Michael MacCracken and John Walton of the LLNL and the CCAS team introduced more realistic feedbacks into their two-layer GCMs, whereas the NCAR group focused on the model `physics' first to keep firm footing. A visit in Moscow, coincidentally just before the 1983 Washington conference, triggered a study series by Stenchikov and Carl that addressed a `minimum' disturbance (without minimizing the problem), traced conditions for Southern Hemisphere impacts, and explored the transient response for hints to answer the 1975 NAS question on `postnuclear' climate relaxation. This induced a closer view on the complexity of the acute phase of perturbation and its implications. Just during startup of this common work in Berlin, on 31 March 1985, Vladimir Aleksandrov vanished without a trace in Madrid. The shock and irritation about his disappearance and fate (which made him even

an `unperson' for a couple of months) drove the first of those studies into an unexpected tension field. Nevertheless, it helped to overcome the Soviet `hard scenario' attitude and to tear down a barrier to public information at the German east side of the Iron Curtain.

The most detailed results were due to Thomas Malone and co-workers of the Los Alamos National Laboratory (LANL), who extended the NCAR GCM in the vertical to address the smoke transport more precisely. They confirmed the expected lofting into the lower stratosphere and thus a much prolonged residence and forcing. Though the NCAR authors fixed the important issue of `quick freeze' beneath smoke clouds, notably in the subtropics and Tropics at startup of interhemispheric transport, a controversy arose from their inquiries suggesting change of the popular metaphor into `nuclear fall'. Until 1987, persistent efforts to deblur longer-term effects due to the oceanic response have only been undertaken at the CCAS. In a more realistic atmosphere–ocean GCM study, virtually the last `nuclear winter' publication for 15 years, Steve Ghan confirms Alan Robock's (1-D) finding that the acute-phase ocean and sea-ice response may bear climatic impacts for years.

Regional Conflicts and Their Global Effects

The `doomsday scenario', executed by retreating Iraqi troops in February 1991 in setting the Kuwaiti oil fields alight, was meant as a modern version of Kahn's ultimate deterrent – an idea that failed. Two climate modeling responses, from the United Kingdom Meteorological Office and the Max Planck Institute for Meteorology, denied an attenuating impact on the Indian monsoon (a concern that had been expressed before). Successors of their GCMs did correctly represent the major Asian rainbelts as part of a planetary system, and their seasonal migration, but not the seasonal mean distribution, to say nothing about intraseasonal activity. Just those 30–60-day active–break monsoon cycles, including realistic motions of the major Asian systems, were now found in the Berlin version (`CCAS-B') of the CCAS GCM in an own Kuwait oil well fire study. This GCM version is a completely regenerated, flexible tool of dynamic systems analysis. Its boreal summer monsoons turned out indeed to be part of an interhemispheric, oscillatory seasonal climate regime between critical transitions in June and September. The Kuwait oil fire smoke caused a regional lower-troposphere heating anomaly, and thus an `exciting' disturbance that fanned the GCM's dynamics in a way not dissimilar to the observed 1991 season. Such a type of monsoon climate may thus be the `playing ground' for martial adventures seizing the source regions of the atmospheric water cycle. Its structural robustness is unknown.

The theme is again put on the agenda by recent studies into the climatic effects of a potential regional nuclear conflict of 1.5 Mt `size' in Southeast Asia, using the full atmosphere–ocean GCM with high vertical resolution of NASA's Goddard Institute of Space Studies (GISS), which has been successfully applied to study the climatic impact of volcanic eruptions. The GISS model shows extremely long smoke residence times, up to a decade, due to efficient lofting into the upper stratosphere, all year round in these latitudes. The surface air temperature drop is much less than in the `nuclear winter' case, of course, but still considerable if compared with the climate record: a global cooling from 1.25 to 0.5 K over a decade, with minima of several kelvin (degrees centigrade) over large areas of North America and Eurasia. A 10% weakening of the global precipitation is concentrated in the Tropics, but substantial (seasonal mean) reductions of the Asian subtropical summer monsoons are also found, with potentially serious human impacts.

Final Remarks

The scientific consensus as settled on the pages of SCOPE-28 was a snapshot taken from a dynamic research process. Shortly after the second edition, the Cold War ended, and modeling the climatic response to massive smoke injections was terminated just when it had reached more firm grounds. The theme was picked up not before another recent revision using the GISS model. Questions like that of the 1975 NAS study on climate relaxation remain unanswered as yet. Summarizing the status of the smoke source term discussion in their last common paper, though, TTAPS had shown that figures which were finally used in the climate model studies of the 1980s remained in the vicinity of earlier assumptions – a consequence of mutually balancing changes in detail. It has been learnt, for example, that smoke consists of fractal aggregates which have little in common with the earlier picture of largely spherical objects. This reduces the rate at which their short-wave absorptivity decreases and prolongs the direct radiative forcing of climatic effects. The debate about nuclear `winter' or `fall' occupied the community but did not fundamentally change the perspective as well. A detailed study of atmospheric coastal flow fields did not even confirm a mitigating oceanic impact on the surface air temperature drop over land.

We do not mirror and discuss the points here that have been made with due justification concerning the political response to nuclear winter. Science itself is the addressee of a disturbing question: Was there a potential to substantially influence public and strategic thinking by timely, deliberate inquiry? A `doomsday potential' was inherent to nuclear deterrence since the 1960s, at the latest, and it may be questioned that the `policy war' between MAD and NUT was predicated to end at the terms of the war-fighting strategists. Game theory was abused to justify NUT, risky nuclear weapons tests were conducted, and the Cuban missile crisis made humankind totter at the brink of its ultimate catastrophe. Though lately a result of the arms race, MAD was a vulnerable and immoral posture. Remarkable activities of the 1960s notwithstanding, though, did nuclear deterrence and nuclear war become great themes for the general scientific community only during the 1980s. A largely unmonitored evolution toward `wars of the

twenty-first century' is likewise a risky habit. It has `tradition' in military politics to occupy gray zones of knowledge, and in scientific `surveillance' to lag behind the arsenals and strategies of war.

Gaia Hypothesis

PJ Boston, New Mexico Institute of Mining and Technology, Socorro, NM, USA

Introduction

The Gaia hypothesis, named after the ancient Greek goddess of Earth, posits that Earth and its biological systems behave as a huge single entity. This entity has closely controlled self-regulatory negative feedback loops that keep the conditions on the planet within boundaries that are favorable to life. Introduced in the early 1970s, the idea was conceived by chemist and inventor James E. Lovelock and biologist Lynn Margulis. This new way of looking at global ecology and evolution differs from the classical picture of ecology as a biological response to a menu of physical conditions. The idea of co-evolution of biology and the physical environment where each influences the other was suggested as early as the mid-1700s, but never as strongly as Gaia, which claims the power of biology to control the nonliving environment. More recently, the terms Gaian science or Gaian theory have become more common than the original Gaia hypothesis because of modifications in response to criticisms and expansion of our scientific understanding.

Gaia – Original Versions

In the late 1960s, James Lovelock was working for NASA on life detection methods for Mars. With his chemistry training, this experience caused him to think deeply about what makes Earth different from Mars or her other neighbors in the solar system and the role that life might be playing in those differences. The imprint that life leaves on the chemistry of our own atmosphere stood out as a significant fingerprint of Earth's ecosystems. These musings led to the formulation of the first incarnation of the Gaia hypothesis. The early notion advanced by Lovelock is summarized in his 1972 paper, ``Life regulates the climate and the chemical composition of the atmosphere at an optimum for itself.'' Novelist William Golding, who lived near Lovelock, suggested naming the idea after the Greek goddess. This was lovely and poetic, but probably contributed to early perceptions that the concept was cultic or New Age, not scientific.

After significant initial criticism, Lovelock and Margulis realized the flaws in the initial version that laid them open to criticism. Biologist Ford Doolittle was particularly helpful in pointing out that the hypothesis as stated required foresight and planning on the part of collections of organisms toward a common goal. This appeared to be a teleological (purposeful or designed) notion that is not in keeping with the scientific view of causality.

Later, the revised formulation appeared in a number of written and oral presentations that can be paraphrased as: ``The whole system of life and its material environment is self-regulating at a state comfortable for the organisms.'' This was eventually restated by Lovelock in 1988 in his book *The Ages of Gaia* as ``Living organisms and their material environment are tightly coupled. The coupled system is a superorganism, and as it evolves there emerges a new property, the ability to self-regulate climate and chemistry.'' Lynn Margulis, the innovator of the endosymbiotic theory of eukaryotic cell origins, emphasizes the role of symbiosis in biology. Her statements about Gaia usually include the phrase superorganismic system. In her view, evolution is the result of cooperation, not competition, and this is in keeping with the Gaian interpretation of global ecology.

The initial conception involved the idea of homeostasis, that is, regulation around a narrow range of physical variables and resistance to perturbation via cybernetic feedback loops. However, Margulis particularly argued that Gaian systems are rather homeorhetic, meaning that the Earth's atmosphere, hydrosphere, and lithosphere are regulated around set points that can change in time as the whole system evolves essentially through a life cycle. The basic logic of negative and positive feedback loops is illustrated in **Fig. 1**.

Possible Evidence of Gaian Mechanisms

Biogeochemistry and Gaia

The chemical disequilibrium of the Earth's atmosphere is the feature that first captured Lovelock's attention. He noticed that on Venus and Mars (planets apparently with no life at least on the surface) the atmospheres are primarily CO_2. On Earth, the dominant constituents are reactive species of nitrogen, oxygen, and minor constituents (methane, ammonia, nitrous oxide, etc.). In the absence of other factors, over time, one would predict that Earth would resemble her neighbor planets but she does not. According to Gaia, life is the factor that maintains this disequilibrium over time. **Table 1** shows various parameters that have been suggested as possibly Gaia-controlled. The chemical compounds involved and their various reactions and fluxes control the large-scale biogeochemical cycles that enable Earth to constantly recycle materials and make them available for succeeding generations of life.

 doi:10.1016/B978-0-444-63768-0.00735-6

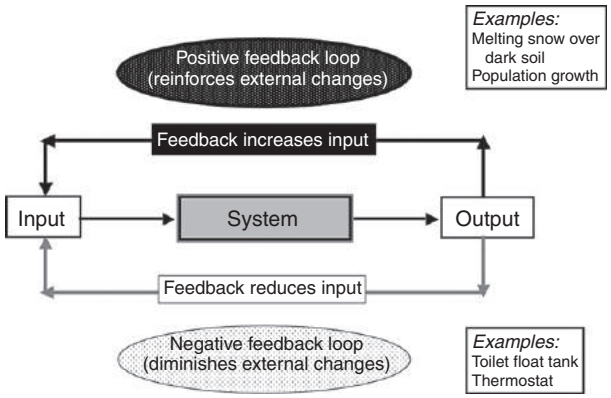

Fig. 1 Logic of negative and positive feedback loops.

Table 1 Proposed Gaian-controlled parameters

- Temperature, gas balance, greenhouse feedback
- Plant-albedo feedback (e.g., Daisyworld-like mechanisms)
- Evapotranspiration, latent heat, climate feedback
- Photosynthetic manipulation of air composition
- Dimethyl sulfide (DMS), marine cloud, algae association
- Microbial respiration rates and the carbon cycle
- Methanogenesis and greenhouse warming
- Carbon dioxide levels and carbonate cycle
- Carbonate-shelled organisms as long-term carbon sink
- Continental weathering rates via lichen, other microorganisms, etc.
- Oxygen levels, biomass burning feedback
- Ocean salinity levels

Bioweathering and Gaia

In 1989, Tyler Volk and Dave Schwartzman showed convincingly that the rock weathering rate increased by three orders of magnitude in the presence of life compared to the lifeless case. Gaian proponents viewed this as a major piece of supporting evidence in their contention that CO_2 effects on climate, known to be very powerful, could be significantly affected, even controlled, by the biologically enhanced rate of weathering. Lovelock has said of their work ``This is much more than is needed to enable a powerful physiological regulation of climate and carbon dioxide. We think it could account for the 300-fold decline in carbon dioxide since life began on Earth."

A Controversial Idea from the Beginning

Early Criticisms

Since its inception, the Gaia hypothesis has been controversial. For a few years, it was simply ignored. Further papers and presentations caught attention and the notion was widely castigated. It was criticized as being merely a restatement of ideas that already had a long history, as early as the work of James Hutton (1727–97), the founder of modern geoscience, who suggested that the study of Earth should be considered geophysiology. Further, Earth viewed as a single entity is in conflict with the fundamental ecological ideas of organisms engaged in Darwinian competition and narrowly defined survival and reproductive success. It has also been pointed out that maybe we do not need to invoke Gaia because proposed geochemical mechanisms can adequately explain many aspects of the Earth system without biological processes. Besides genuine weaknesses in the arguments, initial negative reactions to Gaia may in part be blamed on the lack of common language between Earth sciences and biology in the early 1970s.

Kirchner's Formulations

The best critical analysis of Gaian ideas was done by Jim Kirchner, at a Chapman Conference (American Geophysical Union) in San Diego in 1988 that was devoted to the scientific consideration of Gaia. He separated the jumble of ideas into four clear levels in order of increasing strength of claims from weak to strong (Table 2). These ranged from (1) `co-evolutionary Gaia' that merely

Table 2 The many types of Gaia according to Kirchner[a]

Hypothesis type	*Properties*	*Likely consensus*
Influential	Biology exerts significant influence over some aspects of theplanetary system	Testable and supported by evidence
Co-evolutionary	Darwinian process in which biota affects nonliving systems,in turn they affect biota	Testable and under active debate
Homeostatic	System is stabilized by negative feedback loops involvingbiota and physical/chemical systems	Testable and under active debate
Teleological	Conditions maintained by the biosphere for its own benefit	Testable, refuted by the Daisyworld demonstration
Optimizing	The biosphere directly manipulates its environment to provide optimum conditions for itself	Skeptically received, possibly not testable, not self-consistent

[a]Strength of statement in order from highest (influential) to lowest (optimizing).

claimed life and Earth had evolved together over time affecting each other; (2) `homeostatic Gaia' involving self-regulation around set points; (3) `geophysical Gaia', which overlapped significantly with the physical Earth sciences; and (4) the most extreme claim of `optimizing Gaia' that life was molding the planet's behavior into a state most favorable toward all life. The latter notion came in for the most criticism as being scientifically untestable and the most radical Gaian idea.

Further General Criticisms

Our planet has a long and dynamic history. How narrowly can Gaia be said to have constrained conditions? As we learn more about Earth's history, it is clear that huge changes have occurred in the climate, position of land masses, ocean currents, and other global-scale properties. For example, several times in the planet's history, we believe that it has been largely covered with ice. During the Mesozoic period, it appears that the planet was much warmer than it has been since. The atmosphere has evolved from anaerobic to a high level of free oxygen and many other major chemical changes have occurred. Against the dramatic backdrop of these changes, it is hard to claim that Gaia has held conditions constant and the window of variability seems very large even to qualify as homeorhesis.

Gaia as an organism has foundered on another point. Organisms reproduce. How can an entity the size of a whole planet reproduce? Gaia has not yet done so, but it has been suggested by some that space colonization may be the biosphere's first attempt to reproduce itself on other planetary bodies. The notion of Earth as superorganism may be specious and not central to the idea of global homeorhesis; thus, this may be a fairly trivial semantic criticism.

Because the notion has evoked visions of Gaia as the `mother goddess', as a benign entity and protector of life, it is appealing to people outside the scientific community. This has also been another point of attack for its critics, who view it as overly romanticized, more philosophical in nature, and scientifically untestable, thus, not of value in the strict scientific sense. If Gaia is the mother goddess, then her first-born were probably bacteria-like organisms who would be poisoned by our current oxygen-containing atmosphere. Her enormous family includes countless species whose individual needs and welfare conflict with each other. This has resulted in the natural extinctions of the bulk of all species that have ever arisen. The interpretation of such a system as benign or nurturing is stretching it too far.

Specific Criticisms

There are numerous specific criticisms that have been leveled against examples that Lovelock, Margulis, and other proponents have put forth as evidence for Gaia. Only one is given here for brevity. For example, Lovelock invoked Gaia to explain life's survival during the rise of oxygen in the early Earth atmosphere. Photosynthetically produced high levels of oxygen (the so-called `oxygen crisis') were lethal for the largely anaerobic lifeforms of the day. Ultimately, the oxygen atmosphere probably enabled a net increase in biodiversity and total biomass over time, but it spelled doom for many of the organisms then alive. If Gaia favors life, how can changes that favor some life but destroy large numbers of other organisms be reconciled? How can a mechanism be proposed that would amount to altruistic suicide on the part of many organisms on behalf of unrelated organisms? Kirchner summed up the dilemma in his 1989 paper, ``If the most destabilizing biotic event in Earth's history can be construed as evidence for Gaia, and the relative stability since then can also be cited as evidence for Gaia, one wonders what conceivable events could not be interpreted as supporting the Gaia hypothesis. If there are none, Gaia cannot be tested against the geologic record.... If Gaia stabilizes and Gaia destabilizes... is there any possible behavior which is not Gaian?"

If Gaia cannot be disproved in any case, then it does not meet the criterion for falsifiability developed by philosopher of science, Karl Popper, in the 1930s. An idea must, in principle, be able to be proved false for it to be considered testable. Popperian falsifiability has itself been attacked, notably by Alan Sokal and Jean Bricmont in their 1998 book, *Fashionable Nonsense*. Some argue that Popperian falsifiability is already biased toward only the methodology of reductionism, and that it may be inherently unable to fully define the essence of extremely complex and closely coupled systems, especially those that change over time in some sort of ontological process. Nevertheless, it is a useful indicator of whether a concept can be considered scientifically

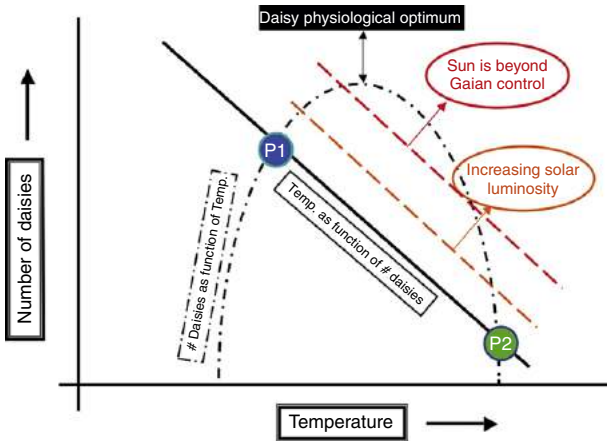

Fig. 2 The Daisyworld computer model.

testable at least in the narrow sense. The major result of Kirchner's criticism has resulted in attempts at crisper formulations of the ideas and has pushed Gaia to the weaker versions.

The highly reductionist geneticist Richard Dawkins believes that individual genes are in control of evolution and has entirely dismissed Gaia on that basis. Genes are grouped together into replicator packets. These are the functional units that Dawkins contends were both the first form of life and still remain the functional unit of selection. He dubs cells and organisms survival machines, and claims that they serve only to help the replicators propagate. Certainly any superorganismic concept violates Dawkins' notion of a single exclusive level of selection. Such an intensely reductionistic view does not take into account higher-order properties that may emerge from complex system interactions, and some scholars working on the mathematics of complex systems have in turn dismissed Dawkins' views as overly simplified.

Countering the reductionist view, J. Z. Young pointed out in the book *Doubt and Certainty in Science* that ``Biology, like physics, has ceased to be materialist. Its basic unit is a non-material entity, namely an organization.'' Here the emphasis is on pattern, because matter is frequently replaced and thus, transient, in biological processes. An organism is not a particular chunk of matter, but a persistent pattern through which material flows. With such a definition, the notion of the Earth system as a superorganism becomes less strained and does not require a slavish point-by-point comparison to the properties of individual organisms.

Daisyworld

Lovelock and his collaborators' greatest effort to counter the teleological criticism and show that undirected negative feedback can result in homeostatic regulation came in the form of a computer model, Daisyworld (Fig. 2). In the first and simplest version of the model, the imaginary planet Daisyworld has only one species of plant, white daisies. It has soil that is darker than the daisies. The star of this planet grows more and more luminous as we believe our sun to have done during the early history of the Earth. The relative abundance of daisies versus soil controls the temperature environment of the planet. The daisies have a physiological temperature window within which they are viable and reproductive. Using very simple rules, the differential albedos of soil and daisies combine to enable Daisyworld to remain habitable even as its sun is growing brighter. Of course, later versions of the model have added more biological variables and more complex physics of the environment, but the essence of the demonstration remains the same.

Where Is Gaian Science Headed?

Because of the global scale of Gaian processes, field observations of potential evidence supporting or refuting Gaia is difficult to obtain. Efforts continue sporadically to advance on this front, usually as a by-product of investigators' more mainstream activities. Possibly the most promising arena for testing Gaian ideas currently available lies in modeling and the understanding of complex systems. An early paper by Tregonning and Roberts in 1979 looked at how simple models of complex systems could develop homeostasis, and was seminal in early thinking about Gaia. Recently, the study of complex adaptive systems (CAS) has begun to advance our general understanding of the behavior of massively coupled complex systems. As this science progresses, insights applicable to testing Gaian predictions may well emerge.

Global Carbon Cycle 1: Short-Term Dynamics☆

GA Alexandrov, Russian Academy of Sciences, Moscow, Russia

Introduction

Short-term dynamics of the global carbon cycle is closely related to the concept of climate system: the totality of the atmosphere, hydrosphere, biosphere, and their interactions. Human activities have been substantially increasing the concentrations of carbon dioxide and other greenhouse gases in the atmosphere and thus inducing potentially adverse changes in the climate system. This tendency has become of public concern that led to the United Nations Framework Convention on Climate Change (UNFCCC). This convention suggests protection of carbon pools, enhancement of carbon sinks, and reduction of emissions from carbon sources.

Carbon Pools

Carbon pool (or reservoir, or storage) is a system that has the capacity to accumulate or release carbon. The absolute quantity of carbon held within at a specified time is called carbon stock. Transfer of carbon from one carbon pool to another is called carbon flux. Transfer from the atmosphere to any other carbon pool is said to be carbon sequestration. The addition of carbon to a pool is referred to as uptake.

Carbon Sink

Carbon sink is a process or mechanism that removes carbon dioxide from the atmosphere. A given carbon pool can be a sink, during a given time interval, if carbon inflow exceeds carbon outflow.

Carbon Source

Carbon source is a process or mechanism that releases carbon dioxide to the atmosphere. A given carbon pool can be a source, during a given time interval, if carbon outflow exceeds carbon inflow.

☆*Change History:* December 2015. GA Alexandrov updated the sections, further readings and Figure to this entire article.

Carbon Budget

The estimates of carbon stocks and carbon fluxes form the carbon budget, which is normally used as a kind of diagnostic tool in the studies of the short-term dynamics of the global carbon cycle.

Carbon Budget Components

The components of the global carbon budget may be subdivided into fossil and dynamic categories (Figure 1).

Fossil Components

The fossil components are naturally inert. The stock of fossil organic carbon and mineral carbonates (estimated at 65.5×10^6 PgC) is relatively constant and would not dramatically change within a century. The lithospheric part of the carbon cycle is very slow; all the fluxes are less than 1 PgC year^{-1}. For example, volcanic emissions are estimated at 0.15–0.25 PgC year^{-1}. Therefore, the turnover time of the storage amounts to millions or hundred millions of years.

Dynamic Components

The dynamic components are not inert. The carbon stocks in the atmosphere, ocean, soil, and vegetation remain constant as long as they are at dynamic equilibrium.

Atmosphere

The turnover time of atmospheric carbon is very short. It is less than 5 years. Therefore, the balance of atmospheric carbon strongly depends on the gas exchange between the atmosphere and ocean as well as on the gas exchange between the atmosphere and terrestrial ecosystems.

Atmospheric CO_2 content

The atmospheric content of carbon dioxide gradually increased from 680 PgC in 1960–69 to 760 PgC in 1990–99 and reached 830 PgC in 2011. The rate of increase was 3.2 ± 0.2 PgC year^{-1} during 1980–89, 3.1 ± 0.2 PgC year^{-1} during 1990–99, 4.0 ± 0.2 PgC year^{-1} during 2000–09, and 4.3 ± 0.2 PgC year^{-1} during 2002–11. Interannual variations were significantly wider. The lowest rate of 1.9 PgC year^{-1} was observed in 1992, and the highest rate of 6.0 PgC year^{-1} was observed in 1998. Since fossil fuel emission does not show short-term variability of this magnitude, the interannual variations are normally attributed to the climate-induced variations in the land–atmosphere flux, or the ocean–atmosphere flux, or both.

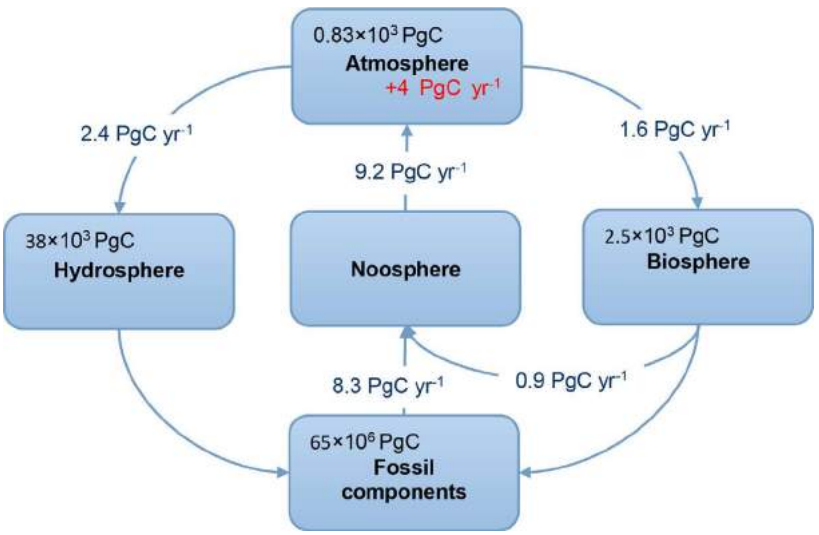

Figure 1 Dynamic components of the global carbon cycle.

Air/sea exchange

The gross carbon exchange between the atmosphere and ocean is estimated at 80 PgC year^{-1}. Since atmospheric CO_2 concentration is increasing, there is net uptake of carbon by the ocean, driven by the atmosphere–ocean difference in partial pressure of CO_2. The magnitude of the uptake slightly increases on decadal scale: 2.0 ± 0.7 PgC year^{-1} for 1980–89, 2.2 ± 0.7 PgC year^{-1} for 1990–99, 2.3 ± 0.7 PgC year^{-1} for 2000–09, 2.4 ± 0.7 PgC year^{-1} for 2002–11. The weak upward trend in the the magnitude of net oceanic uptake is attributed to large scale climate re-organizations.

Air/land exchange

The gross carbon exchange between the atmosphere and land is estimated at 60 PgC year^{-1}. Despite the net release of CO_2 associated with land use, the balance between emissions from fossil fuel combustion, net ocean uptake, and accumulation in the atmosphere is positive suggesting net uptake of carbon by the land. The magnitude of the net terrestrial uptake dramatically increased in 1990s, and remained quite stable in this century: 0.1 ± 0.8 PgC year^{-1} for 1980–89, 1.1 ± 0.9 PgC year^{-1} for 1990–99, 1.5 ± 0.9 PgC year^{-1} for 2000–09, 1.6 ± 1.0 PgC year^{-1} for 2002–11.

Ocean

The total amount of inorganic carbon in the sea is about 38,000 PgC. This includes dissolved carbon dioxide, HCO_3^-, and CO_3^{2-}. The dissolved carbon dioxide forms only one per mille of the total. Most of carbon is stored in the form of HCO_3^-. The share of CO_3^{2-} is less than 15% (about 13%).

The ocean storage is divided into surface water and deep sea. The surface water is in turn divided into cold surface water and warm surface water, both extending to 75 m depth – that is, the depth of seasonal thermocline. Warm surface water is a part of ocean between 40°N and 40°S where a well-defined permanent thermocline exists. Cold surface water is the rest of the ocean, which exchanges with deeper layers of the ocean by convection.

The surface water contains about 10% more carbon than the atmosphere that constitutes about 2% of the total carbon content in the ocean.

The concentration of dissolved carbon dioxide is proportional to its partial pressure above ocean surface (P_{CO_2}). The coefficient of proportionality is called solubility coefficient. The solubility of CO_2 varies with temperature suggesting a transfer of CO_2 in the atmosphere from warm regions to polar regions where CO_2 solubility is higher. This atmospheric transfer is balanced by the backward net oceanic transfer, the so-called 'conveyer belt'.

The dissolved carbon dioxide forms about 0.5% of the total dissolved inorganic carbon (DIC). The concentration of DIC also depends on P_{CO_2}, but in a more complicated way:

$$\frac{\Delta \mathrm{DIC}}{\mathrm{DIC}} = \frac{1}{\xi} \frac{\Delta P_{CO_2}}{P_{CO_2}}$$

where ξ is the buffer factor.

The surface water contains a significant amount of organic carbon: about 50 PgC of dissolved organic carbon (DOC), 30 PgC of particulate organic carbon (POC), and 3 PgC of plankton. The rate of photosynthesis varies from 0.06 gC m^{-2} day^{-1} in the desert regions which are characterized by downwelling and lack of nutrients to 0.6 gC m^{-2} day^{-1} in areas of intense upwelling. The total primary production amounts to 50 PgC year^{-1}. About 25% of the primary production reaches the deep water that contains about 700 PgC of DOC.

Land

Terrestrial ecosystems store about 2500 PgC: 500 PgC in vegetation and 2000 PgC in soil. The amount of carbon stored in vegetation varies significantly depending on vegetation type. Forests generally store ten times more carbon than grasslands. However, forest soils do not necessarily contain more carbon than grassland soils, for carbon stock in soil depends on the factors that control the rate of organic matter decomposition.

The global net production of organic matter by plants, net primary production (NPP), is about 60 PgC year^{-1}. This input to the pool of living organic matter is compensated by litter fall. The residence time of the pool is 1 year in case of annual grasslands, but it may be 100 years in case of pristine forests.

The litter fall in its turn is the input to the pool of nonliving organic matter, which is compensated by heterotrophic respiration (i.e., by CO_2 released with the respiration of soil biota decomposing organic debris). The net accumulation of carbon by ecosystem, including both soil and vegetation, is called net ecosystem production (NEP).

NEP of an undisturbed ecosystem should be close to 0. However, most of ecosystems are disturbed in some way (harvesting, fire, etc.). Therefore, global NEP is estimated at 10 PgC year^{-1}. This value characterizes nonrespiratory losses such as release of carbon due to forest fires, or relocation of carbon to wood products and other components of urban metabolism.

The net accumulation of carbon that includes both respiratory and nonrespiratory losses is called net biome production (NBP). NBP for a relatively short period of time may differ from 0, reflecting continued effect of the losses occurred in the past. Thus, global NBP (i.e., net terrestrial uptake) for the decade 2002–11 has been estimated to be positive (1.6 ± 0.7 PgC year^{-1}).

Human Intervention

Fossil Fuel Combustion and Cement Production

The main anthropogenic source of CO_2 emissions is the combustion of carbon-based fuels. Since 1860, industrialization has progressed with an increase in the use of fuels – especially fossil fuels – and a corresponding increase in CO_2 emissions. The growth has been steady and exponential, interrupted only by the two World Wars and the Great Crash of 1929. In 2103 the emissions reached a maximum of 9.9 PgC year^{-1} (0.2 PgC year^{-1} of this was from cement production). The average value of emissions increased from 5.5 ± 0.4 PgC year^{-1} in 1980s to 8.3 ± 0.7 PgC year^{-1} in 2002–11.

Land-Use Change

About 10–30% of the current total anthropogenic emissions of CO_2 are estimated to be caused by land-use conversion. In the historical perspective, the share of land use is larger. From 1750 to 2011, 375 ± 30 PgC has been emitted as a result of fossil fuel burning, and 180 ± 55 PgC as a result of land-use change.

The current net land-use flux comprises the balance of positive terms due to deforestation and negative terms due to regrowth on abandoned agricultural land. During 1980s the net land-use flux of 1.4 ± 0.8 PgC year^{-1} was almost entirely due to deforestation of tropical regions. Temperate forests show approximate balance between carbon uptake in regrowing forests and carbon lost in oxidation of wood products. Since the rates of deforestation are declining, the net land-use flux was slightly smaller in the beginning of this century: 1.1 ± 0.8 PgC year^{-1} in 2000–09 and 0.9 ± 0.8 PgC year^{-1} in 2002–11.

Biosphere Response

Growth Rate of Atmospheric CO_2

From 1750 to 2011, atmospheric concentration of CO_2 increased by 40%, from 280 to 390 ppm, that corresponds to 240 ± 10 PgC increase in the atmospheric content of CO_2 and to 43% of the total anthropogenic emission over this time. More than half (57%) of the anthropogenic emission has been taken up in the ocean and the terrestrial ecosystems.

Net Oceanic Uptake

The cumulative ocean uptake during the period from 1750 to 2011 is estimated to be 155 ± 30 PgC – that is, about 30% of anthropogenic emission has been taken up in the ocean.

The fraction of anthropogenic CO_2 that is taken up in the ocean declines with increasing CO_2 concentration in the atmosphere. Increasing atmospheric CO_2 concentration maintains the atmosphere–ocean difference in partial pressure of CO_2 that causes net uptake of carbon by the ocean. However, increasing DIC reduces the buffer capacity of the carbonate system, and thus weakens the capacity of the oceanic uptake.

The capacity of the ocean uptake is also sensitive to the rate of increase of atmospheric CO_2. The uptake is limited with the rate of mixing between deep water and surface water, and hence the lower the growth rate of atmospheric CO_2, the higher the rate of CO_2 sequestration.

Residual Terrestrial Uptake

Balancing the carbon budget for the period from 1750 to 2011 yields a global net terrestrial source of 30 ± 45 PgC. Hence, a residual terrestrial sink of 160 ± 90 PgC is required to reconcile the difference between the relatively small net terrestrial source and the relatively large terrestrial source resulted from land-use change (180 ± 80 PgC). This residual terrestrial uptake is sometime referred to as the 'missing carbon sink', although it can be attributed to well-known biophysical mechanisms.

Carbon dioxide fertilization

Stimulation of photosynthesis at higher CO_2 is one of the well-known mechanisms to which the 'missing carbon sink' is normally attributed. Carbon dioxide fertilization effect on plant productivity is not linear:

$$\frac{\Delta \mathrm{NPP}}{\mathrm{NPP}} = \gamma \ln\left(1 + \frac{\Delta P_{\mathrm{CO_2}}}{P_{\mathrm{CO_2}}}\right)$$

It is weakening at high atmospheric concentration of CO_2. If $\gamma = 0.35$, then NPP increases by 24%, when CO_2 increases two times. Thus, the growth of atmospheric concentration of CO_2 enhanced plant productivity by 10% or little more in comparison to 1750.

Carbon dioxide fertilization produces only an excess amount of organic matter. The mechanism of carbon sequestration associated with CO_2 growth is more complicated. Carbon sequestration stems from imbalance between production and decomposition of organic matter – that is, from NEP. NEP approaches to naught when ecosystem approaches to equilibrium. Continuous

growth of CO_2 maintains ecosystem disequilibrium. Therefore, the rate of carbon sequestration is determined by the rate of atmospheric CO_2 growth and the rate of carbon turnover in terrestrial ecosystems.

Nitrogen deposition

Production of organic matter is generally limited with nitrogen and some other nutrients. Therefore, NPP is expected to increase with a rapid growth in reactive nitrogen deposition over the last 150 years. Reactive nitrogen is released into the atmosphere in the form of nitrogen oxides (NO_x) during fossil fuel and biomass combustion. The annual deposition even in rural areas may amount to 40 kg ha^{-1}. Another source (mainly of ammonia) is animal husbandry and fertilizer use. The nitrogen deposition mainly affects ecosystems close to cities and industrial centers as well as in the vicinity of intensive agricultural enterprises.

Land-use management

Agricultural and forest management practices significantly affect carbon stocks in managed ecosystems. These practices dramatically changed since 1750; they began to be oriented to the sustainable use of natural resources. A forest that is managed in sustainable manner operates as a machine that removes carbon from atmosphere and exports it as forest products. Similarly, alteration of tillage practices leads to protection and increase of soil carbon content.

Concluding Remarks

This article presents an overview of basic biogeochemical concepts related to short-term dynamics of global carbon cycle. It is intended to make short-term dynamics of global carbon cycle understandable to ecologists who are involved in carbon management and related ecological applications and targeted to a reader who has basic background in ecology or is familiar with the basic ideas of sustainable development, biosphere equilibrium, and environmental protection. The 'Further reading' list provides the information on a broad context in which the basic concepts overviewed in this article (or their modifications) normally appear.

Global Negative Emission Land Use Scenarios and Their Ecological Implications

Yoshiki Yamagata, National Institute for Environmental Studies, Tsukuba, Japan

Glossary

Negative emission In order to limit global temperature rises to below 2°C, "negative emissions" technologies are expected to be applied to remove carbon from the atmosphere. This can be done easily at small scale by restoring forests, planting trees to absorb carbon dioxide from the atmosphere. However, most of the current IPCC scenario suggest that large scale deployment of negative emission is necessary to achieve the low carbon target by growing bioenergy crop and using bioenergy, capturing the carbon emitted and pumping it into underground geological reservoirs as bioenergy, carbon, capture and storage (BECCS).

Land use scenario Land use has been changing due to the change of socio-economic development as well as natural environment. IPCC and other scientific assessments are using land use scenarios for the future to assess the impact of climate change and evaluate the potential of mitigation and adaptation policies. Most land use changes are induced by mainly by economic growth, migration or agricultural and industrial productivity changes. Scenario analysis comparing business as usual and possible narrative cases allow assessing the influence of policies.

Ecosystem services There are many human benefits that are contributed as services from the natural ecosystems. Such ecosystem services are also supplied from semi-natural agroecosystems, forest ecosystems, grassland ecosystems and aquatic ecosystems. These benefits are in combination recognized Nature's Contribution to People (NCP) in the recent IPBES assessment report. In general, ecosystem services are grouped into four categories: provisioning (e.g., production of food and water); regulating (e.g., control of climate and disease); supporting (e.g., nutrient cycles and crop pollination); and cultural (e.g., such as spiritual and recreational benefits). Usually these values are not capitalized and often neglected. There have been a lot of economic studies to support decision-makers by valuing ecosystem services in economic term.

Paris agreement At the Paris climate conference (COP21) in December 2015, 195 countries adopted this global climate deal. The agreement sets out to avoid dangerous climate change by limiting global warming to long-term goal of keeping the increase in global average temperature to well below 2°C above pre-industrial levels. It also aim to limit the increase to 1.5°C, since this would significantly reduce risks and the impacts of climate change. There is the need for global emissions to peak as soon as possible to undertake rapid reductions thereafter. Before the Paris conference, countries submitted comprehensive national climate action plans (INDCs).

SDGs In September 2015, the UN committed to the 2030 agenda for sustainable development (2030 agenda) containing 17 Goals and 169 targets called sustainable development goals (SDGs). SDGs include: poverty, hunger, wellbeing, education, equity, water and sanitation, energy, economic growth, employment, infrastructure and innovation, sustainable cities, sustainable consumption and production, climate change, oceans, terrestrial ecosystems, societies, global partnership. Most of goals need to be achieved by addressing the need for sustainable development that works for all people. Encompassing universal, transformative, inclusive and integrated goals and targets is one of the most comprehensive global agenda adopted.

Introduction

In December 2015, the Conference of the Parties (COP) to the United Nations Framework Convention on Climate Change (UNFCCC) adopted the "Paris Agreement" that stipulates "holding the increase in the global average temperature to well below 2°C above preindustrial levels" (Article 2). Considering the risk of crossing the dangerous tipping point of abrupt and irreversible change above a certain temperature (Schellnhuber *et al.*, 2016; Schleussner *et al.*, 2016), this "2°C target," or even "1.5°C target" if possible, is internationally agreed as a very important global common goal to achieve.

In fact, from a scenario point of view, "2°C target" corresponds to the IPCC representative concentration pathway (RCP) 2.6 scenario (van Vuuren *et al.*, 2011). According to the underlying scenarios corresponding to the RCP2.6 scenario, it is supposed that the global total carbon emission (human emissions minus natural absorption) will go negative near the end of this century (Fuss *et al.*, 2014).

On the other hand, regarding more comprehensive global sustainability, heads of states also agreed on yet another very important treaty in the same year. Namely, on September 25, 2015, the United Nations adopted the "sustainable development goals (SDGs)" which demand all UN countries to make all efforts to end poverty, protect the planet, and ensure prosperity for all as part of a new sustainable development agenda. Although the 17 SDG compliances are voluntary, each goal has specific targets (measured by corresponding indicators) to be achieved by 2030. Actually, "Climate action" is the 13th goal of the 17 SDGs. So, the

 doi:10.1016/B978-0-12-409548-9.10893-0

climate change mitigation policy (until 2030) of the Paris Agreement is a part of SDGs. Under the SDGs, it is recommended that governments achieve all goals at the same time. However, in fact, there are trade-offs and synergies between the goals. So, we need to understand the interactions between the goals to come up with a better scenario to achieve the SDGs. This is the background why we need to study the impacts of climate change mitigation for other types of sustainability such as water, food and ecosystems.

