Two-sample t-*test*							*Simple linear regression*				
Sex	*n*	*Mean*	*Variance*	*t*	*df*	*P*	*Coefficient*	*Estimate*	*SE*	*t*	*P*
Female	51	2.64	0.39	**2.51**	122	**0.007**[a]	Intercept	2.64	0.09	28.78	
Male	73	2.94	0.46				Sex	0.30	0.12	**2.51**	**0.007**

[a]The *P* can be interpreted as, if you decide to conclude that males are indeed larger than females, there is a 0.007 probability that you are incorrect. Because of the small probability, the conclusion is that males are heavier than females.

The data set is birth mass (kg) of female and male white-tailed deer born to 2 year old mothers fed a pelleted-diet rich in nutrients. For the simple linear regression sex was coded 0 for females and 1 for males. Note the *t* and *P* values (in bold font) of the two-sample *t*-test and sex coefficient of the regression are identical. Because I expected males to be heavier than female a one-tailed alternative hypothesis was used instead of the default two-tailed alternative.

Examples of general linear models include *t*-tests, analysis of variance (ANOVA), simple and multiple regression. Simple regression has one predictor variable (sometimes referred to as an explanatory variable or independent variable) and multiple regression has two or more predictor variables. The choice of a general linear model depends on the number of groups or samples and the number of variables measured from observations. It might also be supposed that method of choice is dictated by whether you need to test for differences among means or estimate relationships. Yet, these boundaries that seemingly determine the kind of method to use are actually blurred (Draper and Smith, 1998). Realizing how the same data set can be analyzed by more than one general linear model is useful to grasping that categorical as well as numeric variables can be analyzed in a regression analysis. To illustrate, we compare findings from a two-sample *t*-test and a simple linear regression. The data was birth mass of female and male white-tailed deer (*Odocoileus virginianus*) born to 2-year-old mothers on a high nutritional plane. Mothers only gave birth to a single young (Wolcott *et al.*, 2015). Our goal was to test whether male birth mass was greater than female birth mass. In size-dimorphic ungulates, adult males are larger than adult females and the difference can manifest at birth (Wolcott *et al.*, 2015). Findings from the two-sample *t*-test indicated that males, on average, were heavier than females (**Table 1**). The *t* value was 2.51 and with 122 degrees of freedom the *P* was 0.007. A *P* is the probability of a type I error, which occurs when you conclude that there are differences when there actually are no differences. The critical or α value for a *P* (the cutoff in which you decide there is a difference or not) that is most often used in ecology is 0.05; however, 0.1 and 0.01 are also used. The other kind of error is a type II error, which is failing to detect differences that truly exist, a possibility that seems remote in this example due to the relatively large sample size, substantial size dimorphism and low variances between the sexes. To conduct a simple linear regression on this data, the categorical variable sex was coded as a dummy variable (Draper and Smith, 1998). Here, we arbitrarily assigned 0 to females and 1 to males. In the parlance of regression, the predictor was sex and the response variable was birth mass. Because females were coded 0, the intercept of the regression is the estimate of mean birth mass of females (**Table 1**). The estimated slope measures the difference in means between male and female birth masses because males were coded 1. On average, male birth mass was 0.30 kg heavier than females. If 0.30 is added to 2.64, the intercept, you arrive at the mean birth mass of males (2.94 kg). Thus, sometimes the distinction between two-sample *t*-test and simple linear regression is in name only.

A large part of the popularity with general linear models is the versatility to summarize complex relationships. When the response variable is continuous and there are multiple categorical, numeric, or both kinds of predictors; multiple regression is appropriate. To illustrate, we estimated relationships between body mass, age and liver mass of male white-tailed deer during the mating season (Parra *et al.*, 2014). Deer age was either young (1.5–2.5 years-old, $n = 26$) or prime-aged (4.5–6.5, 13). Body mass was continuous and age was categorical. During the mating season, prime-aged, but not young, males engage in physically demanding activities to attain copulations. The consequence is that energetic demands usually exceed energy intake in prime-aged males. To meet the energy demands, prime-aged males mobilize adipose tissue, which is a function of the liver that leads to a heavier liver mass because the workload of the liver increases (Parra *et al.*, 2014). There is a complication, however, in that prime-aged male deer are larger than young deer and also require larger livers simply due to their larger body size. Thus, the need to include body mass as a predictor to control for this effect. The estimated multiple regression revealed that body mass was positively related to liver mass and that prime-aged males had heavier livers (**Fig. 2**). Accounting for body mass, prime-aged males had livers that were, on average, 0.21 kg heavier than young males. The R^2, adjusted for number of predictors, (0.75) indicated that about 75% of the variation in liver mass was accounted for by the regression. In addition to versatility, general linear models are appealing because they can be used to predict and scatterplots help to visually display complex relationships in data.

Hierarchical Models

In many ecological studies, efficient sampling design often entails repeated or clustered measurements of subjects or observations. These types of sampling designs inherently create hierarchical structure within the data, which are often correlated spatially and temporally. Correlations between measurements violate one of the foundational assumptions that each observation is

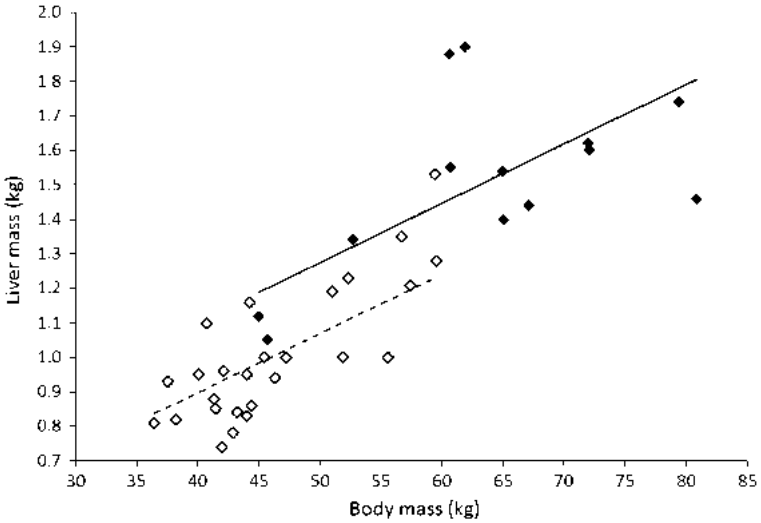

Fig. 2 Scatterplot of data and relationships between body (minus rumen-reticulum and liver organ masses) and liver masses of young (1.5–2.5 years of age, open diamonds, dashed line) and prime-aged (4.5–6.5, filled diamonds, solid line) male, white-tailed deer. The general linear model or multiple regression was: Liver mass $= 0.21 + 0.02$*body mass $+ 0.21$*age. Body mass and age were influential ($t \geq 2.7$, df $= 36$, $P \leq 0.011$). Young males were coded 0 and prime-aged males were coded 1. The adjusted R^2 was 0.75.

independent and identically distributed. Repeated measures analyses have been devised to account for the issue of dependence among observations, however, many of these analyses are not flexible about missing data (i.e., unequal sample size among levels) or uneven temporal spacing of repeated measurements. Fortunately, mixed-effect models account for these issues and are also more easily interpretable than most classical repeated measures analyses.