In fact, considering the cumulative emission of anthropogenic greenhouse gases (GHGs) until today and projected emissions accompanying human activities in the future (Creutzig *et al.*, 2016), it is quite challenging to achieve the "2°C target" by only reducing GHGs. In this regard, BioEnergy with Carbon Capture and Storage (BECCS) is highlighted as a promising "Negative Emission" technology which allows us both to earn more carbon-neutral energy and reduce atmospheric CO_2 concentrations at the same time (Smith *et al.*, 2016). The technology would produce electricity by bioenergy combustion, then capture CO_2 emissions and store it into deep ground.

However, producing a massive amount of bioenergy crop requires the vast use of agricultural cropland. Smith *et al.* (2016) estimated that the mean land requirement for BECCS would be 380–700 106 ha in 2100. The land requirement would be partly suppressed by enhancing agricultural productivity by irrigation. Hejazi *et al.* (2015) projected the total water use in the United States under a stringent GHG emission reduction policy. They found that the policy could increase water stress more than the climate change itself mainly due to bioenergy irrigation. Bonsch *et al.* (2016) estimated how much land and water was required to produce 300 EJ $year^{-1}$ of bioenergy. They found that 486 106 ha of cropland and 3000 km^3 $year^{-1}$ of irrigation water withdrawal were needed. In case no irrigation was applied, 41% of cropland was additionally required (total 689 106 ha).

Although the abovementioned two studies have quantified the trade-offs between mitigation and water scarcity, and land and water, respectively, further investigation is needed to explore whether irrigation water is stably and sustainably available. From the perspective of its impact on land use and ecosystem services, deployment of BECCS may have ramifications such as loss of biodiversity, deterioration of water quality, and additional emissions of nitrous oxide to the atmosphere (Melillo *et al.*, 2009; Smith *et al.*, 2016). Expansion of plantation of bioenergy crops (e.g., oil-palm) would exert influences on atmospheric quality by emitting volatile organic compounds (Misztal *et al.*, 2011). However, our knowledge on the direct and indirect impacts of BECCS on ecological systems is far from sufficient to conduct a reliable evaluation and to plan feasible management.

To fill the gap of the knowledge required from the urgency to the need to implement climate change mitigation activities and their sufficient assessments regarding their impact to other sustainability indicators, many researchers used multiple models to simulate the trade-offs between water, food, and ecosystems under three different land-use scenarios to produce bioenergy crop in agricultural land with/without irrigation and in converted forest lands. Using these models, the impacts from the BECCS deployment scenarios are assessed with the total amount of up to 3.3 GtC $year^{-1}$ (annual negative emission potential required for RCP2.6; see Smith *et al.* 2016) of bioenergy by growing bio-crops with substantive use of global agricultural and forest lands. Especially, the effects and sustainability of irrigation for global massive production of bioenergy is investigated by using the hydrological models (Hanasaki *et al.*, 2008a,b, 2010). The impacts of massive use of converted forest land are assessed using terrestrial ecosystem models (Ito and Inatomi, 2012).

BECCS Assessment Methods

There are some studies that have assessed the impacts of BECCS deployment scenarios on land systems including land use, water resources, and ecosystem services. **Fig. 1** shows the general explanation of the models used in a study (Yamagata *et al.*, 2018) and illustrates the parameters and variables exchanged between the water resources, ecosystems, and land-use models. There are some dependences between the models. For example, irrigation for bioenergy crop will decrease renewable water resources, while land conversion for bioenergy cropland will decrease the forest area etc.

Land use change impacts are tested using land-use scenarios (**Fig. 2**) to achieve the annual emission reduction of 3.3 GtC $year^{-1}$ (required for IPCC-RCP 2.6). Cropland scenarios can be used such as harmonized global land use (Chini *et al.*, 2014) for RCP2.6. It projects that global total cropland area reaches 2.12 billion ha in 2100. Since this kind of scenario does not specify the land used for food and bioenergy production, researchers need to assume how much land is required to achieve 3.3 GtC of BECCS. In the case of (Yamagata *et al.*, 2018), it indicates that cropland for food production would be 1.62 billion ha, or approximately 10% larger than the present areal extent. However, as it could be necessary to save cropland for food from the view point of food security in the future, because difficult food supply and demand condition are expected due to climatic change impacts on food production, population growth etc. So, Yamagata *et al.* (2018) considered two additional land use scenarios other than the use of rainfed cropland for the bio-crop production (S2), namely intensive irrigation for bioenergy crop (S1) and additional use of forest land (S3) as is explained in **Fig. 2**.

In case of S2, assuming BECCS for the RCP2.6, very large areas (500 million ha, or up to 25% of the global farm lands) need to be used for bioenergy crop production (rainfed) all over the world. Comparing the case of S1, the demand for farm lands is relaxed by assuming that bio-energy crop is irrigated to increase productivity to reduce the required land to half. In the case of the S3 scenario, large natural lands (500 million ha, or up to 10% of the total current forest land area) are assumed to be converted into bioenergy crop lands.

Another approach is to consider two subscenarios: (S3-1) no reserved area, allowing conversion of high biodiversity tropical forests, and (S3-2) biodiversity hotspots are reserved on the basis of the map by World Wide Fund for Nature. By assessing such

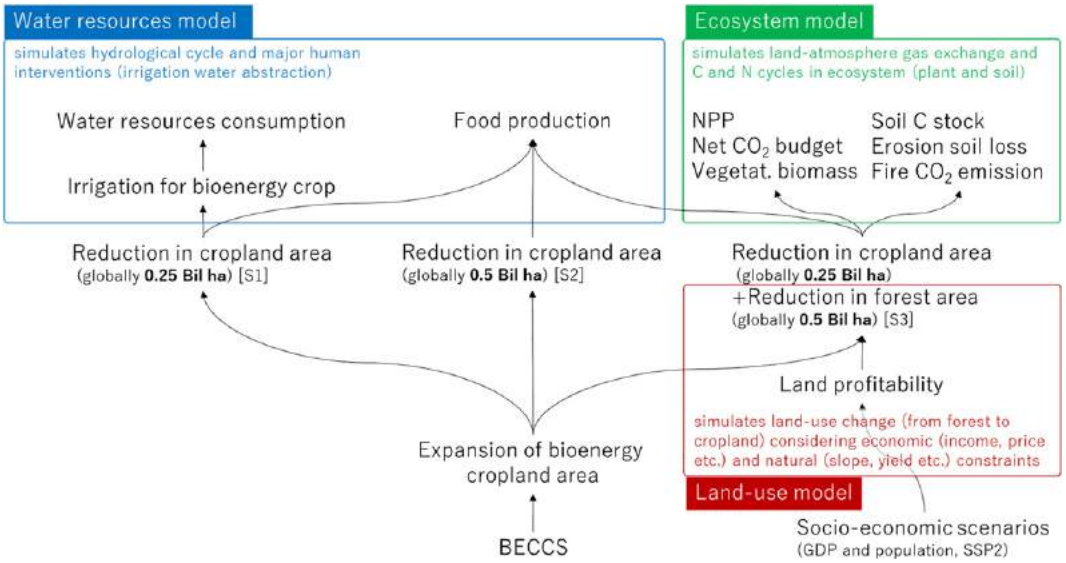

Fig. 1 Explanation of the models used to assess the impacts of different land- use scenarios and interactions between model parameters and variables. They are used to project situations in 2100 (Yamagata et al., 2018).

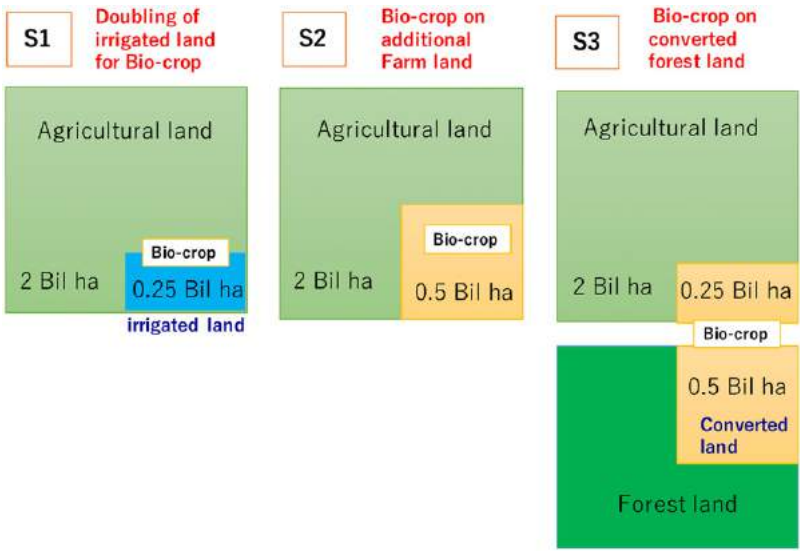

Fig. 2 Land-use scenarios for bioenergy crop production for RCP2.6 in 2100 (Yamagata *et al.*, 2018).

variety of land use scenarios, we can clarify the potential impacts and risks of the land use scenarios more clearly in a spatially explicit manner. For creating these variety of scenarios, land-use change models can be used by considering the land productivity for growing crops with allocation of the necessary areas for conversion.

Using these S1, S2, S3 land-use scenarios, the models such as described in **Fig. 1** can used to analyze the impacts for sustainability of land-use scenarios under RCP 2.6 from the perspectives of ecosystem and water resource in the future. In the land-use modeling, the suitability of bioenergy crop cultivation can be estimated in a similar manner to other food crops (i.e., wheat and maize) for simplicity. The base cropland area used in future land-use scenario such as S1 (with irrigation) and S2 (without irrigation) in 2000 can be derived from harmonized global land use (Chini *et al.*, 2014) which is consistent with RCP 2.6 (van Vuuren *et al.*, 2011) and cropland expansion for BECCS was assumed to occur in the 21st century at a constant rate. The scenario type such as S3 in which forests are consumed for bio-crop production can be derived from a land-use model considering socio-economic factors.

The spatial distribution of forest conversion into cropland for bio-energy can be developed based on the land suitability for agriculture. In the case of Yamagata *et al.* (2018), this was estimated in each 30 arc *sec* grid cell using explanatory variables such as wage, slope angle of land, bio-crop price and bio-crop yield defined by the socio economic scenario using GTOPO30 (available from USGS). The spatial distribution of bio-crop yield can be given by downscaling the results of a model whose resolution was

half-degree grid cell. It can be assumed that bioenergy crops such as Miscanthus and Switchgrass would be used and their yields were estimated by a model (Kato *et al.*, 2013). The socio-economic scenario such as wage and crop price can be provided by Integrated Assessment Model such as Asia-Pacific Integrated Model (Fujimori *et al.*, 2014). However, for simplicity, it was also assumed that the spatial distribution of cropland for food and pasture land would not change from 2000.

Simulations can be conducted using the climate scenario developed for the Inter-Sectoral Impact Model Intercomparison Project (ISIMIP; Hempel *et al.*, 2013). In case of Yamagata *et al.* (2018), scenarios is conducted using the MIROC-ESM-CHEM Earth System Model under the RCP2.6 scenario (van Vuuren *et al.*, 2011). The MIROC-ESM-CHEM tends to give a high warming trend, making it easy to assess possible climate impacts. Nevertheless, the magnitude of warming in the 21st century under RCP2.6 scenario (about 2.3 K land-average) was comparable with other climate models.

Water Resource Models

The H08 model is a physically-based global hydrological model (Hanasaki *et al.*, 2008a,b, 2010). It simulates basic hydrological components globally at $0.5^\circ \times 0.5^\circ$spatial resolution by solving the energy and water balance at land surface. H08 explicitly expresses major human interventions in the natural hydrological cycle, namely, water abstraction for irrigation, industrial, and domestic use, and reservoir operation of major dams. All the natural and human processes interact at a daily interval.

H08 incorporates submodels to estimate the potential crop yield, the cropping calendar, and irrigation water requirement for annual food crops, but not for perennial bioenergy crops. These submodels were enhanced to deal with giant miscanthus (Miscanthus giganteus) and switchgrass (*Panicum virgatum*) which are both so-called second-generation bioenergy crops as follows. First, the crop-specific parameters for miscanthus and switchgrass were added to the crop yield submodel which were taken from the SWAT model version 2012 (Arnold *et al.*, 2012). Next the cropping calendar submodel was enhanced to deal with perennial plants. The growing period was estimated by searching the longest continuous days above the base air temperature (10°C for miscanthus and 12°C for switchgrass) in a year. If it exceeded 300 days, the continuous 300 days which produced the maximum mean yield was selected. Irrigation water was applied to keep soil moisture above 75% of the field capacity during the cropping period. Note that these submodels are independent from that of Kato *et al.* (2013) which was used to develop the land-use scenarios: the submodels are tightly incorporated into the H08 model and it was unable to replace them with Kato *et al.* (2013). In H08, soil moisture (or water and energy balance) is calculated for each land use. The standard H08 subdivides a grid cell into four different land uses, namely double-crop irrigated food cropland, single-crop irrigated food cropland, rainfed food cropland, and nonagricultural land. We newly added two land uses for irrigated and rainfed bio energy cropland.

Using the enhanced H08, three simulations were conducted. The first simulation was the base simulation. The simulation period is 1996–2005. It assumed no production of massive second-generation bioenergy crop in this period. The H08 simulated the natural hydrological cycle and human water use using the present spatial distribution of irrigated and rainfed cropland. The second simulation assumed that 250 million ha of cropland was changed into irrigated bioenergy cropland by 2100 (Scenario S1). The simulation period is 2006–2100. Irrigation water was primarily taken from rivers in the same grid cell. We estimated how much additional water was required when the rivers were depleted. The third simulation assumed that 500 million ha of cropland was changed into rainfed bioenergy cropland by 2100 (Scenario S2). The boundary conditions given to H08 were identical to those of Hanasaki *et al.* (2008a,b). Irrigated cropland area, and crop type were obtained from Siebert *et al.* (2005) and Monfreda *et al.* (2008), respectively and fixed throughout the simulation period. In this study, the effects of CO_2 fertilizer were not considered. It was expected that crop yield would grow by time due to technological advancement, that effect was not considered either.

Ecosystem Models

To evaluate the impacts to the terrestrial ecosystem services, various ecosystem models can be used. In Yamagata *et al.* (2018), Vegetation Integrated SImulator for Trace gases (VISIT) model was employed. The model is a process-based model of the terrestrial biogeochemical cycle and ecosystem dynamics (Ito and Inatomi, 2012), focusing on atmosphere–ecosystem interactions under changing climate conditions. The model simulates water, carbon, and nitrogen cycles in terrestrial ecosystems using a simple box-flow framework, enabling us to apply this model to point to global scales. Particularly, this model simulates atmosphere–ecosystem exchange of trace gases such as greenhouse gases (CO_2, CH_4, and N_2O), biomass-burning emissions (e.g., CO and black carbon), and biogenic volatile organic compounds.

In Yamagata *et al.* (2018), terrestrial ecosystem services was evaluated for: (1) net primary production (NPP) related to fundamental and provisional services, (2) net ecosystem CO_2 exchange related to regulation services, (3) vegetation biomass related to fundamental, provisional, and cultural (by scenery) services, (4) soil carbon stock related to fundamental services, (5) soil loss due to erosion, and (6) biomass burning related to degradation of ecosystem services.

In general, carbon dynamics in terrestrial ecosystems can be estimated on the basis of leaf-level gas exchange and canopy radiation transfer (Ito and Oikawa, 2002). Mass balance of carbon stocks in vegetation and soil pools can be estimated by accounting the carbon input and output for each of the eight carbon pools: three for C3-type vegetation, three for C4-type

vegetation, and two soil organic carbon. Soil loss by water erosion was estimated using the revised universal soil loss equation, which accounts for slope, soil stability, precipitation, vegetation cover, and human management factors (Ito, 2007). Biomass burning can be simulated using an empirical scheme to estimate burnt area and combustion intensity, which are functions of fuel load and soil wetness.

Land-Use Scenarios

Fig. 3 displays projected bio-crops distributions in 2100 under S1 and S3 (a), and S2 (b) in Yamagata *et al.* (2018). The figure shows that S2 increases land for bio-crops globally. The large increase is especially expected in South Africa, North America, and Europe. **Fig. 4** shows the distribution under S3 with assumption of additional use of natural forest land without or with biodiversity reserved lands. In the case of S3-1 which does not take into account forest protection regulations such as REDD, the rain forest of Brazil is predicted to change into bioenergy crop land first, followed by the rain forest of Congo. On the other hand, if the biodiversity rich tropical forests are protected (S3-2), bioenergy crop land is predicted to increase more in semi-arid land in Australia and southern Africa and boreal forest land in Canada and Russia.

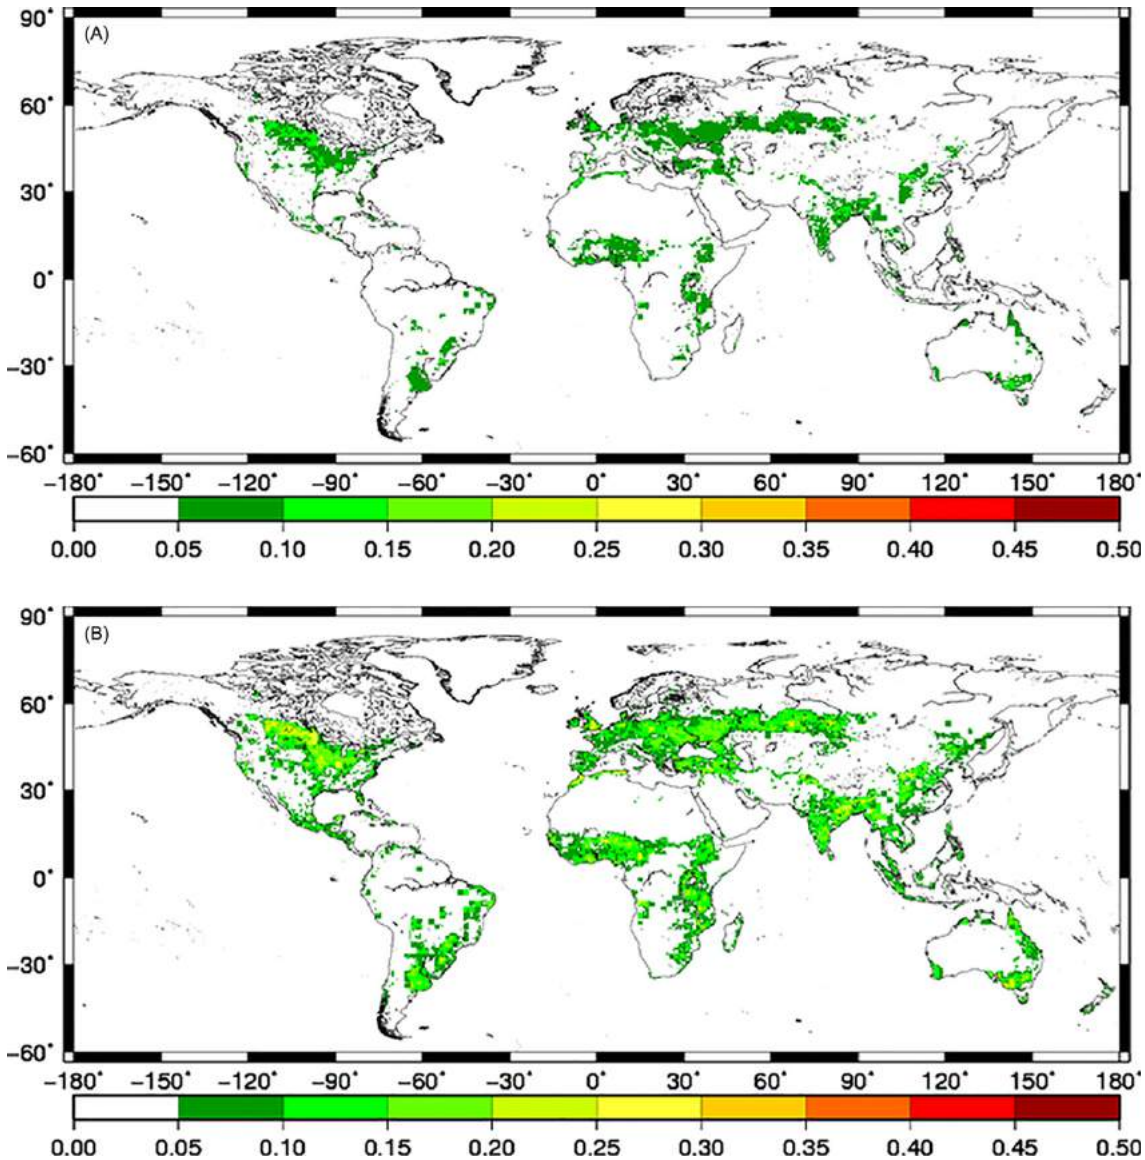

Fig. 3 Areal fraction of bio-crop farmland in 2100. (A) S1 and S3 (excluding farmland transferred from forest) and (B) S2 (Yamagata *et al.*, 2018).

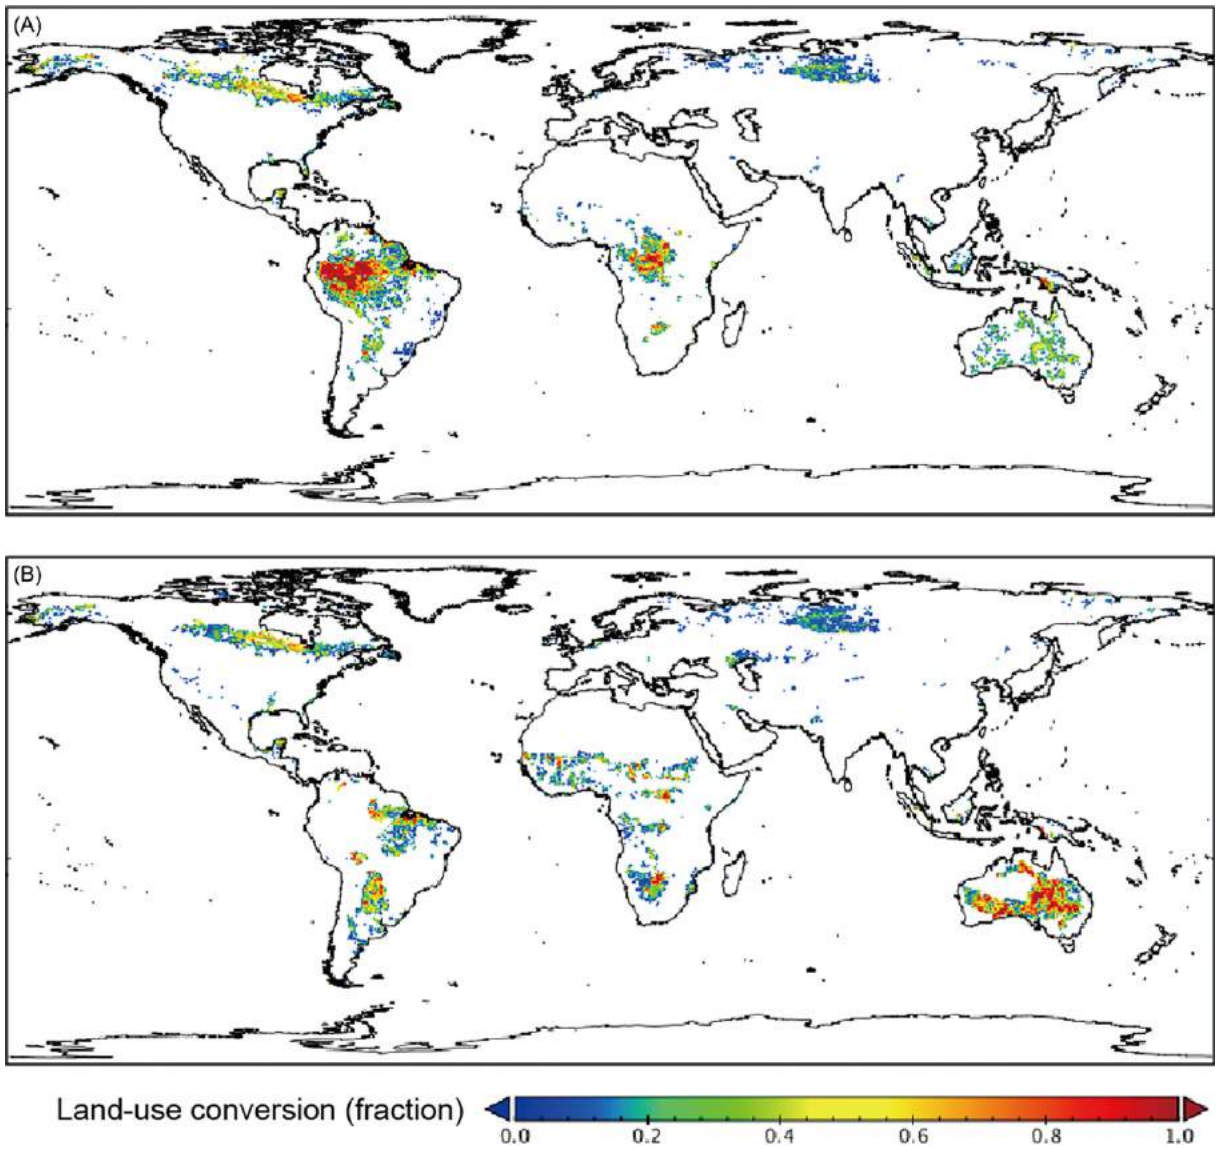

Fig. 4 Areal fraction of bio-crop farmland in 2099 transferred from forest (S3) [land fraction]. (A) No reserved land (S3–1) and (B) with reserved lands for biodiversity hot spots (S3–2) (Yamagata *et al.*, 2018).

Assessment of Land Use Scenarios With Water Resource Models

Irrigation water use for bioenergy can be calculated as shown in Yamagata *et al.* (2018), for Scenario S1, the volume of consumptive irrigation water use to produce bioenergy was estimated at 1910 km^3 $year^{-1}$ in 2090s (the mean of 2091–2100). This volume is as much as 135% of the volume for food production (1420 km^3 $year^{-1}$) of the base simulation which is fairly comparable with earlier independent estimates (e.g., 1231 km^3 $year^{-1}$ in Döll *et al.*, 2012). Irrigation water use for bioenergy is expected to concentrate in some parts of South America, central Sahel, eastern India, and northern and southern Australia (**Fig. 5**).

The spatial distribution in the figure reflects three aspects: the distribution of irrigated bioenergy cropland, soil moisture deficit, and length of growing period. In the paper (Yamagata *et al.*, 2018), Scenario S1 assumed that 250 million ha of cropland was converted into that for bioenergy proportional to the total cropland, hence irrigation is concentrated in the world's major breadbasket areas. Second, since irrigation was applied to maintain soil moisture above 75% of the field capacity, it tends to be concentrated in semi-arid regions. Third, since this study assumed that irrigation was applied throughout the cropping period, warm regions with long cropping period tend to require a large volume of irrigation. Of the total irrigation water requirement, rivers supplied only 1580 km^3 $year^{-1}$ of water. The remaining 1910 km^3 $year^{-1}$ should be supplied from other sources. This is mainly explained by the opposite temporal phase between river discharge and irrigation water: irrigation water requirement is

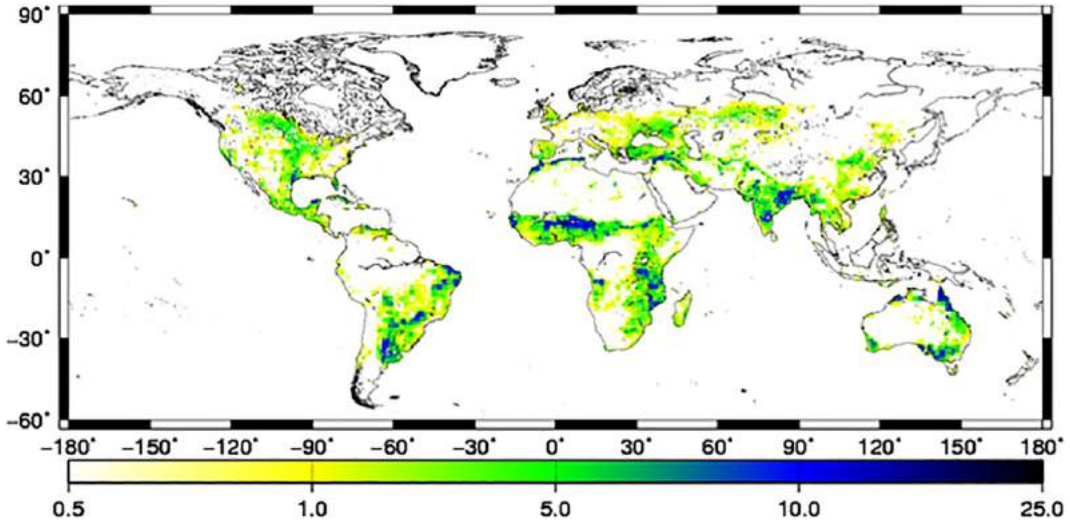

Fig. 5 Irrigation water requirement for bioenergy crops under Scenario S1 in the 2090s ($m^3\ s^{-1}$) (Yamagata *et al.*, 2018).

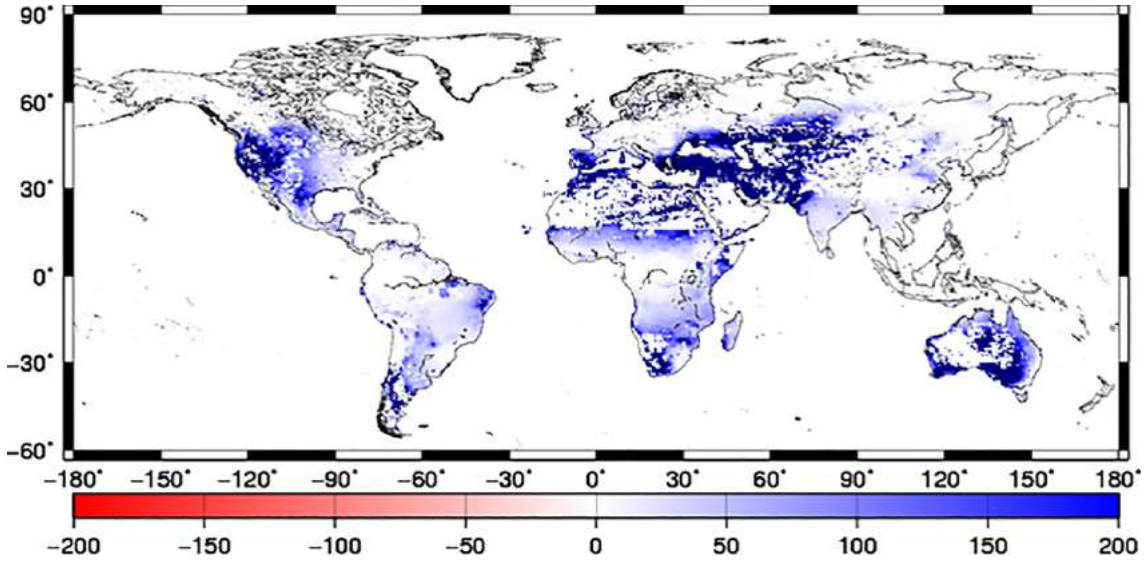

Fig. 6 The effect of irrigation on yield of bioenergy crop or the percentage change of the yield between irrigated and rainfed bioenergy crop in the 2090s [%] (Yamagata *et al.*, 2018).

intensive when the soil gets drier, and the condition also restricts the runoff of the surrounding regions (for further discussion, see Hanasaki *et al.*, 2017).

The production of food in the rainfed cropland is primarily influenced by the cropland area, but it is also affected by climatic change. The production of bioenergy crop was estimated at 8800 106 t for Scenario S1 and 12,300 106 t for Scenario S2. The estimated total bioenergy production goes along with the 3.3 GtC $year^{-1}$ of BECCS or the primary assumption of this study. The relationship between bio-energy crop production and BECCS is expressed as follows (Eq. 5 of Kato and Yamagata, 2014).

The global average yield of bioenergy crop was estimated 35.2 t/ha (with irrigation) and 24.6 t/ha (without irrigation) respectively, indicating that irrigation increased the yield by approximately 50% (i.e., required land use became 2/3). The effect of irrigation, or the fractional change in crop yield due to application of irrigation is shown in **Fig. 6**. The effect is prominent in arid and semiarid regions in western North America, the Mediterranean, southern Africa, Central Asia, western South Asia, and eastern Australia. The abundant irrigation boosted the crop yield in these regions, because limitation in precipitation is the key restricting factor of the crop growth. However, available water from river is quite limited in these regions, which pushed up the fraction of non-river-originated water resources of Scenario S1. Moreover, vast irrigated food cropland area is concentrated in these regions as of today. Further enhancement of irrigation for growing bioenergy crop would likely conflict with food production. This could be a major problem because climate models are projecting a large decrease of food crop yield due to the climatic change even during this century.

Assessment of Land Use Scenarios With Ecosystem Models

Under the S3-1 (no reserved land) and S3-2 (with reserved land) scenarios, a vast area of natural ecosystems is converted to bioenergy crop cultivation. In our simulation, global NPP increased from 56.5 GtC $year^{-1}$ in the 1990s to 65.6 GtC $year^{-1}$ in the 2090s, mainly because of the effects of CO_2 fertilization. Because crops have high productivity comparable with those in forests, the prescribed land-use conversion did not largely affect global total NPP.

In the Yamagata *et al.* (2018), as shown in **Fig. 7**A, global NPP increased almost linearly until around 2060 when it peaked; such trend is in parallel with atmospheric CO_2 concentrations. In each case, terrestrial ecosystems acted as a small net sink of CO_2 including emissions from land-use change and biomass burning, with a considerable range of interannual variability due to climate condition (**Fig. 7**B). Note that this net CO_2 sink is only by ecosystem carbon stock, and sequestration by CCS should be evaluated separately. Carbon stocks in vegetation biomass (**Fig. 7**C) and soil organic carbon (**Fig. 7**D) showed, in our simulation, clear difference among scenarios with a small range of decadal variability. With no land-use change after 2000, vegetation biomass increased from 483 GtC in the 1990s to 544 GtC in the 2090s.

Under the S3-1 scenario, it decreased to 460 GtC due to deforestation in tropical forests. In contrast, under the S3-2 scenario, vegetation biomass increased slightly (495 GtC in the 2090s, a bit lower than 509 GtC of the RCP2.6-based case), indicating the effectiveness of reservation for biodiversity hotspots. Soil carbon stock decreased in the land-use cases to some extent in the early 21st century and then increased gradually due to accumulation in temperate and boreal ecosystems. Here, difference between the results of S3-1 and S3-2 was not so large, because soil carbon stock in tropical rainforests is low and comparable with rangelands. The average rate of net carbon sequestration under S3-2 scenario (about 0.3 GtC $year^{-1}$) is comparable with the present level of terrestrial uptake or climate regulation services including the effect of land-use change (Le Quéré *et al.*, 2016).

Interestingly, these simulations for land-use cases (RCP2.6, S3-1, and S3-2) shows that soil loss by water erosion would be increasing during the 21st century, in contrast with the constant to weak decreasing trends during the 21st century of the fixed land-use case. Because soils provide fundamental support for many ecosystem services, such a loss of soil carbon could result in ecosystem degradation that could have adverse influences on the human society. On the other hand, biomass burning would increase until around 2040 probably due to the increase of fuel supplied from vegetation biomass production.

The terrestrial ecosystem functions are expected to change over the land surface. For example, vegetation biomass is expected to increase in the middle to high latitudes, because plants in these regions would enjoy favorable effects from higher atmospheric CO_2 concentrations and global warming even under the RCP2.6-based climate. In contrast, under the S3-1 scenario, vegetation biomass in lower latitudes such as forests in Amazon Basin, Central Africa, and Southeast Asia is estimated to decrease largely during the 21st century (**Fig. 8**A–C), as a result of land-use conversion for bioenergy crop production. Because these tropical forests support important biodiversity and associated ecosystem services, such an intense biomass decrease should bring about adverse influences on local communities.

Under the S3-2 scenario, biodiversity hotspots such as central Amazon are preserved. However, surrounding natural ecosystems were still seriously affected by land-use for bioenergy production (**Fig. 8**D–E). In Australia, expansion of bioenergy cultivation led to a slight increase of vegetation biomass, but it could not compensate for the massive loss in other forests. In our simulation, the loss of vegetation cover resulted also in deterioration of soil loss due to water erosion. As shown in **Fig. 8**F, the present soil loss by water erosion occurs mainly in mountain areas, croplands, and monsoon Asia with high precipitation. Soils of tropical forests in the Amazon Basin and Central Africa are protected by dense vegetation cover, leading to lower soil loss due to water erosion than high precipitation. The intense land-cover change for bioenergy crop production in the tropics (S3-1) and subtropics (S3-2) could cause serious deterioration of soil loss (**Fig. 8**G–J) accompanied with degradation of vegetation productivity, hydrologic regulation, and biodiversity. Such soil loss also occurred in boreal regions but with lower intensity.

Total BECCS Impacts on Land Systems

By using state-of-the-art global land models and systematic land-use scenarios, a set of comprehensive simulations on the massive production of bioenergy can be conducted. If approximately one eighth of the cropland in 2090s was transferred into cropland for irrigated bioenergy, or in case of S1, 8800 106 t of bioenergy crop together with 9% of increase in total food would be produced instead of 135% of additional water consumption. In case of S2, 12,300 106 t would be produced instead of 5% of reduction in food production (Yamagata *et al.*, 2018).

From the view point of water resources, S1 is challenging because it more than doubles the present water use. Water scarcity is observed in many parts of the world, and further increase in river water would exacerbate the problem. The additional water would be abstracted from other than river water, which implies the need for intensive water resources development (dams, aqueducts, groundwater development).

From the view point of food production, S2 is also challenging because it decreases food production. The global average crop yield of food for S1 and S2 is approximately 7% smaller than the present level (notice that the CO_2 fertilization effect and yield growth in the future are not taken into account in this study), indicating that a considerable improvement in efficiency is needed for food distribution to feed the world.

From the view point of ecosystem services, S3 could be problematic with regard to ecosystem sustainability, because the extensive conversion of natural forests exerts undesirable impacts to ecosystem integrity as it was the case where large-scale

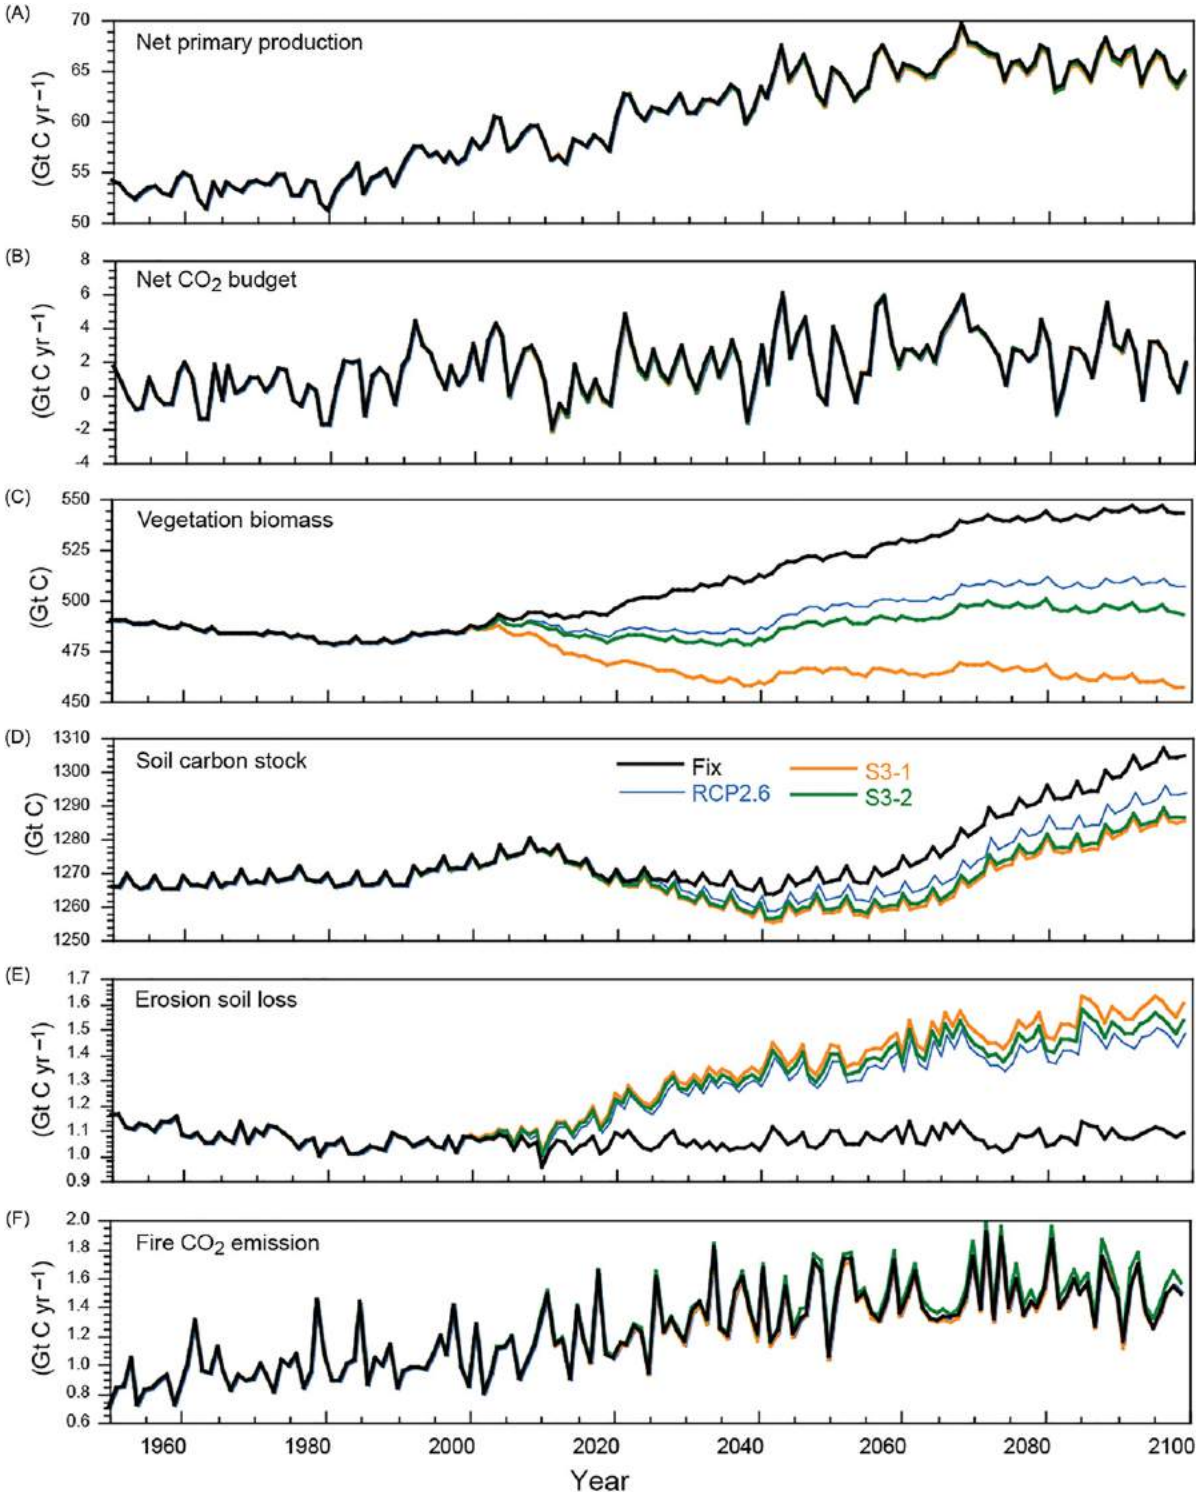

Fig. 7 Time-series of simulated terrestrial properties related to ecosystem services using the S3 scenarios. (A) Net primary production, (B) Net ecosystem CO_2 exchange, (C) Vegetation biomass, (D) Soil carbon stock, (E) Soil loss from erosion, and (F) CO_2 emissions from biomass burning. Thick *black line* shows the result for fixed land-use case, thin blue for RCP2.6-based land-use case, thick orange for S3-1 (no reserved land) case, and thick green for S3-2 (with reserved land) case (Yamagata *et al.*, 2018).

deforestations occurred in the tropical regions due to the rapid expansion of palm oil plantations. Moreover, loss of tropical forests in Amazon and Congo Basin would bring about serious decline of biodiversity in these regions. Soil loss could be caused by exacerbated water erosion due to land-use conversion, if no strong deforestation regulation (such as REDD +) is implemented.

(A) Vegetation biomass and (F) soil erosion loss in the 2090s, respectively. Difference between the 1990s and 2090s for (B) vegetation biomass under S3-1 (no reserve land), (D) vegetation biomass under S3-2 (with reserve land), (G) soil erosion under S3-1, (I) oil erosion under S3-2, respectively. (C, E, H, J) Difference between the S3-based results in (B, D, G, I) and RCP2.6-based ones, showing the impacts of BECCS deployment (Yamagata *et al.*, 2018).

Large scale bioenergy crop deployment could also cause land degradations such as collapse of ecosystem structure and declined productivity.

It might be over-simplistic to assume that a vast extent of food cropland could be successfully transferred into bioenergy cropland in proportion to the total cropland area. It would likely be more realistic to assume an expansion of bioenergy cropland utilizing the scenarios developed by more sophisticated land use models.

In general, complex trade-offs could occur among land (and ecosystem conservation), water, and food when a massive amount of bioenergy is produced. Internationally coordinated developments of integrated models that can deal with these interactions are urgently needed. For example, trade-offs between biodiversity conservation and land use become complicated when considering the existence of prioritized biodiversity hot-spots (e.g., Myers *et al.*, 2000; Newbold *et al.*, 2016). Our knowledge on ecosystem functions and services are inadequate, such that forests can exert both positive and negative feedback effects on climate change depending on climatic conditions (Betts, 2011). We need to deepen our understanding on specific land processes and their interactions.

Several current land use scenario-based assessments show that, especially in terms of sustainability of ecosystem services, unrestricted expansion of bioenergy crop cultivation at the expense of natural forests will not be feasible, because it can cause serious extensive decline in carbon stock and related ecosystem services, although several regions receive some benefits. In this regard, we should pay more attention to the cobenefits and synergies between the biodiversity conservation and climatic change mitigation activities for optimizing various sustainability benefits.

Spatially Explicit Socio-Economic Scenarios

Another remaining issue for this kind of land use modeling is a more detailed consideration of socio-economic scenarios such as the shared socioeconomic pathways (SSPs; see Riahi *et al.*, 2017). SSPs, which are scenarios describing alternative future developments, consist of the sustainability (SSP1), middle of the road (SSP2), fragmentation (SSP3), inequality (SSP4), and fossil-fueled development (SSP5) scenarios. While we constrained land use assuming SSP2, different scenarios can lead to different conclusions. Besides, while SSPs and other socio-economic scenarios are typically country-level scenarios, regional/local-level socio-economic development is actually influential on water-food-ecosystems and land use in the regions. Use of spatially fine dataset on SSP1-5 would be an interesting next topic.

There are already several studies that have downscaled country-level socioeconomic scenarios into spatially fine scenarios (e.g., Bengtsson *et al.*, 2006; Grübler *et al.*, 2007; van Vuuren *et al.*, 2007; Gaffin *et al.*, 2004; Hachadoorian *et al.*, 2011; McKee *et al.*, 2015; Nam and Reilly, 2013; Yamagata *et al.*, 2015, 2018; Jones and O'Neill, 2016; Murakami and Yamagata, 2016). Especially, as it could influence the future land use drastically, we need to study spatially explicit economic growth (GDP) impacts on food preferences and food security and the trade-offs between water, food, and ecosystems. To support this kind of studies, we have also developed gridded GDP scenarios for SSP 1–3 (Murakami and Yamagata, 2016) in addition to SSP2. Our newly developed socio-economic dataset will be used for the ISIMIP as one of the standardized input datasets. The datasets are downloadable from GCP website (http://www.cger.nies.go.jp/gcp/population-and-gdp.html).

Information and Information Flows in the Biosphere

PJ Georgievich, Russian Academy of Sciences, Moscow, Russia

Information is a concept intuitively clear to everybody and quite correctly associated with knowledge or – which is similar in meaning – with eliminating uncertainties. Knowledge is naturally considered to be useful as it increases efficiency of person's activities, ensures his better adaptability to changing environments, and therefore enhances his vital capacity and sustainability. In fact, however, that is not always so and excessive knowledge may be dangerous. Whether the knowledge appears to be constructive or destructive for an entity (subject) depends mostly on the subject's own state or own structure. When turning our own attention to ourselves, we could confidently assert that information (knowledge) obtained is capable of making changes in organization (structure, order, regulations) of our thoughts, organization of technological processes, engineering structures, social communities, etc., the latter gaining in efficiency and stability in the process.

C. Shannon worked out the law of the rate of information transfer from transmitter to receiver over a channel of any physical nature with noise. The law has been derived from a random process model and has direct analogy with models of thermostatics and therefore with models of diversity.

The capacity of a channel of band W perturbed by white thermal noise power N when the average transmitter power is limited to P is given by

$$C = w\log\left(1 + \frac{P}{N}\right) \qquad [1]$$

where $N = wN_0$ (N_0 is the power of noise on unit of a band of frequencies).

It is easily seen that this law is nothing else than a logarithmical form of allometric relationship which widely occurs both in living organisms and in inorganic nature. By conditions, the law of information transfer gives rise to a fractal set. In linguistics, the frequency band is related with the alphabet length, and the signal power with the length of a word. For biological systems, the frequency band is associated with the specialization level (the narrower is the band, the more specialized is the system). The signal power (dispersion) depends on the environment strength (energy) and diversity. There is a linear dependence between noise and frequency band – the narrower is the band, the less are errors, though communication channel capacity decreases accordingly. Assuming that there is some probability of errors becoming lethal on accumulation, the individual stability of the receiver (in terms of error-free operation) would increase with narrowing of the frequency band (increasing specialization). Taking improvement of stability to be a target function of evolution, we come to a conclusion that specialization is a natural way to this target. A specialized system, however, has a lower channel capacity and therefore lesser resistance to fluctuations in environments. If we assume, for example, that a population of organisms should have a certain minimum of diversity, it is easy to see that the most specialized and least fertile organisms are likely to inhabit environments of tropical rainforests, while the least specialized organisms of maximum fertility would be found under conditions of cold climate of taiga and tundra, and partly in deserts. This dependence is a matter of common knowledge. It follows from the law of communication channel capacity that there exists a limit of information amount that can be transmitted per unit of frequency band equal to 1.443 natural units. All the limitations bring us to the conclusion that no supersystem can exist that could receive information within an arbitrary large frequency band; a number of receiving systems (mutually complementary by alphabet) are necessary for effective transformation of the information. Hence it immediately follows that a diversity is necessary in the receiving system, and the more powerful is the transmitter, the greater is the number of various receivers needed for complete transformation of information. Under certain simple assumptions, it may be inferred from eqn [1] that the diversity is given approximately by

$$\text{Number of species } S = aN^b$$

where $b < 1$ and N is sample size and $N = f$(area, habitat capacity). This is identical to the relationships derived from thermostatics. A connection between the quantitative information model and thermostatic model is determined by their common mathematical basis: information is defined as the inverse of the entropy.

If a noisy channel is fed by a source, there are two statistical processes at work: the source and the noise. Thus there are a number of entropies that can be calculated. First there is the entropy $H(x)$ of the source or of the input to the channel (these will be equal if the transmitter is nonsingular). The entropy of the output of the channel, that is, the received signal, will be denoted by $H(y)$. In the noiseless case $H(y) = H(x)$. The joint entropy of input and output will be $H(xy)$. Finally, there are two conditional entropies, $H_x(y)$ and $H_y(x)$ – the entropy of the output when the input is known and conversely. Among these quantities, we have the relations $H(x,y) = H(x) + H_x(y) = H(y) + H_y(x)$ All of these entropies can be measured on a per-second or a per-symbol basis. The rate of transmission I can be written in two other forms due to the identities noted above. We have $I = H(x) - H_y(x) = H(y) - H_x(y) = H(x) + H(y) - H(x,y)$.

Entropy differs from diversity in that a quantity of information within a closed system transmitter increases, and not decreases, with time, as uncertainty of the transmitter decreases with time and its behavior may be more reliably predicted by the receiver. If, however, the transmitter is an open system, its uncertainties do not depend generally on the duration of transmission, and its

 doi:10.1016/B978-0-444-63768-0.00742-3

behavior keeps up at a constant level of unpredictability. As the model of the communication channel capacity is homologous to the thermostatic model, information may be considered a phenomenon of universal occurrence. It is the transmission of information from environment to any object within a certain frequency band that controls the existing order or structure of the object. Even in case of ceasing external action or transfer of information from outside, the structure appears steady for a long time in the existing environments. In that case, there is a good reason to speak of stored information.

The rate of information flow received by the system within a certain time interval may be estimated in terms of difference in diversity at the moments of time under comparison. Information may also be measured by Kulback entropy in comparison with a diversity under conditions of equilibrium or steady (stationary) state. There is practically no study aimed at measurement of the quantitative information flows. There was a rather keen interest in information theory as applied to natural sciences, and to biology in particular, in the 1950s and the 1960s. One of the sections of information theory (i.e., theory of coding) made a considerable contribution to solving problems of genetic code and molecular synthesis. Limited possibilities for measurements and inadequate equipment hindered fruitful application of information theory for ecological research. Though a connection between information theory and thermodynamics was evident as early as the 1950s, a real integration of the two branches became possible only on a basis of developed theory of nonequilibrium thermodynamics and synergetics. All the above accounts for an exponential growth of published papers dealing with the considered problem during the last 10–15 years. The studies are mainly focused on explaining the evolution of both living matter and human society.

Evidently, the law of quantitative transfer of information does not cover all the aspects of what we instinctively associate with knowledge. A signal received may be meaningless in the receiver's perception and would not change its state, and, vice versa, a signal of negligible strength may induce drastic changes. Accordingly, information includes both quantitative and semantic components. In the simplest case, the latter may be dealt with in terms of decoding of signals coming from transmitter to receiver. It implies that there is an outside observer who establishes rules of decoding, and records signal characteristics at the input and consequent changes in the receiver state. Formally, it is a problem of statistic analysis aimed at a search for invariants with respect to signal receiver toward the transmitter. This important and by no means trivial problem of biosemiotics is related to partial interaction analysis and is potentially capable of simulation of all possible partial relations. However, its solution does not necessarily give an insight into the problem at the macroscopic level.

It should be stressed that, as follows unambiguously from our experience, an interaction between two systems may produce some new systems, and structure and properties of the latter may appear completely unpredictable, even if we have a complete knowledge of the initially interacting systems (emergence). Generally, it is impossible even to define a set of possible outcomes, that is, expected uncertainty. Therefore, the appearance (emergence) of a new, earlier unknown structure may be defined as origination of new information. The only condition for it is some energy input to the system. On the other hand, any former locally steady structure may disappear, together with related information. It seems conceivable, therefore, that conservation laws do not apply to information at the macroscopic level. Being a measure of order, information arises from chaos and returns to it; the evolution based on memory (selection of locally stable structures) proceeds by progressive retrieval of order and accumulation of information. Open macrosystem receives energy in various forms from conventionally separated environment and generates flow of information and its continuous increase.

Actually, it is this phenomenon that brings us to change our understanding of entropy as a measure of disorder; it makes us revise the classic thermodynamic model (that admits only mechanical forms of energy conversion), thus eliminating discrepancy between the observed evolution and the second principle of thermodynamics. There are numerous researches dealing with this problem. More than 60 monographs have been recently published by Springer-Verlag publishers. S. D. Khaitun, in particular, gives a meticulous review of existing opinions on thermodynamic irreversibility and concludes on advisability of coming back to wording of the second principle as stated by W. Thomson (Lord Kelvin); according to the latter, mechanical energy dissipates (depreciates) in the course of irreversible processes – its amount decreases when passing into other kinds of energy. It is a mechanical approach, where all the processes in the system are described by movement of constituent particles and its state is exhaustingly characterized in terms of coordinates and impulses so that the energy appears to be their function. Mechanical energy differs from nonmechanical in that its movement may be completely described by a set of coordinates and impulses; in other words, the energy is described by the Hamiltonian function. Nonmechanical energy is related to entropy information, because a part of the energy is spent for new structure synthesis and maintenance and for synthesis of new information. When considered together with the law of the information transfer rate over a communication channel, the results bring us to a conclusion that power (energy) of any external action is spent partly for synthesis of some elements of known type and partly for creation of new structures, with unknown characteristics; those enlarge the band (where the external actions are reproduced) and reduce the noise level in every individual case of the information reception.

S. E. Jorgensen and Yu. M. Svirezhev introduce information into a biological system through Kulback entropy, the latter being a measure of the system deviation from the stationary state. In their model, the system evolution is governed by consumed energy and inner order generated by the system itself and controlling the exergy (useful work). The evolution is aimed at increase in exergy, that is, at a synthesis of structures far from equilibrium or stationary state. Demonstrating a fact of information synthesis, A. M. Khasen supplemented the nonequilibrium thermodynamics model developed by I. Prigogine. He considered entropy information as a function of complex variables, which permitted to recognize it in two constituents, namely basic information and semantic information. The expanded model generates new structures and increases entropy information within the self-developing and self-organizing system. It would be natural to suggest that a constant analogous to Boltzmann constant (length of a word or width of frequency band) appears as a function of self-development and creates a hierarchy (of the word–phrase–paragraph type).

The hierarchy arises from a limited transmission capacity at a currently accepted level of energy transformation. Increase of the transmissivity is due to self-organization of the synthesized systems into systems of the next (higher) level, with narrower frequency band. Accordingly, the number of hierarchic levels increases with total signal strength, while diversity decreases at every higher level.

The chosen descriptive (qualitative) models of information synthesis and transformation, in common with other analogous models, predict an exponential growth of information in biosphere and therefore `cancel' a danger of the `heat death' imminent according to the second principle of thermodynamics. Within the frame of those models, the biosphere is considered a system of a practically unlimited growth of information complexity. That does not mean that individual elements cannot fail; but every lost element would be replaced by two to four new ones, so that the rate of diversity synthesis grows progressively. It should be noted, however, that there is no universally accepted model of information processes in the biosphere; at present, we can only speak about a search for an adequate theory.

Summary

At present, there is no general information theory. In the theory of quantitative information, it is described as elimination of uncertainty. This definition implies existence of a finite set of possible states or relationships and their prior probabilities. In a more comprehensive sense, information is understood as the appearance (emergence) of order or structure with unknown characteristics from the chaos. In that case, there is no closed set of states or their prior probabilities. The information may be measured post factum, for example, in terms of distance between the emerged structure and its stationary analog, by some other means. There exists a distinct trend toward inclusion of information into thermostatic model as a missing variable which controls evolution and its irreversibility. The very fact of living matter evolution (including evolution of human beings) demonstrates that in the course of time the set of its stages gains in power and new locally stabilized systems appear; they become more and more complicated and require increasing flow of energy for their maintenance. A growth of the consumed energy flow is compensated by enhanced total transmission capacity. A great problem in synthesis of new structures consists of balance between the memory controlling admissible variants of new structures (targeted evolution) and environmental influence either through selection or by way of direct or indirect perception of its properties by the evolving object. Under actual conditions, the information flows are measurable, though an experience in such measurements is rather scarce.

Iron Cycle

KA Hunter and R Strzepek, University of Otago, Dunedin, New Zealand

Introduction

This article presents a scientific overview of the biogeochemical cycling of iron in the ocean, focusing in particular on what is currently known about the importance of this element as a micronutrient for the growth of oceanic phytoplankton. The first section focuses on the basic biochemistry of iron in phytoplankton metabolism, followed by consideration of the biogeochemistry of this element and how this affects its chemical speciation and bioavailability. The remaining sections deal with large-scale experiments involving iron enrichment in the ocean and the mechanisms that phytoplankton have developed to acquire iron for metabolic processes.

Why Is Iron Important to Phytoplankton?

It has long been known that iron is an essential element for the metabolism of many organisms, including humans. Iron is one of the most abundant elements in the Earth's crust, and the Fe(II)–Fe(III) redox couple provides for facile electron-transfer reactions:

$$Fe^{3+} + e^- \rightarrow Fe^{2+}$$

$$E^0 = 0.77\ \text{V}$$

As a result, iron-containing enzyme proteins are among the most common electron-transfer catalysts (**Table 1**).

Of particular importance to photosynthesizing algae are the photosystem proteins which are involved in the splitting of water to form O_2 and which contain a number of Fe redox centers. Prokaryotic phytoplankton (microbes lacking a cell nucleus), which evolved early on in the evolution of the ocean during the Archean period at least 2.5 billion years ago, used iron as the basis of these redox catalysts because of the high abundance of iron in the early ocean. In the absence of free O_2, iron forms the quite soluble form Fe(II) and probably had concentrations on the order of 1 mM during Archean times.

Ironically, photosynthesis began to win out over other biological strategies, and free O_2 became increasingly available during Proterozoic times. This change in the oxygen status of the ocean had serious consequences for the photosynthesizing algae, for it led to the oxidation of Fe(II) to the much less soluble form Fe(III). During the latter stages of the Archean, this gave rise to immense deposits of Fe(III) oxides on the seafloor known as the `banded iron formations' (BIFs). The banded nature of BIFs resulted from periodic cycles of `boom and bust' as the algae coped with the episodic delivery of Fe(II) through upwelling from the anaerobic deep ocean and its subsequent oxidation by the O_2 generated by the algae. This process resembles a giant titration of the Earth's Fe (II), both in the ocean and on the land, by the algal waste product O_2.

Abundance and Sources of Fe in the Ocean

Eventually, the modern ocean evolved about 1.2 billion years ago in which O_2 of photosynthetic origin permeated almost all of the ocean's depth, not to mention the atmosphere, laying the foundation for the rich and complex biological systems we know today. Under these conditions, iron has become a very rare trace element in the oceans, having concentrations in most regions of the order of 1 nM or less, except in coastal and estuarine regions under the influence of terrestrial runoff.

In surface waters, where Fe is needed for phytoplankton growth, the lowest Fe concentrations are found in those oceanic regions most remote from land. More specifically, away from the direct runoff of Fe in rivers, the main external source of Fe entering oceanic surface waters in the modern Earth system is soil-derived dust transported over great distances from the arid areas of the Earth's surface (**Table 2**). Of particular importance are the Sahara and Sahel desert regions which deliver Fe to the equatorial and North Atlantic Ocean, and the Asian deserts which are a major source for the western North Pacific Ocean. The Southern Ocean contains no major dust sources other than the desert regions of Australia and Patagonia well to the north. Not surprisingly, this region turns out to be particularly depleted in iron.

Iron Limitation and Iron-Enrichment Experiments

Less than two decades ago it became clear that the low abundance of iron in certain remote areas of the surface ocean represented an important limitation to phytoplankton growth. Over most of the temperate and tropical latitudes of the world's oceans, the main factor controlling phytoplankton growth rates is thought to be the availability of the nutrients nitrate and phosphate. The

concentrations of both of these nutrients are extremely low in such waters, having been efficiently consumed by plankton. Indeed, as originally postulated by Arthur Redfield, the molar ratio of nitrate to phosphate in the global ocean is remarkably constant at about 15:1, almost exactly the same as the requirements of phytoplankton for these elements. This constant ratio is probably maintained by a balance between phosphate availability and the more biochemical alternative of nitrogen fixation that is available to nitrogen-fixing plankton.

However, in certain areas of the ocean, these nutrients remain at high residual concentrations, suggesting that another factor has come into play as a limitation on growth. These regions, which are characterized by high nutrient but low chlorophyll (HNLC), became strikingly obvious once both detailed surface maps of nutrients became available (starting with the pioneering GEOSCS Program in the 1960s and later through the programs JGOFS and WOCE) (e.g., **Fig. 1**) and also the ability to map surface water chlorophyll concentrations using satellites such as the Coastal Zone Color Scanner (**Fig. 2**). A comparison of these figures indicates that relatively low chlorophyll concentrations are found in regions of high nutrients, especially the Southern Ocean HNLC region.

The late John Martin, of Moss Landing Marine Laboratory in California, first made the suggestion that a lack of iron inhibited phytoplankton growth in these HNLC waters. He did this using incubation experiments in which seawater samples were inoculated with small additions (1–2 nM) of iron. Several days after inoculation, considerable increases in chlorophyll and plankton growth rate were observed compared to controls. A key to the success of these experiments was the ability to collect and handle seawater samples under scrupulously clean conditions that minimized the influence of dust contamination introduced by the experimenter. From these results, Martin speculated that iron was the growth-limiting factor in HNLC waters. He also went on to claim that periods of enhanced growth during glacial times might have been a result of enhanced dust input during more arid glacial climates. Periodic inputs of such dust are recorded in the polar ice core record, and seem to correlate well with periods of low atmospheric CO_2, consistent with enhanced plankton growth.

In spite of these convincing arguments, there were many skeptics. A major criticism centered on the artificiality of the small bottle incubation experiments. Grazing is also an important controlling factor on phytoplankton populations, and small bottles would not contain a sufficient population of the larger grazers. This criticism was settled by several mesoscale iron-enrichment experiments initiated in the mid-1990s. In these, a large area typically $8 \times 8\ km^2$ was fertilized with several tonnes of iron (as $FeSO_4$) along with an inert tracer SF_6 to mark the patch of iron-fertilized water. The first two experiments, IronEx I and II, took place in the equatorial Pacific Ocean, which is mildly HNLC. However, in 2002 a group of NZ and British scientists conducted the Southern Ocean Iron Enrichment Experiment (SOIREE) in the HNLC waters of the Southern Ocean south of Tasmania.

In these experiments a dramatic increase in chlorophyll as a result of a phytoplankton bloom was observed several days after the initial infusion of iron. This was accompanied by a decrease in the CO_2 equilibrium partial pressure in the water, indicating biological uptake of CO_2 by plankton. More detailed examination showed that the main beneficiaries of the added iron, and thus the main source of the new chlorophyll, were large pennate diatoms such as *Fragilieria kergulensis*. These are not the dominant organisms under normal, low-Fe conditions. All other things being equal, the best strategy for surviving under limited iron

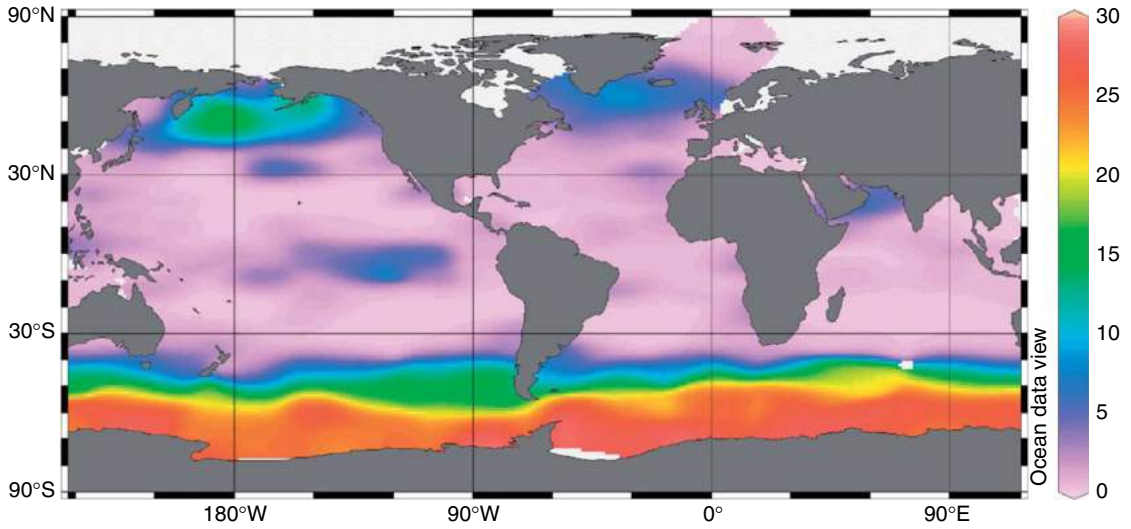

Fig. 1 Map showing the annual mean concentration of nitrate in ocean surface waters. Drawn by the authors using data collected during the World Ocean Circulation Experiment (WOCE).

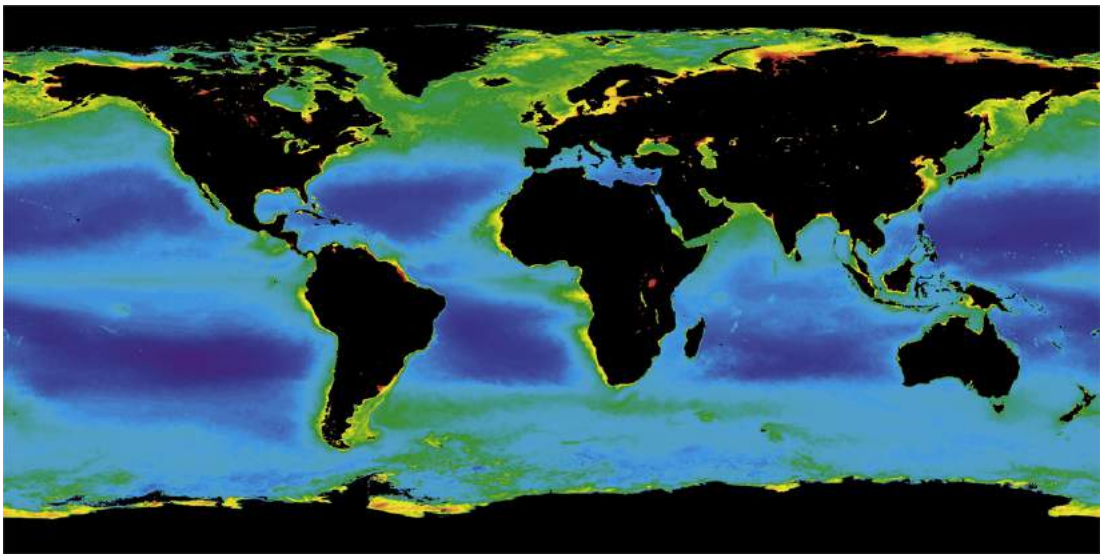

Fig. 2 Satellite map showing the annual mean chlorophyll concentration of ocean surface waters (blue indicates low values; red indicates high values). Provided by the SeaWiFS Project, NASA/Goddard Space Flight Center, and ORBIMAGE.

conditions is to have as small a cell as possible. The SOIREE iron-induced bloom was particularly intense, and evidence was still visible in chlorophyll satellite images up to 55 days after the initial iron infusion.

The Geritol Fix

These iron-enrichment experiments engendered considerable interest both inside and outside the scientific community. They raised the possibility of bioengineering of the oceanic ecosystem as a palliative measure against rising levels of fossil fuel CO_2 by the controlled addition of iron to HNLC areas of the ocean. This became known as the `Geritol fix', named after a popular iron-containing tonic for `tired blood' that was popular many decades ago.

Initially, this idea looked promising. Calculations based on the biological response in these enrichment experiments indicated that a single Fe atom could theoretically initiate the uptake of many thousands of CO_2 molecules. This means that to sequester billions of tonnes of fossil fuel carbon (the current global input from fossil fuels) might only require a few million tonnes per year of iron. This is a very small fraction of the total amount of iron smelted each year. Iron is, after all, an extremely abundant element in the Earth's crust. It has even been reported that John Martin quipped ``Give me half a tanker of iron and I'll give you an ice age.''

However, things are not that simple. It is not sufficient for iron enrichment to stimulate new CO_2 uptake through additional phytoplankton growth. It is also necessary for the biological carbon sequestered in this way to survive respiration long enough to sink out of the mixed layer, thus removing the sequestered carbon from the ocean–atmosphere system. Once `pumped' into deep water in this manner, the sequestered carbon will not return to equilibrate with the atmosphere for 1000–2000 years, the turnover time of the deep water circulation system.

Thus, experiments were conducted to measure the flux of biological carbon sinking into deep water as a result of iron enrichment, and here things began to look less promising. In the initial IronEx experiment, some sinking of carbon into deep water was observed, but this may have merely been a result of subduction of the water itself. In the remaining experiments, especially during SOIREE, no increase in the flux of biological carbon to deep water was observed. This was in spite of the fact that the majority of organisms that bloomed were relatively large diatoms.

In reality, the sinking of biological carbon into deep water is a much more complex process because an entire food web is involved. Much of the carbon flux is mediated by grazing zooplankton which produce large, rapidly settling fecal pellets. During artificial experiments like SOIREE, the principal grazers of the large diatoms are probably not very abundant before iron infusion stimulates the rapid growth in numbers of their prey, and the predominant grazers may have been too small to take advantage of a bloom of very large phytoplankton. However, if iron infusions were carried out on a semicontinuous basis, who knows what permanent changes to the food web might be induced? Although this offers tantalizing benefits for mitigating climate change, it does seem to be a very dangerous experiment.

Speciation and the Bioavailability Conundrum

Not surprisingly, the discovery of the importance of iron in regulating plankton productivity in HNLC areas of the ocean stimulated a renaissance of interest in the marine chemistry of this element. Very quickly, new knowledge began to emerge that made out understanding of this complex situation even more difficult. As already mentioned, iron is very difficult to measure accurately at the very low concentrations observed in seawater, and even now there is no universal agreement on its distribution in ocean waters. This is in spite of some carefully designed intercalibration experiments that have attempted to sort out the best experimental methods for sample collection, handling, and analysis. Nonetheless, some features are now clear.

As mentioned, in the modern ocean iron is present mostly as Fe(III); this oxidation state is very insoluble in seawater at its normal pH of about 8 because of the very insoluble hydroxide $Fe(OH)_3$. Careful laboratory measurements using purely inorganic salt solutions suggest that at this pH the solubility of $Fe(OH)_3$ is about 0.2 nM. Yet the so-called `dissolved' Fe concentrations, measured using filtered samples of seawater, are invariably up to 3–4 times higher, even in remote regions. One reason for this discrepancy is that Fe(III) readily forms colloidal particles of $Fe(OH)_3$ which are small enough to pass through most filters, thus masquerading as `dissolved' Fe. However, very small ultrafilters can be used to eliminate a lot of the colloidal fraction, but even then the concentrations of the apparently soluble fraction still exceeds the theoretical solubility limit of 0.2 nM.

We now know that this is a result of the interaction of Fe(III) with natural organic matter (NOM) dissolved in seawater which form coordination complexes with NOM ligands. A number of very sensitive techniques are now available to probe the nature of these NOM complexes, and while there is some variation in the reported results, some general trends are clear. Seawater appears to universally contain an excess of NOM ligands that bind Fe(III), some of which are extremely strong in a thermodynamic sense (large equilibrium constant for formation). In surface waters, there is mounting evidence that the main NOM ligands are of direct biological origin, similar to the `siderophore' compounds known to be produced by certain terrestrial microorganisms as a mechanism to sequester iron in, for example, soil waters. Iron-binding NOM persists throughout the oceanic water column, and it has been estimated that as a result of their presence, the total oceanic inventory of Fe(III) is raised by a factor of at least 4 over the solubility limit. Clearly this is very important, especially for phytoplankton growing in HNLC areas such as the Southern Ocean, where the main Fe supply may well be the upwelling of deep waters rich (relatively speaking) in NOM-bound iron.

Increasing the solubility of dissolved Fe is advantageous only if the Fe bound to NOM can then be rapidly taken up and released as inorganic Fe inside the cell. This may not be a problem for marine prokaryotes. Heterotrophic bacteria and cyanobacteria isolated from marine habitats also produce siderophores when Fe-limited, some of which have been isolated and chemically characterized. Moreover, marine bacteria transport Fe bound to siderophores regardless of whether or not they produce their own. Little is known of the mechanism by which marine bacteria obtain siderophore-bound Fe, but there is evidence that its fundamental features resemble those of terrestrial bacteria, which possess outer-membrane receptors that transport a wide range of intact Fe(III)–siderophore complexes through the cell wall.

However, the binding of Fe by NOM ligands generates a puzzling conundrum for marine eukaryotic phytoplankton. For these organisms, the principal effect of the formation of a coordination complex by a metal ion with NOM ligands is considered to be a `reduction' in bioavailability. In this paradigm, in order for a metal ion to become available for cellular uptake, it must first dissociate from the NOM complex and become converted into a kinetically available inorganic form such as the free ion Fe^{3+} or its complexes formed with simple ligands such as OH^- or Cl^-. Only these forms are considered kinetically accessible to ion-uptake mechanisms on the cell wall.

This is why the chelator ethylenediamine tetraacetic acid (EDTA) is added to many culture media. Without it, the metal ions present as impurities in the salts used to prepare the media would be far too toxic for any phytoplankton to grow. Similarly, chelators like EDTA are used to strip metal ions like Pb^{2+} when people suffer from lead poisoning.

The conundrum is that Fe, a biologically essential element in drastically short supply in HNLC areas, appears to be bound up by NOM that ought to make it unavailable to much of the phytoplankton community. Worse still, the NOM appears to be of biological origin. So what is really going on with Fe(III) and the NOM complexes it forms? It does not make sense that phytoplankton, already struggling with a lack of iron supply, should synthesize iron-binding compounds like siderophores unless the formation of Fe(III) complexes by these materials actually assists them in acquiring iron. That implies that they have some specific mechanisms on the cell surface for unlocking Fe bound by NOM. In support of this, some very elegant culture experiments using radiolabeled Fe conducted on board ship made it clear that oceanic plankton from HNLC areas were able to take up iron much faster than it could possibly dissociate from NOM complexes to form readily available inorganic forms of Fe(III).

However, at the time of writing, we have no clear idea how this works. One possibility is that photochemistry may play a role. Fe(III)-containing complexes can be photochemically reduced to Fe(II) in seawater, in which form the Fe is much more biologically available. However, although recent work has shown that Fe(II) is generated during daylight hours in seawater, the amount of Fe(II) produced does not seem to be enough to support much plankton growth.

Biologically mediated reduction of Fe may be an alternative means to increase the biological availability of Fe bound to NOM. Experiments conducted on marine diatoms have shown that Fe(III)–NOM complexes can be accessed through use of a cell membrane Fe(III) reductase, similar to systems found in some vascular plants and other eukaryotes. Under Fe deficiency the activity of the reductase is enhanced, enabling these diatoms to acquire Fe bound to a number of natural and synthetic Fe chelators and to grow rapidly. In this type of non-ligand-specific system, reduction of organically bound Fe(III) results in dissociation of the complex, allowing uptake as inorganic Fe(II) or as Fe(III) after reoxidation.

An interesting twist in the reductive uptake process of Fe NOM complexes is the possible involvement of copper. There is evidence from a marine diatom that Fe acquisition involves two consecutive redox transformations of Fe. First Fe(III) is enzymatically reduced to Fe(II) by cell membrane reductases, then Fe is taken up by a protein complex containing a multicopper oxidase, which oxidizes Fe(II) back to Fe(III) during the membrane transport step. Even though the oxidation of Fe(II) occurs spontaneously and rapidly in oxygenated seawater, a multicopper oxidase may be important in order to acquire Fe before it diffuses away from the cell. This Fe transport pathway is highly analogous to that identified in common yeast, and some fungi and green algae. Genes homologous to those that encode for the proteins of this pathway have been identified in the recently sequenced genome of the diatom *Thalassiosira pseudonana*.

Material and Metal Ecology

MA Reuter, Ausmelt Ltd, Melbourne, VIC, Australia
A van Schaik, MARAS (Material Recycling and Sustainability), Den Haag, The Netherlands

Introduction

`Metals and materials´ are used in a wide range of products and applications ranging from consumer products (cars, electronics, white and brown goods, etc.) to constructions (buildings, roads) and agriculture (fertilizers), etc. The social and ecological value of the materials in these applications is not only determined by the `in-use value´ of these applications such as functionality, durability, safety, reduced energy consumption, esthetics, etc., but also by the possibility of these materials to return from their original application into the `resource cycle´ after their functional lives/use at the lowest environmental impact. The design of the product determines the selection of materials to be applied in the products as well as the complexity of the material combinations and interactions within this product (e.g., welded, glued, alloyed, layered). These actions directly affect the recyclability of the materials, that is, whether the material cycle can be closed and whether one can speak of an industrial ecological system.

Fig. 1 indicates that the social/environmental value of materials and metals can only be properly determined if both the resource cycle and the `technology/design cycle´ are fundamentally understood and described, but more important that tools are available to link these three inseparable disciplines. The interconnectivity between the resource cycle (i.e., the primary and secondary material cycles), the technology/design cycle (i.e., product design, recycling technology, materials processing, etc.) and the nature (social/environmental) cycle is depicted by Fig. 1.