Mixed-effect modeling is a powerful tool that uses both fixed and random variables within the same model. Whether a variable should be considered as fixed or random is largely dependent on the question of interest and the number of levels within the variable. If the number of levels for the variable is representative of the population and the question of interest involves finding differences between levels, utilizing the variable as a fixed component is the recommended approach. If the levels of the variable are a randomly selected subset of all available levels and the question of interest involves understanding the variation within the population, treating the variable as a random variable is the recommended approach. Understanding the desired objective of the research question is of great importance when considering whether a variable should be treated as fixed or random. Further, while variables treated as fixed can be of several types (e.g., continuous, categorical, etc.) random variables must be categorical with a large enough number of levels to achieve an accurate representation of the variance in the population (usually >4 but preferably >10 levels, Zuur *et al.*, 2007).

Mixed-effect models demonstrate tremendous flexibility in how the random components can be modeled. For example, consider a study in which 10 individuals were repeatedly sampled across time to measure the influence of a continuous predictor (X) on the response variable (Y). We could simply regress X against Y at a cost of three parameters (one intercept, one slope of X, and residual error); however, we know that repeatedly sampling 10 individuals is most likely creating correlations within the residual error because individuals are more likely to be similar to themselves than the other nine individuals. We could account for this, in a fixed effect only framework, by incorporating the individual identification as a categorical covariate. Inclusion of this covariate would create a regression line with a different intercept but same slope for each one of the sampled individuals, which increases the number of parameters drastically to 12 (10 unique intercepts, 1 slope for all sampled individuals, and residual error). The inclusion of an individual-specific variable quickly inflates the number of parameters, which penalizes the ability to detect differences through the loss of degrees of freedom. Instead, we could include the individuals as a random effect when regressing X against Y. This essentially produces the same outcome as the above fixed effect only model except it only costs us four parameters (one intercept, one random effect to estimate variation of individuals around the intercept, one slope, and residual error). With this mixed-effect model we are able to reduce the residual error by accounting for the variation created by sampling the 10 individuals. Mixed-effect models are even more powerful than this simple problem. Random effects can be modeled to assess variation in intercepts only (like the above example), slopes only, intercepts and slopes, and even residual error itself. We strongly encourage the reader to continue to explore the many possible ways that mixed-effect modeling can be used to partition variance structures (see Pinheiro and Bates, 2000, and Zuur *et al.*, 2007 for more in-depth examples).

Invariably, mixed-effect model development will require some form of selection process to assess which fixed variables and random components are necessary to accurately describe reality, within a modeling framework, without overfitting (i.e., include too many predictors and random components) the data. The generally accepted approach consists of a top-down strategy beginning with a saturated model that includes all fixed factors of interest as well as any interactions between fixed factors that are thought to be biologically relevant (Zuur *et al.*, 2007). The next step is to assess which random error structure is most optimal (e.g.,

random intercept, slopes, or intercept and slopes, etc.) using restricted maximum likelihood estimation. Once the optimal random error structure is defined for the saturated model, assess which fixed variables should be kept to form an optimal model using maximum likelihood estimation. Finally, conclusions from the optimal model, using the estimated parameters and standard errors, should be presented and discussed using restricted maximum likelihood estimation to avoid biased variance estimates.

When comparing models with the same fixed effects and different random effects through hypothesis testing, it is important to note that significance values are only approximations, which should be assessed with caution if the value is on the cusp of the selected α level. This approximation is a consequence of two-tailed hypothesis testing during model comparison. Since variances, which are centered on zero, can only be positive values, a two-tailed hypothesis test inaccurately assesses the range of variance values yielding a significance value that is generally inflated higher than expected. There is limited concern for significance values that are very large or very small as compared to the α level; however, the concept of "testing on the boundary" should be considered when the significance value nears the value for α.

Bayesian Inference

Up until now we have described the process of statistical inference using what is known as a classical or frequentist paradigm. However, the use of Bayesian inference within ecological studies has increased in the past decade, so a chapter focused on statistical inference would be inadequate without some mention of it. For an in-depth description of the background information and application of Bayesian inference, we recommend readers consult Link and Barker (2010) and Hobbs and Hooten (2015). It should be stated that there is no such thing as a "Bayesian model" despite the term used within the peer-reviewed literature. As Kéry and Schaub (2012) discuss, ecologists develop models to represent hypotheses they want to explore in data, and they can choose to fit the model(s) to the data in either a Bayesian or frequentist framework. Indeed, the regression models described above as well as many complex hierarchical models can be fit under both paradigms (Royle and Dorazio, 2008; Kéry and Royle, 2016). Furthermore, when prior distributions are specified as diffuse or noninformative in Bayesian statistics there is a great deal of agreement in the output estimates from the two paradigms (Kéry, 2010).

So what is the difference in the two paradigms and why would you choose to fit models using one paradigm versus the other? In a frequentist paradigm, parameters are treated as fixed and unknown constants, and inferences are based on the notion of repeated experiments or the frequency of hypothetical replicates. Here, ecologists make probability statements about the data and the probability is based on the hypothetical replicates. Thus, a confidence interval is interpreted as "If I performed this experiment an infinite number of times, X% of the parameters would fall within this range." In contrast, under the Bayesian paradigm all parameters are treated as random variables and the unknown quantities are modeled using the statistical distributions introduced above, among others. Here, our knowledge of parameters is updated using data, rules of conditional probability, and Bayes' theorem. In other words, prior (knowledge) distributions and data are used to obtain or yield posterior distributions to make inferences. This is usually accomplished with the aid of simulation methods, such as Markov chain Monte Carlo (MCMC) algorithms, to characterize the posterior distribution of parameters. Because parameters are treated as random variables, under the Bayesian paradigm credible intervals, which are the Bayesian analog of confidence intervals in frequentist statistics, are interpretable as "I am X% confident the parameter is within this range." Although appealing from an interpretability standpoint, in practice this difference is of little consequence as confidence intervals and credible intervals are typically applied in the same manner.

As we mentioned earlier, Bayesian inference can accommodate previous knowledge from other studies via informative priors so that inferences are based on both the current and previous studies. Also, in Bayesian inference all results are exact even for small datasets because Bayesian analyses do not rely on asymptotic approximations that are used in frequentist analyses (Conroy and Peterson, 2013). This is particularly appealing because data are often limited in ecological studies. The BUGS language that is often used to fit models using a Bayesian analysis, offers a framework for better understanding the structure of statistical models and by extension a more transparent structure for accounting for sources of variation in the data. Once ecologists have gained the skills to develop simpler models in BUGS, more complicated models are a relatively simple extension that use the same rulesets. Thus, more complicated models can be fit using a Bayesian framework relatively easy, including models in which there is no frequentist method available. This has led to the recent increase in the use of integrated analysis of multiple but related datasets within the ecological literature. These integrated analyses represent an important advancement in the ecological sciences because they allow for the development of tailored analyses for specific datasets, which, in turn, allow for the incorporation and estimation of complex ecological relationships. Similarly, derived parameters (i.e., estimates that are calculated from other estimated parameters) that propagate the full uncertainty of estimates can be calculated in a straightforward manner using BUGS. In the frequentist paradigm, deriving fitted models requires using the delta method or the omission of parameter uncertainty.

It should be noted that there are also drawbacks to fitting models in a Bayesian framework. First, the BUGS programming language can admittedly be intimidating when getting started, particularly if you are not well acquainted with statistical distributions. Nonetheless, we stress that if fitting more complex models is a necessary objective, the time investment to overcome the initial learning curve is well worth it. Also, it should be noted that the number of iterations required during the MCMC simulations to achieve convergence when fitting more complex models to large data sets can take hours to weeks, whereas the same model using a frequentist analysis may be much quicker. We view the frequentist and Bayesian paradigms as useful tools for statistical inference and stress that ecologists do not have to choose one or the other. Instead, we recommend ecologist consider the pros and cons of each approach as they relate to the objectives of a particular study and choose the best tool for the task.