This section shows how complexly linked (nano-/micro-) metals (with their associated materials, plastics, etc.) that is, the resource cycle is related to products, production, manufacturing technology, and the product designer, that is, the technology and design. Ultimately these cycles intersect with nature, that is, the nature cycle, but this is disregarded from the discussion here; however, the link to geology, ores, and metal-containing minerals is considered as is the environmental impact of waste and residues from anthropogenic activity. This together composes the complex `web of metals and materials´ from an anthropogenic point of view. This web depicts the flow of metals/materials into consumer products; subsequently as consumer products into most regions of the world and finally either recycled back into consumer products and/or into nature and/or humans and/or disposed. Central to this is the metallurgical processing technology, which constitutes the `ecological organism´ in this industrial ecological system; the `organism´ that closes the anthropogenic material and metal cycles.

The web of metals and materials or `industrial ecological metal and material system´ shows how metals and associated materials flow through the resources industry as well as the consumer product and waste system. It describes this flow on the basis of the first principles of recycling technology and metallurgical processing technology theory which are closely linked to product design. This technology- and engineering-based approach provides insight into the complex web of metals and materials providing information on how to monitor, control, and improve the system (and on this basis its economics), at the same time linking this information back to product design. The best manner in which to map the complex interactions between metals is by the application of dynamic modeling, which is more advanced than material flow analysis (MFA) and provides valuable insights into the dynamic interaction and movement of metals and materials linked to consumer products. This is crucial to ensure that valuable minor elements find their way back into products, visualizing and controlling the distribution of these elements onto the surface of the Earth due to the action of consumer society and original equipment manufacturers (OEMs). Therefore, the following will be discussed providing a holistic and fundamental approach to material and metal ecology.

- Resource efficiency and future availability of materials/minor elements is of environmental, economic, and societal concern. Therefore, the recovery of material and metals within the highly connected web of metals and materials in the resource cycles of both base metals and especially environmentally relevant and valuable minor elements for automobiles, consumer electronics, miniaturization applications, and nanotechnology is of crucial importance from a sustainability perspective. Crucial here is also the effect of the closely connected materials in consumer products that cannot be separated due to their close association in end-of-life products.
- Time dependencies as well as process dynamics often have a crucial impact on the web of metals and materials and hence on the impact these metals and materials have on the environment. This is important since it takes time for consumer products and their associated metals and materials to flow through the system. Also the complex connection between the linked primary ore and secondary recycled materials chains, and rapidly changing product compositions have an important effect on determining where metals and materials report to. Social aspects such as the concentration of labor in certain parts of the world associated with metal production and recycling could be dynamically illustrated by such a dynamic visualization.
- Energy and climate change effects are directly connected to recycling as many of the environmental impacts are dominated by the energy needed and CO_2 produced to extract materials associated with products or by the prevention of this by proper recycling activities. Recycling is therefore of extreme importance to lower the consumption of energy during their production, hence directly having an impact on greenhouse gas emissions. It is shown how the web of metals and materials can be arranged

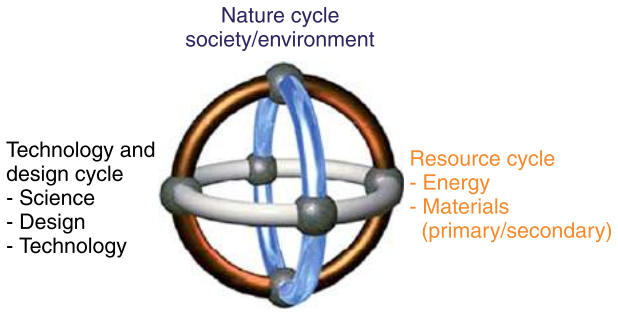

Fig. 1 Philosophy: toward sustainability and material and metal ecology by linking the indicated cycles. Reproduced from van Schaik, A., Reuter, M.A., 2004. The time-varying factors influencing the recycling rate of products. Resources, Conservation and Recycling 40 (4), 301–328, with permission from Elsevier.

to maximize energy recovery, support light-weight design, minimize toxic emissions by basing the system models on the first principles of process engineering.

- The role of product design is demonstrated by discussing the design wheel, which shows how computer-aided design (CAD) is linked to recycling, recyclate quality, metal and energy recovery, and waste creation/prevention. Often materials are connected to each other, alloyed, welded, glued, etc., which makes it impossible to consider the ecology of metals and materials only on a linear and single-element basis.

This rigorous approach provides a basis for quantifying legislation on a more technological and fundamental basis (i.e., physics, chemistry, and thermodynamics) hence providing a first-principles basis for recycling targets and a solid legal basis which OEMs can safely operate on and manufacture products (e.g., future energy-efficient recyclable light-weight cars). This dynamic and technological detailed first-principles approach supports the simplistic life cycle assessment (LCA) approach and provides the consumer with transparent information on all issues surrounding the ecological safe production and use of the product until its end-of-life phase and subsequently its recycling back into metals, materials, and energy.

The Metal Wheel – Material and Metal Ecology

Consumer products are a complex mixture of closely associated metals, plastics, chemicals, inorganic compounds, and materials. These complex connections are often difficult to separate due to the limitations of the applicable separation physics as well as incompatible thermodynamics, which sometimes render the complete recycling chain uneconomical, subject to product type. The result could be that these end-of-life products are then shipped to low-cost countries where these are hand-processed (often more efficiently than present technology permits) and/or dumped or even reused but then eventually finding their plight on an unsafe dump in an uncontrolled economic environment. The result is obviously that hazardous materials could report to the ground-water with all subsequent consequences to health by for example uncontrolled burning of these goods.

Therefore, any modeling and assessment approaches should provide valuable information to the legislator to provide a fundamental basis for global environmental legislation based on achievable technology and economics incorporating the dynamics of market flexibility and consumer behavior. Mapping of materials will inform the original equipment manufacturers (OEMs) on a technology basis where materials and elements in their products are reporting to, ensuring that a solid legal and environmental basis is maintained for marketing these products. On the other hand, the consumer can be transparently informed of all benefits and risks of using the products of the OEM, as well as providing the legislator the means to monitor the (likely) movement of end-of-life products across the globe to ensure that nature and humans do not ultimately come to harm. Thus, a first-principles modeling and simulation approach ensures that the recycling loop can be mapped and subsequently `closed´ for metals and related materials in relation to design. This approach that quantifies the material and metal flows is the only manner to ensure that sustainable resource usage will be attained.

Therefore, judicious management and understanding of the plight of valuable (and also possibly toxic) minor elements is a matter of extreme importance to OEMs, legislators, recyclers, ecologists, environmentalists as well as sociologists, general population, nongovernmental organizations (NGOs), to name but a few. Therefore, for all the issues that will be discussed below to discuss the `ecology of materials and metals´, a fundamental understanding of the size and nature of resource cycles over time is needed in order to address environmental impacts and to formulate policy, design, technological and system organizational strategies for more sustainable global resource cycles.

Fig. 2 shows that each carrier commodity metal is associated in nature (geology) by a unique blend of valuable minor elements (with or without own processing infrastructure) as well as harmful elements of no economic value that are lost due to unfavorable thermodynamic and other conditions within the processing chain. The carrier element can in some cases be only the secondary material being recovered since the minor elements are of much higher economic value. Therefore, affecting the production of these carrier elements could in the end adversely affect the production of the valuable minor elements. Green processing would imply minimizing the losses of elements to the green outside band of Fig. 2.

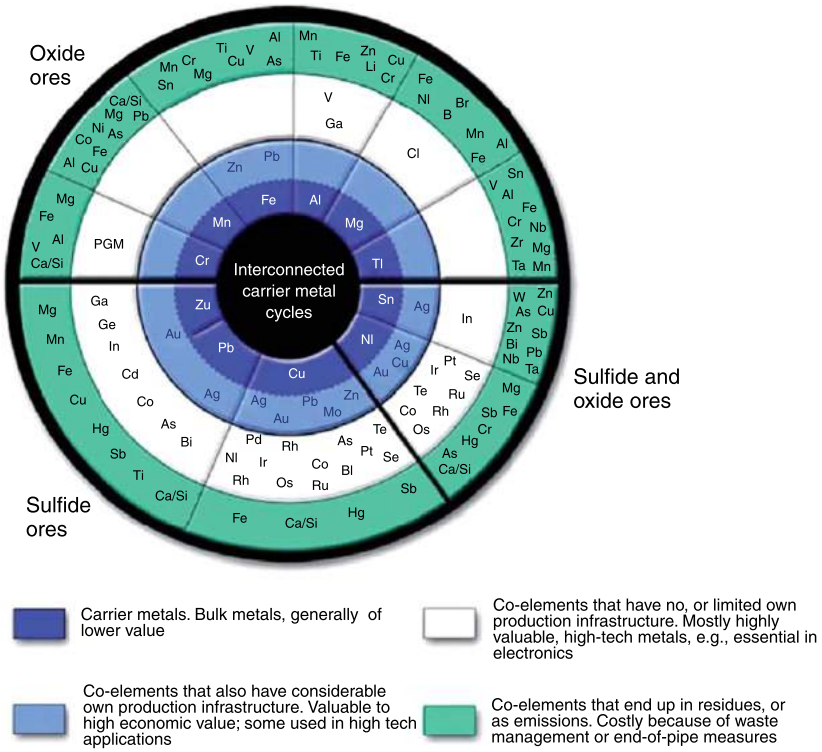

Fig. 2 The `metal wheel´ showing the complex interactions between different metals as well as the economically and thermodynamically recoverability of (co-)elements. Reproduced from Reuter, M.A., Heiskanen, K., Boin, U.M.J., *et al.*, 2005. The Metrics of Material and Metal Ecology. 760 pp Amsterdam: Elsevier Science, ISBN - 13: 978-0-444-51137-9, with permission from Elsevier.

The intricate and unique blend of elements within each ore has led to metallurgical processing being honed to effectively recover and contain most elements economically. This complex link of materials, processing of ores, metals, and end-of-life products has led the creation of a complex web of metals and materials, in which each element has a unique position. Hence affecting the production of one element has an effect over other elements within the web.

An interesting example is indium that is used in flat TV panels. The question is how much is required, where, when, and how this changes dynamically due to the metal (especially zinc) market? For example, a country such as Japan requires around 160 t per annum but can only obtain a fraction of this via primary ore sources. Therefore, recycling has to supply the rest, but this is only achieved partially, that is, in total primary and secondary recovery only reaches around $\gtrsim 100$ t.

Fig. 3 shows a model that simulates this complex link between various elements and predicts their global flow over time through the complete metal and material chain, also for example the passage of the metal Indium (used in flat panel displays) through the complete material and metal system in time. Environmental indicators have been linked to the output in order to quantify the environmental performance of the complete global anthropogenic system.

Product Design and Fundamental Recycling Optimization Models

The design of a product is linked to recycling as depicted in Fig. 4. The design does affect how materials are liberated during shredding, how efficient materials can be separated, and what the composition and quality of the recyclates will be. This determines if these recyclates can be recycled or not, therefore what the losses will be from the recycling chain. The control of the recycling chain determines what the qualities of the streams are and whether or not the recycling rate is high. This in essence determines whether materials and metals can be recycled, hence the pivot of `industrial ecology of the materials and metals´ within the car. This section will discuss the various factors influencing the `material and metal ecology´ of a consumer product, for example, the car.

Product Design, the `Metal Wheel´, and Recycling Technology

Product designers select the produced metals and materials from (primary) resources as depicted by Fig. 2 and apply them in products and applications. The product designers determine which interconnected materials are to be separated and recovered from primary ores for application in the car.

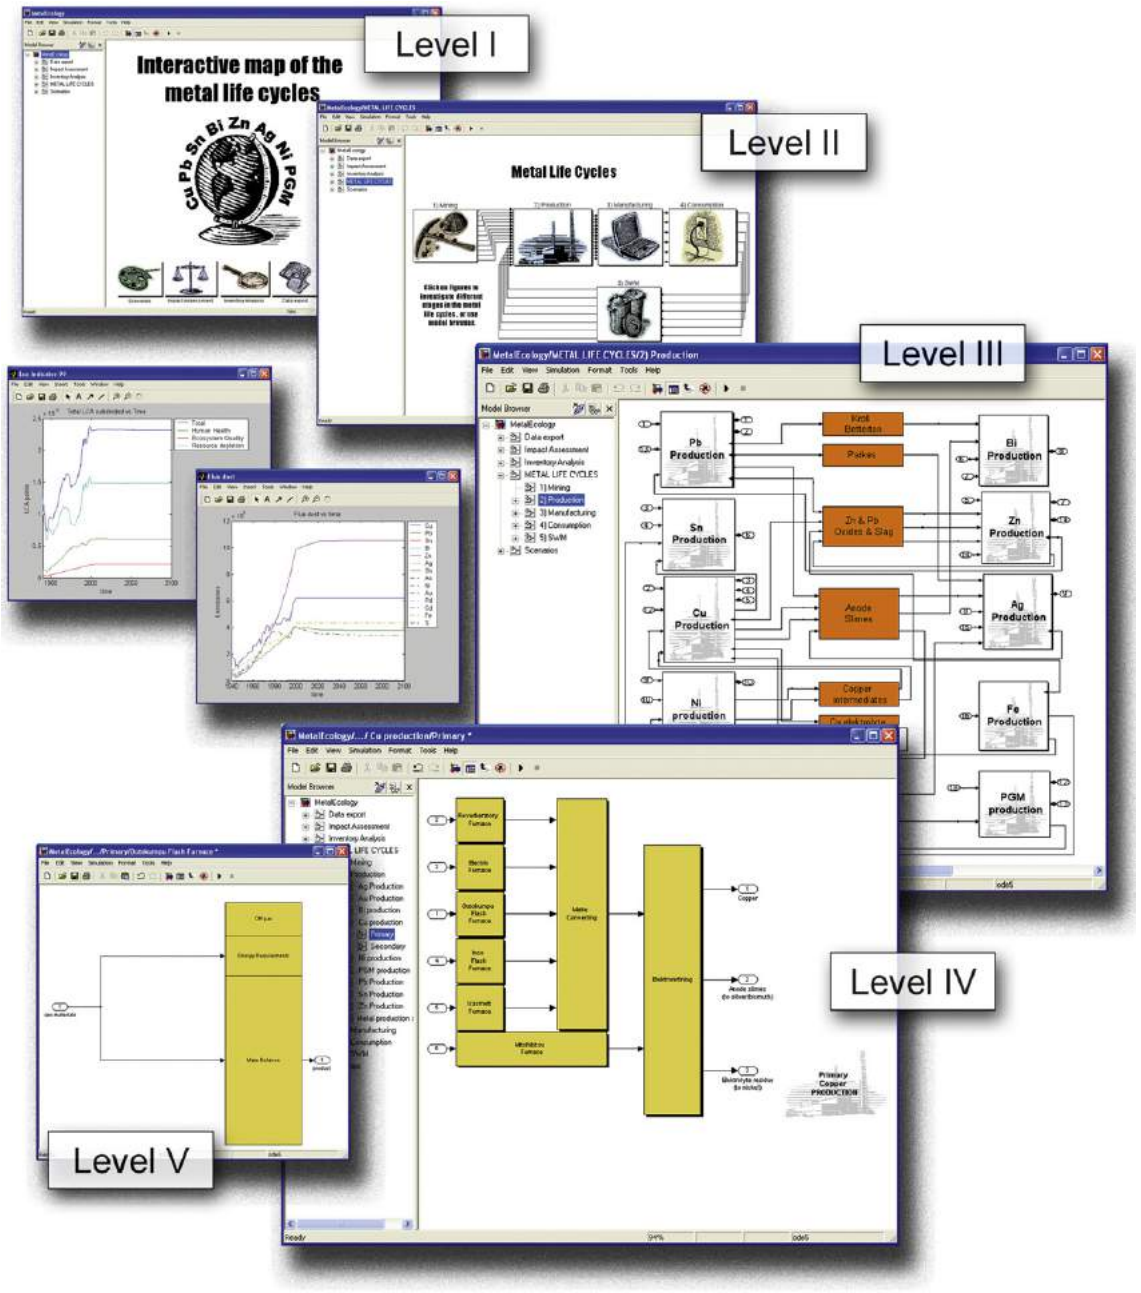

Fig. 3 The various levels of the dynamic Simulink model that dynamically links the metal flow of various metals as shown in the level III slide, producing a dynamic LCA environmental score for the complete system (two small gray windows left middle). Reproduced from Reuter, M.A., Heiskanen, K., Boin, U.M.J., *et al.*, 2005. The Metrics of Material and Metal Ecology. 760 pp Amsterdam: Elsevier Science, ISBN - 13: 978-0-444-51137-9, with permission from Elsevier.

During the design of the product a range of materials/elements are once again mixed and complexly connected (gluing, welding, alloying, etc.). Modern products contain a combination of metals that are not necessarily linked in the natural resource systems as shown in **Fig. 2**. As a consequence, these materials are not always compatible with the current processes in the metals production network, which was developed and optimized for the processing of primary natural resources and associated minor elements.

In general an increased complexity of recycling pyrometallurgy has arisen through the development and design of modern consumer products (such as passenger vehicles and consumer electronics). The consequence is the formation of complex residue streams or undesired harmful emissions that cannot be handled in the current system (thus the processing and recycling of those products at their end-of-life). This can be prevented by linking product design with optimized recycling technology, therefore minimizing the loss of valuable material and preventing the decrease of both quality of recyclates and recycling rates of these products.

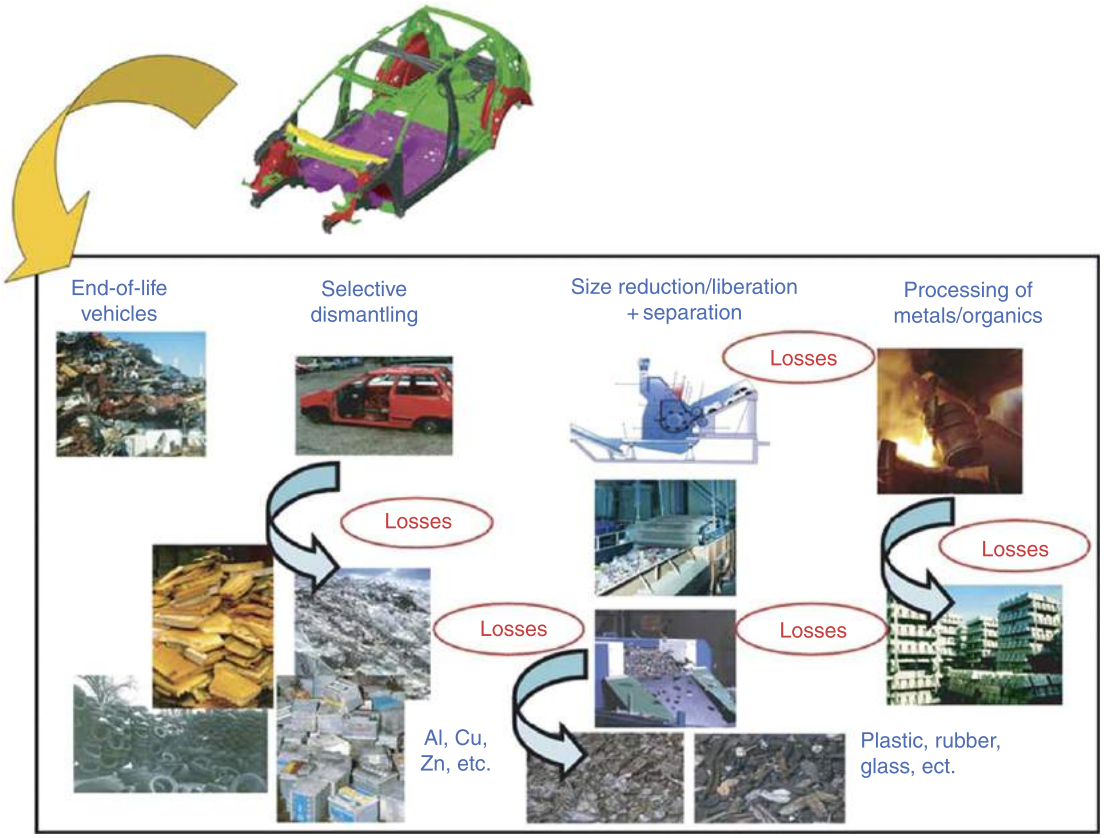

Fig. 4 The link of a car design to the recycling chain, which includes selective dismantling, size reduction, and subsequent physical separation, metallurgical, and thermal treatment.

Recycling Optimization Models

Commercial recycling systems never create pure material streams (see **Fig. 5** for materials from end-of-life-vehicles (ELVs) recycling collected from various shredder plants), never achieves 100% material recovery (recycling) during physical separation (dictated by separation physics), neither achieves 100% material recovery (recycling) during high-temperature metal production (dictated by thermodynamics), and nor achieves 100% energy recovery (dictated by thermodynamics).

The recyclability of a product is not only determined by the intrinsic property of the different materials used, but by the quality of the recycling streams (see **Fig. 5**), which is determined by the mineral classes (combination of materials due to design, shredding, and separation), particle-size distribution, and degree of liberation (multimaterial particles) (see **Fig. 6**). All these affect the physical separation efficiency, metallurgical and energy recovery, which all in turn determine the quality and economic value of the recycling (intermediate) products in the recycling system, which can be applied as secondary resources.

Since the quality of recyclates and the recycling rate of a product is largely affected by the design of the product (see **Fig. 7**), it is required that tools are available that link CAD software and recycling models in order to predict recyclability of the car during the design phase. In addition, this predicts and determines the social and environmental value of the materials applied in the product. Fundamental knowledge of recycling processes, such as shredding, mechanical separation processes and metallurgy, and material characteristics of recycling (intermediate) products (material type, liberation, etc.) have to be combined with that of the design of the product (material combinations and connections). In order to optimize the resource cycle and maximize the recycling rate of (future) products all the parameters determining the recycling/recovery rate for each of the materials present in the multimaterial designs and applications of the present and future have to be fully understood. This should all embrace the dynamics and statistically distributed nature of the resource cycle system.

The prediction of the recyclability and recoverability of products already in the design stage requires the exploration of the limits of recycling on a fundamental basis as has been discussed by Reuter *et al.* Recycling models have been developed by Reuter and van Schaik. These recycling models take into consideration (1) material quality (physical and chemical) and calorific values of the (intermediate) recycling streams being a function of material/mineral classes, particle-size classes, liberation classes (degree of liberation); (2) the value of intermediate streams; (3) separation physics and thermodynamics; (4) losses and emissions; (5) harmonization of plant/flowsheet architecture with changing product design; and (6) distributed and dynamic properties of present and future product designs (see **Fig. 8** for a detailed flowsheet of the recycling optimization model).

Fig. 7 Possible connection types in car design with distinctive liberation behavior. From van Schaik, A., Reuter, M.A., Richard, A., 2005. A comparison of the modelling and liberation in minerals processing and shredding of passenger vehicles. In: Schlesinger, M. E. (Ed.), EDP Congress 2005. Warrendale: TMS (The Minerals, Metals & Materials Society), pp. 1039–1052.

Fig. 9 shows how after shredding, shredded particles have different degrees of liberation, therefore creating streams of different composition (quality and economic value). This is partially caused by imperfect separation in the physical separation stage of these particles and also by the design choices as shown in Fig. 7, affecting particle composition after shredding. The quality of recyclate streams ultimately determines in which processing steps depicted in the detail flow sheet in Fig. 8 these materials can be processed and hence how much material of sufficient quality and economic value can be recycled.

Fig. 10 depicts how product design selects materials from the primary metal and material cycles and combines them into a complex multimaterial design, in which the various materials (metals and nonmetals) are complexly integrated. The combination and connection of the materials in the product design is linked (on the basis of the discussed recycling models) to the quality of recyclates as a function of the degree of liberation of the various particles after shredding. The colors in the `design wheel´ of Fig. 10 reflect the (in)compatibility of material combinations in the recyclates (either due to imperfect liberation or separation) based on the material combination matrix given in Fig. 11, in which the (in)compatibility of material combinations is based on the thermodynamics and kinetics of metallurgical processing (see also Fig. 2).

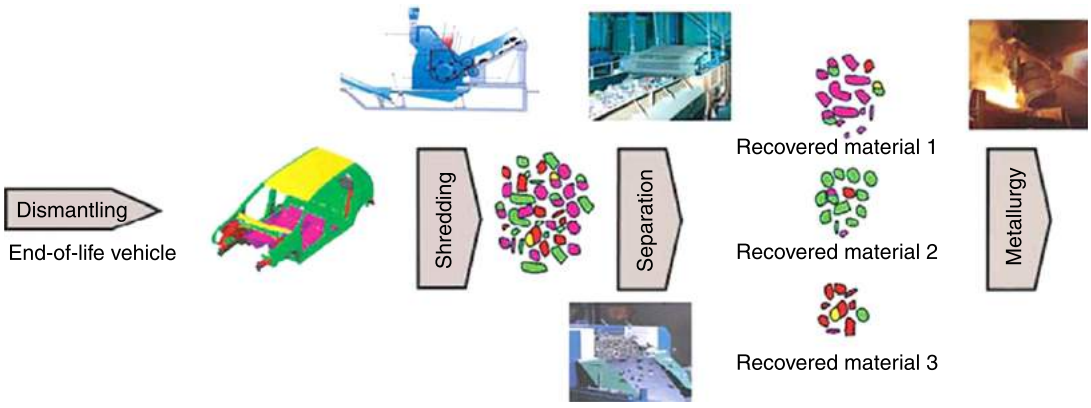

Fig. 9 Shredding of a car and the creation of liberated and unliberated materials.

Fig. 10 reflects the knowledge and modeling detail captured by the developed recycling optimization tools and provides feedback to the designer on desired and undesired material combinations in the design. The wheel acts as a preliminary design for recycling (DfR) tool, reflecting the complexity and detail of the developed recycling models to ensure a proper reflection of the reality of recycling system behavior and the quality and value of produced recyclates. The wheel enables DfR based on the limits and possibilities of recycling technology and recyclates quality as a function of design and separation efficiency. In summary therefore this wheel shows what can be achieved as a function of design in combination with `best available technology´ (BAT) and hence the limits of physics and chemistry as taking place in the technology.

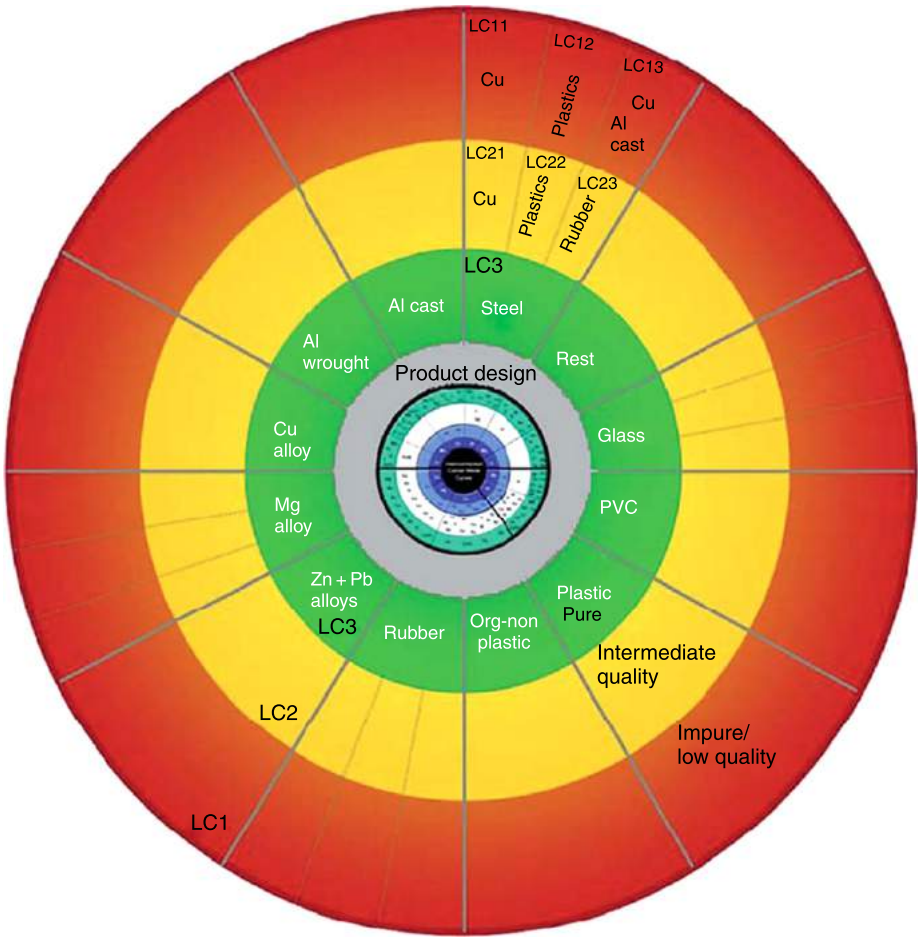

Fig. 10 The `design wheel´ illustrating the underlying liberation classes that are created as a function of product design as predicted by the recycling model depicted in Fig. 8. Reproduced from van Schaik, A., Reuter, M.A., 2007. The use of fuzzy rule models to link product design to recycling rate calculations. Minerals Engineering 20, 875 -890, with permission from Elsevier.

Linking Design and Recycling

Figs. 4, 8, and 9, respectively, depict a simple scheme for car recycling and a complex optimization model for recycling of end-of-life products such as a car. Fig. 12 depicts the (un)liberated particles after shredding (Figs. 6 and 9) which determines its recyclability due its quality (and hence its economic value). These determine whether or not the material chain can be closed.

Table 1 explains why, if certain fractions are liberated, unliberated, whether they can be fully recycled or not. For example, copper connected to steel will dissolve in steel. Since copper is more noble (less reactive to oxygen) than steel it cannot readily be removed from the steel. This affects the steel quality negatively (e.g., its mechanical properties) and therefore it is given a red color in Table 1. Note, that this is dependent on the amount of the one material connected to the other (the concentration of the contaminant). In many cases, although red material combinations exist, shredding liberates the materials, which are subsequently separated during physical processing and hence they are recyclable. Fig. 11 and Table 1 are only true if there are reasonable amounts of materials connected in the recyclates (exceeding the contamination limits), hence producing alloys outside their normal definitions. The type of models as discussed above can predict the recyclate quality and therefore link design to recycling and restrictions as indicated in Table 1.

The optimization model of which the flowsheet basis is depicted by Fig. 8 is far too complex to link to CAD directly, therefore fuzzy logic rule-based models that mirror the results of this complex model have been developed from the numerical results of the recycling models, and linked to CAD software and the design of the product (© MARAS). Not only can these fuzzy logic models be linked to CAD software, but they can also be integrated into LCA tools, in order to ensure that environmental models are provided with fundamental information on the end-of-life behavior of products which include (1) physics and thermodynamics of separation processes, (2) the quality and value of recyclates as a function of physical design choices (material combinations and connections), and (3) physical separation and metallurgical and thermal processing technology on a statistical basis.

Recycling 1153 ELVs – From Theory to Practice

The developed theory as described in the previous section provides a fundamental basis for proper collection of data, supported by a good mass balance based on data reconciliation, and the corresponding statistics and how this should be performed when carrying out experiments or auditing a plant. This theory is essential to characterize and control the material and element flows in recycling plants and through the complete recycling system, which is extremely important for good metal/material accounting, the

Table 1 The reasons for certain materials being compatible or not (also see Figs. 11 and 12) explained on a thermodynamic basis

Input streams (secondary) = recyclates	*Industrial streams (metals)* *Aluminum cast*	*Copper*	*Steel + cast iron*
Aluminum cast	Similar material	During copper processing Al is lost to slag	Loss of Al; Al less noble
Copper	Cu is more noble than Al cast; a certain % of Cu is allowed being one of the alloying elements for Al cast	Similar material	Cu is more noble than steel
Steel + cast iron	Steel+cast iron more noble than Al cast	Creates excessive slags, loss of steel to slag	Similar material
Plastics	Limited due to reaction of Al with C and subsequent loss of Al (Al_4C_3)	Affects energy balance of processing; fillers affect slag properties; possible dioxine creation	Affects energy balance of processing; fillers affect slag properties; possible dioxine creation

calculations of recycling rate on a sound statistical basis, as well as quality control of recycling streams. In fact this is the basis of any meaningful discussion on `material and metal ecology´.

Experimental and industrial data on the composition of the car, the separation efficiency of the various processes, liberation and particle-size reduction in the shredder, the quality (or grade) of the recycling (intermediate) material streams is typical information that becomes available through a good understanding of the theory of recycling as discussed in the previous section. Furthermore, the collection of industrial data on recycling based on best available technology is essential to predict and calculate the recyclability of passenger vehicles, using the developed models. This is of extreme importance for a realistic definition of the type approval and end-of-life legislation of vehicles or any other consumer product. This type of data hence underpins the viability of material and metal ecology.

The theory is applied to provide a procedural basis from which the recycling rate can be calculated from an industrial experiment, in which 1153 ELVs were recycled. This experiment was executed at a large-scale industrial recycling plant and clearly illustrates how statistically sound recycling rates can and therefore should be calculated from data collected from recycling experiments based on the developed theory and classical sampling theory and statistics.

Practical Procedures for Performing Large-Scale Industrial Recycling Experiments

Mass balances of plants based on measured data mostly do not close due to inevitable weighing and sampling errors, as is also the case for the shredding and `postshredder technology (PST)´ trial as discussed here. Data reconciliation has been applied to close total and element/compound mass balances over the plant and its unit operations. A large body of data renders the mass balance more accurate and makes it possible to calculate the recovery and grade for each of the different materials over the various process steps. These data are used to calibrate the models in the optimization and dynamic models mentioned above. Classical sampling theory has been applied to calculate statistically correct sample sizes for analyses of the various material flows throughout the plant (see Fig. 4). The mass flows and composition of the streams were measured and analyzed over all unit operations in the plant that is, on the input, intermediate, and output streams, in order to increase the amount of data available for data reconciliation, which increases the accuracy of the mass balance and its statistics.

Calculation of Recycling/Recovery Rate

Based on the mass balance and its statistics, the recycling rate of ELVs based on the discussed test could be calculated for best available technology as shown in Fig. 13. For the first time a test was therefore concluded in which the recycling rate was calculated within a statistical framework, crucial to proving the validity of the recycling rate calculation. Ultimately the recycling rate is determined by the possibility of the market to absorb the produced output streams (either for direct application or in metallurgical or thermal processes) and is therefore determined by the quality of the recycling (intermediate) products as well as by the geographic location of the plant (due to local environmental legislation).

Statistics

Only data reported within a statistical and theoretical framework can have a legal basis and can find their way into design software for cars in order to perform `DfR´ and hence real `material and metal ecology´ on a large industrial scale. Moreover the statistics around the calculation of the recycling rate based on plant data indicates that the (calculations for the) recycling/recovery rates and requirements for type-approval of cars as imposed by legislation in Europe should also be based on a statistical basis and are meaningless if represented by a single value as is required at the moment. Any methodology to assess end-of-life systems has to take into account the statistics of design and end-of-life technology.

Material and Metal Ecology

The fundamental basis of `material and metal ecology´ is discussed in this section. The discussed aspects provide fundamentally based answers and approaches to questions of crucial importance to the industry and environmentalists such as the magnitude of the legally required recycling rate of presently designed products, emissions of processes and end-of-life products to nature, etc. This approach is being adopted by the automobile industry to ensure among others that recycling rates have the fundamental basis that challenges but also provides the legal basis for recycling legislation. It can also provide the basis for risk analyses for new car designs from a recycling point of view.

Any evaluation of the economic and/or environmental consequences and calculation of environmental scores of product and material applications can only be conducted if the interconnectivity of material/metal cycles is recognized and recycling rate calculations are based on fundamental recycling models. The model structure should be linkable to CAD product design activities, material choices, joints, etc. This is not possible with a LCA approach on its own, since it is not a simulation or predictive tool, it only represents the present and does not give technological advice about the future, how technology should be controlled and adapted, how the physical design of products have to be changed to ensure that economic recyclates can be created.

In summary the discussed approach provides a basis to `material and metal ecology´ in the following areas, which should ideally be integrated:

- Creation of a fundamental basis to define and realize `material and metal ecology´. All the models are predictive as a function of physics, thermodynamics, and chemistry as well as time, hence they are dynamic.
- Development of fundamental recycling models for interconnected metals and materials applied in various products/applications, for example, the models are applied by the authors for the recycling of passenger vehicles, waste electric and electronic equipment (WEEE), as well as for other waste/material systems.
- Development of fuzzy logic rule-based models to link fundamental recycling models on a simplified basis to design tools and material choices, while still maintaining the detail knowledge (process, material, quality, etc.) as captured by the complex models, hence providing simple risk models for designers.
- Fundamental recycling models (calibrated with data based on a statistical basis) can be linked to environmental LCA tools/software in order to provide a fundamental technological and statistical basis for the calculations of recycling/recovery rates, prediction of quality of recyclates, process operation, recycling system architecture, etc.

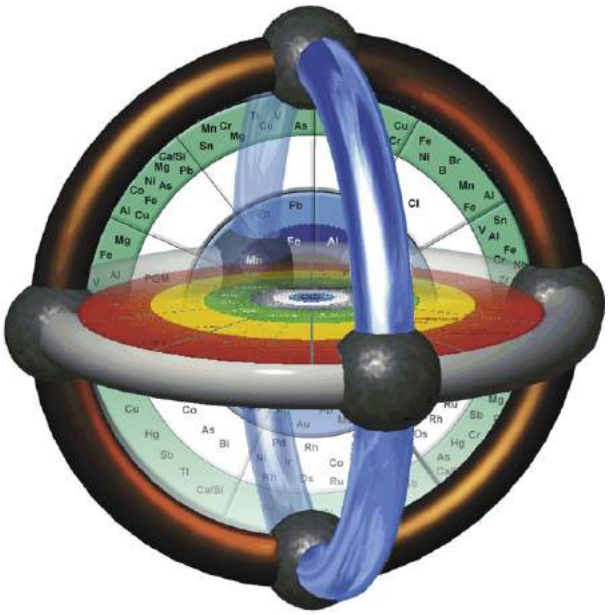

Fig. 14 The interlinked disciplines – applying fundamental models to link design to recycling and interconnected metal cycles providing fundamental knowledge and data to environmental models (LCA, MFA, etc.).

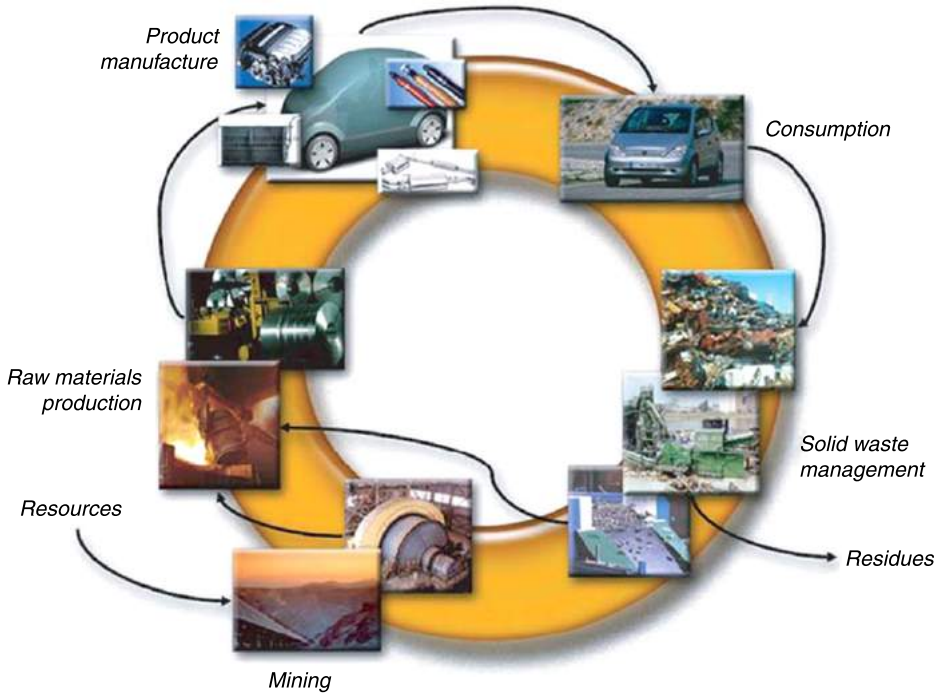

Fig. 15 The anthropogenic material and metal cycle. Reproduced from Reuter, M.A., Heiskanen, K., Boin, U.M.J., *et al.*, 2005. The Metrics of Material and Metal Ecology. 760 pp Amsterdam: Elsevier Science, ISBN - 13: 978-0-444-51137-9, with permission from Elsevier.

- A first-principles and technological basis for `DfR´ guidelines is provided which include (1) the influence of material combinations and connections, (2) liberation, (3) particle size, and (4) physical/chemical/thermodynamical process efficiency on the quality of recyclates and the maximum achievable recycling rates.
- Support eco-design by providing fundamental knowledge on recycling systems and DfR.