Model Selection

To aid in statistical inference, models are developed to mimic the underlying distribution of a population using empirical data. In an ecological context, most studies are considered to be observational with limited ability to set up control–treatment experiments that include proper randomization and replication. Since it is rarely possible to create a model that describes a population with complete accuracy, a suite of variables that are hypothesized to be responsible for some portion of the observed phenomenon are measured and multiple competing models are developed. Because of this, it is necessary to choose a model that best approximates the underlying distribution of the sampled population, without overfitting the available data, through a model selection process.

The coefficient of determination (R^2), as an example and demonstrated above, is a useful tool to assess how well a model replicates observed data. Although a useful tool to assess how well a single model explains the observed data, it is not useful for comparison between competing models. The R^2 value will almost always increase with each additional inclusion of a predictor variable, which leads to the selection of a complicated model that probably over fits the observed data. To account for this issue, various stepwise procedures have been developed to assess how strongly each variable influences the predictive power of a model using hypothesis tests.

Hypothesis testing procedures are popular techniques for model selection and include forward selection, backward elimination, or stepwise processes. The forward selection process begins with the most simplified (null) model and compares the null model to another model that includes a single added variable. These two models are then compared using an F-test. If the F statistic is larger than the set threshold, the model with the added variable has a stronger predictive power than the null model and is considered the null model thereafter. The procedure repeats itself by including additional variables and comparing the newest model to the previously selected model until a candidate variable no longer increases the F statistic above the accepted threshold. The backward elimination process is similar except that it begins with a global model that contains all predictor variables. This model is tested against another model that is reduced by a single variable with a subsequent F-test assessing if the variable should be included or not. Stepwise procedures were developed as an extension of forward and backward selection processes to remedy flexibility issues after a variable is considered in the analysis. In the stepwise process, all variables are considered, at each step, for inclusion or omission from the model even if they were previously included or excluded in a previous model. While these procedures are widely used it is important to note that they are not without flaws. Specifically, there is no clear criterion for model choice and the final model choice is usually a good model but not always the optimal model. An optimal model does not under- or over fit the data. Indeed, using forward and backward processes on the same dataset can often lead to the selection of very different models.

An information-theoretic approach to model selection seeks to find the optimal model that bests describes the relationship between the response variable and a set of predictors. Unlike hypothesis testing, it uses a criterion, involving the log likelihood (a maximum likelihood measure of model fit), to assess the distance (i.e., information lost) between a model and the observed data. Instead of focusing on the significance of individual predictor variables within a model, information-theoretic model selection assesses the likelihood of a model as a whole. The intent of multimodel inference in an information-theoretic framework is to be a confirmatory analysis rather than an exploratory analysis so the process of data dredging (assessing all possible models) is strongly discouraged (Burnham and Anderson, 2003). Instead, the goal is to develop models with sound biological reasoning for comparison through multimodel inference to determine the best approximating model given the data through strength of evidence. Yet, information-theoretic approaches have been applied to traditional hypothesis testing procedures such as the forward selection, backward elimination and stepwise processes because of simplicity and flexibility.

One of the most common forms of information-theoretic model selection in ecology, from the frequentist perspective, is the Akaike's Information Criterion (AIC). The criterion is simply defined and calculated as "deviance plus $2K$," where deviance is a measure of the information loss between the model and the observed data (-2 times the log likelihood) and $2K$ is a penalty for increasing model complexity (K is the number of parameters estimated in the model). A second-order bias correction (AICc) has also been developed for use when sample size is low (generally $n/K < 40$). Since AIC and AICc values converge as sample size increases, the use of AICc in all cases is common. Multimodel inference from AIC is very simple because the model with the lowest AIC value is the best approximating model. For competing models (models with <2 AIC value difference from the best model), it is possible to model average parameter estimates, however, parsimony should also be considered before model averaging competing models. Burnham and Anderson (2003) demonstrate the process, flexibility, and advantages to AIC model selection, which includes valuable resources necessary to calculate evidence ratios between models and the assessment of relative variable importance within the selected model. We advise reading this resource for further information.

An information-theoretic approach to model selection is also possible from the Bayesian perspective. The most commonly used criterion for Bayesian inference is the Deviance Information Criterion (DIC) because it is effective for models with informative prior information and is readily accessible as a function in the BUGS software. Although DIC has been widely used over the past decade, it has come under increasing criticism for several reasons (e.g., model selection is not always consistent and tends to produce over-fitted models). A relatively new addition to the expanding field of information criterion is the Watanabe–Akaike information criterion or widely applicable information criterion (WAIC). It has been shown to be asymptotically equal to Bayesian cross-validation procedures and is the most fully Bayesian process because it uses the full posterior distribution (rather than using a point estimate like AIC and DIC). WAIC is still not without limitations and has some difficulties with spatially structured data. For Bayesian inference, cross-validation is still the recommended method for model validation with WAIC used as a more computationally expedient option (Gelman *et al.*, 2014).

Structural Dynamic Models☆

Arnab Banerjee, Nabyendu Rakshit, and Santanu Ray, Visva-Bharati University, Santiniketan, India

Introduction

Ecosystems are well-established network organizations consisting of various kinds of biotic and abiotic components. The main basis of network establishment and its subsequent maintenance is solar energy that is trapped and stored into potential energy by plants and is subsequently utilized by heterotrophs via grazing and detrital pathways in ecological networks.

Owing to the dynamic nature of storage and utilization of solar energy, an ecosystem continuously evolves in order to modify, regulate and change to accommodate for maximum efficiency. It is thus very important to apprehend this aspect in order to understand ecosystem functioning and hence arise the need for mathematical models describing the structural dynamics of ecosystems.

Ecosystems are constantly affected by various environmental factors (forcing functions) such as nutrient loading, natural calamities, anthropogenic activities, etc. that affect an ecosystem continuously and force it move toward thermodynamic equilibrium. In order to cope with this ever changing scenario, an ecosystem may undergo minor to extensive structural changes so as to maintain its organization and efficiency. Structural dynamic modeling (SDM) is a tool for predicting or assessing such dynamic changes in an ecological organization that is able to continuously optimize system properties (parameters) in response to such dynamic fluctuations (Jørgensen and Bendoricchio, 2001).

Structural dynamic models are radically different and more advanced than previously used dynamic models (which were much more rigid) and have been referred to as fifth generation modeling tool (Jørgensen and Bendoricchio, 2001). In the past few decades, a good number of studies have been conducted on the structural dynamic models with specific underlying goal functions. Recently, there has been increasing concern for environmental remediation technologies on the basis of ecological methodology, which strongly depends on the ecological structure and also promotes the study on structural dynamic models.

Deterministic mass balanced models have been utilized in order to achieve a better understanding and interpreting the underlying cause–effect (feedback) mechanisms in ecological observations. These models range from simpler N-P-Z models having nutrient, phytoplankton and zooplankton as state variables to complex physico-biological coupled models incorporating time-series data with the intention of describing the ecological organization and structure, optimization of exergy as goal function with implications of phytoplankton and zooplankton body size, etc. (Banerjee et al., 2017a; Bierman Jr et al., 1994; Hofmann and Ambler, 1988; Kremer and Nixon, 2012; Mandal et al., 2009; O'Connor, 1981; Ray et al., 2001a).

In this article, methodology of modeling approaches for SDM have been introduced, especially focusing on the holistic approaches as well as classical bottom-up-style modeling approach. Structural dynamic models have also been described in the backdrop of ecological exergy and ascendancy as goal functions followed by several case studies.

Feedbacks in Ecosystem

A large number and wide variety of feedback mechanisms are in constant action in any ecosystem at any time that fluctuates in strength and timescale. Keeping in mind the fact that a model is just a replica of the concerned system it is impossible to include all

☆*Change History*: March 2018. Arnab Banerjee, Nabyendu Rakshit and Santanu Ray modified sections Abstract, Keywords, Introduction, Feedbacks in Ecosystem, Experiments and Observations, Holistic Approach, Eco-exergy or Exergy, References and Further Readings. The section that have been introduced are Structural Dynamic Modelling Approach (majorly rewritten as a new section), Bottom-up Approach, Goal Functions and Ascendancy.

feedbacks into a singular model. Therefore, in order to formulate the flows in an ecosystem, it becomes necessary to understand what kinds of feedbacks are dominant in the targeted ecosystem and discuss how to incorporate these feedbacks into the model. Modeling of an ecosystem structure is the finding out of the dominant feedback mechanisms in the ecosystem and mathematical description of these dominant feedbacks in the model. These feedbacks with widely different action mechanisms; especially, the response timescale, is one of the important points to describe the structural dynamics, varies greatly from case to case (Jørgensen and Bendoricchio, 2001).

For example, in an aquatic ecosystem, over a short timescale, growth of phytoplankton is controlled by available nutrient concentrations dissolved in water and/or the intracellular nutrient concentration. When the concentration of a nutrient is far less relative to requirement (e.g., half-saturation constant of the phytoplankton for the concerned nutrient), the growth rate of the phytoplankton is far below the maximum growth rate. On the other hand, if the concentration is enough (and there are no other limitation, such as toxic substances), phytoplankton grows in accordance to their maximum growth rate. This is an inherent property of phytoplankton growth and most lake ecological models include these feedbacks. However, more long-term feedbacks—such as biochemical adaptation, biological adaptation, species selection, selection of predator–prey relationship, etc. are sometimes required to be introduced through structural dynamic models. Furthermore, the emergence of new species may be required in a structural dynamic model which is used to assess the very long-term ecological succession.

Hence modeling strategies should be changed depending on the feedback timescales which are introduced into a model. Particularly, the long-term feedbacks tend to be important in the structural dynamic models.

Structural Dynamic Modeling Approach

The ability of ecosystems to replace currently constituent species (components) with others (better fitted) that can be utilized for successful optimization, can be reflected by constructing complex models that encompass all of the actual constituent components, on the basis of experimental observations or literature information, for the entire period that the model embodies. This is a major aspect in modeling studies and is the most advanced tool for development of more realistic and scientific ecological models refining the structure of a model by accumulating information on all components and their interactions. This classic approach of SDM methodology includes the "bottom-up approach" and here the model structure is determined based on experimental and observational knowledge.

However, incorporation of a larger set of model parameters that require calibration and validation introduce high uncertainties in the models. In that context, another approach that estimates the dynamics of the system from a comprehensive viewpoint—ecological goal functions—have been introduced to overcome the cumbersome difficulties of tedious parameter calibration. This relatively new approach is called as the "holistic approach" and not many structurally dynamic models are present which account for goal functions of system performance. Of the several goal functions proposed for such holistic modeling, exergy, emergy and ascendancy principles have been widely used by several authors.

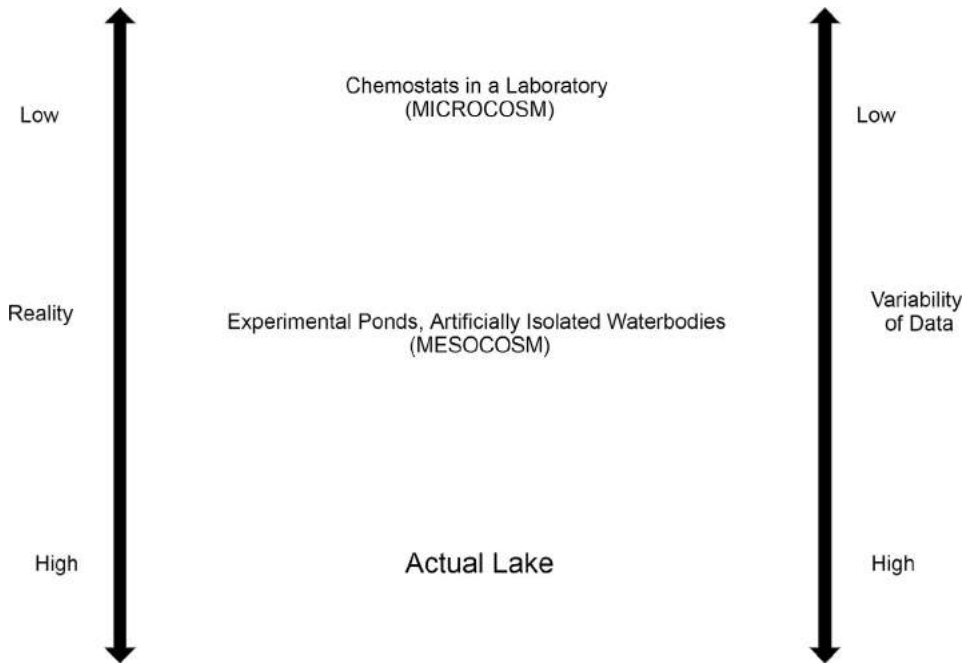

Fig. 1 An example of mass balance in a lake.

Experiments and Observations

In many cases, most of data used to develop of a model are obtained from the experiments and past observations or from published literature. In some cases, however, newly designed experiments and observations are implemented for the particular requirements of the modelers. For adequate designing of experiments and observations, it is desirable for modelers to understand the feature of the experiments and observations of the target ecosystems.

In the model of lake ecosystems, for example, various scales of experiments and observations can be designed and implemented as described by Nielsen (1995). These size variations and properties are shown in Fig. 1. The experiments and observation size can be roughly divided into three classes: chemostats (flasks, small-scale incubators, etc.) in a laboratory (the so-called microcosm); experimental pond, artificially isolated water bodies, etc. (the so-called mesocosm) and the observations of actual lakes.

The chemostat experiments are useful to obtain the fundamental property of growth kinetics such as maximum growth rate, half-saturation constant of nutrient uptake, respiration rate, etc., under well-controlled environmental factors such as irradiation and temperature. In these experiments, single species or a few species of organisms are incubated under various conditions (e.g., incubation of *Microcystis* sp. under various phosphorus concentrations) and the time variations of the biomasses of organisms are measured.

Organisms can be incubated in the mesocosm experiments at the same time. The time variations of relatively small organisms (e.g., phytoplankton and zooplankton) under artificially controlled environments (e.g., fish biomass, irradiance) are observed. The information about the structural dynamics in a water ecosystem during the relatively short periods can be obtained. The fluctuations of environmental factors are relatively easy in the mesocosm experiments. Whole mass balance of an ecosystem can be approximately obtained under nearly natural conditions. Mesocosm experiments have been attracting increasing attention in practice of structural dynamic modeling. Of course, it is desirable to install the mesocosm into or nearby the actual lake in question.

Larger-scale and long-duration information, of course, should be obtained from the actual lake and consist of the most important information. However, in many cases, data may not be newly collected especially for the purpose of the structural dynamic modeling (secondary data from literature). Therefore, the sampling points and sampling intervals are generally limited. As a result, it essentially has high variability.

Therefore, these data may be combined to model the structural dynamics of the lake (see the next section).