Fig. 14 summarizes the application of material and metal ecology, in which fundamental models link material choices in product design to recycling and interconnected material cycles. This provides fundamental knowledge and data for environmental

models (LCA, MFA, etc.), therefore linking the various disciplines related to the ecological value of materials in our society. It is still required to link these material and metal ecology models to the environment so that the effect of a product design on the environment can be directly determined. This would then constitute the final objective of true material and metal ecology in the present industrialized society. **Fig. 3** depicts a dynamic model that provides a basis for mapping dynamically the flow of elements, while the model depicted by **Fig. 8** depicts a recycling system model. The true innovation of this work is depicted by **Fig. 14** shows how **Fig. 2** (metal wheel) is linked to product design (design wheel). This innovation is a key issue in controlling the anthropogenic material and metal cycle (resource cycle), ensuring that the positive interaction with the nature cycle as shown in **Fig. 1** is optimized.

In order to realize a `sustainable´ material and metal ecology, the system depicted by **Fig. 15** should be in balance with the material and metal cycles in nature. In summary, visualizing and describing mathematically the link between our industrialized societies with nature, as discussed above, is key to providing a measure for `sustainability´ in our present consumer society. This measure provides a tool to shape a more harmonious future!

Microbial Cycles

GA Zavarzin, Russian Academy of Sciences, Moscow, Russia

Introduction

Microorganisms, particularly bacteria (=prokaryotes), represent the first sustainable system in the biosphere into which all other living beings are superimposed and included. Sustainability of the system depends on the catalytic role of bacteria in the cycles of biogenic elements and their mediating role in the transformation of other elements. Development of cooperative microbial community led to the biogeochemical succession, the most prominent result being oxygenation of the atmosphere around 2.4 billion years ago with interconnected changes for chemical compounds. The role of bacteria in the biosphere depends on their functional diversity and formation of cooperative trophic systems, scaling up from the local ecosystems to the biosphere as a whole. The limits of life are delineated by the topic adaptability of bacteria, while all other living beings remain within these frames. The number of bacteria exceeds 10^{28} in the active layers with rapid turnover and might be 10^{30} in total. It makes them by far the most important group in the conceptual structure of the sustainable biosphere. The trophic structure of the microbial system makes the framework of the biosphere. The interconnection of biogeochemical cycles makes the functional role of microorganisms in the biosphere most fundamental.

Biogeochemical cycles represent the main system by which the energy of the Sun is transformed into energy of the chemical compounds by living beings and products of their activity. The cyclic arrangement is the main principle of sustainability in the Earth system. It means that the compound involved in the process after sequential transformations is regenerated as its end product. Cycles are regarded as the cycles of the elements. Stepwise reactions of the cycles are catalyzed by specific groups of microorganisms. The system of higher organisms is superimposed into the initial cooperative system constructed by bacteria.

C_{org}-Cycle

The driving force of the system of interlinked cycles is the cycle of organic carbon (C_{org}). The cycle involves two steps: production and destruction. During production CO_2 is assimilated in the biomass; during destruction dead biomass is decomposed into CO_2. Composition of biomass includes in addition to C_{org}, as the main components N_{org} and P_{org} in approximate molar ratio 106:16:1. This ratio calculated for marine phytoplankton is quoted as 'Redfield ratio'. H and O are included in the biomass in water in the ratio 2:1, making the reductive level of C_{org} close to $[CH_2O]$. Strong deviations from Redfield ratio are known for terrestrial biomass with organic supportive structures as in trees with C_{org}:N_{org} about 500; minor deviations are caused by storage products. There are other elements included in the biomass such as S_{org}, and a number of essential 'mineral' elements beginning with K, Fe, Mg, Ca, and microelements. Composition of the living biomass might be considered as invariable with minor deviations (Fig. 1).

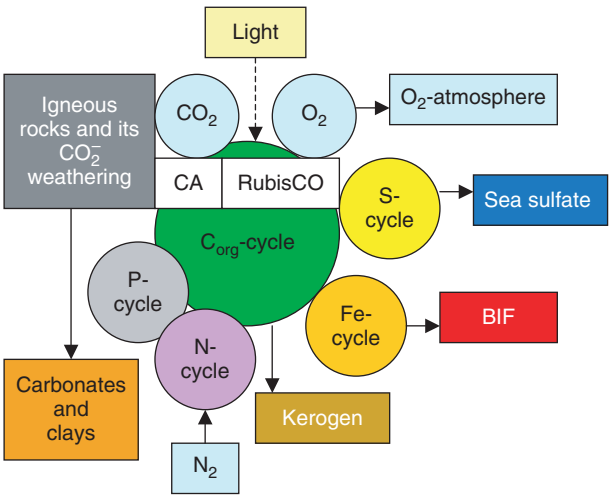

Fig. 1 Interlink between the cycles of the main biogenic elements. Cycle of C_{org} makes the main driving force of machinery coupled to the cycles of biomass constituents N_{org} and P_{org} and catabolic cycles of oxygen, sulfur, and iron. Cycles of these elements are coupled to reservoirs of inorganic matter in the geosphere. For each time period approximate material balance should be sustained. Misbalance leads to the biogeochemical succession on the large time scale. Modified from Zavarzin GA (2004) *Lekcii po Prirodovedcheskoi Mikrobiologii* (*Lectures in Environmental Microbiology*). Moscow: Nauka.

 doi:10.1016/B978-0-444-63768-0.00745-9

Transformation of CO_2 into C_{org} is performed by autotrophic organisms by the metabolic pathways where the Calvin cycle is quantitatively dominating; other autotrophic reactions seem not important quantitatively on the global scale. The key enzyme is ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) which carboxylates phosphopentose regenerated in the cyclic metabolic pathway (Calvin cycle). Due to the discrimination of ^{13}C during autotrophic assimilation isotopically lighter carbon with $\delta^{13}C_{org} \sim -25‰$ is produced, which is considered as the isotopic signature of a biotic source. Careful interpretation of isotope fractionation data is strongly recommended since they depend both on biotic pathways and inorganic diffusion. Assimilation depends on the source of energy, light of the Sun for photosynthesis, or oxido-reductive reaction of inorganic compounds for chemosynthesis (chemolithotrophy is the later synonym) in subterranean systems. In photosynthesis the overall reaction $CO_2 + H_2O \rightarrow [CH_2O] + O_2$ takes place. It makes a coupled cycle with an equimolar ratio of CO_2/O_2. The quantity of O_2 liberated is equivalent to the total C_{org} extracted from the system into the biomass and the reduced products of its decomposition. The link between reservoirs of inorganic and organic carbon is performed by enzyme carboanhydrase (CA) in the reaction $CO_2 + H_2O + CA \leftrightarrow H_2O - CA - CO_2 \leftrightarrow HCO_3^- + H^+ + CA$. In cyanobacteria, CA and RubisCO are integrated into the structural unit carboxysome. In eukaryotes, intracellular localization of enzymes is different. CA is responsible for CO_2 evolution during respiration. The production is measured either by O_2 production in water systems or by ^{14}C-bicarbonate assimilation. The cycle of C_{org} is linked to the reservoir of C_{inorg} with a strong influence of the calcium cycle.

Photosynthesis is the dominating process in production. Primary production is proportional to the illuminated surface or more precisely to the density of chlorophyll, with an approximate ratio of annual assimilation 145 kg C_{org} per kg of chlorophyll in terrestrial boreal ecosystems. Formation of C_{org}-pool occurs through several steps. The first one is gross primary production (GPP), counterbalanced by photorespiration in which approximately half of carbon is lost. Netto primary production (NPP) is calculated on the annual basis of the growing season for a plant. Evidently for algae with a short life cycle, the concept is different. C_{org} balance in the ecosystem is different and includes losses by the respiration of decomposers; it is referred to as Netto ecosystem production (NEP). Optimal conditions for photosynthesis and destruction are different: destruction has higher optimal temperature than photosynthesis, and different dependence on water, being suppressed by the excess of water, causing anaerobiosis. This causes zonal variance for biomes. The accumulation of C_{org} on the decadal scale is designated as Netto biome production (NBP) for which accumulation of nondecomposed C_{org} as humic substances and peat is the main parameter. For marine ecosystems, 'dissolved C_{org}' substitutes soil humus. The recalcitrant C_{org} of humic substances has a residence time of about millennia. It is converted into carbon of sedimentary rocks known as 'kerogen', which makes the main reservoir of reduced carbon on the planetary scale with a residence time of more than millions of years, depending on geological recycle. The reservoir of kerogen is sufficient to balance oxygen in marine sulfates and iron oxides deposits. Only 5% of the total oxygen produced remains in the transitionary reservoir of the atmosphere.

From a brief description of C_{org}-cycle, it is evident that the residence time in reservoirs is to be included into consideration. Seasonal variations in CO_2 fluxes are illustrated by the annual oscillations of atmospheric CO_2 in the continental Northern Hemisphere with an amplitude of about 20 ppm (parts per million) in Hawai and increasing in higher latitudes. In the oceanic Southern Hemisphere, oscillations are smoothened by the carbonate/bicarbonate system of the ocean.

Destructive pathways begin by decomposition of the dead biomass. Transition from living to dead biomass is accompanied by autolysis, which liberates part of the organic matter. For cyanobacteria and algae, lysis induced by viruses or phagi is quite important. Density of population is important, and below 10^5 cells per milliliter, phagolysis is ineffective. Lysis produces two components: dissolved organic compounds (DOCs) and particulated organic compounds (POCs), which consist mainly of structural components of the cell. Osmotrophic microorganisms can immediately use DOC; the threshold depends on the dilution with 1–10 mg l^{-1} still utilizable depending on the inflow. POC is to be hydrolyzed by hydrolytic exoenzymes before osmotrophic organisms can utilize it – bacteria in the sea or fungi in terrestrial ecosystems. Destructive pathways are formed by organotrophic organisms, which traditionally are named heterotrophs. This term is imprecise since it refers to the assimilative pathway leading at the end to the secondary production. There are three main metabolic pathways for C_{org}: proteolytic, saccharolytic, and lypolytic, according to the composition of biomass. The Winogradsky rule (1896) says that each natural compound has its specific microbial decomposer. The number of species of prokaryotes exceeds 5000 of cultivated and 2×10^4 clones of noncultivated. That gives sufficient functional diversity to perform biogeochemical essential reactions. As a result, specific trophic groups of organisms characterized by the utilizable substrate (e.g., cellulolytic, or lypolytic, or lignin-decomposing fungi), appear. The set of these organisms makes the functional biodiversity in the trophic system, which should make a complete community for each habitat. In the terrestrial environment, mycelial fungi are most important. Wood consists of 20%–30% lignin, which is decomposed by fungi and that gives the lower limit of their involvement in terrestrial C_{org}-cycle as 1/3–1/4 of CO_2 producers. Adding cellulose decomposition would at least double their contribution.

In the presence of O_2, aerobic organisms regenerate approximately one-third of C_{org} in secondary production with CO_2 as the product of respiration. Consumption of O_2 in the dark is by the usual estimation of respiration by the so-called biochemical oxygen demand (BOD) test.

In an anoxic environment, a cascade of reactions begins with fermentation, which is also the main pathway for many hydrolytic decomposers. As products, a mixture of organic acids and H_2 appears, and this is the reason why this stage is designated as acidogenic or hydrogen producing. Organic acids as nonfermentable compounds can be utilized only with an external oxidant, such as nitrate or ferric iron, sulfate, or CO_2. A cascade of anaerobic reactions makes a community function as an entity with an integrated trophic network.

Without an external oxidant, anaerobic decomposition is completed by methanogenesis, a process which dominates in terrestrial mires and lake mud. In the sea, it takes place in deep layers of sediments, when sulfate is exhausted from interstitial water. Methanogens make a group of Euryarchaeota usually named as *Methano-*…. There are three pathways for methanogenesis:

either hydrogenotrophic with $H_2 + CO_2$, or acetoclastic, or methylotrophic for C-1 compounds. Acetoclastic pathway dominates in C_{org}-abundant environment, for instance, in methane tanks. Methylotrophic methanogens develop noncompetitive pathways in saline environment, while they do not compete with sulfate reducers. Hydrogenotrophic methanogens can use endogenous H_2 formed by reaction of water with superheated rocks and belong to hyperthermophiles, for example, *Methanobacterium fervidus*, which develops at temperatures over 100 °C. More important is the role of hydrogenotrophic methanogens in community, where they act as H_2-sink. They establish H_2-concentration below 10^5 ppm and this allows us to oxidize acetate and other nonfermentable substrates in cooperative action with H_2-producing syntrophic organisms. Biogenic methane is identified by its isotopically light composition. Most of methane is ^{13}C-depleted.

Methane either remains in the sediments or escapes into the oxic zone where it is oxidized with O_2 by a specific group of methanotrophs. Under geologically favorable conditions, methane is stored in sedimentary rocks. Another possibility is the formation of crystallohydrates, which at appropriate hydrostatic pressure and low temperature make an ice-like cover for deep methane. At present, about 500 Mt yr^{-1} of methane comes into the atmosphere, where it is oxidized photochemically. Many times more than this quantity is oxidized by methanotrophs, which form an oxidative filter on the path of CH_4 to the atmosphere. The genera of methanotrophs are designated as *Methylo-*…. Oxidation of CH_4 includes its enzymatic transformation in C-1 compounds in the cell by a special metabolic pathway and thus methanotrophs represent a specialized group of the Proteobacteria. In the ocean, methane is oxidized by anaerobic consortia of methanogens with sulfate-reducing or denitrifying bacteria. The microbial cycle of CH_4 is most important for the biosphere.

Involvement of oxidized N, Fe, and S compounds as oxidants conjugates C_{org}-cycle with cycles of other elements. Transition from oxic to anoxic zone favors retainment of nondecomposed organic matter and leads to formation of oil and gas deposits in aquatic environments and coal in terrestrial ecosystems.

Particulated components including bodies of bacteria are consumed by phagotrophic Protists or/and by zootrophic multicellular animals. The trophic chains of animals are arranged into a trophic pyramid with a number of levels, including herbivorous and carnivorous. The size of the prey determines the nutritional pyramid. Animals that use filtration for nutrition are important in aquatic environment, keeping the density of microorganisms on the threshold level of about 10^5 cells ml^{-1}. The total amount of bacteria in the active zone of the ocean and soil is at least of the order 10^{28}, with the biomass of each cell about 10^{-12} g.

Microbial Nitrogen Cycle

C_{org}-cycle is coupled with N_{org}-cycle. Nitrogen cycle begins by nitrogen fixation. Nitrogenase enzyme is present in prokaryotes exclusively and distributed among different groups. N_2-fixation is an energetically expensive process. It occurs only on severe limitation on the bound nitrogen. It is facilitated in a reductive environment. The main groups of nitrogen-fixing bacteria are cyanobacteria and anaerobic bacteria. Aerobic nitrogen-fixing bacteria are either plant symbionts or organisms within the community supplied in excess by the nitrogen-free organic matter. C_{org}:N_{org} ratio over 20 stimulates N_2-fixation. Fixed N_2 is included into the biomass. Then the regenerative cycle begins. In the sea, its zone is just below the photic zone. Nitrogen is liberated in the proteolytic pathway with ammonification as summation of the process. NH_4^+ is either re-assimilated, or is metabolized by the two-step conversion into nitrate by chemosynthetic nitrifiers in the presence of O_2. Nitrate is assimilated by phytoplankton or plants. Part of it escapes from the productive zone. In the anoxic zone, in the presence of available organic matter, various denitrifiers use nitrate and nitrite as oxidants and reduce it to N_2 closing the cycle. As a variant, nitrate reduction to ammonia occurs but this is a less important pathway. Denitrification is the closing step in the nitrogen cycle. Nitrate makes a reservoir of bound nitrogen in the deep cold ocean of $\sim$20Eg. It is noticeable how important denitrification is in the marine environment for decomposition of organic compounds including hydrocarbons. Limitation of the availability of bound nitrogen is the major problem for plant productivity. In the sea, seasonal exhaust of nitrates definitely determines algal development as it was demonstrated for the Northern Sea. For the Pacific, a peculiar change in plankton composition indicates an N- and P-cycle interrelation: in nitrate-limited conditions cyanobacteria dominate when there is enough phosphate, whereas in phosphate-limited conditions algae are the main group in phytoplankton.

Phosphorus

Phosphorus comes into the ecosystem due to the weathering of rocks. The productivity of the lakes is proportional to the phosphate availability. For instance, soda lakes are often eutrophic in spite of extreme environment and limitation by other elements. Phosphorus is mobilized from its minerals by many acid-producing microorganisms, which make dissolution zones on the plates with an enamel of phosphate containing minerals. Phosphorus of the sea has terrestrial origin. Assimilated phosphate is included into the nucleic acids and phospholipids of the biomass. Regenerative cycle of phosphorus includes liberation of phosphate by the action of phosphatases. Phosphorus escapes from the cycle by binding into insoluble compounds of phosphorites on reaction with Ca and F. It should be noted that deposits of micritic phosphorites were formed by cyano-bacterial mat; phosphatisized microfossils of cyanobacteria are clearly visible in the scanning electron microscope. Cyanobacteria store phosphate as intracellular polyphosphate, which is the transitional source for rapid phosphatization. The iron pump demonstrates liberation of phosphate in anoxic environment: ferric iron binds phosphate in an insoluble compound but reduction to ferrous state liberates phosphates. On a large scale, phosphorus is the limiting element for primary production, which depends on its availability.

Sulfur Cycle

Sulfur cycle is the most important cycle conjugated to C_{org}. Assimilation of sulfate into S_{org} is quantitatively of minor importance in spite of the fact that it is the main source of dimethylsulfide – a volatile compound contributing to the source of S in the atmosphere. Its photochemical oxidation leads to the formation of aerosol in the stratosphere and is most important for the climate. In the destructive pathway coupled to the C_{org}-cycle, sulfate is reduced to H_2S by sulfate-reducing bacteria (SRBs), which by now are taxonomically numerous but functionally uniform. There are the following trophic groups: H_2-utilizers, SRBs with incomplete oxidation of organic acids (*Desulfovibrio*-type) producing acetate, and complete oxidizers (*Desulfobacter*-type), which use various unfermentable products of fermentations. Hydrogenotrophic SRBs are H_2-scavengers, which allow them to serve as intermediary oxidants to H_2-producing syntrophic bacteria and thus oxidize a variety of organic compounds. Most interesting is their interaction with methanogens in anaerobic methane oxidation in marine sediments. Methane is oxidized by reversed methanogenesis with the formation of isotopically light carbonates and evolution of H_2S by SRBs. H_2S, if not bound by iron into pyrite, escapes to the surface of the mud where it is oxidized by pelophilic sulfur bacteria, which can either use intracellular S_0 for oxidation into sulfate, if O_2 or NO_3^- is available, or use it as an oxidant in sulfur reduction. Magnificent benthic mats of trichomic sulfur bacteria are found on the shelf close to Chile and West Africa. Here, the so-called thiobios is formed by sulfur bacteria of *Thioploca*-type. Large filamentous bacteria cross the ox–red boundary and receive H_2S from the anaerobic layer and the current near the surface of the mud brings oxidant as nitrate or O_2, which is used for chemosynthesis. H_2S escaping in the water mass in the bodies of water with limited circulation makes a chemocline with the reductive zone below the oxic zone; Black Sea is a conventional example. The same occurs in stratified lakes. It is supposed that Mid-Proterozoic stratified ocean had the same structure. If H_2S zone comes to the photic zone, anoxic sulfur phototrophs develop. There are a variety of anoxygenic phototrophic bacteria, which belong to phylogenetically distant phyla. Purple layers of phototrophs make a remarkable landscape when they come up to the surface on the beach or in the soda lakes. In oxygenated photic zone, H_2S is oxidized into sulfate by various thionic bacteria. It is noteworthy that the appearance of sulfates in the palaeocean correlates with the oxygenation of the atmosphere around 2.4 Ga, and before 1 Ga its composition became close to the present one. It might be speculated that sulfates of the sea are biogenic in their origin. What was the initial source of mineral S? If the source was massive sulfides, then for their mobilization oxidative step was needed by aerobic acidothiobacteria used now in biohydrometallurgy in the general reaction, $FeS + O_2 \rightarrow Fe^{3+} + SO_4{}^{2-}$. The reaction strongly depends on the availability of O_2. Oxidation of sulfides leads to the formation of extreme acid conditions. It is most spectacular on volcanic thermal fields with sulfur exhalations, so-called solfataras. When A. Humboldt visited Vesuvius before its eruption, he noted that hot vapors were neutral in spite of possible SO_2 production in the heat, while cold walls of the crater were strongly acidic for Lakmus paper. Now it is known that oxidation of sulfur occurs mainly by acidophilic thionic bacteria and only in outlets of fumaroles, extremely thermophilic archaea are active. In the deeper parts of thermal fields, S_0 is used as an oxidant by anaerobic archaea with H_2S production. Short cycle $S_0 \leftrightarrow H_2S$ works also in microbial mats where white sulfur is deposited from H_2S by microaerobic sulfur bacteria and reduced when oxidant is not available. A large variety of microorganisms are involved in the cycle. Sulfur cycle closes destruction of organic matter in anoxic zone with sulfate regeneration either by anaerobic phototrophs or by aerobic sulfur oxidizers. Its function strongly depends on the transport processes across chemocline. The outcome from the cycle depends on availability of iron, which forms insoluble sulfides first as hydrotroillit and then pyrite.

Iron Cycle

The production of H_2S is environmentally incompatible with dissolved iron because of the formation of sulfides. Thus in terrestrial wetlands, where sulfate is limiting, iron cycle develops. Bacterial Fe-cycle takes place now in swamps. It includes oxidation of Fe^{2+}-bicarbonate under O_2-limited conditions with formation of $Fe(OH)_3$ ferrihydrite. Energy of oxidation might be used for chemosynthesis by *Gallionella* with precipitation of Fe(III) on the slimy stalks. Precipitation of Fe(III) on slimy structures is well known for the number of so-called 'iron bacteria', among which *Leptothrix ochracea* is best known for large deposits of ochre in slow-flowing water. Historically, that was the first example of geological activity of microorganisms described by Ehrenberg. Ochre-forming deposits were used as a 'swamp-ore' in the beginning of the Iron Age. However, two processes should be distinguished: chemosynthetic oxidation of iron and precipitation of iron hydroxides on mucous polysaccharides. Both processes are geologically significant. Ferrihydrite is readily reduced by iron-reducing bacteria, which use H_2, acetate, and a number of other C_{org}-compounds as electron donors. There are two possible end products: siderite $FeCO_3$ is formed in excess of organic matter and magnetite Fe_3O_4 under more restricted conditions. Iron-reducing bacteria substitute nitrate reducers in moderately reductive habitats. There are also thermophilic iron reducers. For formation of ferrihydrite in anoxic environment, there are two possible pathways, both phototrophic: one possibility is oxidation of Fe^{2+} by cyanobacteria but it is unclear if it is direct or indirect and caused by O_2 production; and the other is definitely direct and is performed by nonsulfur purple bacteria such as *Rhodomicrobium*. Oxidation of Fe^{2+} by anoxygenic phototrophic nonsulfur bacteria was described only recently. Product of oxidation in the light is ferrihydrite. This process closes the iron cycle in anoxic environment. Large deposits of layered silicified iron oxides composed of alternating layers of hematite and magnetite known as banded-iron formations (BIFs) were formed during the Early Proterozoic 1.8 billion years ago. Their origin remains unclarified. Fe is of hydrothermal origin. Total amount of iron oxides contains about 40% of O_2 evolved corresponding to C_{org} of kerogen. Iron migrated in the ancient ocean most probably as bicarbonate. Period of BIF is clearly incompatible with sulfate reduction.

Oxidation of sulfides, first of all pyrite, involves both cycles of iron and sulfur. Oxidation involves two functions. At low pH Fe^{2+} is stable in the air. Oxidation of sulfide produces sulfuric acid with a drop to pH <2. Some pyrite-oxidizing chemosynthetic bacteria such as *Acidothiobacillus ferrooxidans* use energy of both sulfur and iron oxidation. However in nature, these two functions are often divided between iron-oxidizing *Leptospirillum* and sulfur-oxidizing *Acidothiobacteria* working in concert. There are also other examples of these bacteria, especially thermophilic, which are most important in bacterial hydrometallurgy because they are able to dissolve various sulfides, and copper, gold, and other metals that also come into solution.

In addition to the cycles of major elements used by chemosynthetic bacteria, it is worth mentioning cycles of arsenic, manganese, and selenium, where both oxidative and reductive pathways operate. The general rule is, chemosynthetic microbes use oxido-reductive reaction and develop in the thermodynamic field of stability of the product of this reaction. Energy generated in the reaction must be sufficient to support the formation of ATP.

Biologically Mediated Reactions

The so-called biologically mediated reactions are also very significant in the involvement of microorganisms in the biogeochemical cycles. In these reactions, microbes form an environment in which certain forms of minerals are stable according to the fields of thermodynamic stability. It is most important for rare elements, whose amount is insufficient to ensure the existence of certain specific groups. These trace elements act as indicators of the environment. Uranium is one of the examples. Another example is the deposition of metals in the zone of sulfate reduction. Such microbially mediated pathways form many sedimentary deposits. The so-called biogeochemical barriers represent the sites of drastic changes in the environment, which cause precipitation of minerals. Biogeochemical barriers are sustained by countercurrents of solutes and by the activity of microorganisms. There are different kinds of barriers: oxido-reductive, alkaline, sulfidic, etc. Chemocline in the lakes is an example. Change in the state of environment often causes transition from migrating chemical species to insoluble one.

The cycle of calcium belongs to biologically mediated reactions. It begins by CO_2 weathering of rocks. The essential point here is the concentration of carbon in the biomass and concentrated release of CO_2 during decomposition. Formation of active products of decomposition as acids or chelators is also important. Released Ca^{2+} comes into waterways as $Ca(HCO_3)_2$ and migrates to the ocean. Here it might be used by calcareous eukaryotes for the formation of skeleton and release of CO_2. The main part of $CaCO_3$ at present is biogenic by origin. Another possibility is the release of CO_2 in warm shallow water when its solubility decreases and the reaction, $Ca(HCO_3)_2 \rightarrow \downarrow CaCO_3 + \uparrow CO_2 + H_2O$ develops. The surface of precipitated $CaCO_3$ is covered by a microbial biofilm. It gives to the precipitate a laminated texture due to the slime produced. If the microbial biofilm is formed by cyanobacteria, then the additional sink of CO_2 assimilated in C_{org} might result in a drop of pH and precipitation of carbonate. The layered structures of precipitated carbonates are known as stromatolites. They are recorded for Proterozoic as the most important deposits. Their abundance indicates that they represent significant deposits of CO_2. Stromatolites correlate with deposits of dolomites, but sometimes pieces of black chert are included and in these cherts, silicified microfossils of cyanobacteria are observed. Preservation is excellent and one can identify taxa, with the aid of books on systematics, of extant cyanobacteria to approximately 2.4 billion years ago. The scale of stromatolite formation delineating ancient warm shallow water environment is of the order of millions of square kilometers. Height of such deposits is up to hundreds of meters. Mass development of stromatolites ended with the end of bacterial exclusive domination in the biosphere. Calcium cycle contributes to the neutrophilic conditions on the Earth.

Trophic Organization of Microbial Communities

The organization of the prokaryotic community is most clearly demonstrated by the cyano-bacterial mat. Sign (-) denotes here two components: cyanos as prime producers and bacteria as decomposers in regenerative cycle. In the mat, distinct layers are found: the upper illuminated level is occupied by cyanobacteria; below is the white layer of sulfur bacteria, followed by the purple layer of anoxygenic phototrophs, and then the black layer of sulfide-producing bacteria. Still below are the layers of dead bacteria. The whole system has dimensions of 2–4 mm. It is called in German 'Streiffarbsandwatt'. The architecture of cyano-bacterial mats is similar in hypersaline lagoons, soda lakes, thermal springs, etc. The structure of mat is maintained by exopolysaccharides produced by cyanobacteria, which are edificators (from 'edifice') for the community. The main factor is illumination and self-shadowing by the upper layers of cyanobacteria, which move to the optimal illumination. Minor differences in the composition of mats are caused, for instance, by the absence of purple bacteria in thermal habitats or strong development of planktonic forms in soda lakes. The 'Winogradsky column' illustrates stratified planktonic microbial community: cylinder with water from the site supplemented by mud with organic debris and gypsum at the bottom. Blooming microbes in the column produce alternating black, purple, and green layers. The column might sustain for years.

Trophic links in the microbial community are organized into the trophic network of a cascade of degradative reactions. The rule is that each step should be sufficient to support the species performing the transformation. Degradation begins with hydrolysis of biopolymers, the most resistant being structural components of the cell walls. Aerobic and anaerobic dissipotrophic bacteria in the cascade of reactions utilize low-molecular-weight compounds, dissipating from the sites of hydrolysis. The final result should be complete decomposition of organic matter, so-called 'mineralization'. In fact, decomposition is not complete and recalcitrant

substances are formed in minor part, giving rise to humic substances, and dispersed organic matter. It should be noted that the physical environment strongly contributes to the trapping of undecomposed organic matter, preventing microbial activity.

This is a brief description of biogeochemical cycles catalyzed by bacteria. The main conclusion is that bacteria act as a cooperative community with the interlinked metabolic pathways of the main elements; only the cooperative community is autonomous due to the links between productive and regenerative cycles. Each step of catalysis is performed by a functional or trophic group of specialized bacteria. Links provide the trophic network. Cyclic pathways make such a community autonomous, depending mainly on the energy for photosynthesis. Cooperative community is an operational unit for the ecosystem at the landscape level. However, biogeochemical cycles are not entirely closed: there is formation of products, which escape recycle. The changes in the community composition known as succession are caused by the accumulation of products as well as exhaust of substrates. In the microbial community, it is the development from fast-growing copiotrophs to a climacteric community with well-balanced interactions. In fact, the microbial community exists all the time in a transitional state.

When we consider a larger temporal scale, the most important concept of biogeochemical succession arises. It may be illustrated by the composition of the atmosphere, which is formed by microbial activity, since the main components of the atmosphere are metabolized by bacteria: CO_2, O_2, CH_4, CO, H_2, N_2, NO_x, NH_3, and sulfur species. Due to the accumulation of the waste products – oxygen is the most evident example – biosphere becomes uncomfortable to the community, here the initial anoxic microbial community. Less evident but more important is accumulation of C_{org} in sedimentary rocks, which rolls cycles with the passage of time. As a result, the atmosphere moves from the neutral to the oxygenated state. It changed conditions on the Earth's surface. Biosphere overturned: anaerobic pockets remain under the shield of aerobic O_2 consumers. Much the same occurred with the ocean (or hydrosphere), which is in equilibrium with the atmosphere. Three main steps seem to be identified: the first before approximately 2.4 billion years with the domination of iron cycle; beginning of the biosphere with O_2 in the atmosphere and pronounced S-cycle; and present-day biosphere with O_2-atmosphere where biogenic O_2 substituted part of CO_2. Pathways in the community were reoriented to the new environment. Consider that any sustainable system should be able to support its own existence by effective feedbacks otherwise it is not sustainable. S. Winogradsky in 1896 suggested the qualitative concept of cycle of life as a 'huge organism' (or the goal-oriented system) with microorganisms acting as the main catalysts. Later V. Vernadsky in *The Biosphere* (1926) introduced the quantitative approach, considering biogeochemical cycles as the main mechanisms. The Geospheric–Biospheric Program and Global Change concept represent the contemporary approach to the problem. The expediency of the links in the biosphere leads to its interpretation as 'Gaia'.

However, biosphere was always within the geographic envelope of the Earth. This means that there was always a mosaic of landscapes arranged in climatic zones. Landscapes give the possibility of lateral interaction and formation of geochemical barriers. The mosaic of landscapes furnishes refugia, places for survival of particular communities. Landscapes on geological timescale are dependent on the tectonic. Weathering–sedimentation pathway leads to equilibrium if no metamorphism and geological cycle occurs.

Since bacteria catalyzed main cycles and established the primary biogeochemical system, they form the dynamic environment, into which Protists, Metaphyta, and Metazoa were incorporated in the course of evolution. The system was developed by the substitution of prime producers by algae, kelps, and plants. The terrestrial system changed with the appearance, about 300 Ma ago, of vascular plants, which changed the atmospheric hydrological cycle by the involvement of deeper layers of ground water and producing a new illuminated surface within the leaves for derivates of cyanobacteria converted into chloroplasts. Plant cover significantly changed the terrestrial environment. However, microbes remain as the main catalysts in the system of biogeochemical cycles.

Nitrogen Cycle☆

TP Burt, Durham University, Durham, UK

Introduction

The nitrogen cycle is arguably the second most important cycle, after the carbon cycle, to living organisms. Nitrogen is essential to plant growth, and therefore is a significant contributor to the human food chain, but its presence in the environment is strongly influenced by anthropogenic activities.

The global nitrogen cycle is outlined first; then long-term trends are examined at national and global scales for both terrestrial and aquatic ecosystems; next the transport of nitrogen at local and long-distance scales is described; finally there is consideration of how public policy for environmental protection can seek to mitigate against pollution effects.

Nitrogen was discovered in 1772 by Daniel Rutherford, who called the gas 'noxious air'. During the late eighteenth century other chemists, such as Scheele, Cavendish, Priestley, and Lavoisier were also studying 'dephlogisticated' air, the term then used for air without oxygen. By the late nineteenth century its vital role as a plant nutrient was understood and by the early twentieth century, the Haber–Bosch process was able to 'fix' nitrogen from the atmosphere on an industrial scale. Nitrogen fixation influences the amount of food present within an ecosystem. Prior to the industrial process of N production, crop growth was sustained by recycling crop residues and manures on the same land where food was grown. Any 'new' N was created by growing rice or legumes, or by mining guano and nitrate deposits. However, as the human population increased, so has the demand for food and with that the dependence on inorganic fertilizers to sustain agriculture. This trend has affected the nitrogen cycle at global, national, and local scales.

The Nitrogen Cycle

Nitrogen comprises approximately 79% of the Earth's atmosphere in the form of biologically unavailable dinitrogen (N_2) gas. This reservoir is estimated to be in the order of 3.8×10^9 kg N, approximately 90% of the global reservoir. Crustal reservoirs comprise the remaining 10% (Figure 1). By comparison, the amount of N stored in the biomass (terrestrial and oceanic) and soil is small, but this, of course, is the vital component as far as living organisms are concerned.

The global nitrogen cycle (Figure 2) is driven by biological and physical processes, which depend on a variety of environmental factors such as solar energy, precipitation, temperature, soil texture, soil moisture, the presence of other nutrients, and atmospheric CO_2 concentrations.

These factors control N fluxes into and out of soils and vegetation, thereby influencing the mass of N in these compartments, and therefore its availability. Figure 3 illustrates the global distribution of nitrogen in soil and vegetation. Tropical forest soils show the least amount of storage because of high decomposition and uptake rates but have higher N storage. In general terms, human activity has tended to accelerate nitrogen cycling, increasing flux rates from one store to another.

In order for nitrogen to be used for plant growth, it must be available in inorganic formal ammonia (NH_3), ammonium (NH_4), nitrite, (NO_2), or nitrate (NO_3). In the terrestrial nitrogen cycle (Figure 4), soil nitrogen cycling processes dominate, with surface application (fertilizer and manure) providing most of the nitrogen inputs. Microbes break down organic matter to produce much of the available nitrogen in soils. Mineralization/immobilization, nitrification, nitrate leaching, denitrification, and plant uptake can then occur. Nitrate is completely soluble in water and since it is not adsorbed to clay particles, it is vulnerable to being leached out of the soil by percolating rainfall or irrigation water. Generally, the movement of nitrogen can occur in one of three directions: (1) upward – crop uptake and gaseous loss, (2) downward – as leaching to groundwater, and (3) lateral – via surface and subsurface flow to surface waters.

The nitrogen cycle is strongly influenced by anthropogenic activities. During the twentieth century, land-use changes, such as intensive agriculture, over-fertilization, deforestation, biomass burning, combustion of fossil fuels, industrial activities, and energy production, have significantly disturbed 'natural' N biogeochemical cycling. In natural ecosystems plant growth rates are low and annual uptake of N is relatively small. Cultivated crops are much more demanding with nutrient uptake ranging from about 100 kg N ha $year^{-1}$ for wheat and up to 450 kg N ha $year^{-1}$ for sugar cane. Improved grasslands for livestock rearing typically require 250 kg N ha $year^{-1}$. The mineralization capacity of soils is almost always insufficient to maintain optimum

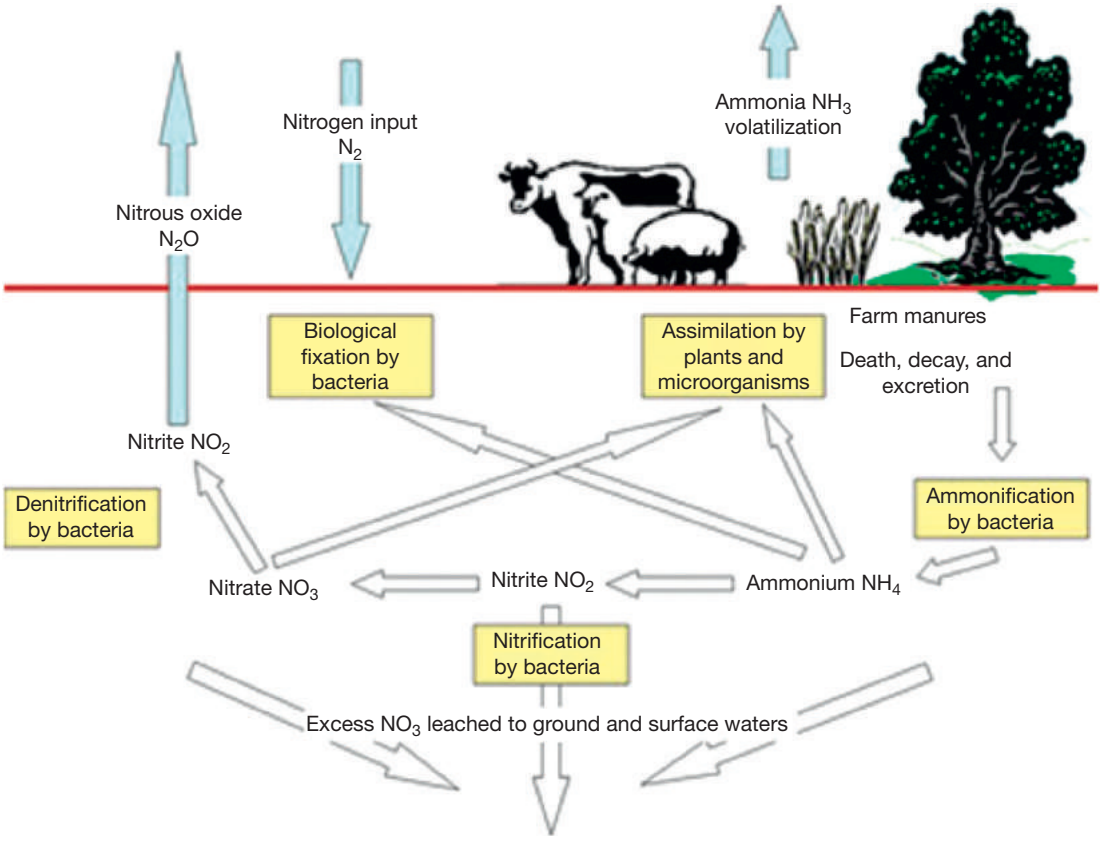

Figure 4 The terrestrial nitrogen cycle.

growth; therefore, chemical fertilizers and manures are required to supply N for intensive agriculture. This has resulted in changes to the long-term trends within the N cycle at global, regional, and local scales.

Long-Term Global and Regional Trends in the Nitrogen Cycle

Globally, nitrogen is found in the terrestrial ecosystem as dead organic matter (89.5%), with live biomass accounting for 4% and inorganic nitrogen 6.5% of this source. Natural sources of nitrogen have seen a small decline since 1890 (Table 1). Losses of biomass due to large-scale burning and forest clearances during the late twentieth century have contributed to the decline of this reservoir.

Natural reservoirs now cannot provide nitrogen in the quantity required for global food production. In 1890, total anthropogenic N production was approximately 15×10^9 kg N year^{-1}, but by 1990 this had risen by approximately an order of magnitude to 140×10^9 kg N year^{-1}.

In the terrestrial ecosystem, globally, nitrogen production is generally driven by the use of fertilizers for intensive agriculture, with cultivation and combustion contributing approximately 38% to all anthropogenic sources. However, this is not evenly distributed across the world regions. Asia produces almost half the world's nitrogen fertilizers, followed by Europe then North America (Table 2). Africa, Latin America, and Oceania combined contribute less than 12% of global nitrogen production.