Bottom-Up Approach

The bottom-up approach is one of the most fundamental approaches to modeling the structural dynamics of an ecosystem where the structure of an ecosystem network is determined on the basis of experimental and observational knowledge. In practice, some of the important and dominant components from ecological viewpoint are selected and introduced in the model. The kinetics of material flows is also formulated in the same manner. In this approach, the selection of adequate experiments and observations and a reasonable processing method of the obtained data are important.

An Example of Bottom-Up Approach

An example of bottom-up approach of structural dynamic modeling has been presented here in pertaining to a lake ecosystem using experimental and observational data.

At the first stage, the flow diagram of the model (Fig. 2) (inclusive of multispecies details of phytoplankton and zooplankton, multigrowth stages of zooplankton, etc.) is determined. Of course, most aspects of concern must be included. In this stage, the structure of the food-web network can be determined on the basis of the correlations between organisms obtained from the above-mentioned mesocosm experiments, or actual lake observations.

In the next stage, the kinetic equations and their parameters for each organism are determined, based on the knowledge from literature and/or chemostat experiments. After complete formulation of the model for the concerned system, parametric sensitivity

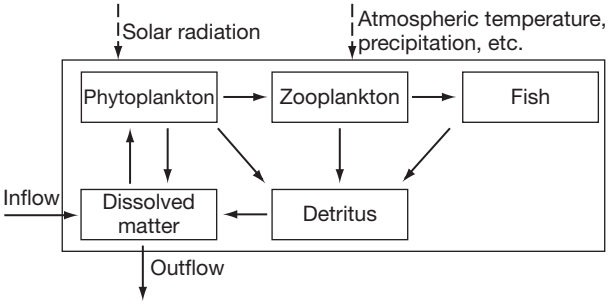

Fig. 2 Size variations of some experiments and observations and their properties for the modeling of a lake.

analysis have to be performed and the sensitive (critical) parameter set is to be elucidated. This is followed by sensitive parameter set calibration within certain ranges on the basis of the data from mesocosm observations. Calibration ranges of the parameter set are also determined based on the knowledge from the literature and/or the chemostat observations. Note that the kinetic parameters of natural organisms are essentially distributed. From this circumstance, the probability distributions of kinetic parameters are assumed in some cases. Of course, in these cases, the calculated values also have probability distributions.

Then, in the final stage, the model is extrapolated to the subject lake by considering its physiographic characteristics and environmental factors. The model validation is performed using the actual observation data. Of course, in most cases, relative minor calibration is required in this stage.

However, as mentioned above, several organisms should be included in a model to describe the structural dynamics in an ecosystem. Thus, as many organisms (state variables) as possible (if possible all) should be included in the model. It is also clear that this leads to an increase not only in the number of parameters that should be calibrated, but also in the whole uncertainty of the model. Furthermore, there is also a certain limitation of kinetic data. This is a fundamental drawback of the bottom-up and structure refinement modeling approach. To reduce this drawback, some rationalization methods such as likelihood test can be applied to modify the models. Furthermore, descriptions of the long-term feedbacks such as various adaptations, selections and emergence of new species, as described before, are essentially difficult or impossible in this modeling procedure. This is also why a holistic approach, described in the next section, is now desired, especially for the description of long-term structural dynamics.

Holistic Approach

It is obvious that a food-web network in an ecosystem is very complicated in most cases. Furthermore, the food selectivity of a predator changes due to a change in the availability of prey (if a species is in a starvation state, it may eat a wide range of preys), or change in environmental condition. Properties of the biotic components (organisms) are fundamentally varied, for example, it is often observed that same species have different properties depending on the location of ecosystem; and many organism groups have age distribution and as a result, the body size and their growth kinetics vary. Rational modeling of these properties is the key to describe the structural dynamics in an ecosystem.

From this point of view, a holistic approach to construct structural dynamic models is receiving more attention today. The concept of holistic approach for ecological modeling is discussed in depth mainly by Jørgensen and colleagues in a series of studies that appeared in the journal *Ecological Modelling* and elsewhere. The most important point of holistic approach is that the kinetic parameters of the model are assumed to change depending on the time elapsed and the parameter values are calibrated to be consistent with the ecological principles. To estimate the degree of consistency with the ecological principles, an index called "goal function" is introduced in the approach.

Goal Functions

If any ecosystem face threating conditions such as environmental disaster or anthropogenic disturbance it cannot escape from that condition, but instead it has to adapt itself to those conditions in an efficient manner. The maximum efficiency regards to moving system far from thermodynamic equilibrium. This property indicates the goal functions of any ecosystem which they try to achieve in order to maximize their performance. For example exergy (means the amount of stored workable energy), ascendency (means the degree of system organization), entropy (its minimum value indicated highest efficiency of system performance).

Only a few structurally dynamic models have been introduced till date which accounts for goal functions of system performance.

For example, optimization of exergy (maximum stored workable energy) as a goal function for system performance indicator has been studied in detail by Santanu Ray and colleagues (Banerjee et al., 2017a; Ray et al., 2001a). Here they have studied the implications of body sizes of phytoplankton and zooplankton as an important parameter for total system dynamics by optimizing exergy and also the effect of phosphorus input corresponding different type of system such as oligotrophic, mesotrophic and eutrophic on its dynamics; also the variations in exergy content of a reservoir system following hypothetical perturbations scenarios (representing realistic situations) have been studied. In addition to exergy, "ascendency" as a goal function or indicator of system performance under the above prevailing conditions have also been studied (Ray et al., 2001b). Ascendency quantifies the growth and development of an ecosystem as a product of total system throughflow and the mutual information inherent in the pattern of internal system flows. For a detailed description of these goal functions, the reader is referred to literature.

In the following section, exergy and ascendancy are briefly reviewed as a goal function for ecological structural dynamic modeling.

Eco-Exergy or Exergy

Exergy describes the maximum work which can be produced from a system under a given environment. This concept is commonly used in process engineering to estimate (or design) various energy systems such as co-generation systems. Exergy is one of the most widely used goal functions in the structural dynamic modeling. Jørgensen suggested a typical procedure of the holistic approach of structural dynamic modeling (Fig. 3). In this approach, exergy is used as a goal function.

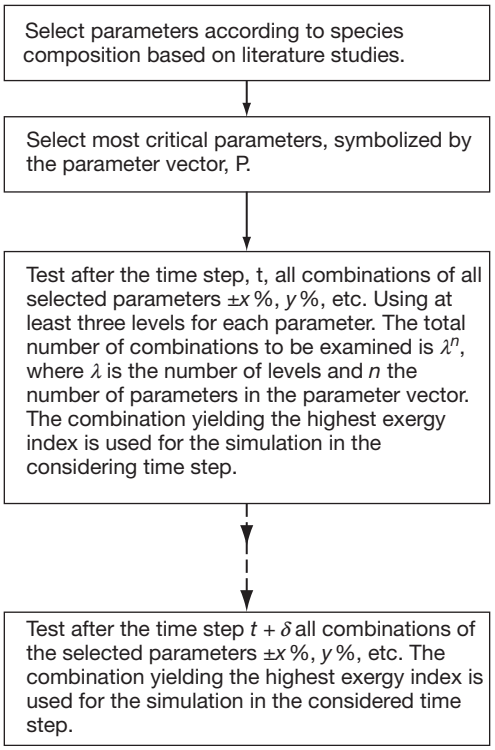

Fig. 3 A typical holistic approach of structural dynamic modeling using exergy as goal function. Adapted from Jørgensen, S.E. and Fath, B.D. (2004) Modelling the selective adaptation of Dawin's Finches. *Ecological Modelling* **176**, 409–418, with permission from Elsevier.

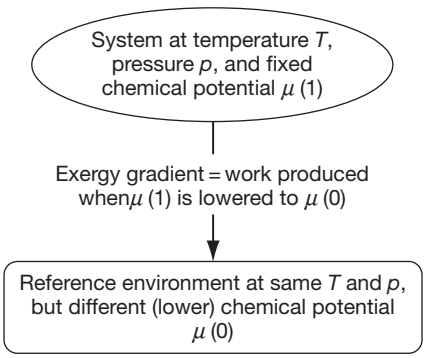

Fig. 4 Idea of the ecological exergy. Adapted from Jørgensen, S.E., Patten, B.C., and Straškraba, M. (2000). Ecosystem emerging: 4. growth. *Ecological Modeling* **126**, 249–284, with permission from Elsevier.

In relation to different goal functions, exergy has been used most widely in ecological models. Exergy has some advantage compared to others: it is related to state variables, which are easily determined or measured. It can be considered as fuel for any system to convert energy and matter in metabolic processes. The concept of exergy on thermodynamical aspect has been described in detail in previous studies, where detailed exergy calculation and future scope of study on various nonlinear effects like structural instability, dynamic chaos etc. are thoroughly discussed (Mandal et al., 2009).

The exergy concept is useful to assess the thermodynamical state of a system, and is extended to the ecosystem analysis, where it is called ecological exergy. The idea of the ecological exergy is depicted in Fig. 4. An ecosystem that has temperature T, pressure p, and chemical potential $\mu(1)$ is assumed to exist under a reference environment that has temperature T, pressure p, and chemical potential $\mu(0)$ (only chemical potential is different). The exergy gradient can be identified as the work produced, and the gradient is calculated by the difference in chemical potential. This is the principle of the ecological exergy.

Ecological exergy and its application for structural dynamic modeling have been studied in detail by Jørgensen and colleagues. The principle of the application of exergy is that the ecosystem tends to develop with maximizing the exergy to keep the organization far from the thermodynamic equilibrium. According to Jørgensen, the conceptual diagram of the change in the ecological exergy can

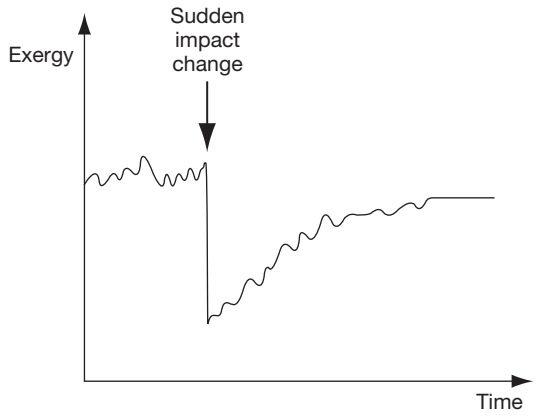

Fig. 5 Conceptual diagram of the trends in the ecological exergy changes. Adapted from Jørgensen, S.E. (1986). Structural dynamic model. *Ecological Modeling* **31**, 1–9, with permission from Elsevier.

be depicted as in Fig. 5. One of the main purposes of the structural dynamic modeling is to predict these organizational trends as a result of some impact, as in Fig. 5. Thus, a modeling approach based on exergy (or some other goal functions) is thought to be required.

One of the advantages of using exergy as a goal function is that it is easily calculated from the state variables in an ecological model. The ecological exergy is defined, with some approximations as

$$Ex = RT \sum_{i=0}^{N} c_i \left(\mu_i - \mu_{i,0}\right)$$

where Ex is the ecological exergy, R is the gas constant, T is the absolute temperature, c_i is the concentration of ith component in the ecosystem, μ is the chemical potential, and $(\mu_i - \mu_{i,0})$ is the difference in chemical potential of ith component between the ecosystem and its corresponding thermodynamic equilibrium under given environment. For a detailed description of the derivation of this equation, the reader is referred to works by Mejer, Jørgensen, and others.

Some applications of exergy for actual structural dynamic modeling, especially for the water ecosystems, can be found in the literature. These outcomes show the reasonability of the utilization of ecological exergy compared with the phenomena observed in the actual ecosystems.

Ascendency

Ascendency quantifies the growth and development of an ecosystem as a product of total system throughflow and the mutual information inherent in the pattern of internal system flows. Total system throughflow indicates the amount of energy or materials flowing into the system and ascendency quantify both the amount of energy flowing through the system and how much it retained into system at a given time. Maximum ascendency value indicates the highest system performance and maturity. Studies related to ascendancy fluctuations in relation to autotroph and fish biomass perturbation scenarios and also in relation to keystone species variations have also been reported (using mass balanced models) previously (Banerjee et al., 2017a,b).

Applications of Structural Dynamic Models

One of the essential objectives of the structural dynamic models is to assess the dynamics of the ecosystems. Currently, one of the most important issues in global environment is the extinction of rare and endangered species. Accordingly, the concern for the importance of biodiversity has been growing today. These topics can be dealt with in the structural dynamic models. In this circumstance, the expectation from the structural dynamic models will increase more and more in the future.

On the other hand, some environmental purification and remediation methods using ecological techniques have been brought to public attention. These are especially, applied for water treatment, or remediation of water environments. Some of them require the ecological structural dynamic models as a tool for the assessment of the methods. Biomanipulation, which has been brought to public attention, is one of the better examples of the remediation of water environment using the ecological technique. Biomanipulation aims to prevent the unusual growth of phytoplankton as a result of eutrophication in a lake. The basic concept of biomanipulation is that if the effective grazing of phytoplankton by zooplankton is achieved in a lake, the unusual phytoplankton growth is suppressed at certain levels of nutrient loadings. To construct this adequate ecological structure, the biomass of planktivorous fish (which is a predator of zooplankton) should be suppressed and the biomass of piscivorous fish (which is a

predator of the planktivorous fish) should be maintained. To do so, planktivorous fish is removed from a lake and/or piscivorous fish is introduced into a lake in the implementation of biomanipulation. For more detailed information about the biomanipulation, the reader is referred to the literature. The success/failure of biomanipulation strongly depends on the structural change in lake ecosystem after the manipulations. Especially, the succession of zooplankton is thought to be the most important. In general, in cases where biomanipulation is a success, the large-size zooplankton such as *Daphnia* sp. dominates. It is clear that the large-size zooplankton can essentially graze phytoplankton of various sizes at a high rate and is effective in suppressing the unusual growth of phytoplankton. For successful biomanipulation, therefore, some kinds of zooplankton, which graze harmful phytoplankton such as *Microcystis* sp., should dominate. To do so, sufficient prediction of zooplankton succession should be required prior to the implementation of biomanipulation. That is why the analysis of structural dynamics in the lake is strongly required for the implementation of biomanipulation, and the structural dynamic models become a strong tool to deal with this subject.

Summary

The complex but precise ecosystem networks have been attracting the attention of many researchers for a long time and, as a result, many useful ecological models have been proposed. In this circumstance, the concern with structural dynamic models of ecosystems has been growing from the viewpoints of not only mathematical ecology but also environmental technology.

The structural change in ecosystems is fairly complicated, because there exists a great number of components and their feedbacks, as described in the text. The holistic approach for the structural dynamic models, which is also described in the text, is one of the keys to solve the problem. A continuous research on the feedback mechanisms in ecosystems and the holistic approach would strengthen the methodology of the structural dynamic modeling for various ecosystems.