Significant changes to the nitrogen cycle have been apparent since the 1960s. This is closely linked to expanding human populations and an increasing demand for food and energy. Creation of anthropogenic nitrogen in Asia increased from $\sim 14.4 \times 10^9$ kg N year^{-1} in 1961 to $\sim 68 \times 10^9$ kg N year^{-1} by 2000, and is set to increase to 105×10^9 kg N year^{-1} by 2030. North America doubled its N production between 1961 and 1997, with most of the increase occurring during the 1960s and 1970s. Although the largest increase was in use of inorganic N fertilizer, emissions of NO_x from fossil fuel combustion also increased substantially. By 1997, even though N fixation had increased, fertilizer use and NO_x emissions had increased more rapidly and two-thirds of reactive N inputs were denitrified or stored in soils and biota, while one-third was exported, the largest export being in riverine flux to coastal oceans, followed by export in food and feeds, and atmospheric advection to the oceans. The consumption of meat protein is a major driver behind N use in agriculture in North America. Without changes in diet or agricultural practices, fertilizer use will increase over the next 30 years, and fluxes to coastal oceans may increase by another 30%.

Similar trends are mirrored in the European N budget (Table 3). By 1990, N inputs are approximately 34.5×10^9 kg N year^{-1}, the major process of N fixation being fertilizer production at $\sim 14.0 \times 10^9$ kg N year^{-1}, with industry and combustion accounting for a further $\sim 3.3 \times 10^9$ kg N year^{-1}. Imported N from products such as animals, animal feeds, food, fertilizers, forestry products, exceeds the amount of N exported outside Europe. Furthermore, exports in riverine flux to oceans accounts for $\sim 4.0 \times 10^9$ kg N year^{-1}.

Nitrogen Export by Rivers

Water is a carrier of N from pollution source to river outlet. The fraction that ultimately reaches the outlet depends on amount of runoff and distribution between different runoff components. Time delay between inputs at the soil surface and inputs to surface water additionally depends on groundwater residence times. The natural water quality of a river will be determined primarily by the catchment soil type and underlying geology to which water, falling on the catchment as rain, is exposed as it drains to the river. Climate provides an important context for nitrogen cycling by controlling the propensity for carbon and nitrogen to be stored within the catchment; thus in the UK, upland soils tend to conserve organic matter as peat, whereas organic matter tends to decompose much more readily in lowland soils. Deviations from this baseline water quality are generally caused by the influence of human activities through point and diffuse pollution sources. Up to 40% of the total nitrogen flux reaches the aquatic system through direct surface runoff or subsurface flow. Nitrogen delivery to surface waters is further controlled by (1) soil structure and type, (2) rainfall, (3) the amount of nitrate supplied by fertilizers, and (4) plant cover and root activity.

In pristine river systems, the average level of nitrate is about 0.1 mg l^{-1} as nitrogen (mg l^{-1} NO_3-N). However, in Western Europe, high atmospheric nitrogen deposition results in nitrogen levels of relatively unpolluted rivers to range from 0.1 to 0.5 mg l^{-1} NO_3-N. In recent years, nitrate concentrations in European rivers have remained relatively stable after rising rapidly towards the end of the twentieth century; progress still needs to be made in reducing the concentration of nitrate in Europe's rivers. High rates of nitrogen input to rivers and coastal waters are not confined to Europe. In USA as late as 1998, more than one-third of

all river miles, lakes (excluding the Great Lakes), and estuaries did not support the uses for which they were designated under the Clean Water Act (1987). For example, Table 4 illustrates the extent of N inputs to rivers and coasts in areas of America, Africa, and Asia. These trends are cause for concern as seasonal hypoxia develops during the summer months, resulting in a depletion of sea bed vegetation and changes in fish stocks.

It is now widely acknowledged that agriculture is the main source of N pollution in surface waters and groundwater in rural areas of Western Europe and USA. The UK House of Lords' report Nitrate in Water (1989) commented on the conflicts that can arise when the use of land for farming comes into conflict with the use of land for water supply. Concern for this initially focused on the alleged links between high nitrate concentrations in drinking water and two health problems in humans: the 'blue-baby' syndrome (*methaemoglobinaemia*) and gastric cancer. Now, there are also major concerns about environmental degradation. Nutrient enrichment in water bodies encourages the growth of aquatic plants (see Figure 5).

Reed beds and other marginal plants may be attractive on a small scale, but when these and, particularly, underwater plant growth are excessive, this can cause a narrowing of waterways, and become a nuisance to recreational users of rivers and lakes. Furthermore, eutrophication (a group of effects caused by nutrient enrichment of water bodies) can adversely affect the aquatic ecosystem, especially in marine systems where nitrogen may be the limiting nutrient. An algal bloom may cut out light to the subsurface, and when it dies, decomposition uses the oxygen supply needed by other species. Some algae are toxic to fish, while others, for example, cyanobacterial species, are toxic to mammals including domestic pets. Studies in Asia have demonstrated the link between increasing use of fertilizers and increasing incidence of algal blooms. For example in some Chinese provinces, fertilizer application is greater than 400 kg N ha^{-1}. This is usually applied as a single application and with crop utilization efficiency as little as 30–40%, a high proportion is lost to rivers, lakes, and coastal waters. The environmental impact at the regional level is the incidence of red tides (algal blooms). During the 1960s less than 10 red tides per year were recorded, but in the late 1990s over 300 per year were being recorded.

Land-Use Controls to Reduce N Enrichment to Surface Waters

The popular misconception that the nitrate problem is caused by farmers applying too much nitrate fertilizer is too simplistic. Nevertheless, there is now little doubt that the high concentrations of nitrate in freshwaters noted in recent years have mainly resulted from runoff from agricultural land and that the progressive intensification of agricultural practices, with increasing reliance on the use of nitrogenous fertilizer, has contributed significantly to this problem. Since 1945, agriculture in the industrialized world has become much more intensive. Fields are ploughed more frequently; more land is devoted to arable crops, most of which demand large amounts of fertilizer; grassland too receives large applications of fertilizer to ensure a high-quality silage for winter feed; stocking densities in general are higher leading to increased inputs of manure on grassland and problems of disposal of stored slurry; cattle often have direct access to water courses resulting in soil and bank erosion and direct contamination from animal waste; many low-lying fields are now under-drained, encouraging more productive use of the land and speeding the transport of leached nitrate to surface water courses. Lowland rivers close to urban areas may receive larger quantities of nitrogen from sewage effluent, but budgetting studies confirm that agriculture is still the main source of nitrate in river water, except in the most urbanized river basins. Nevertheless, sewage now provides a greater proportion of total nitrogen flux than in former decades following policy initiatives to limit nitrogen losses from agriculture.

In mainland Britain mapped nitrate concentrations demonstrate a marked northwest to southeast gradient, reflecting relief, climatic conditions, and agricultural activity. Upland areas in the north and west are usually characterized by nitrate concentrations below 1 mg NO_3-N l^{-1}. This reflects the high rainfall and low temperatures of such areas: upland soils tend to conserve organic matter and mineralization rates are low. In contrast, a decreasing ratio of runoff to rainfall and an increasing intensity of agricultural land use toward the south and east of Britain results in higher mean concentrations of nitrate in river water. Many of the lowland rivers are characterized by concentrations above 5 mg NO_3-N l^{-1}; in East Anglia and parts of the Thames basin, mean nitrate concentrations in rivers are close to the European Union limit of 11.3 mg NO_3-N l^{-1}, a level exceeded in some spring waters especially in the Jurassic limestone of the Cotswold's and Lincolnshire Wolds.

The changing pattern of British lowland agriculture since 1945 is reflected in long-term records of nitrate for surface and groundwaters (Figure 6). Such graphs confirm the accelerated nitrogen cycling in recent decades and increasing fluxes from the terrestrial to aquatic compartments of the N cycle.

For both large and small rivers, there has been a relatively steady upward trend in nitrate concentrations, often of the order of 0.1–0.2 mg NO_3-N l^{-1} a^{-1}. Analyses for relatively short time series of just a few years have shown that the upward trend may be interrupted, either because of climatic variability (drier years are associated with lower nitrate concentrations) or because of land-use change. Nevertheless, analysis of long time series shows that the main effect is a steady increase in nitrate levels over time which is independent of climate. If trends continue, the mean nitrate concentration of many rivers in Europe will soon be above the EU limit; in many cases this level is already exceeded during the winter when nitrate concentrations reach their maximum. However, modelling studies now suggest that trends are beginning to level off and will gradually fall over the next few decades, although the downward trend is at a disappointingly slow rate. In catchments where groundwater is the dominant discharge source, this

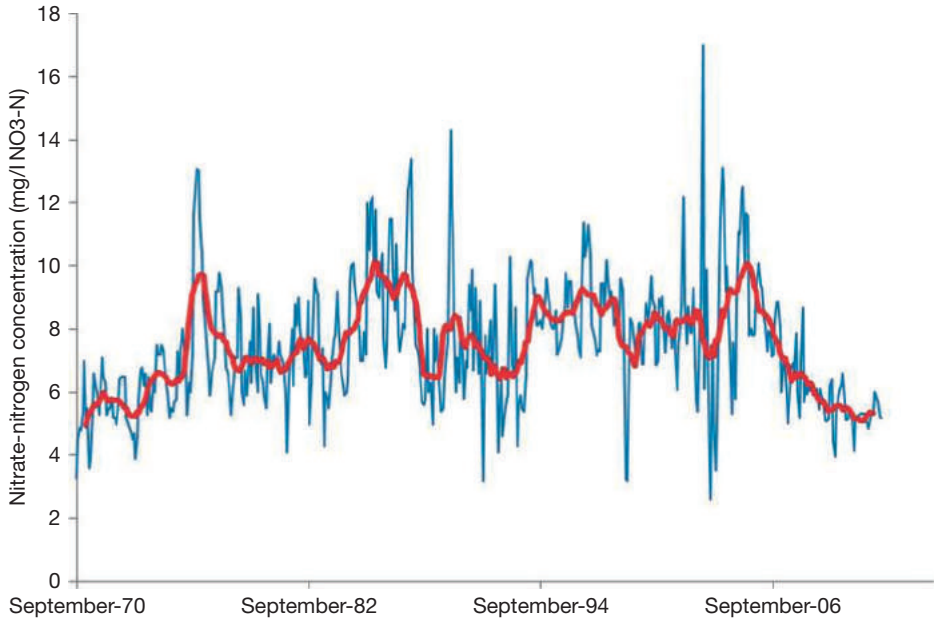

Figure 6 Long-term nitrate record 1970–2012: Slapton Wood catchment (UK).

long-term trend may be prolonged since it may take years for nitrate to percolate down to the saturated zone. In such basins, nitrate pollution will remain a problem for decades to come. In recent years, a number of options have been considered as a means of halting the upward trend.

Trends in water management in Europe include moves toward catchment-level management, improved intersectoral coordination and cooperation, and frameworks facilitating stakeholder participation. This approach is developed by the European Union in its Water Framework Directive (2000/60/EC), which sets targets for good ecological status for all types of surface water bodies and good quantitative status for groundwater. More localized schemes, like the UK Nitrate Vulnerable Zones, involve greater restrictions on farming practice, such as restricting the amount and timing of organic and inorganic fertilizer application. The EU Common Agricultural Policy has changed the way payments are made to farmers. Single-farm payments encourage farming in a more environmentally friendly way. Financial payments are available to farmers for loss of income or for changing farming practice such as improving slurry storage and fencing off watercourses to restrict livestock access. Much interest currently focuses on the use of riparian land as nitrate buffer zones.

The terrestrial–aquatic ecotone occupies the boundary zone between the hillslope and the river channel, usually coinciding with the floodplain. Given their position, near-stream ecotones can potentially function as natural sinks for sediment and nutrients emanating from farmland. Observed denitrification rates in floodplain sediments may be sufficient to remove all nitrate from groundwater flowing under a riparian woodland, with a floodplain width of 30 m. Saturated, anoxic soils, rich in carbon, are exposed to nitrate-rich groundwater. Rates of denitrification are high within this zone since the nutrients required by denitrifying bacteria are abundant. Wetlands and wet meadows (defined as areas where the water table is at or above land surface for long enough each year to promote the formation of hydric soils and support the growth of aquatic vegetation) also have potential as nitrogen sinks. High production rates by wetland vegetation result in an abundance of carbon providing an organic substrate for bacterial processes. Wetland plants transport oxygen into anaerobic sediments which can enhance denitrification leading to losses of nitrogen as N_2O or N_2 from wetland sediments.

The type of vegetation found on the floodplain controlling the efficiency of nitrate absorption is the subject of much debate. Several studies have argued the presence of trees is crucial, yet others state the role of surface vegetation is secondary to presence of saturated conditions together with a carbon-rich sediment. Denitrifying bacteria operate best at the junction anaerobic/aerobic zones where both carbon and nitrate are abundant. It is clear that nitrate losses may be reduced by creating a nutrient-retention zone between the farmland and the river. Given that many floodplains around the world are part of an intensive agricultural system, creating permanently vegetated buffer strips between field and water courses is an idea that should be actively promoted. However, buffer strips will only be successful nutrient sinks if they are managed in an appropriate way. Underlying artificial drainage should be broken or blocked up to prevent a direct route to the watercourse for solutes and grassland strips need maintenance to prevent them becoming choked with sediment and losing their sediment retention potential.

Solving the problem of nutrient enrichment of surface waters cannot be seen in the short-term. Long-term land-use change is needed. Taking farm land immediately adjacent to water courses out of production is one option that could go some way to allow modern agriculture and water supply to coexist in the same basin. Such proposals inevitably raise questions about who pays for them – farmers, water supply companies, or the taxpayers.

Noosphere

C Jäger, Potsdam Institute for Climate Impact Research, Potsdam, Germany

The Noosphere Concept

The noosphere concept is best developed before the background of the related concept of ecosphere. The ecosphere is usually understood to be the space inhabited by living beings. It comprises the living organisms (biosphere), the lower atmosphere, the hydrosphere (oceans, lakes, glaciers, etc.), and the highest layer of the lithosphere (topsoil as well as various kinds of rocky ground). The word biosphere was invented by the Austrian geologist Eduard Süß, who used it more or less in passing, in an influential textbook on the formation of the Alps. In 1911, Süß met the Russian-Ukrainian mineralogist and geochemist Vladimir Vernadsky, who gave the word its current meaning. This meaning includes the fact that the biosphere is connected in space and time, that all living beings are related to each other by evolution, and that not only the biological, but also the chemical and physical, processes in the biosphere are shaped to a considerable extent by the functioning of living beings. A major example is the oxygen content of the atmosphere resulting from photosynthesis.

In the 1920s, Vernadsky was staying in Paris where he met the philosopher and mathematician Edouard LeRoy, whose lectures on biogeochemistry he attended. Through LeRoy, Vernadsky got exposed to a concept that Teilhard de Chardin, who also attended LeRoy's lectures, was developing in those days: the concept of noosphere. (The term noosphere, is derived from the Greek root *nous* meaning mind.)

Teilhard, a French geologist and Catholic priest, saw the emergence of the human species out of biological evolution as the beginning of a far-reaching transformation of the world we live in. The human mind would gradually learn to shape the world to a larger and larger extent, transforming the biosphere into the noosphere. Vernadsky related the concept to the historical dimension he had experienced in World War II. In his mind, this war showed that humankind was beginning to act on a global scale, but was not yet able to do so in a responsible way. The development of nuclear physics – that Vernadsky had been following already before World War I – presented the same challenge in an even more dramatic form. The transition from the biosphere to the noosphere, then, was to be the process in which humankind would learn to consciously and responsibly shape the ecosphere. This idea has been taken up in various forms by current authors interested in global environmental change.

Related Concepts

According to Venadsky, ``The Noosphere is the last of many stages in the evolution of the biosphere in geological history'' (Vernadsky, 1945, p. 10). The word ``evolution'' here does not refer to the interplay of variation and selection that Darwin saw at work in the evolution of biological species. Rather, it hints at a process in which new realities emerge in the course of time without any need for inheritance of traits between biological generations. This line of thinking is related to the idea of `emergent evolution' proposed by the psychologist Lloyd Morgan and further developed by LeRoy. Today, the emergence of new realities in the course of time is often described as a process of self-organization in complex systems. Evolutionary history then becomes an overarching narrative telling the story of the world as a whole. It tells how physical matter rearranged itself up to the point where portions of it became the first living organisms, how these then evolved into species of increasing organic complexity, how the complexity of some organisms enabled them to develop the mental faculties that characterize humankind, and how humankind is now beginning to understand its own global environmental impacts.

The concept of the noosphere is also related to the concept of Gaia proposed by Lovelock and Margulis. The Gaia concept pictures the Earth as a complex, self-regulating system, a kind of organism that maintains conditions favorable to life despite a variety of disturbances. The emergence of the noosphere then means that some living beings – humans – became aware of this larger organism they are part of, of their capability to modify it by technological means, and of their responsibility to develop these means in ways that do not disrupt Gaia.

Closely related is a new concept of Earth system. Traditionally, Earth scientists considered as the Earth system those physical and chemical processes taking place on planet Earth that shaped oceans and continents, forming rocks, causing earthquakes, etc. Living beings were seen as playing a rather peripheral role (although for obvious reasons fossil fuels always were a big topic for the Earth sciences), and the influence of human beings on the Earth system was considered negligible. The debate about global environmental change and sustainability has changed this situation. As a result, a broader concept of Earth system has been proposed by Schellnhuber and others. In this perspective, the Earth system is seen as a complex system including physical, chemical, biological, as well as social and mental processes. Some sort of emergent evolution is seen as leading from a purely physicochemical system first to a biogeochemical system and then to one including human beings and their interactions. The first transition can be described as the emergence of the ecosphere, the latter as the emergence of the noosphere.

Finally, the role of humankind in shaping the face of the Earth has been used to propose a new geological epoch, the Anthropocene, supposed to start more or less with increased control over natural resources due to application of fossil energies during the industrial revolution in the nineteenth century. So far, geological epochs were defined to be periods of millions of years, and the last such epoch, the Holocene, has been defined to start just about 10 000 years ago. The concept of the Anthropocene marks a clear break with the previous practice of structuring a geological timeline. However, others have suggested that humankind significantly altered the climate system already some 8000 years ago by clearing forests. On a timescale of millions of years, this would make the beginning of the Holocene and the Anthropocene indistinguishable. On a conceptual level, of course, there still is a major difference between defining the current geological epoch in terms of an ice age that came to an end independent from any human action or in terms of the emergence of humankind as a new geological force. It is the latter approach that clearly relates to the concept of the noosphere.

Mechanisms and Institutions

As Vernadsky realized, the concept of the noosphere implies a causal chain from human thoughts to large-scale physical effects. This poses two challenges for research. First, there is the question of how the movements of human hands, legs, and bodies can be amplified so as to have effects that are observable at a planetary scale. And second, there is the question of how human thoughts can cause movements of hands, legs, and bodies.

As for the first question, fire has been a key amplification mechanism of human action since prehistorical times. Clearly, the burning of fossil fuels with the resulting emission of greenhouse gases is a related mechanism today. Vernadsky was particularly impressed by an amplification mechanism that was developed during his lifetime. The human capability to think had led to an understanding of subatomic processes that enabled human beings to build atomic bombs as well as to generate electricity from nuclear power plants. Vernadsky had studied radioactive materials already before World War I; during World War II he played a key role in triggering the nuclear weapons program under Stalin, and he forcefully supported the Soviet nuclear energy program. It is noteworthy that Lovelock, champion of the Gaia concept, strongly advocates nuclear power as the way to meet the challenge of anthropogenic climate change.

Nuclear physics is a prime example of human thoughts whose material impacts – while clearly being huge – depend mainly on political decisions. However, it is clear that the market institution is one of the most effective mechanisms to enlarge the range of human actions. The market economy has enabled human beings to develop global patterns of division of labor, of cooperation and competition. So far, research drawing directly or indirectly on the noosphere concept has not paid much attention to the economic links in the causal chain from thoughts to material impacts. This clearly is a major research challenge for the future. It includes the task of distinguishing those impacts of the market economy that change our global environment without impairing it from those that jeopardize properties of our environment that we value and need. Will the noosphere concept be helpful in new discoveries about how markets work and how key instances of market failure can be addressed?

Body and Soul

Vernadsky was fully aware of the fact that the second question – how human thoughts can cause changes in the material environment – was a key research challenge posed by the noosphere concept. Nowadays, brain research holds promise of important elements to address that question. However, when imagining that these elements will be sufficient to answer the question, a simple fact is ignored: what can be found in the human skull are neurons, synapses, electrochemical reactions, but no thoughts. One may expect that some day we will be able to establish a one-to-one relation between certain brain processes and certain thoughts, a bit as playing music from notes is based on a correspondence between certain marks on paper and certain sounds. But this does not mean that marks on paper and sounds are the same things. The noosphere concept challenges environmental research to reflect on one of the weak points of contemporary scientific culture: the difficulty in developing coherent arguments about the relations between movements of the human body and what was once called the human soul.

Research in logic has helped to clarify the role of domains of discourse for the development of arguments. For logical inference to be possible, participants in a debate must share the ability to refer to individuals – stones, dreams, numbers, rainbows, people, whatever – in some reasonably well-defined domain. This ability has a price, however: the domain itself must be presupposed; attempts to refer to it within the logical discourse it supports lead to paradoxes and eventually contradictions. Discourse A can refer to the domain of discourse B, but not to its own domain. The domains of discourse used in biogeochemistry, however, are quite different from the ones needed to talk about human thoughts. Perhaps a new domain of discourse needs to be established before the intuition conveyed by the noosphere concept can be used in reliable professional research. Using a word like `noosphere' as if one had a great unified domain of discourse at hand, however, can be not only inspiring, but also seriously confusing.

The world as a whole is not a possible subject of logical inferences. This led Wittgenstein to suggest that accepting silence, mysticism if one wishes, was the appropriate stance toward the world in its entirety. Later, however, he realized that this silence was interwoven with a different kind of speech. In a letter to his friend Drury, a psychiatrist who at one stage wondered whether it would not have been better to become an academic, he wrote: ``Look at your patients more closely as human beings in trouble and enjoy more the opportunity you have to say `good night' to so many people'' (Rhees, 1984, p.109f). We may call this way of using

words – as in honestly wishing `good night' to somebody in trouble – poetic. Developing a domain of discourse is a poetic craft, a way of world-making, perhaps. Of course, the argumentative and the poetic use of words are not mutually exclusive; but sometimes the former is more appropriate, sometimes the latter. And this can lead one to wonder whether the noosphere concept does not fit a poetic use of language more than an argumentative one.

Oxygen Cycle☆

DJ Wuebbles, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Introduction

Without atmospheric oxygen, life on Earth would be extremely different. The increase in atmospheric oxygen to present levels, and the corresponding increase in atmospheric levels of ozone, with their ability to absorb biologically harmful high-energy radiation from the Sun, allowed life to evolve and to emerge from the oceans to the land, undergoing an amazing evolution to its present diversity.

Oxygen is one of the most abundant elements on our planet. It is the most abundant element by mass in Earth's crust and is found in most rocks. Oxygen also accounts for 89% of the mass of the oceans. After molecular nitrogen, oxygen is the second most abundant element in Earth's atmosphere, with molecular oxygen accounting for 20.95% of the atmospheric content. There is nearly uniform mixing of molecular oxygen in the atmosphere until above the mesosphere, roughly 80 km above Earth's surface. Therefore, because of the nearly exponential decrease in pressure with altitude, the bulk of molecular oxygen is found in the first few kilometers above Earth's surface. However, although the turbulent mixing in the lower atmosphere keeps the molecular oxygen in a nearly constant mixing ratio (relative to the total air density), measurements indicate that there are seasonal latitudinal variations of as much as 15 ppm (parts per million molecules of air). These seasonal variations are most pronounced at high latitudes in the Northern Hemisphere, where the seasonal cyclic variations in photosynthesis and respiration are most strongly felt.

While there are many gases and particles in the atmosphere containing oxygen, the other gas that needs to be discussed as part of the oxygen cycle because of its great importance to both the atmosphere and life on Earth is ozone. While atmospheric concentrations of ozone are much smaller (ppm levels) than that for molecular oxygen, ozone is important for several reasons: (1) it absorbs biologically harmful levels of ultraviolet (UV) radiation, keeping this radiation from reaching the Earth's surface; (2) it is a 'greenhouse' gas that influences the Earth's climate; and (3) the direct contact with ozone pollution in the lower atmosphere can be harmful to plants, animals, and humans.

The following sections discuss the oxygen cycle in more detail, focusing on the processes affecting molecular oxygen and ozone in the atmosphere, the historical changes in the amounts of these important gases, and their projections for the future.

The Oxygen Budget

Atmospheric molecular oxygen is generated and consumed by a wide range of processes in the Earth system. Biological, chemical, and physical processes, both on and beneath Earth's surface, all contribute to the budget for oxygen in Earth's atmosphere. **Figure 1** shows a simple representation of the budget for oxygen. This figure also shows how the oxygen budget is closely linked to the carbon cycle. While it is difficult to measure the annual fluxes shown in **Figure 1**, oxygen isotopes (^{17}O, ^{18}O) do provide constraints leading to the approximate values shown.

The major mechanism by which molecular oxygen is produced on our planet is through photosynthesis. As seen in **Figures 2** and **3**, the net reaction of photosynthesis is to convert carbon dioxide (CO_2) and water to molecular oxygen. This large annual flux is counteracted by the equally large annual flux from the effects of respiration in removing oxygen from the atmosphere. Thus, as suggested by **Figures 1** and **2**, the current atmospheric equilibrium is maintained by this cycle between photosynthesis and respiration. As indicated in **Figure 3**, there are several slower removal processes in addition to this more rapid cycling.

The mean residence time of molecular oxygen in the atmosphere is roughly 4000 years. With the approximate balance between photolysis and respiration, this residence time is largely controlled by the long-term burial of reduced carbon in ocean sediments. This burial of organic matter results is initiated via the photosynthesis from organisms in the upper levels of the ocean, whose carbon is then deposited to deeper levels of the ocean. The actual rate of burial depends on the area of the ocean floor subjected to anoxic conditions, which in turn varies inversely with the concentration of atmospheric oxygen. The balance between the burial of

☆*Change History:* February 2013. DJ Wuebbles updated the following sections: The Recent Decline in Atmospheric Oxygen and Human Effects on Ozone, Figures 5 and 6, and the Further Reading.

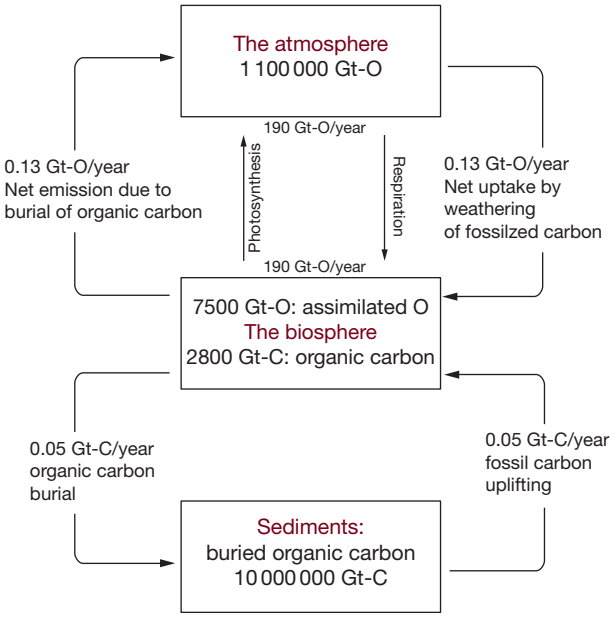

Figure 1 A simple model of the oxygen cycle, and its relationship to the carbon cycle, that considers the three major reservoirs: the atmosphere, the biosphere, and the sediments. Redrawn from graph presented by http://atoc.colorado.edu/~fasullo/pjw_class/images/oxygencycle.gif.

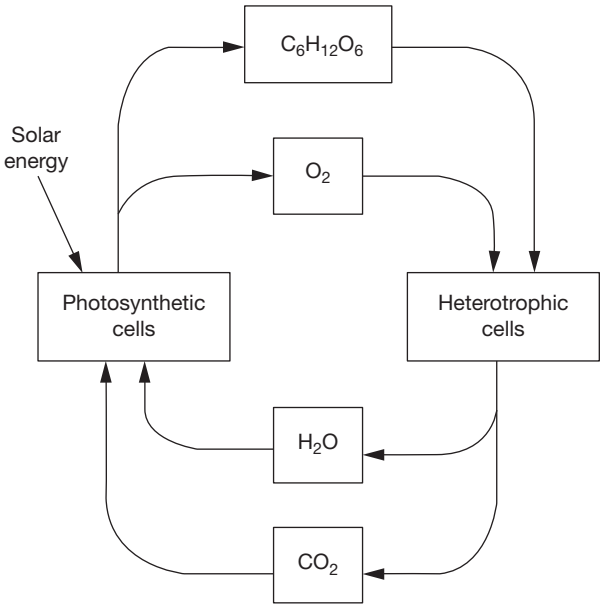

Figure 2 A representation of the basic exchange of atmospheric oxygen between biospheric systems.

organic matter and its oxidation thus plays a significant role in the maintenance of the atmospheric molecular oxygen at 20.95% of the atmospheric density.

A large amount of oxygen has also been consumed by weathering of reduced crustal materials, such as those containing iron and sulfur, through the geologic history. However, the residence time of atmospheric oxygen at the current rate of exposure would be roughly 2 My because of removal mechanisms.

The History of Atmospheric Oxygen

Primitive life began in the absence of free oxygen. However, in the first 400 My of Earth, bacteria-like organisms developed that could take advantage of the light energy from the Sun to initiate photosynthesis, although early production of oxygen likely oxidized crustal materials instead of building up in the atmosphere. Geochemical evidence suggests that there was little oxygen in

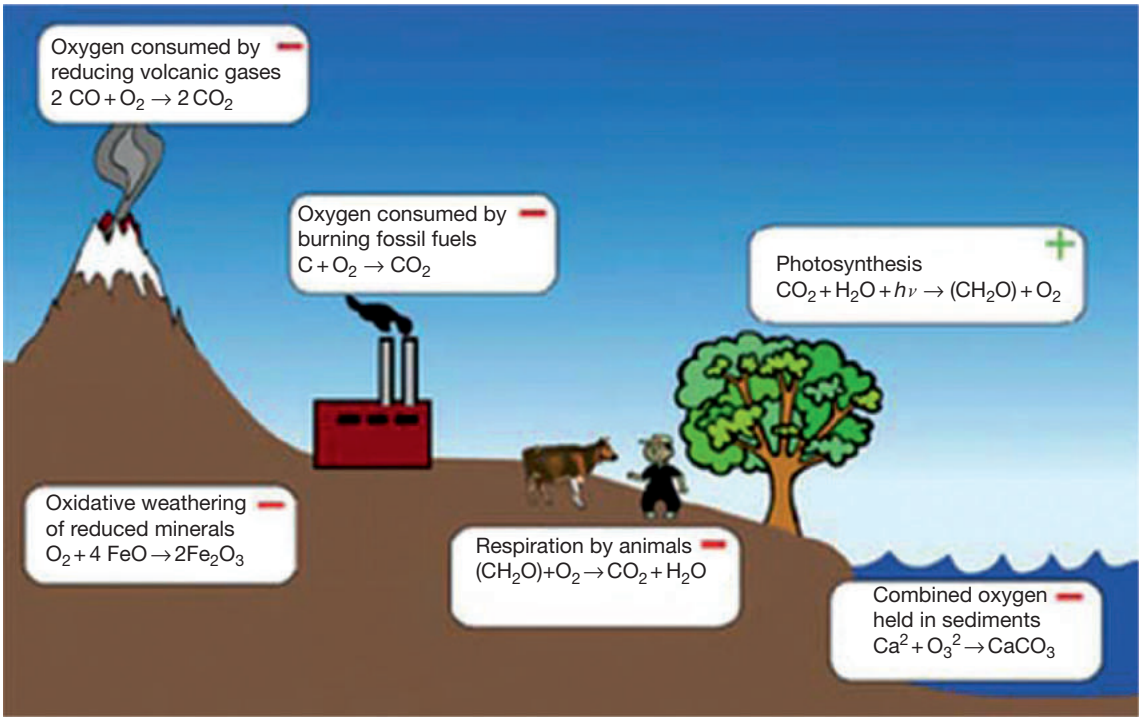

Figure 3 A simple representation of the key chemical reactions controlling the fluxes of oxygen to and from the atmosphere.

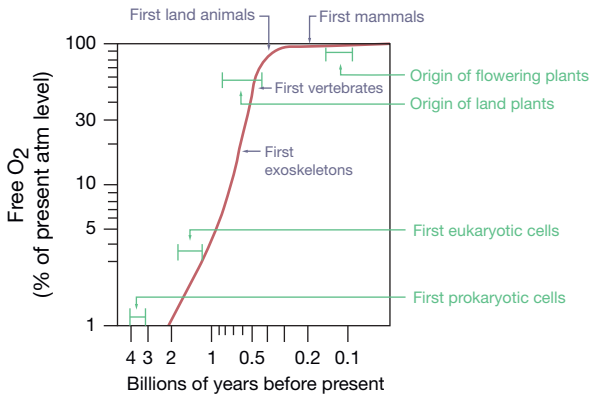

Figure 4 Estimated growth of free oxygen in Earth's atmosphere. Based on graph from http://www.ldeo.columbia.edu/edu/dees/U4735/projections/free_o.html.

the atmosphere during the Achaean (~2.5–4 billion years ago), but near the beginning of the Proterozoic, about 2.5 billion years ago, cyanobacteria – photosynthetic prokaryotes also known as blue-green algae – started the process that eventually led to a massive increase in the concentration of atmospheric oxygen. The definitive worldwide change that signaled the appearance of a significant increase in free oxygen was the appearance of red beds, stratified layers of sedimentary rocks, characterized by abundant red oxides of iron (ferric oxides), which occurred about 2 billion years ago. When the oxygen began to accumulate, the resulting oxidation of other atmospheric constituents totally changed the nature of the atmosphere and the oxygen 'poisoning' was devastating to many of the existing life forms then found on Earth and its oceans. Some bacteria, however, were able to endure the oxygen atmosphere. A symbiosis between bacteria and the former free-living mitochondria enabled eukaryotes to eventually evolve in response to the crisis. Oxygen-based metabolism came into being. The environment changed and life began to evolve.

Figure 4 provides an estimate of the growth of free oxygen in Earth's atmosphere, along with the corresponding evolution of various types of life forms found on our planet. With the increasing proliferation of life, the amount of photosynthesis increased and atmospheric oxygen also continued to increase. The oxygen buildup eventually resulted in the appearance of the first higher order cells with nuclei, called eukaryotes or eukaryotic cells (some analyses suggest this occurred earlier than shown in the figure). These cells depend on atmospheric oxygen for the formation of complex energy-producing compounds. Such cells provide the makeup of all nonbacterial (or nonbacteria-like) forms of life on Earth.

Atmospheric oxygen grew to its present levels of roughly 21% of the atmospheric content about 400 Ma. While it was likely slowed in reaching this state by consumption in terrestrial weathering processes, the amount of atmospheric oxygen, as suggested by the paleontologic record, appears to have varied little since then. The variations that have occurred (while we have little evidence of actual variations, concentrations may have varied from as little as 15% to as much as 30% during the last 500 My) are likely related to the periods when there were strong variations in the deposition of organic matter.

The Recent Decline in Atmospheric Oxygen

Since 1989, when Ralph Keeling of the Scripps Institution of Oceanography began extremely high precision measurements, there has been a steady decline of molecular oxygen in our atmosphere. The decrease is small, just 0.04% through 2009 or an annual rate of about 20 molecules per million molecules of atmospheric oxygen. Measurements of the bubbles of air trapped in ice cores from Greenland and Antarctica suggest that this oxygen decline started in the late eighteenth century, at the beginning of the industrial revolution, when fossil-fuel burning increased dramatically.

This decrease in atmospheric oxygen is not unexpected, for the combustion of fossil fuels, while in the process of producing carbon dioxide, destroys O_2. For every 100 atoms of fossil-fuel carbon burned, it has been estimated that roughly 140 molecules of O_2 are consumed. Since every molecule of additional carbon dioxide locks up two oxygen atoms, the free oxygen decline is greater than the carbon dioxide increase. However, the rate of decline in molecular oxygen is only about two-thirds of that expected from fossil-fuel combustion. While it has not been fully verified, the difference may be explained by the increase in biomass known to occur as a result of the increase in CO_2. Plants grow a bit faster than before, leading to a greater storage of carbon in tree wood and soil humus. For each atom of extra carbon stored in this way, roughly one molecule of extra oxygen accumulates in the atmosphere.

Although the oxygen decrease is unlikely to get to be large enough an effect to be of major concern, it is expected to continue in the future as fossil burning continues and concentrations of atmospheric carbon dioxide continue to increase.

The Role of Ozone

As oxygen increased in Earth's atmosphere, so did the levels of ozone, O_3. The formation of the ozone layer in the upper atmosphere is generally believed to have played an important role in the development of life on Earth, particular in the development of life on land. The accumulation of oxygen molecules in the atmosphere allowed for the production of ozone. Gradually, the increasing levels of ozone led to the formation of the stratosphere, a region of the upper atmosphere where temperature increases with altitude largely as a result of the absorption of solar radiation by ozone. The resulting screening of lethal levels of solar UV radiation by the ozone layer is thought to have been important in allowing life to migrate from the oceans onto the land.

Ozone, O_3, is composed of three oxygen atoms and is a gas at atmospheric pressures and temperatures. Approximately 90% of the atmospheric ozone is in the stratosphere. Most of the remaining ozone is in the troposphere, the lower region of the atmosphere extending from Earth's surface up to roughly 10 km at midlatitudes and 16 km in the tropics. At midlatitudes, the peak concentrations of ozone occur at altitudes between 20 and 30 km. At high latitudes, the peak occurs at lower altitudes, largely as the result of atmospheric transport processes and the lower height of the tropopause (the transition region between the troposphere and the stratosphere).

Ozone in the stratosphere is often called 'good' ozone because it protects life on Earth from harmful levels of UV radiation from the Sun. Therefore, a decrease in the amount of ozone would allow an increase in the amount of the UV radiation from the Sun to reach Earth's surface. Corresponding to an increase in UV are projected significant impacts on ecosystems and human health, including increase in incidences of skin cancer, eye cataracts, damage to genetic DNA, and suppression of the efficiency of the immune system. It is the concern about the increased biologically harmful levels of UV from the decreasing levels of ozone that has largely been the driver for policy actions to protect the ozone layer.

On the other hand, ozone near Earth's surface is called 'bad' ozone because of its direct effects on plants, ecosystems, and humans. Ozone pollution is a concern during the summer months because strong sunlight and hot weather result in harmful ozone concentrations in the air we breathe. Many urban and suburban areas throughout the world have high levels of 'bad' ozone during summer months, and the effects of winds can carry these high ozone levels to rural areas.

Breathing ozone can trigger a variety of health problems including chest pain, coughing, throat irritation, and congestion. It can worsen bronchitis, emphysema, and asthma. 'Bad' ozone can also reduce lung function and inflame the linings of the lungs. Repeated exposure may permanently scar lung tissue. Ground-level ozone also damages vegetation and ecosystems. It leads to reduced agricultural crops and commercial forest yields, reduced growth and survivability of tree seedlings, and increased susceptibility to diseases, pests, and other stresses such as severe weather.

Ozone can also radiatively affect Earth's climate. Ozone absorbs solar radiation but it is also a so-called greenhouse gas that can absorb infrared radiation from Earth that otherwise would be emitted to space. It is the balance between the solar and infrared radiative processes that determines the net effect of ozone on climate. Decreases in ozone in the stratosphere above about 30 km (roughly 18 miles above Earth's surface) tend to increase the surface temperature as a result of the increased absorption of solar radiation, effectively increasing the solar energy that warms Earth's surface. Below about 30 km, decreases in ozone tend to cool the

surface temperature, as the infrared greenhouse effect dominates in this region. Scientific analyses have shown that the decrease in stratospheric ozone over recent decades has had a cooling effect, counteracting a fraction of the warming effect over this time from increasing concentrations of carbon dioxide and other greenhouse gases.

The Production and Destruction of Ozone

Without human intervention, the stratospheric ozone layer would be produced and destroyed through natural processes. The amounts of ozone in the stratosphere vary naturally throughout the year as a result of production and destruction processes, and as a result of winds and other transport processes that move the ozone molecules around the planet. In addition, changes in ozone occur associated with changes in the solar radiation reaching the Earth during the 11-year solar cycle and with various events such as large explosive volcanic eruptions.

Production of ozone in the stratosphere results primarily from photodissociation of oxygen, O_2, molecules. The breaking of the molecular bond by high-energy solar photons at wavelengths less than 242 nm results in oxygen atoms that generally react rapidly with an oxygen molecule to form ozone. The sequence of reactions to form ozone is represented as

$$O_2 + h\nu(\lambda < 242\,\text{nm}) \rightarrow O + O \quad [1]$$

$$O + O_2 + M \rightarrow O_3 + M \quad [2]$$

where $h\nu$ represents a photon, λ is wavelength, and M is a third atmospheric gas, normally N_2 or O_2, the primary components of air.