In the future, more knowledge about the structural changes of various ecosystems should be clarified. Structural dynamic models become a good tool to summarize the knowledge. To elucidate the fundamentals underlying the ecosystem functions, analysis through the structural dynamic models will also be required.

Visualization as a Tool for Ecological Analysis

S Kyle McKay, U.S. Army Engineer Research and Development Center, New York, NY, United States

Glossary

Information visualization "The processes of producing visual representations of data and the outputs of that work. Information visualisation aims to enhance one's ability to carry out a task by encoding often highly abstract information into a visual form. Visualisations can be static, or interactive and dynamic, and hosted in a variety of media (e.g., journal poster, website, or software)" (McInerny *et al.*, 2014).

Visual analytics "The science of analytical reasoning facilitated by interactive visual interfaces" (Thomas and Cook 2005 in Keim *et al.*, 2008) or "combines automated analysis techniques with interactive visualizations for an effective understanding, reasoning and decision-making on the basis of very large and complex data sets" (Keim *et al.*, 2008).

Visualization "A method of computing, [which] transforms the symbolic into the geometric, enabling researchers to observe their simulations and computations. Visualization offers a method for seeing the unseen. It enriches the process of scientific discovery and fosters profound and unexpected insights" (McCormick *et al.*, 1987).

Introduction

Visual exploration of empirical, experimental, or model data is a powerful tool for increasing understanding of complex, long-term, and variable data sets common in ecology (Keim *et al.*, 2008; Fox and Hendler, 2011; McInerny *et al.*, 2014). Data visualization methods are well-studied in fields of visual analytics, information visualization, computer graphics, and scientific communication (e.g., McCormick *et al.*, 1987; Tufte, 2001; Keim *et al.*, 2008; Aigner *et al.*, 2011). Ecologists informally use visualization to parse data sets, guide analyses, and explore new ideas, but the field rarely acknowledges formally the role of visualization in ecological analysis and synthesis.

Large data sets are increasingly available in ecology (e.g., stream gage networks, high resolution sensor networks, large-scale remote sensing), and effective visualization techniques will be crucial to rapidly and efficiently understand and communicate these observations (Michener and Jones, 2012). Visualization cannot substitute for more rigorous quantitative and statistical methods (Garbrecht and Fernandez, 1994). However, visual exploration takes advantage of the capacity of the human eye to rapidly detect and discern visual patterns (e.g., color, shape, grouping), when presented effectively (McCormick *et al.*, 1987; Keim *et al.*, 2008; Fox and Hendler, 2011; Healey and Enns, 2012).

Given the breadth of ecological data types, formats, volumes, and analytical needs, innumerable data visualization approaches are potentially pertinent to the ecological community of practice. Rather than undertake a foolhardy review of these methods, the objective of this article is to highlight the value of visualization as a component of ecological analysis and synthesis and to present a variety of key issues that must be addressed in the selection and application of a visualization approach. The fields of visual analytics, information visualization, computer graphics, and scientific communication provide a rich body of literature on the subject, and this article serves only as an entry point for uncovering the seemingly endless body of data visualization approaches. To this end, data visualization examples are presented relative to four common ecological applications: data exploration, experimental analysis, numerical model output and evaluation, and ecological decision-making. The article concludes with a set of questions to guide ecologists in the selection and application of a visualization approach.

Reviewing Data Visualization Via Case Study

Ecological data visualization is inherently specific to a problem, purpose, or question. For instance, three questions about the management of an invasive riparian plant would drive an analyst to explore vastly different visual media: What is the plant's current extent (may lead to a map)? What environmental conditions influence the current distribution (may lead to a scatterplot between variable-x and plant density)? Does chemical-y effectively control the invasive plant (may lead to a barplot of mortality relative to treatment and control groups)? This pedestrian example is merely intended to suggest that visualizations are akin to other ecological analysis tools; the method must befit the need. Because of this intimate connection to applications, case studies are used herein to review common issues in visualization of complex ecological data sets. These examples often omit ecologically and analytically relevant details in the interest of focusing of key aspects of the visual approach. Case studies were selected to present a diversity of ecological applications and highlight crucial considerations for the visual presentation. Many potentially interesting visualization approaches were not considered (e.g., interactive graphics, animations) due to the constraints of the two-dimensional, print medium (See section Selecting a Visualization Method).

Data Exploration

Often ecological data are collected over long time scales to understand trends, patterns, and variability associated an ongoing process or system. Additionally, the resolution of these data streams is increasing as sensor networks improve and computational power increases. This often leads to the need to analyze patterns in large, complex data sets, and visualization provides an ideal tool for exploration of large data sets. For example, the Luquillo Long-Term Ecological Research Program in eastern Puerto Rico has trapped freshwater shrimp in tropical streams weekly for more than 20 years (Crowl *et al.*, 2017). Here, catch per unit effort from a single pool (Pool 0 in Quebrada Prieta) and species (*Atya lanipes*) from 1993 to 2014 are examined through the lens of multiple time series visualization methods (**Fig. 1**).

Many visualization analyses begin with traditional plotting methods such as line, scatter, or bar plots, and these simple figures can prove extremely valuable, particularly if a visual benchmark is used to call attention to a specific aspect of the data (e.g., the mean and standard deviation are shown in the upper left figure). As with quantitative methods, a variable may be transformed to highlight important nonlinearity in the distribution of a variable, but for visualization transformations should be conducted by way of altering the axis not the data to maintain natural units for the analyst. For instance, shrimp catch data are logarithmically