Since the atmosphere is uniformly filled with oxygen molecules, most of the ozone is generated where there is a balance between the decreasing atmospheric density with altitude and where there is available UV solar radiation in the wavelength region less than 242 nm. This occurs primarily in the upper stratosphere.

The high-energy solar radiation needed to produce ozone is largely absorbed in the stratosphere resulting in the production of the ozone layer. Too little UV radiation reaches the troposphere for it to be a major cause of ozone production in this region. In contrast, the lesser amount of ozone formed in the troposphere is largely through a series of chemical reactions, generally referred to as smog reactions. The primary source of ozone in the troposphere (and in the smog in urban areas) is the conversion of nitric oxide, NO, to nitrogen dioxide, NO_2, which then photolyzes at visible wavelengths to release an oxygen atom that produces ozone through reaction (see eqn [2]). The transport of stratospheric ozone to the troposphere is also important to the budget of tropospheric ozone.

If there was no natural ozone destruction, most of the oxygen in the stratosphere, and perhaps throughout the atmosphere, would eventually be converted to ozone. Such concentrations of ozone would be intolerable to many forms of life on Earth, both because of the direct toxicity of ozone and because of the resultant elimination of any UV radiation reaching Earth's surface.

Ozone photodissociates at UV and visible wavelengths to produce O and O_2. However, because the oxygen atom will generally react to reform ozone, this mechanism produces no net change in the amount of odd oxygen. The actual destruction of ozone and odd oxygen in the stratosphere occurs mainly through catalytic reactions with other gases. In the stratosphere, important catalysts for ozone destruction include nitric oxide (NO), hydroxyl (OH), chlorine (Cl), and bromine (Br). Such gases can be directly substituted for X in the following catalytic mechanism,

$$X + O_3 \rightarrow XO + O_2 \quad [3]$$

$$XO + O \rightarrow X + O_2 \quad [4]$$

which results in the net reaction of $O + O_3$ being converted to two oxygen molecules. As gas X is recycled through these reactions, it continues to destroy ozone until some other reaction converts X to a less reactive form, such as HNO_3 or HCl. In addition to the mechanism described by reactions [3] and [4], there are a number of other catalytic mechanisms also affecting ozone. In this way, a single chlorine atom can lead to the net destruction of thousands of ozone molecules. Because of such cyclic reaction mechanisms, relatively small concentrations of reactive chlorine in the stratosphere can have a significant impact on the amount and distribution of stratospheric ozone.

Human Effects on Ozone

Human activities have had a devastating effect on the concentration and distribution of stratospheric ozone over the last few decades. Measurements of ozone by satellite and ground-based measurements over the last several decades indicate that stratospheric ozone levels have decreased. Atmospheric ozone has decreased globally by more than 10% since 1970 (see **Figure 5**). Atmospheric measurements have also shown that the depleted levels of ozone have indeed increased the amount of UV at the surface. The significant global decrease in stratospheric ozone since the 1970s is well correlated with the increasing amounts of chlorine and bromine in the stratosphere. The sources of this chlorine and bromine are chlorofluorocarbons (CFCs) and other halocarbons produced industrially for a variety of uses such as refrigerants in refrigerators, air conditioners, and large chillers; as propellants for aerosol cans; as blowing agents for making plastic foams; and as solvents for dry-cleaning and for degreasing of

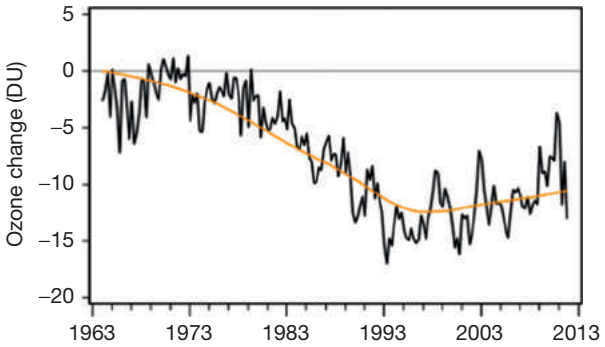

Figure 5 Deviations in total ozone with time relative to 1964 from various ground-based and satellite measurements (TOMS and SBUV). The data are area weighted over 90° S–90° N with seasonal, quasi-biennial oscillations and 11-year solar cycle variations removed. Graph provided by Vitali Fioletov as an update to earlier analyses presented in Fioletov, V.E. (2008). Ozone climatology, trends, and substances that control ozone. *Atmosphere–Ocean* **46**(1), 39–67, http://dx.doi.org/10.3137/ao.460103.

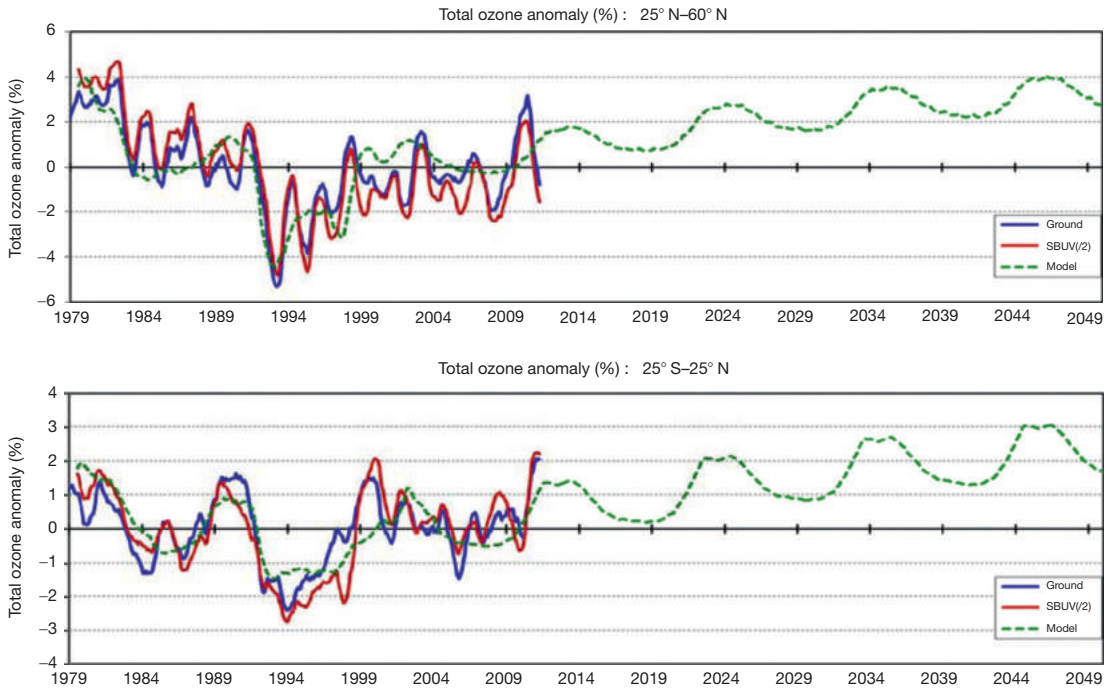

Figure 6 Annual average total ozone for region 25–60 N (top) and 25° S–25° N (bottom) as percent departure from the monthly average climatology from 1979 to 2011. Comparison of trend based on measurements from the solar backscatter ultraviolet (SBUV) satellite instrument relative to ground-based observations and with the derived trend from the University of Illinois zonally averaged chemistry-transport model of the global atmosphere. The effects of the natural cycle due to the quasi-biennial oscillation (QBO) have been removed from the satellite data. While the overall decline in ozone results from increases in concentrations of stratospheric chlorine and bromine from human-related emissions of various halocarbons, the cyclic variations in the observations and model results are due to the effects of the 11-year solar sunspot cycle, while the extra deep minimum in ozone in the early 1990s is due to the effects of emissions from the Mount Pinatubo volcanic eruption in 1991. The model results also show the projected recovery of ozone if the Montreal Protocol reduces halocarbon emissions and atmospheric concentrations as expected. Note that the zonally averaged model does not represent QBO effects on variations in ozone.

materials. Atmospheric measurements have clearly corroborated theoretical studies showing that the chlorine and bromine released from the destruction of these halocarbons in the stratosphere are reacting to destroy ozone. Figure 6 shows an excellent comparison between the observed trend in ozone based on measurements from the total ozone mapping spectrometer (TOMS) and the solar backscatter ultraviolet (SBUV) satellite instrument along with ground-based data and results from the University of Illinois zonally averaged model that is based on the changes in atmospheric gases and particles. In addition to the human-related emissions, natural forcings on ozone from the effects of the 1991 Mount Pinatubo volcanic eruption (due to sulfur emissions) and from the effects of solar flux variations during the 11-year sunspot cycle also contribute to the observed trends. Figures 5 and 6 also show that since the late 1990s, ozone has begun to increase slowly as the effects of the Montreal Protocol to protect the ozone layer have reduced the amounts of chlorine and bromine in the stratosphere. However, as discussed later, full recovery from these effects will take many more decades.

Beginning in the late 1970s, a special phenomenon began to occur in the springtime over Antarctica, referred to as the Antarctic ozone 'hole.' A large decrease in total ozone, now over 60% relative to prehole levels, has been observed in the springtime (September–November) over Antarctica. Dr. Joseph Farman and colleagues first documented this rapid springtime decrease in Antarctic ozone over their British Antarctic Survey station at Halley Bay, Antarctica. These analyses attracted the attention of the scientific community, who soon found that decreases in the total ozone column were greater than 50% compared with the historical values observed by both ground-based and satellite techniques. At the time, there was no expectation that such a phenomenon would be discovered. As a result of the Farman paper, a number of hypotheses arose attempting to explain the large ozone destruction in the springtime over Antarctica. It was initially proposed that the chlorine catalytic cycle might explain the observed ozone decrease, but this did not match the expected ozone decrease possible from the reactive chlorine available at the high latitudes. A special measurement campaign in 1987, as well as later measurements, proved that chlorine and bromine chemistry was indeed responsible for the ozone 'hole,' but because of heterogeneous reactions occurring on polar stratospheric clouds in the lower stratosphere.

The air over the Antarctic becomes extremely cold during the winter as a result of the lack of sunlight over the polar region and because of the greatly reduced mixing of the lower stratospheric air over this region with the air outside this region. During the winter, a circumpolar vortex, also called the polar winter vortex, forms, which isolates the air in the polar region from that outside the region as a result of a stratospheric jet of wind circulating between approximately 50° and 65° S. The extremely cold temperatures inside the vortex lead to the formation of clouds in the lower stratosphere (from roughly 12 to 22 km), called 'polar stratospheric clouds.' Heterogeneous reactions occur on these particles that convert less reactive forms of chlorine to ones that are much more reactive with ozone. When daylight starts to occur over Antarctica in the early spring, this chlorine is available to react with and destroy ozone. Bromine compounds and nitrogen oxides can also react heterogeneously on the particles of these clouds. The ozone destruction continues until the polar vortex breaks up, usually in November.

In the late 1980s, it was generally thought that the Arctic lower stratosphere did not get cold enough to lead to decreases in ozone during the winter and springtime such as those found in the Antarctic. The polar vortex is not generally as strong in the Northern Hemisphere, and, although polar stratospheric clouds would form, it is not likely that they would last long enough for extensive decreases in ozone. However, since 1990, ozone decreases of as much as 30% have been found in the Arctic in those years when lower stratospheric temperatures in the Arctic vortex have been sufficiently low to lead to ozone destruction processes similar to those found in the Antarctic ozone 'hole.' As with Antarctica, large increases in reactive chlorine concentrations have been measured in the regions where the large ozone destruction is occurring.

The recognition of the harmful effect of chlorine and bromine on ozone triggered international policies to restrict the production and use of CFCs and halons and protect stratospheric ozone. These included the 1987 Montreal Protocol on substances that deplete the ozone layer, the subsequent 1990 London Amendment, the 1992 Copenhagen Amendment, and the 1997 Montreal Amendment. In the Montreal Protocol and its Amendments, there is a distinction between the control measures in developed and developing countries. These agreements initially called for reduction of CFC consumption in developed countries. A November 1992 meeting of the United Nations Environment Program held in Copenhagen resulted in substantial modifications to the protocol because of the large observed decrease in ozone, and called for the phase-out of CFCs, carbon tetrachloride (CCl_4), and methyl chloroform (CH_3CCl_3) by 1996 in developed countries. As part of this, the United States has, through the Clean Air Act, eliminated production and import of these chemicals. Production of these compounds is to be totally phased out in developing countries by 2006, while production of halons in developed countries was stopped in 1994. Human-related production and emissions of methyl bromide were not to increase after 1994 in developed countries, with total elimination by 2005. Hydrochlorofluorocarbons, many of which have been used as replacements for the CFCs, still contain chlorine that can destroy ozone, and are to be phased out in the developed countries by 2030.

Worldwide compliance with the international agreements to protect ozone is resulting in significant reductions in the emissions of the CFCs, halons, and other halocarbons having the largest effects on ozone; as a result, levels of stratospheric ozone should slowly begin to recover over the coming decades as the reactive chlorine and bromine in the stratosphere declines. This recovery will be gradual, primarily because of the long time it takes for CFCs and halons to be removed from the atmosphere. Atmospheric model results, such as those shown in **Figure 6**, suggest that the effects of halocarbons on ozone should return to 1980 ozone levels by 2040–50. At the same time, changes in Earth's climate and in the amounts of atmospheric methane and nitrous oxide are likely to further affect the amount and distribution of stratospheric ozone.

While ozone slowly recovers, scientists and policymakers will need to work together to ensure that new problems do not develop as a result of the introduction of new chemicals into the marketplace. They will also need to interact with industry and governments to ensure that the potential effects of increasing concentrations of other gases changing as a result of human activities, such as methane and nitrous oxide, do not produce their own significant impacts on ozone. Further understanding of evaluating the potential effects of various natural events, such as volcanic eruptions and solar events, as well as other possible human activities, including nuclear explosions is also needed.

Paleoclimatology

Marcus J Thomson, University of California, Los Angeles, California, United States and International Institute of Applied Systems Analysis (IIASA), Laxenburg, Austria

Nomenclature

BP Before present (1950 CE, by convention)
ka 10^3 years
Ma 10^6 years
Ga 10^9 years

Glossary

Holocene The present geological era, 11.5 ka BP–present.
Isotopes Atoms with the same number of protons and different numbers of neutrons.
Isotopologues Molecules of the same chemical structure comprised of isotopes and combinations of isotopes.
LGM Last glacial maximum (MIS2).
LIG Last interglacial period (MIS3).
MIS Marine isotope stage, counting major interglacial-glacial periods back from the present era, MIS1; where odd numbers stand for interglacials and even numbers stand for glacial periods.
Pleistocene The previous geological era, 2.55 Ma—11.5 ka BP.
Quaternary The present geological period, comprised of the Pleistocene and Holocene eras.

Paleoclimatology

Paleoclimatology is the study of Earth's climate from the formation of the planet to the present. It is distinguished from historical and "modern" climatology by its use of proxies, rather than historical documents and instrumental measurements, to reconstruct past climatic conditions. Proxies are naturally occurring archives of environmental change which are interpreted to infer climate histories. For those interested in past ecosystems, paleoclimatology is important to inform the contexts in which plant and animal communities evolved and lived; for those interested in present and future ecosystems in the context of climate change, paleoclimatology is the only means to establish a baseline against which to assess degrees of change.

Climate Change and Its Causes

Climate is a loose term for the state of the weather in an area over a period of time, usually months or years. Climate change is a result of dynamics of solar insolation, the geometry of the Earth's orbit, the geographical disposition of the continents and oceans, and atmospheric greenhouse gas (GHG) concentrations. Important second-order causes of climate change include dynamics of energy circulation in the ocean and atmosphere, volcanism, ice sheet scale and areal coverage, topography, and vegetative land cover. The Earth's mean annual diurnal variations in temperature, one measure of the planet's climate, for example, is moderated by the general circulation of the atmosphere-ocean system and greenhouse effect of the atmospheric gases.

The degree to which the climate may be said to change depends on its normative state, for which are several scientific conventions. For instance, in the chapter on paleoclimate in its fifth assessment report, the International Panel on Climate Change pays special attention to the past 2000 years (2 ka BP). On a planet whose climate record may be reconstructed or inferred from nearly 4.6 billion years (Ga) BP, choosing the most recent four ten-thousandths of a percent of that period may seem odd. It may even have engendered controversy among observers who are not aware of the vastly different scales over which proxies of paleoclimate change operate. Focusing on the past 2 ka permits paleoclimatologists to draw on data from multiple proxy sources which have good chronological and geographical resolution; and ignore parts of the planet's history which have no modern or probable near-term future analog.

Solar intensity and Milankovitch cycles

The flux of solar energy from the top of the atmosphere to the earth's surface (insolation) is the overwhelming determinant of the planet's environment. The sun's output varies over time as a consequence of complex patterns of solar cycles and, over its long lifetime, the availability of nuclear fuel. Solar cycles occur with fairly regular 11 year periods, although these short cycles are superposed on far longer and less predictable oscillations in output. They manifest as variations in the sun's radiative output of about 0.08%, coronal mass ejections, and visually as changes in sunspots and the auroras seen on Earth. Because of historical sunspot observations in particular, we may be confident that the sun has behaved similarly over the past several centuries. Using cosmogenic radiocarbon (^{14}C) and beryllium (^{10}Be) archived in tree growth rings and ice cores, patterns in solar intensity have been reconstructed for millennia. The sensitivity of the Earth's climate system to these small variations is not well understood.

 doi:10.1016/B978-0-12-409548-9.10894-2

Over timescales on the order of a thousand years and more, variations in the sun's radiative output are less important to the Earth's climate than the solar flux (energy per unit area per unit time) over the northern hemisphere, which depends primarily on orbital geometry. The lower the sun rises in the sky, the lower the flux at the surface. The seasonal position of the sun in the sky is determined by orbital mechanics. Over long timescales these are called Milankovitch cycles. Milankovitch cycles are the summation of several distinct oscillations due to the force of gravity: first is the axial-tilt (obliquity) of the planet's axis of rotation with respect to the plane of its orbit (the ecliptic); second is the precession of the Earth as it spins on its axis, due to net torques on its nonuniform distribution of mass; third is the (apsidal) precession of the Earth's slightly elliptical orbit due to the influence of mass asymmetries in the solar system; and fourth, in addition to those Milankovitch computed, are included variations in the inclination of the ecliptic. The combined effect of these oscillations are modes with beat periods of roughly 100, 41, and 23 ka. The remarkable (although imperfect) correspondence between Milankovitch cycles and glacial-interglacial intervals of over the quaternary period (2.44 Ma BP—present) is the strongest evidence for the dominant Milankovitch Theory of Quaternary glaciation.

Geographic disposition of the continents

The Earth's surface is subdivided into dynamic tectonic plates. Over millions of years, continental plates drifted apart, producing rifts and oceans, and ran together, lifting mountain ranges and forming supercontinents. The present conformation of the continents, with the land area in the northern twice that of the southern hemisphere, was a major factor contributing to Quaternary glaciation, as it enabled the accumulation of ice sheets on continental scale. During cold periods, multiyear snow accumulated as it does presently on Baffin Island, Greenland, and Antarctica. Whereas snow accumulation on Antarctica is restricted by the Southern Ocean, the vast tracts of the North American and Eurasian landmasses straddling the Arctic Circle allowed ice sheets to grow almost without constraint.

Further, the geographic disposition of land and sea controls the general circulation of the oceans and atmosphere. The thermohaline circulation (THC) of the oceans is driven by thermal and salinity gradients. A sudden disruption to the THC in the North Atlantic may have caused the Younger Dryas (12.9–11.7 ka BP), a sudden and short-lived rebound glacial-like conditions at the beginning of the present interglacial period. Measuring climate change in response to internal forcing mechanisms, like emergent disruptions in the THC, are challenging, requiring sophisticated and computationally expensive numerical models. Observing past changes in the THC by proxy is possible, to a limited degree, by comparing isotopic ratios of from disparate sediment cores.

Atmospheric greenhouse gas concentrations

The atmosphere helps to thermally regulate the surface of the planet. Because some of its constituent gases are transparent to incident solar radiation and tend to block lower frequency (thermal) energy that is re-radiated from the surface, it functions like a greenhouse: when there is a net surplus of energy into the Earth-system, it warms up. These constituents are termed greenhouse gases (GHGs). The present composition of dry air in the atmosphere is about 78.08% nitrogen (N_2), 20.95% oxygen (O_2), 0.93% argon (Ar), and 0.04% carbon dioxide (CO_2) by volume, with trace gases. The concentration of water vapor in the atmosphere varies, but is approximately 1%. Water vapor is a critical greenhouse gas (GHG), particularly for its role in cloud formation and due to its high heat capacity.

The atmosphere is structured by gradients in temperature and its constituent gases. The bottom two layers are the stratosphere and, below it, the troposphere. The boundary between troposphere and stratosphere is defined by the tropopause, usually marked by a temperature inversion. This is the altitude at which thermal radiation from the earth is balanced by radiation from the sun. Just above the tropopause is the layer of ozone (O_3) gas which is a critical barrier against high energy cosmic rays which would significantly disrupt the biosphere. There are still higher-elevation structures that shield against particulate radiation harmful to organic life.

The role of CO_2 as a GHG is well understood. The present concentration of CO_2 in the atmosphere is about 410 ppm. This concentration depends on the Carbon Cycle, a biogeochemical exchange between the geosphere, pedosphere, hydrosphere, biosphere, atmosphere, cryosphere, and increasingly the anthropogenic built environment. Archives of CO_2 concentration in the atmosphere (hereafter $[CO_2]_{atm}$) demonstrate that this is an increase of at least 33% from 1800 CE due to the industrial-scale conversion of fossil fuels to energy and waste gases. Over the last 400 ka, $[CO_2]_{atm}$ had a concentration of 180–210 ppm during glacial periods, when ice sheets covered substantial parts of the northern hemisphere, and 280–300 ppm during warm interglacial periods. Finding periods in the atmosphere's history wherein $[CO_2]_{atm}$ was equal to or greater than 400 ppm, and comparing the consequences on climate records, is a major preoccupation of many paleoclimatologists today. For instance, about 125 ka BP, during the Last Interglacial (LIG; 129–118 ka BP), was a period sometimes called the Eemian: this was the warmest period of the past 200 ka, with a climate similar to that of today, and we have no evidence that $[CO_2]_{atm}$ was greater than about 300 ppm. However, there is a growing consensus that regional differences in warming, particularly over the Arctic, were substantially different from the modern (and probable future) case as compared to the Eemian.

Over geological history, which spans about 23,000 times 200 ka, concentrations of constituent gases in the atmosphere have varied so radically that the planet is considered to have experienced at least three entirely different atmospheres. The present composition of the atmosphere was established roughly 3.5 Ga BP, although the relative concentrations of its constituent gases have varied since, primarily as a consequence of biochemical feedbacks within the Earth system.

Paleoclimate Reconstruction Methods

Landforms were long ago recognized as probable archives of climate change. Scientists compared processes of mountain glaciology to features of the landscape of Europe and North America, and saw relicts of enormous ice sheets which predated historical records. Yet in spite of the evidence of environmental change by proxy, there were no reliable methods to determine the age of prehistoric phenomena. The development of radiometric methods after the middle 20th century was revolutionary, as now different proxies could be independently dated and ordered in time to produce a synoptic record of paleoenvironmental change.

Proxies

Proxies are naturally occurring phenomena whose intrinsic alteration, such as growth or accumulation, is sensitive to environmental conditions and whose impressed remains are stable archives through time. Paleoclimatologists interpret patterns in proxy records to reconstruct the environmental conditions under which they were produced. As various proxies respond differently to the same climatic mechanism, paleoclimatologists seek multiple proxies to develop complete synoptic records of climate change. Multiproxy records show that the Earth's mean annual temperature, for example, has followed a linear cooling trend over the past 800 thousand years (800 ka), but also displayed quasi-periodic oscillations from cold glacial to warm interglacial conditions over thousands of years, as well as the seasonal and diurnal ups and downs of everyday experience.

Stable isotopes

When plants respire and process CO_2, for example, plants that follow the C_3 photosynthetic pathway take up less of the heavier isotope than plants which follow the C_4 pathway. This fractionation is written in terms of a standard measure, $\delta^{13}C$, and means that C_3 plants are relatively depleted in ^{13}C ($\delta^{13}C$ of between -33 and $-24‰$) as compared to C_4 plants ($\delta^{13}C$ of between -16 and $-10‰$). In lake sediment cores, $\delta^{13}C$ and $\delta^{15}N$ are used to discriminate between endogenous and exogenous sources of organic carbon.

All water (H_2O) in nature contains the most common isotope of oxygen ($^{16}_{8}O$) and a trace fraction of $^{18}_{8}O$, a stable isotope of oxygen with two additional neutrons. During glaciations, the accumulation of continental scale ice sheets sequestered vast amounts of precipitated water on land. Evaporation thermodynamically favors $H_2^{16}O$, due to its lower mass, so meteoric water tends to be depleted in $H_2^{18}O$; that is, during periods of glaciation, the seawater from which meteoric water was ultimately sourced was enriched in $H_2^{18}O$. This is measured in terms of $\delta^{18}O$, an isotopic fraction of heavy oxygen normalized by a standard value.

Strontium is abundant in nature, readily substitutes for Ca^{2+} in crystals of $CaCO_3$ wherein resists diagenetic alteration. Ratios of strontium isotopes ($^{87}Sr/^{86}Sr$) can be uses as geological fingerprints to determine the provenience of sediment. This has been applied to reconstruct the Quaternary paleohydroclimate of the Nile River, whose main tributaries, the Blue Nile and the White Nile are driven by different climatic mechanisms (Talbot *et al.*, 2000). The relative strength of these mechanisms is important to questions of Holocene climate change over Africa and the Indian Ocean.

One of the most exciting methodological developments in paleoclimatology is the application of 'clumped' isotopes to temperature reconstruction (Eiler, 2011). For example, carbonate (CO_3^{2-}) crystals appear in nature as molecular combinations (isotopologues) of stable isotopes of carbon (^{13}C, ^{12}C) and oxygen (^{16}O, ^{17}O, ^{18}O). As a crystal lattice forms, isotopologues will equilibrate according to their slight mass differences, with higher mass isotopologues thermodynamically favored at lower temperatures and vice versa. By comparing isotopologue abundances in CO_2 from carbonate crystals (written as Δ_{47}) to that which would be expected from their natural abundances alone (i.e., no "clumping"), researchers estimate isotopologues equilibrium constants and thus create a paleothermometer. The great strength of this method is that it depends exclusively on thermodynamics; the weakness, for the moment, is that the small temperature dependence of "clumping" means that carbonate samples must be uncontaminated and large.

Proxies for the quaternary period

Ice cores

Ice records changes in polar and high elevation glaciers from entrained dust, pollen, and charcoal, or from ancient gases trapped in interstitial pockets. Ice sheets form from snow that continues to accumulate over many years. Sublimation and melting causes snow to recrystallize as "firn," a granular manifestation of snow-ice that forms the uppermost laminae of an ice core. Firn sequesters air bubbles that sample the atmosphere at the time of its formation. With depth, the considerable weight of multiyear firn reorganizes water-ice crystals to produce solid ice below about 10 m; and ice sheets on Greenland and Antarctica are kilometers thick.

Speleothems

Common salts of carbonate (CO_3^{2-}) dissolve readily in water. A consequence is that sedimentary carbonate formations of limestone, dolomite, gypsum and like underlying water-saturated soils are characterized by subterranean cave systems; and within the caves, carbonate salts precipitate onto the various surfaces of the void spaces, producing cave deposits, termed speleothems. The most common minerals comprising speleothems of interest to paleoclimatologists are calcareous carbonates ($CaCO_3$), such as calcite and aragonite.

The dissolution of atmospheric carbon dioxide into water forms weakly acidic carbonic acid (H_2CO_3). In the archetypical case, this percolates through the subsoil and weathered limestone substrate, dissolving and mobilizing calcium and bicarbonate, via the

reaction, $CaCO_3 + H_2CO_3 \rightarrow Ca^{2+} + 2HCO_3^-$. When this solution percolates into the cave system, it loses dissolved carbon dioxide to the low partial pressure of CO_2 in the void space, thereby precipitating calcium carbonate via the reaction, $Ca^{2+} + 2HCO^{3-} \rightarrow CaCO_3 + H_2O + CO_2$. A proportion of the molecular carbon and oxygen archived in speleothem carbonates was sourced from the atmosphere and the hydrosphere, respectively. Thus speleothem carbonates may be analyzed for isotopic signatures (e.g., $\delta^{13}C$, $\delta^{18}O$) of the sources of these environmental inputs. Although usually analyzed for patterns of change in the hydrosphere, in some circumstances be dominated by changes in temperature.

Marine and lake sediment cores

A core is a column of sediment that preserves the stratigraphy of its parent material. From top to bottom, they archive sediments from youngest to oldest. The length of a core, compared to the range of time in archives, is determined by the sedimentation rate, the speed at which substrate accumulates. In deep ocean cores, this may be just millimeters per thousands of years, while on a continental shelf, where it is augmented by alluvial matter discharged from rivers, the sedimentation rate may be much faster. Higher sedimentation rates typically produce higher resolution records. Terrestrial wetlands and lakes may accumulate sediment very quickly, particularly if they are susceptible to inwash from flooding, high biotic productivity, and accumulation of peat.

Foraminifera (see below) records from cores of the ocean floor were the first truly global-scale paleoclimatic proxies; and therefore, many other proxies are compared to the sequence of $\delta^{18}O$ lows and highs, numbered down-core, or from youngest to oldest, starting with the present, Holocene Epoch ($\sim$11.5 ka BP to present). Each oddly numbered marine isotope stage (MIS) represents a warm interglacial (or interstadial), such as the Holocene (MIS1); each evenly numbered MIS represents a cold glacial (stadial), such as the LGM (MIS2). Numbering periods according to MIS avoids overtly phenomenological descriptions of climate change, whose effects vary by location. We now understand that large ice sheets persisted over parts of the Northern Hemisphere throughout MIS3, and that the last period which may be practicably termed 'interglacial' was MIS5 (130–80 ka BP). Careful investigation of the MIS sequence and comparisons to other multiproxy records revealed substages, termed "horizons," within the stages themselves. For instance, MIS5 began with the warmest period of the Pleistocene, the Eemian (130–115 ka BP), which is alphanumerically labeled MIS5e to distinguish it from markedly different late-Stage 5 conditions.

Lake and other terrestrial wetland environments readily sequester material from their surroundings, incorporating it into their sediment. Over long periods of time, lakes can significantly change in depth-profile (bathymetry) and volume, based on their water-balance, or net water inflow. Over the short term, on the order of days to decades, water-balance is affected by changes in precipitation, streamflow, and evaporation. Over centuries and more, water-balance can be affected by geomorphic changes to the lake's catchment, chemical changes to the soil profile and drainage, and sediment buildup. When a lake sediments in and dries out, it is called a "playa." The famous Bonneville Salt Flats playa, for example, was formed when the Pleistocene Lake Bonneville dried out ($\sim$14.5 ka BP) and left behind a thick evaporite of salts. The Fayum, in northern Egypt, is an ancient lake basin in what has been, for the past several thousand years, a hyperarid desert. Its modern lake, Birket Qarun, is a fraction the size of its premodern predecessor, Lake Moeris, mostly due to flood control of the Nile River. However, even ancient Lake Moeris was a fraction the scale of the Pleistocene-era Fayum paleolake, whose shorelines are visible in the desert tens of meters above the Qarun shoreline.

Most lakes more than a few meters in depth naturally stratify by temperature due to small differences in density. At the top of the water column is the epilimnion, a stratum of warm, well-mixed water. At the base of the water column is the hypolimnion, a stratum of cold, hypoxic or anoxic water. Between these strata is the metalimnion, sometimes loosely referred to as the thermocline, which is the sudden transition with depth from warm to cold water. Holomictic lakes mix at least once a year; a subset of these, dimictic lakes, mix in both the spring and the fall. In a stratified lake there is no replenishment of dissolved oxygen to the base of the water column; so it is used up quickly by microorganisms, and hypoxic or anoxic conditions develop. As the lake absorbs thermal energy over the course of the summer, the epilimnion will expand until the water column is isothermic due to mixing. The water-sediment interface will oxygenate and the lake is said to have "turned over." In dimictic lakes, turnover will occur again in the spring: when water nears its freezing point, water molecules tend to reorder into complexes which reduce its mass density, making it more buoyant. After the spring melt (ice-out), warming surface water passes through its maximum density at 4°C (at 1 atm of pressure), at which point it sinks, displacing the deeper water below. Over many seasons of regular mixing, "varves," which are laminae in the sediment, develop. Paleoclimatologists seek to core varved lake sediments because varves may often be counted as tree rings are, improving the quality of an age model. Varved sediments from Lake Van in eastern Turkey, for instance, have been used to reconstruct millennia of paleoenvironmental change in the Near East. Lake sediments have proved some of the most geographically distributed and informative sources of paleoclimatic data for the northern hemisphere over the late quaternary period.

Pollen

Palynology is the study of microscopic pollen and spores, collectively termed palynomorphs. Pollen grains and spores have a hard outer coating (exine) made largely of sporopollenin, an inert polymer which makes them highly resilient to diagenesis. Pollen assemblages are used to reconstruct the nearby vegetative environment contemporaneous with their position in a sediment core. Fossil pollen samples are typically prepared by chemically reducing and sieving unwanted sediment substrate, chemically darkening and dyeing grain exines to highlight diagnostic features, and mounting on optical microscope slides. Pollen grains are counted relative to a tracer spore prepared within the sample. Identification to better than genus level is not usually possible; and some grain morphotypes are difficult to identify at better than family level, such as nondomesticated grasses. Fossil pollen-based

paleobotanical reconstructions are approximations limited by identification resolution and bias towards copious, anemophilous (wind-dependent pollinating) plants.

Tree rings

Woody plants grow their trunks by means of a live tissue just beneath the bark called "cambium." For most trees, the cambium is bifacial: it sets down parallel undifferentiated cell pairs, the outer layer of which is the "phloem," and the inner layer of which becomes the "xylem." The phloem transports water and nutrients critical for the tree's growth; the xylem hardens into wood, a material of dense cellulosic fibers. Newer wood layers grow over old layers, forming annuli. Trees that grow seasonally, either because of warm-cold or wet-dry transitions in the climate, suffer periods of growth-stress or dormancy. In temperate climates, where growth stress is a function of the seasonal cycle, common tree rings are produced because wood laid down in the spring and summer ("early wood") is structurally different from that which is laid down in the late fall ("late wood"). A single tree therefore captures snapshots of its local environmental stress history; a copse of trees captures a redundant record of the paleoenvironment for the area. By matching patterns of growth rings between living trees and deadfall, it is also possible to build environmental histories that reach well beyond the lifetime of a tree.

Trees consume CO_2 from the atmosphere via the stomata in their leaves and water (usually via their roots) during photosynthesis. Their tissue is therefore composed of carbon and oxygen atoms in part from the atmosphere and protons and oxygen atoms donated from water. Meteoric and groundwater tend to have different isotopic signatures. Therefore, trees pick up environmentally determined isotopic signals in terms of $\delta^{13}C$, $\delta^{18}O$ and deuterium (δD, used to infer water-balance) from these inputs alone. Tree rings have been used to reconstruct records of prehistoric hurricanes over the southeastern United States, rainfall over isolated parts of Amazonia, and the timing of important modes of internal variability in the Pacific Ocean, such as the El Niño Southern Oscillation (ENSO).

Other biogenic proxies

Many organisms archive records of environmental change over time in the hard tissues (sclera) they grow. Common applications are the cross-sectional analysis of mollusk shells, and piscine otoliths for changes in stable isotope ratios. For instance, corals are important foundational members of many marine ecosystems. Corals are complexes built from the calcareous secretions of coral polyps. Assemblages of coral species are specific to local environmental conditions. Complexes of coral skeletons may be analyzed for changes in marine conditions and even variations in mean sea level.

Midges (Insecta: Diptera: Chironomidae) are flying insects that lay their eggs in water. In fact, the majority of a midge's existence is spent as an aquatic instar; its adult stage is short, merely to translocate and reproduce. Midges are good indicator species, as they reproduce only within a narrow niche defined by environmental factors like water temperature and various solute concentrations. When midge instars undergo ecdysis, their exoskeletons (cuticles) sink and collect in sediment. The cuticles of late-stage instars are especially robust, and may remain preserved in sediment for millennia. Diagnostic features of fossil cuticles are used to identify midge taxa recovered from sediment cores. Assemblages have been used to reconstruct ecological changes to wetland systems, including local air temperature.

Diatoms (Bacillariophyta) are a major class of phytoplankton which have become especially influential in terrestrial wetland paleolimnology, particularly in determining water balance and solute concentration. Diatoms are unicellular autotrophic organisms whose cell walls (frustules) are composed of silica. Frustules of expired diatoms readily collect in sediment and are highly resilient. Fossilized diatoms are found after about 185 Ma BP; and the earliest diatoms may, in fact, date to the permian mass extinction (250 Ma BP).

Otoliths are calcium carbonate masses that grow within the inner ears of vertebrates. Fish otoliths found in sediment cores are analyzed for isotopic differences, such as $\delta^{18}O$ variations down-core to determine the history of evaporative enrichment in a lake. Such data may be inform an estimate of a lake basin's water balance in time series or drought history. In a classic study of paleoclimate change in the Near East, $\delta^{13}C$ in the shells of land snails showed a change in their diet, from C_3 to C_4 pathway plants, indicating a shift in the dominant precipitation regime from relatively wet mid-Holocene to dry modern conditions (Goodfriend, 1988).

Neotoma

Pack rats (*Neotoma* spp.) are a genus of small rodents found throughout northern Mexico, the southern and western United States, and western Canada. The nests, or middens, that they build are highly resilient and may be occupied, and reoccupied, by generations of neotoma over thousands of years. In constructing their middens, neotoma hoard nearby materials and cement them with secretions of their urine. Neotoma urine readily desiccates in their dry habitats becoming amberat, the substance that cements their middens. Additionally, neotoma will seal off midden chambers occupied by previous generations, producing nearly hermetic time capsules of highly localized assemblages of plant macrofossils, shells, bones, insect exoskeletons, and pollen. Neotoma middens containing remarkably well preserved paleoecological material have been radiocarbon dated to the Pleistocene.

Geomorphology

The Earth's surface is constantly under the influence of biotic and abiotic agents of change, whose activity is largely driven by solar radiation and the force of gravity over time. While the lithosphere is a good archive of hundreds of millions of years of this influence, is it commonly encountered in quaternary-age reconstructions. Throughout northern Europe, northeastern North

America, and in mountain valleys all over the world, there is ample evidence of glaciation in the form of moraines, enormous nonvolcanic boulders scattered haphazardly on the landscape (glacial "erratics"), striations in bedrock due to abrasion, and deep reservoirs of rock flour in ancient basins. Isostatic rebound, which is the slow adjustment of continental plates to having the great weight of ice sheets removed, is raising Scotland and making new dry land in northern Canada and the Baltic in spite of sea level rise due to global warming.

Physical histories in basins with no outflow, such as endorheic lakes, can be useful in reconstructing local water balance over many thousands of years. Streams modify the landscape by downcutting into the sediment (degradation) and by building up alluvial deposits (aggradation). The difference between a stream's tendency to downcut or deposit may be due to discharge, the amount of material it carries in suspension, or whether it freezes. Stream terraces form from repeated and alternating episodes of channel degradation and aggradation. Terrace gravels are generally dated radiometrically to unravel the channelization sequence. These have clear dependencies on prevailing climate, as well as dramatic weather related events like floods; and it is a useful technique for Holocene-age xeric environments. Analysis of paleochannels and paleolake shorelines has been particularly successful in the development of evidence for an expansive mid-Holocene subpluvial ("wet" period), sometimes called the "Green Sahara," some 9–5 ka BP across northern Africa; and in reconstructing hydrologic water balance in the Pleistocene Southwest United States. Both results have significant implications for large scale ocean circulation patterns which drive prevailing climates in those regions.

Loess is eolian, or wind-deposited, dust that often accretes in periods of large scale drought. Eolian dust forms when, driven by wind, loose grains skip along the ground with sufficient speed to cause microscale fragments to eject from the grains, a process known as saltation bombardment. In spite of their poor aerodynamics, the fragments become suspended in turbulent air flows and can rise kilometers into the troposphere. Airborne dust can cause moisture to condense and precipitate, and block sunlight. Loess deposits are often interpreted as evidence of drought; but also more subtly as evidence of a breakup of the biological soil crusts in dryland ecosystems. Patterns of cross-bedding in loess and sand dune deposits even carries information on the strength and direction of the prevailing wind.

Proxies for prequaternary ages

Foraminifera and coccoliths

Foraminifera (or commonly just "forams") are protists that inhabit nearly every marine environment, including estuaries. Forams are best known among paleoclimatologists for their utility in reconstructing past sea-surface temperature (SST) variations, because they incorporate the environmental isotopes of their local environments when they grow their shells, termed "tests." Tests from expired forams accumulate in marine sediment. Morphological variations in tests enable researchers to discriminate between different taxa in a fossil foram assemblage from a core. Thus, researchers can infer the former presence of microenvironments in which similar assemblages are found presently, or select the tests of specific taxa for isotopic analyses. An example of the former case is in the reconstruction of mean sea level (MSL), as foram assemblages of from the intertidal and subtidal zones from coastal sediments are very specific; and an example of the latter is SST reconstructions from pelagic forams, or those that live in the open ocean. In both cases, fossil assemblages must be converted to MSL or SST estimates by means of transfer functions, which are usually regressions of instrumental data on modern foram assemblages.

Another important fossil resource found in marine sediments are "coccoliths," calcium carbonate scales produced within an ancient group of phytoplanktons, coccolithophores. As phytoplankton, they are obliged to live at the top of the water column, where there is sufficient light for photosynthesis, in the euphotic zone. The euphotic is the brightest part of the epipelagic zone, or depth over which any light penetrates at all. As such, it can be radiatively warmed and remains relatively well mixed; that is to say, in good contact with the atmosphere and the isotopic ratios of its constituent gases.

Age modeling

Age models are built in a variety of ways. It is often impossible or impractical to determine the age for every element in a series of proxies, such as a sediment core. In such a case, material from a subset of the core sediment is sampled for radiometric dating. The result will be an ordered sequence of radiometric ages which, following calibration to some standard, are interpolated to produce a sediment age-depth model. Similarly, age models are generated for speleothems using uranium-series or uranium'thorium dating, for dunes and sediment deposits using luminescence techniques, and for glacial erratics and moraines using cosmogenic nuclides.

Prior to the advent of radiometric methods after the middle 20th century, ages of phenomena were estimated by their relative positions within geological sequences or by comparison with documentary historical evidence, such as Egyptian papyri and ships' logs. Geological phenomena, such as the uplift and degradation of mountains, downcutting of river channels, and sedimentation and lithification of stone, were clearly older by orders of magnitude. Comparative anatomists could build up a sequence of similar life forms from their fossils in different geological facies, and thus deduce which were likely more or less recent in time. These were methods of relative age determination. Methods of direct age determination require independent clocks, such as radioactive decay, and detectors of sufficient sensitivity that only became practicable after the middle 20th century.

Dendrochronology and sclerochronology

Tree rings were long known to represent the conditions under which trees grew, but the first systematic use of tree rings for age determination (dendrochronology) was not developed until the early 20th century by astronomer A. E. Douglass, who realized that growth-stressed trees were good independent clocks. Trees grow by laying down new cellulosic matrix on their cambium layer,

just beneath their bark. In extratropical environments, there are seasonally expressed differences in environmental stress, and trees cycle through periods of dormancy and growth. Similarly, the use of time-dependent information archived in biotic sclera is termed sclerochronology.

Radiometric dating

Radiometric methods rely on radioactive beta-decay, a fundamental process in nature, during which a neutron spontaneously transforms into a proton and an electron, and an energetic but weakly interacting neutrino. Individual neutron decays are unpredictable, but the average rate of decay of a large population of neutrons follows a simple exponential decay, the rate of which depends on the mass of the particle into which a neutron is bound. The radioactive decay rate of any isotope may therefore be represented by a single number, its characteristic "half-life," $t_{\frac{1}{2}}$, the average time it would take for a population of radioactive particles to decline by one-half, or its inverse, the decay constant, λ.

Radiocarbon (^{14}C), with a half-life of about 5730 years, is ideally suited to radiometric age determination because it is abundant in nature, chemically indistinguishable from common ^{12}C. Carbon-14 is produced in the upper atmosphere by collisions between nitrogen (^{14}N) and cosmic rays, mixes to sea level in about 6 months, and is promptly insinuated into the carbon cycle of the biosphere. The ratio of $^{14}C/^{12}C$ remains in equilibrium with the environment in an organism until death, whereupon no new ^{14}C is contributed and the $^{14}C/^{12}C$ ratio is determined by the rate of decay of ^{14}C (into ^{14}N). Careful measurement of this $^{14}C/^{12}C$ ratio enables age determination with a precision of as little as a few percent over the half-life of ^{14}C and with a practicable maximum age of about seven half-lives using a state-of-the-art, accelerated mass spectrometer (AMS) measurement. The $^{14}C/^{12}C$ ratio is given in terms of ^{14}C-years, which are nonuniform units of time, whose zero-point is defined as 1950 CE. Converting ^{14}C-years to a meaningful age determination requires correcting for nonequilibrium ancient carbon (reservoir effect), differences in physiological and taphonomic processing of carbon (fractionalization), and postdepositional changes (diagenesis) to the organic crystal; and most important, calibrating for the variable rate of production of atmospheric ^{14}C. In spite of its long history of use, radiocarbon research remains an active area of research, with considerable resources dedicated to improving calibration curves.

Many other radionuclides are important for age determination. For example, an isotope of chlorine (^{36}Cl) is produced by cosmogenic and terrigenous nuclear reactions in the atmosphere in immediately beneath the Earth's surface, respectively, is used for dating samples of middle to late-Pleistocene age. Uranium-series dating is used extensively for corals and speleothems. The uranium-series method measures the proportion of ^{234}U to its radioactive daughter product, ^{230}Th; and because the half-life of ^{234}U is much greater than that of ^{230}Th, over time, the rate of production of ^{230}Th will equal its rate of decay. At this point, ^{234}U and ^{230}Th are in secular equilibrium. Since uranium is water-soluble and thorium is not, thorium atoms will accumulate in precipitated carbonate (modulated by their decay rate) while the concentration of uranium remains constant. The method can be used to determine carbonate ages to some 500 ka BP.

Secondary effects of exposure to radiation on crystals includes two classes of very successful methods: fission-track and luminescence dating. Fissile atoms eject energetic charged particles which damage or disrupt crystal lattices. In fission-track dating, the cumulative damage as a consequence to exposure to ^{238}U provides an estimate of the duration of the crystal's exposure to the source. In luminescence dating, the method takes advantage of naturally occurring anomalies, termed traps, in the lattice that tend to accumulate small amounts of charge over time, partly due to exposure to low levels of background radiation (see Rhodes, 2011). Exciting the crystals with light or by heating causes the traps to discharge, which is monitored in the lab. By estimating the time required to accumulate the excess of electrons in crystal traps, based on a gross estimate of ambient radioactivity, the dose rate, researchers make a clock which can determine the duration a crystal has been buried (not exposed to light or excessive heat).

Tephrochronology

Tephrochronology uses layers of volcanic ash (tephra) to confine age limits of sedimentary facies. Where a tephra is often traceable to a specific volcanic eruption of known age, a sediment may be confidently dated. Bracketing is the term used to describe the method of bookending facies of interest between two or more tephras, thus finding upper and lower age limits.

Synopsis

The study of paleoclimates is, by the nature of the problems involved, methodologically flexible and interdisciplinary. Methods are unified by the use of proxies, a category of phenomena whose only shared characteristic is their response to environmental change. The range of timescales requires synthesizing archives whose comparison is not straightforward, or whose individual responses to the same environmental stimulus changes in time and by context.

Increasingly sophisticated computer models, including fully coupled Earth system models, are tasked with reproducing patterns of climate change at 2° of resolution or better for the last millennium. The architecture of these models, the community of experts they engender, and the software tools that they produce are dramatically improving the general understanding of climate and the complex dynamics of the Earth system. Modelers can incorporate hundreds of influences, over dozens of scenarios, to estimate climatic variables, and thereby test hypotheses of the underlying mechanisms of climate change, patterns of teleconnections (covariances between different elements of the climate system), and the effects of combined changes on the Earth system through time. Although computers have been applied to problems of climate since the middle 20th century, the growth rate of affordable

computing power and data science analytics is another revolution in the offing. Yet collecting, analyzing, and producing new and better paleoclimate proxy data remains essential.

Every discipline cherishes its own conventions. Paleoclimatology is therefore complicated by procedural questions such as which is or is not the 'best' practice or proxy. Normalizing the practice of science, in general, remains a challenge in many disciplines, and therefore a constant tension in a diverse one like paleoclimatology. Nevertheless, paleoclimatologists have demonstrated sincere commitment to publicly databasing their datasets, including raw measurements. This is a critical piece of the evolution towards "big data" analytics, which will almost certainly become an essential element of paleoclimatology, on par with radiometric dating, in the near future.

Glossary

Anthroposphere The part of the environment made or modified by humans.
Atmosphere The gases surrounding Earth.
Biosphere The living organisms occupying Earth.
Geomorphic Relating to the Earth's surface features.
Horizons As relates to soils, a layer of uniform properties that forms parallel to Earth's surface.
Hydrosphere All waters found at Earth's surface and the interactions between them.
Lithosphere The solid outer part of the Earth, composed of minerals and rocks.
Pedogenic Processes related to the soil or soil formation.

Concepts

The pedosphere is the soil mantle of the Earth. This concept evolved from the basic scientific concept of soils as specific bodies in nature that developed in time and space in situ at the land surface due to processes resulting from interactions of soil-forming factors. These factors are parent material, climate, organisms, topography, and time. In this way, the pedosphere represents the intersection of the lithosphere, atmosphere, hydrosphere, and biosphere (Fig. 1).

This basic concept of soils as accepted by modern scientists was described by V.V. Dokuchaev in the 19th century and has generally been accepted worldwide. Humans as components of the biosphere have increasingly become a significant factor interacting with the other spheres; consequently, the anthroposphere (realm of human society) is now considered to be a major influence. Being at the intersection of all the other spheres, fully understanding the pedosphere requires a systems approach that considers the large number of processes that interact in unique combinations around the world. All of these interactions make soil complex, open, bio-abiotic, nonlinear, multifunctional, multiphased, and spatially diverse.

Soils cover much of the Earth's land surface and the bottom of stable waterbodies as part of a continuum or mantle. This continuum, called the pedosphere (from Greek *pedon* meaning ground), serves as the Earth's biogeomembrane, which is somewhat analogous to the biomembranes of living organisms. As a biogeomembrane, the pedosphere facilitates and regulates the exchange of substances and fluxes of energy among the land biota, atmosphere, hydrosphere, and lithosphere. Additions, removals, translocations, and transformations occur in the pedosphere depending on the interplay of local environmental conditions and the inherent properties within the soil bodies (Fig. 2). Paleosols represent earlier periods of soil formation, and it is expected that in the Mesozoic and Paleozoic eras some extinct types of soils and pedogenic processes could be found. Emphasis has more commonly been given to the major climatic and geomorphic effects on the pedosphere that existed during the Pleistocene and Holocene epochs. Currently, soil properties and functions as influenced by extensive exploitation of soil by humans during the last two centuries are receiving more attention.

☆*Change History*: March 2018. E Brevik and B Miller updated all sections of the entry, the further reading, and Figs. 2 and 5. Fig. 1 was added.

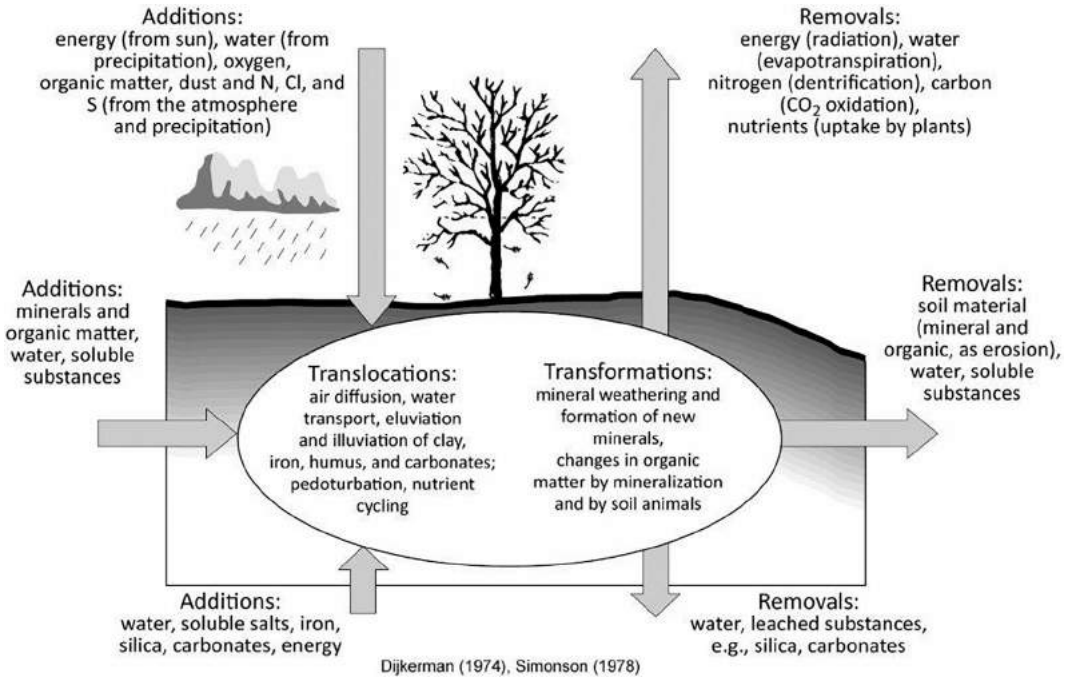

Fig. 2 Generalized processes active in developing soil features and horizons. Modified from Schaetzl, R. and Thompson, M.L. (2015). Soils: Genesis and Geomorphology, 2nd edn. New York: Cambridge University Press.

Processes

Most processes of pedosphere functioning operate in an open system, and although some appear to be cyclic and reversible, for example, biogeochemical cycling of C and N, many of them are unidirectional and irreversible, such as weathering of silicates in a soil and leaching of substances out of a soil. Due to the open and irreversible nature of some processes, there are many residual products, especially solid-phase materials, both organic and mineral, that are produced and retained in the parent materials. The annual formation of such components is very small and hardly detectable; however, when the soil forming processes occur for a long time (10^2–10^6 years), the gradual long-term accumulation of pedogenic solid compounds alters parent materials into soil horizons within soil profiles. Such processes of solid-phase, macrofeature formation during long-term functioning of a soil system can be perceived as a synergetic self-organization of the system—pedogenesis. Pedogenic features making up the solid-phase structure and composition of portions of the pedosphere are more pronounced where the upper unconsolidated layer of the lithosphere has neither been renewed by erosion or sedimentation nor mixed with deeper layers. Where landscapes have been stable and have had long-term functioning of soil-forming processes, gradual accumulation of pedogenic products occurs and well-differentiated soils form. The general development of the pedosphere is conceptually a sequence. There is an accumulation of earthy

materials that over time are altered by processes of interaction with the atmosphere, hydrosphere, and biosphere. A general rule of pedogenesis is: interacting factors open system processes formation of pedogenic properties and features (Fig. 3). Eventually the pedosphere forms into a three-dimensional structure that covers most of the lithosphere's interface with the other spheres.

Structure

The pedosphere has its own specific structure. Vertical variability is the result of processes altering parent materials in situ into pedogenic features and properties that make up horizons and soil profiles; see Fig. 4. These processes are usually called soil-forming, or pedogenic, processes. Many variations are possible due to the wide range of environmental conditions and scope of the factors interacting to form and develop soils. Translocation and transformation processes form a natural sequence of soil horizons that are indicative of the soil's genesis.

Soils, as multiphase bodies in the pedosphere, have several kinds of depth distributions at any moment. There are profiles of temperature, moisture, gases, soil solution and nutrients, macro- and microbiota, and solid-phase properties. The first three or four are mainly functional, that is, they are very labile and change quickly (10^{-1}–10^{1} years). The solid-phase profile is more stable, changing slowly ($10^{1\text{-}2}$–$10^{5\text{-}6}$ years), and is characterized by interrelated horizons with variable texture, structure, and mineralogical and chemical composition (Fig. 5). Many kinds of diagnostic features and horizons are recognized, and their combinations give rise to many unique soils throughout the pedosphere.

Classification systems such as the World Reference Base for Soil Resources and Soil Taxonomy are based on combinations of defined pedogenic properties, mainly solid-phase ones. The organization of these classification systems facilitates representations of the pedosphere at the global scale which facilitates recognition, identification, and classification, as noted by the color patterns in Fig. 6. The lateral combinations of individual soil bodies comprise the continuous soil cover of land, the pedosphere. Spatial patterns or structures of soil cover exist at all scales. In accounting for the dominant pattern at different scales, a general hierarchy relating to the scale at which soil forming factors operate has been observed. Bioclimatic factors tend to relate well to patterns shown on soil maps at the global scale. At more local scales, bioclimatic factors are less variable, but variability relating to differences in parent material are more easily represented. When more detail can be included in the soil map, then the effect of topography on soil variability becomes more evident. However, there are differences of opinion about what and how to define the combinations of pedogenic properties for organizing classification. Because of this, the percentage of soils versus non-soils are not well known partly due to different mapping conventions used by national organizations. Unlike a biological classification system, a soil classification system can be open to integrate both natural patterns as well as perceptions of importance.

Due to major climate changes throughout the Pleistocene and Holocene landscape evolution altered many areas of the pedosphere mainly through erosional and depositional cycles. More recently, human activities have modified most of the land, so that few truly natural soils exist. Those that remain are typically in areas that are largely in-accessible or unused by humans (e.g., tundra and boreal taiga zones, high mountains, tropical rainforests, and extreme deserts). New kinds of anthropic features and soil horizons are being identified, described, and recognized as significant features of the pedosphere. The World Reference Base for

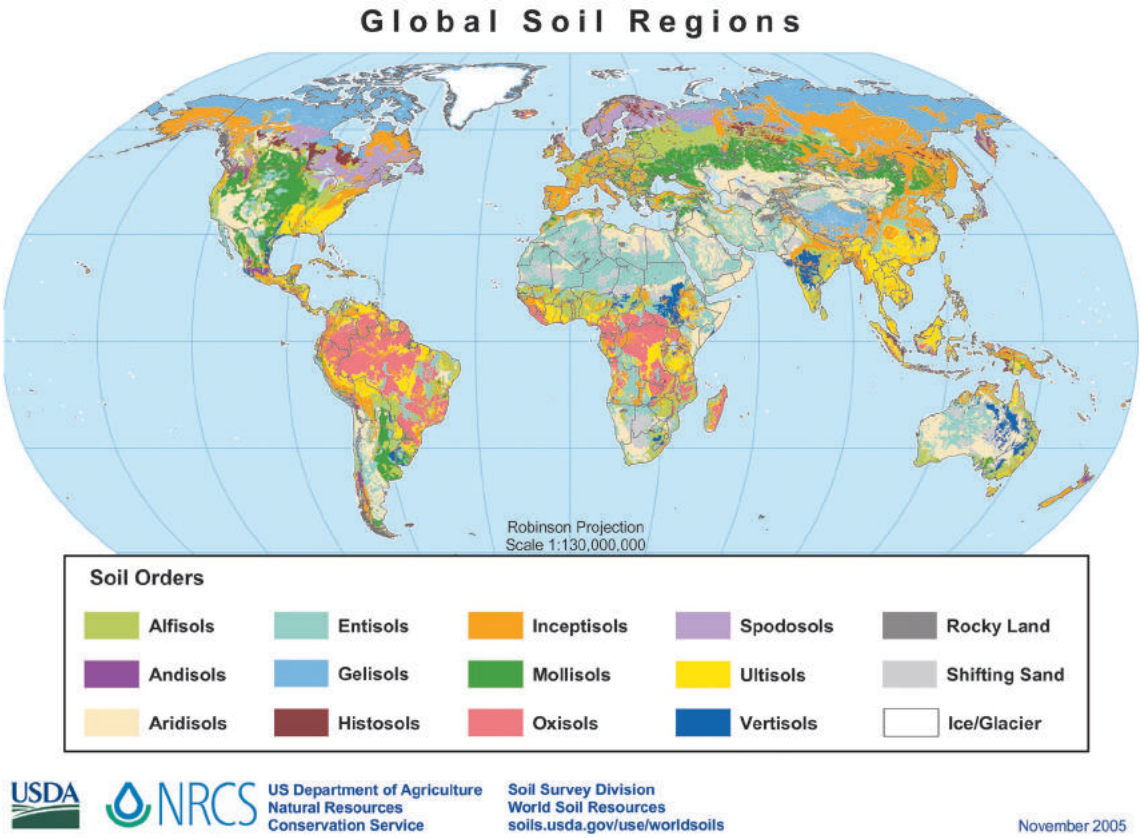

Fig. 6 Map of world soil resources using the orders of Soil Taxonomy. Areas marked as rocky land, shifting sand, and ice/glacier are essentially free of soil, but all other terrestrial areas have soil cover. Map produced by USDA-NRCS.

Soil Resources and Soil Taxonomy now reflect such changes. Refinements of the concept of the pedosphere will be and are being made as improved techniques for their examination and measurement become available.

Pedo-Memory

Most soils are organized, structured, natural entities whose pedogenic properties have recorded the main features of environments and ecosystems that existed during their formation and subsequent changes. Soil, therefore, is commonly a product and an imprint of long-term interactions and functioning in nature. During the past two or three centuries, much of the pedosphere has also recorded many anthropotechnogenic impacts and those portions now have memories of complex biosphere–lithosphere–anthroposphere interactions. Soils have different capacities for recording past and present environments depending on the time required for processes to come into quasi-equilibrium with environmental conditions (characteristic times, CTs). General CTs are: for gaseous phase, CT $\sim 10^{-1}$–10^{1} years; liquid phase, CT $\sim 10^{-1}$–10^{2} years; micro- and macrobiota, CT $\sim 10^{-1}$–10^{3} years; and solid phase, CT $\sim 10^{1}$–10^{6} years. These orders of magnitude are only indicative of the wide ranges involved. Although solid-phase features reflect environmental changes more slowly than the other phases, they retain the changes much longer and are the major recorders of prior environmental conditions.

Pedogenic solid-phase properties also have different characteristic memory retention times; the more rapidly formed properties may record changes for years, decades, and even centuries. Litter leaching and decomposition, soil structure formation and degradation, salinization and desalinization, and reduction and oxidation are examples. The slower-formed properties may record changes for millennia to millions of years, for example, deep and strong weathering, transformation and translocation of clays, and alteration and accumulation of iron-rich compounds. The age of soil memory depends on the duration and interactions of soil-forming and weathering processes that occurred at a specific place.

Soils of the existing pedosphere generally consist of complex combinations of inherited properties of pre-Pleistocene and Pleistocene weathering, landscape evolution, and pedogenesis, as well as more recent Holocene and Anthropocene impacts. Some features of pedogenic properties are partially erased by erosion and other degrading processes such as excessive leaching or acidity, and later processes of landscape and soil evolution overprint properties and memories (a palimpsest phenomena). Usually local knowledge of geomorphology, sedimentation, hydrology, and past climates provide a foundation on which to base pedogenic

interpretations. The complicated records of the pedosphere are slowly being read by pedologists to provide more information about past environmental conditions. Understanding soil components as carriers of pedo-memory and the rates of change of solid-phase properties remains a challenge to understanding and predicting future changes of the pedosphere.

Functions

The pedosphere is an extremely active terrestrial and subaqueous layer surrounding the Earth whose functions are closely linked with other spheres. The biospheric function is the major production function as it provides soil fertility and a suitable habitat for most species of organisms, thereby supporting land biodiversity. By this function, biomass transformations occur, nutrients are supplied and cycled, and the myriad microorganisms in soil enable sustainable biological productivity, diversity, and activity. Their metabolism is the primary basis for regulation and production functions in soils. Most biogenic substance fluxes are known as biogeochemical turnovers. The Millennium Assessment indicates that more land was converted to cropland since 1945 than in the 18th and 19th centuries combined, and that agricultural land uses now cover a quarter of the terrestrial surface.

Because the pedosphere is the zone of interaction between the biosphere and the atmo-hydro-lithospheres, it is commonly thought of as a reactor and regulator that functions to mediate and control fluxes of energy and substances. For example, temperatures are modified by the pedosphere and make most life, as we know it, a possibility.

The atmospheric function includes energy and moisture exchanges, respiration, and transfer of gases, including oxygen and greenhouse gases, and the force that transports and deposits dust derived from soils. Because of porosity, permeability, and absorption, soils have a hydrospheric function to partition water in, through, and out of the pedosphere. The geochemistry of the Earth's waters are mainly determined by the influences of the pedosphere. Where resistance thresholds are exceeded, water erodes surface particles from soils and deposits sediments downstream. Soil erosion degrades soil quality, often jeopardizing sustainable uses of soils, and can cause considerable downstream damages and economic loss. The lithosphere function of soils is that of providing a suitable medium for the biosphere components that support most terrestrial life. The large variability of the geosphere indicates that no single strategy for use and preservation is likely possible. The pedosphere has an important utilization or carrier function manifested as building sites for communities and transportation networks. Soils supply materials for many types of construction, and also are critical areas for waste disposal.

Last but not least is the cultural and historical function of the pedosphere. Society's interactions with soil were initially for agricultural purposes and the lore is rich with stories and myths of the power of unseen forces to help sustain soil fertility. Soils also serve as a repository of archeological artifacts, stratigraphic markers, and memory of ancient settlement environments. In general, human attitudes that define "self" in a context and in relation to nature result in religious beliefs as ways of bringing order into the seeming chaos of nature. The biogeochemical cycling of life, from dust to dust, is such a concept. Sanctity and stewardship of resources have their roots in the pedosphere.

Some Limiting Conditions

The Atlas of the World Reference Base for Soil Resources illustrates the striking variability of soils in the pedosphere, reminding us that there is a lot of uncertainty in the details of spatial patterns and explanations of soil evolution. Because soil conditions such as fertility, drainage, and topography can be artificially modified and changed by external activities, it is often assumed that the pedosphere is a renewable resource. However, experience has demonstrated that maintaining soil functions desired by society is not ecologically sustainable; rather, they must be reinforced with external energy and substances. The characteristic times of formation and/or resilience of many ecologically and agriculturally important soil features are much longer than human lives and even longer than some civilizations. The interactions of environmental conditions in natural ecosystems produce modifications much more slowly in soil than needed by modern society to provide expected products and services. During the next 50 years, demand for food crops is projected to grow by 70%–85% under the Millennium Assessment scenarios, and demand for water by 30%–85%.

The pedosphere with its functional and structural features has its own space and time limitations. Thickness and area are spatial limitations, whereas temporal functions and soil processes vary so widely that incongruencies and inconsistencies often make successful management or control very difficult. Soil thickness is not the thickness of the rooting zone, rather it is the unspecified thickness of an upper layer of the lithosphere involved in regular bio–litho–atmo–hydrosphere interactions. All of the interactions and resulting processes are relevant to defining the functional thickness of soils. This pedosphere thickness strongly controls and regulates the interactions—it is a real biogeomembrane of the Earth. The shallowness of fertile topsoil limits agricultural use and is susceptible to contamination by pollutants, in addition to degradation and destruction due to human-induced erosion.

Assuming the ice-free land area is about 131 Mkm^2, it has been estimated that about 93Mkm^2 is biologically productive land, of which forests are about 33%, pastures 32%, and cropland 11%. Only about a third of the land surface has pedosphere components that can reasonably be expected to provide sufficient food to support our current human civilization. Major limitations for agriculture include drought, nutrient deficiency, pollution, shallow soil depth, excess water, and permafrost. Other use limitations involve expansion of urban areas and transportation networks, small isolated tracts of suitable land, traditional parceling of land ownership, high costs of preparing land for cultivation, and loss of productive land to non-sustainable practices that cause degradation.

Why are temporal functions a limitation? As mentioned, natural changes of the pedosphere occur at rates too slow to satisfy the desires of modern society. Rates and characteristic times of soil functions, formation, and evolution processes cover at least nine orders of magnitude (from 10^{-3} to 10^{6} years). During the Anthropocene, humans have exploited the pedosphere's "treasure trove" that accumulated over millennia and hundreds of thousands of years of natural soil formation and evolution, creating a modern-day dilemma.

Phenomenon of Life: General Aspects

SV Chernyshenko, Dnipropetrovsk National University, Dnipropetrovsk, Ukraine

Introduction

The life phenomenon is one of the basic problems of understanding the universe. It is extremely important for both natural sciences (physics, chemistry, biology, etc.) and humanities (philosophy, psychology, etc.). The process of perception is a loop leading through inorganic nature, life, and consciousness back to reflection of the foundations of nature; so its understanding cannot be complete without answering the question: ``What is life?''

The life phenomenon problem can include two important aspects concerning life, as a general concept, a logical scheme, on the one hand; and as the real object, special natural realization, on the other. This article is devoted to the first approach. The universal definition of life (including, e.g., its potential electronic forms) cannot be complete at the moment in absence of the practical experience of dealing with extraterrestrial or artificial life. However, it can be obtained by way of extrapolation of stored knowledge and is useful for the study of real life forms as a theoretical background, helping interpretation of real observations and giving general perspectives of life science development.

General Principles of Life

Life is a form of matter organization. It is an extremely complex phenomenon, which is still poorly comprehended by both science and common sense. The main features of life as a general phenomenon are the following:

- It is a dynamic process. It is impossible to stop it (even mentally) for investigation. Stopped life is death.
- It is superposition of many different scales. One cannot understand life without understanding of the different level processes: from the microlevel (down to quantum processes) to the macrolevel (up to planetary and space processes). The levels are in permanent interaction. During the evolution of life, both corpusclarization and globalization took place; they have been consistent in both directions.
- It is a hierarchical system of numerous elements. Biological systems can be described by laws of the systems theory and cybernetics. They have abilities for homeostasis, adaptation, use of information, self-organization, and evolution.

Dynamic Nature of Life

Life is not a structure, it is a process. Life units are similar to waves, they permanently renew their composition. The normal state of a biological system is a state of `dynamic equilibrium', when inflow and outflow of matter compensate each other. Metabolism is one of indispensable conditions of a living organism. There is entry of the matter as a source of energy and constructional material, its use (assimilation), and excretion of decay product.

Balance of synthesis and destruction is one of the explanations of the cyclic nature of life. A more general explanation is that, the necessity for a stationary dynamic process to be cyclic, it must coil up in bounded space. At the level of a cell or organism, the cycle is shown as metabolism; at the level of ecosystems it is biogeochemical cycling. The concept of the cyclic character of natural processes is a part of many philosophical and religious doctrines. A good illustration of this fact is the well-known Buddhist Wheel of Life (see **Fig. 1**). The most interesting details are the central circle, where one can see a naive image of closed nutrient cycling and the figure of the demon, personifying time, which gobbles all that is existing.

The next step of development of cyclic movement is iterative dynamics. Recursion, unlimited repetition of itself, can be considered as an important form of nonlinearity. It begets fractals in structure and iterations in dynamics. The main form of iterations in biological systems is replication or reproduction. It is extremely important at least in two aspects. First, it is a way to transmit information from micro- to macrolevel. Second, it is a prerequisite for evolution on the basis of Darwinian natural selection.

Multilayer Character of Life

One of the peculiarities of biology is the fact that it embraces many levels of matter organization, from molecules to biosphere. It results in a large complexity of life, and sometimes complexity and diversity are considered as important characteristics of biological systems. But complexity as such is not a solution; uncontrolled growth of complexity either leads to the reduction of stability, or does not influence it. The stability of real biological systems is a result of very specific interactions between its elements; complex systems must be very well organized. In accordance with the pronouncement of W. Weaver (1948), the subject of biology is `organized complexity', contrary to classical physics (`organized simplicity') and statistical physics (`chaotic

Fig. 1 The Wheel of Life.

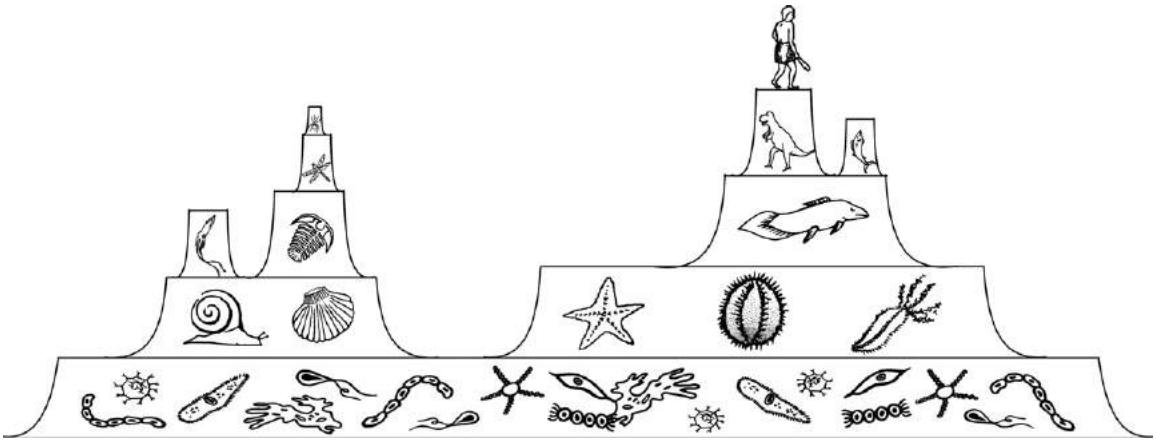

Fig. 2 Pyramid of differentiation of living matter.

complexity'). Dynamic laws should be appropriate for ensuring self-organization. Subjects of biological processes (cells, specimens, etc.) behave not chaotically, but coordinately.

Life development is, particularly, a process of matter differentiation. Step-by-step life makes the world more complex, changes `the space of abilities', creates potential wells in this space (new niches for itself), and fills the wells with new species. In Fig. 2, the niches are shown as a set of more and more narrow trapeziums, one originating from the other.

While `inventing' new levels of matter organization, life keeps previous ones. Usually new forms of matter differentiation cannot exist without older forms, which are parts of their usual environment from their origin. Each step to deeper differentiation needs huge amount of less differentiate matter. Essential progress in producing new abilities usually accelerates the development of living matter, but this acceleration concerns a decreasingly small part of the matter.

Although sometimes a new form can essentially transform or even annihilate a previous one, the latter usually continues to exist as a basis and environment for the former. Life forms itself as a multilayer object. Each new layer emerges by using energy of the predecessors and establishing new forms of connections between the previous layers' elements.

Such an elementary type of formation does not give an optimal result. New objects' functions can duplicate functionality of lower layers or even be at variance with it. The design of the objects would be more rational in the case of starting from the very beginning, without context of previous stages. But nature prefers to build on the old basements from available bricks, which were not initially planned for forming new buildings. Such a choice has some advantages. Losing optimality, nature saves time and gets reliability. Systems with duplicated (and coordinated) functions are more stable; keeping of low-level reactions is useful in case of temporary degradation of environment and so on.

Interaction of different layers is not trivial; their structure and functions are in the permanent process of mutual coordination. The formation of the life multilayer structure was not a unidirectional movement from the lowest level to the highest one. In the course of history of the Earth, after the first chemical layer, the planetary layer of biosphere was formed. All the other levels (cellular, organism, etc.) were wedged between these extreme layers in the course of the process of `discretization'.

Life, Death, and Immortality

The borders between living and inanimate objects are intuitively clear, but not very strict. Such micro-objects as viruses or plasmids are evidently a part of life, but at the same time they are chemical molecules (or a static group of several molecules) only. These obligatory parasites cannot exist as independent organisms, but they should be considered as living because they are part of biological macrosystems and even play an important role in their evolution. It is a good illustration of the fact that living matter sometimes cannot be divided for separate organisms.

Viruses form crystals, which can be disassembled and assembled again. Their individuality is interrupted; life and death lose their usual meaning. Death is not underside of life, and the syllogism ``If there is no life on Mars, it means that there is no death there'' is only a joke. The idea of death corresponds to high form of life only; it is inapplicable to unicellular organisms, which reproduce by division.

For life as a global phenomenon, death does not exist (at least, we know nothing about its imminence for biosphere). Death of individuals is a peculiarity of the life dynamics; it is explained by inexpediency to continue life of organisms, which have functioned their reproductive period.

Immortality, naturally, is impossible; there is nothing eternal in this world. However, individual life of multicellular organisms can be prolonged. Physiological limits of a lifetime are connected with a restriction for the number of divisions of somatic cells, which is connected, in its turn, with genome spoiling. There have now appeared the first ideas of how to struggle against this spoiling; present-day people have a chance for essential prolongation of their lives.

Extraterrestrial and Artificial Life

Our understanding of life is limited by its earth forms. Unfortunately, we do not know about extraterrestrial life, although Epicure spoke about it more than 2000 years ago, and J. Bruno was fagoted in 1600 because of his propagation of ideas about its possibility.

Now it is clear that the solar system planets are not really appropriate places for life, at least in its known forms. Jupiter's atmosphere is, probably, similar to that of the ancient Earth, and life can take its first steps there. Venus is too hot because of the greenhouse effect, and life is possible at some height in the atmosphere only. Mars is too cold, but in rocks found in the Antarctica and, probably, originating from Mars, scientists found microstructures resembling structures of leftovers from bacteria on the Earth. This indication of the existence of ancient life on Mars is very controversial, and the fact is only one `collateral evidence' of extraterrestrial life.

Searching for sentient life in space was started in 1960 by the project OZMA, which was followed by the Cyclops program in 1971 and many others later. The search for artificial radio radiation and other indirect indications of life is still unsuccessful, provoking pessimistic opinion that mankind is alone in the universe.

We are also quite far from the origination of artificial life produced by man. In principle, it is possible to design self-assembling robots, but they cannot be reliable and self-sufficient. Modern electronic devices have some properties of living beings, but they are a part of the global noosphere system (combined biological and technical elements) and cannot exist for a long time without the environment of human civilization. Even if the perspective of electronic life exists, it is a very remote one.

Life as a System

Modern view on biological objects as complex systems is proposed by the prominent Austrian biologist L. von Bertalanfy (1901–84), who established a new scientific discipline – `systems theory'. According to his definition, ``system can be determined as a complex of interacting elements.'' Bertalanfy proposed to consider the role of the systems theory regarding living matter as similar to the role of physics regarding abiotic world.

The systems analysis plays the role of methodological background of biology. Fundamental laws of life (such as the law of natural selection) can be interpreted as universal laws for complex dynamical systems. And, vice versa, systems laws are organic for biology and allow for solving many of its theoretical and practical problems.

The effectiveness of the systems approach in biology is closely connected with high level of emergency, which is typical for biological systems. A biological object, as well as all stable complex systems, cannot be understood as a set of separate elements only. Each new layer of hierarchy is a new special object with its own properties, which are based on properties of its elements, but are not their direct consequence. There are two aspects which can partially explain the phenomenon of emergency:

- A higher level is a very special result of self-organization processes in the lower one. It is a summary of huge current and past processes at the lower level. At the same time, in biology, the higher level plays the role of regulatory mechanism and can radically influence low-level processes. Thus, both levels determine each other.
- Nature prefers `economy' in principles of system organization. Systems can have similar structure, irrespective of elements' nature, and vice versa. It gives a possibility to study systems, abstracting internal elements' organization.

Nonlinearity of Biological Systems

Biological systems can have both linear and nonlinear properties; during their evolution they used all possible types of dynamics to increase their effectiveness and stability. Nevertheless, most biological processes are nonlinear. One can mention the following nonlinear effects: system's state jumping (bifurcation or `transformation of quantity to quality'); system's transition between deterministic and chaotic behaviors; hysteretic effect, that is, the system `remembers' its history; self-organization (purposeful decrease of the system entropy). Examples of evidently nonlinear biological processes are autocatalysis, reproduction, evolution of species, etc.

The analysis of critical regimes and singularities of the parametric space can be used for revealing `acupuncture points', where small local perturbations provoke great large-scale metamorphoses of the system. A spectrum of quasistationary solutions is realized as a set of possible forms of morphogenesis. The discarded forms are still within system's reach but remain dormant, unknown to observers in the course of evolution.

Nonlinear dynamics of living beings is often intuitively incomprehensible; admiration of nonlinear algorithms of life produces paradoxical ideas about intelligence of cytoplasm or bacteria.

Structure and Hierarchy

One of the important characteristics of a system is its structure – a set of links between elements and their space distribution. There are two main structural forms of matter: centralized (hierarchical) and distributed (skeleton). Physical fields have a distributed organization, whereas atoms are centralized. A cell has the center (nucleus); a colony of cells is homogenous; and the organism is centralized again. Centralized organization is rational in the case of high-level differentiation of elements; the distributed one is more typical for systems with homogenous elements.

Often the structure of biological systems is tree-like; they are hierarchical systems. It is the result of two important processes: differentiation of living matter and bunching (oligomerization) of its elements. An important feature of hierarchical systems is the fact that each level is characterized by new emerging properties not presented at lower levels. A scheme of the general hierarchy of biological systems is represented in **Table 1**.

The structure of real systems can be changed, but its dynamics is very slow in comparison with other processes, called functionality of the system. A set of characteristic times can also form a hierarchy. For each process, other ones can be considered as part of the environment: slower ones because of their relative stability, and faster ones because of rapid running to equilibrium.