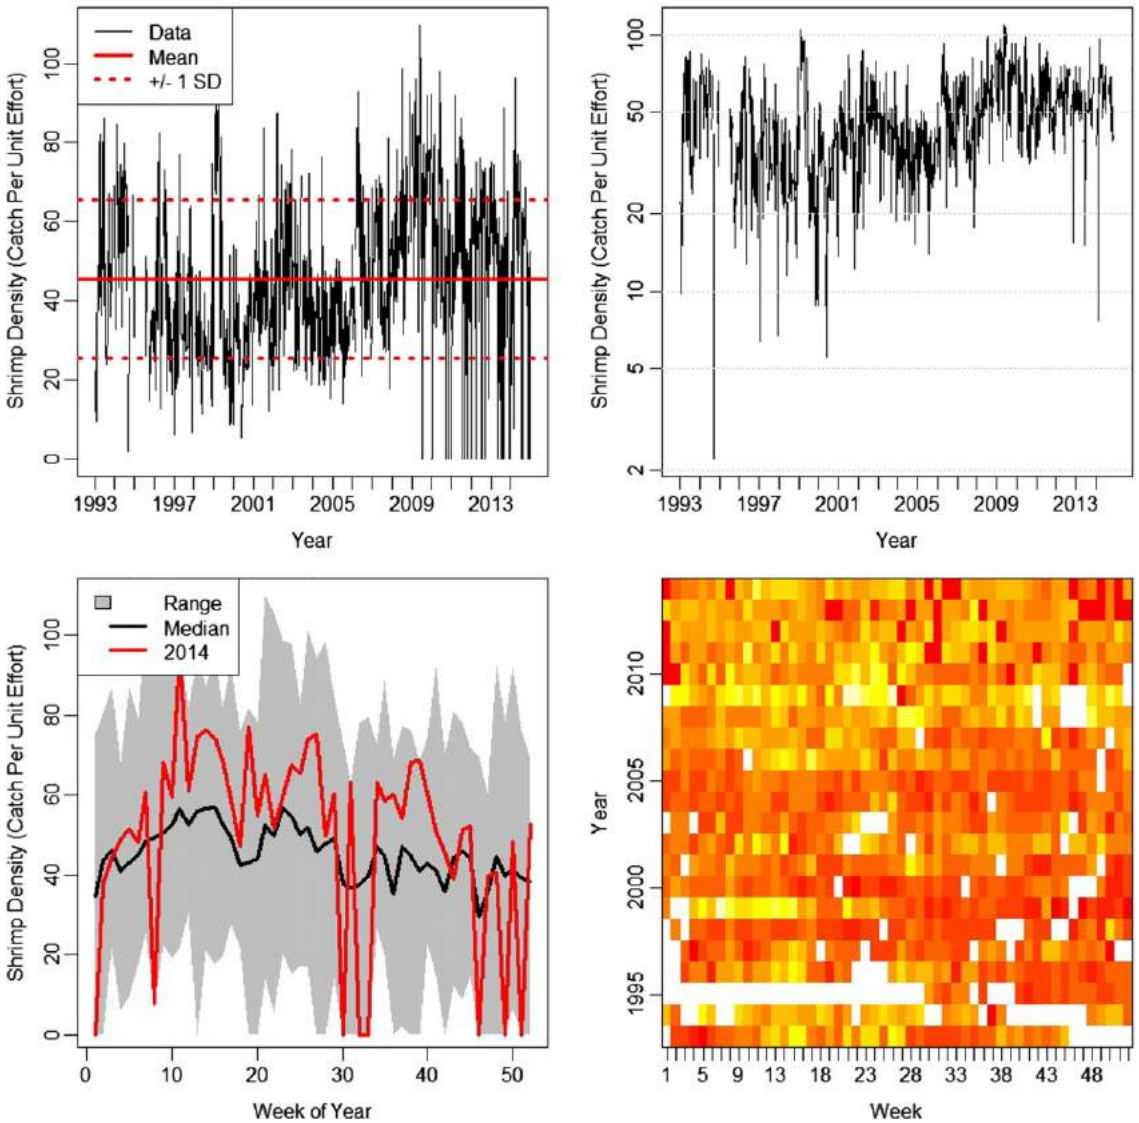

Fig. 1 Multiple visualization methods applied to a long-term, ecological time series. Data represent weekly freshwater shrimp (*Atya lanipes*) trapping densities collected at pool-0 of the Luquillo Long-Term Ecological Research (LTER-LUQ) site in Puerto Rico: (top-left) line plot with linear scale and reference points, (top-right) line plot with logarithmic scale, (bottom-left) envelope plot summarizing 2014 data relative to long-term observations, (bottom-right) a raster plot using color rather than location to represent density (red = high, yellow = low, white = missing).

transformed in the upper right figure, but the original units for catch per unit effort (CPUE) are preserved as a mechanism for maintaining understandability in the plot rather than *log* (*CPUE*). As a result of transformation, a more pronounced pattern of long-term catch declines and variability from 1995 to 2005 is shown, which is followed by a period of relative stability and high catch from 2005 to 2014. Ecological time series often exhibit periodic or cyclical patterns (e.g., diel movement, seasonal rainfall), and periodicity can provide a mechanism for compressing data for visualization. For instance, an envelope plot is used to provide historical context of the data (e.g., the range of observations and median for each sample week) for understanding a particular component of the data set (e.g., 2014 highlighted here; lower left figure). Although these line-based methods can lead to important observations, large data sets are challenging to communicate through this media because data are compressed into a finite plotting space. A variety of time series methods exist for overcoming these weaknesses, and the reader is encouraged to explore these approaches (Aigner *et al.*, 2011). As one example, a raster-based summary (lower right figure) presents the shrimp catch data set, and new observations may be made that were unapparent in other visuals such as data gaps (white cells), interannual variability (e.g., large-scale catch reduction across 2009), and massive intraannual variability (e.g., sequential high and low catch values in 2012).

Experimental Data

Experiments often help distinguish causal mechanisms in ecological systems, and visualization can help identify potential patterns, guide quantitative analyses, and facilitate the presentation of findings. More detailed guidance on the appropriate use of visualization in experimental analysis is addressed elsewhere (e.g., Weissgerber *et al.*, 2015), and only a few common issues are illustrated here. For instance, McKay *et al.* (2017a) used a tethered flight mill to study immune trade-offs with flight effort in North American monarch butterflies (*Danaus plexippus*). The experiments collected flight distance and duration data for individual monarchs in reproductively active summer conditions and reproductively inactive fall conditions for a maximum of four, 60-min flight trials conducted over sequential days. While additional analyses were originally pursued, the simplest form of the raw flight data are used here to address key aspects of experimental data visualization (**Fig. 2**).

The type of data generally serves as the first distinguishing feature driving a particular plotting approach with continuous and categorical data types providing the primary points of differentiation (e.g., 0.1, 0.8, and 1.2 and treatment-A and treatment-B, respectively; Weissgerber *et al.*, 2015). Typically, continuous variables lend themselves well to scatter and line plots, while categorical variables lend themselves to bar and box plots (top and bottom figures, respectively). Data grouping can also lead to alternative observations within a continuous variable. For instance, the top figures address the same data with all trials and individuals lumped into a single data set (left) and data parsed by individual monarch across four trials (right), and the two plots give the reader an alternative understanding of the amount of uncertainty and individual variation within the data. Generally speaking, a set of visualizations that effectively embed more data and information are preferred to those that present a single view of data. For instance, in the bottom figures, the bar plot conveys the general effect of the two seasonal treatments based on the mean observation, but the box plot provides additional information about the distribution of outcomes between the treatments (e.g., the lower tail of the duration data are affected more by season, nonnormality of the distribution is more apparent, the complete range of the data are shown).

Ecological Model Development

In addition to empirical approaches, visualization can inform many of the steps in an ecological model development process of conceptualization, quantification, evaluation, and application. **Fig. 3** presents a diversity of examples of visual approaches used to inform multiple types of ecological models. While not explicitly data visualization, conceptual representations of ecological models can guide the development of a model, structure data input–output, and serve as a mechanism for communication in an interdisciplinary team. For example, a conceptual model helped structure the development of an ecological model for quantifying the benefits of restoration actions in the Proctor Creek Watershed in Atlanta, Georgia (upper left, McKay *et al.*, 2017b), and the model was subsequently used by the restoration team to catalog potential restoration actions (orange boxes), input variables (white boxes), summary variables (gray boxes), and categorical outputs (yellow boxes). Visualization can also inform the evaluation of ecological models during calibration, verification, or testing phases. For instance, Shrestha (2016) developed a watershed-scale hydrologic model and applied separate portions of the streamflow gaging record to calibrate and verify model outcomes (upper right). Joint visualization of these phases, along with reference points of perfect prediction and $\pm 20\%$ error, allowed simultaneous consideration of the relative value of predictions and avoided systematic bias or error (i.e., calibration and verification have similar distributions of observed and predicted values). As ecological models become more sophisticated, so too must the visualization approaches for verification. For instance, Swannack *et al.* (2009) developed a model of Houston toad (*Bufo houstonensis*) movement through a complex, patchy landscape, and model outcomes were verified by a "Turing test," where a local subject matter expert familiar with toad movement was asked to select between observed and modeled landscape utilization patterns. Model results may also be summarized with visualizations in the application phase of ecological model development, but the model type and audience will play a large role in the selection of the visual approach. For instance, a population model of an oyster reef network was used to develop a network representation of the connectivity between reefs as well as a chord diagram summarizing key ecological aspects of connectivity such as the proportion of larvae moving to and from a given reef (middle row;

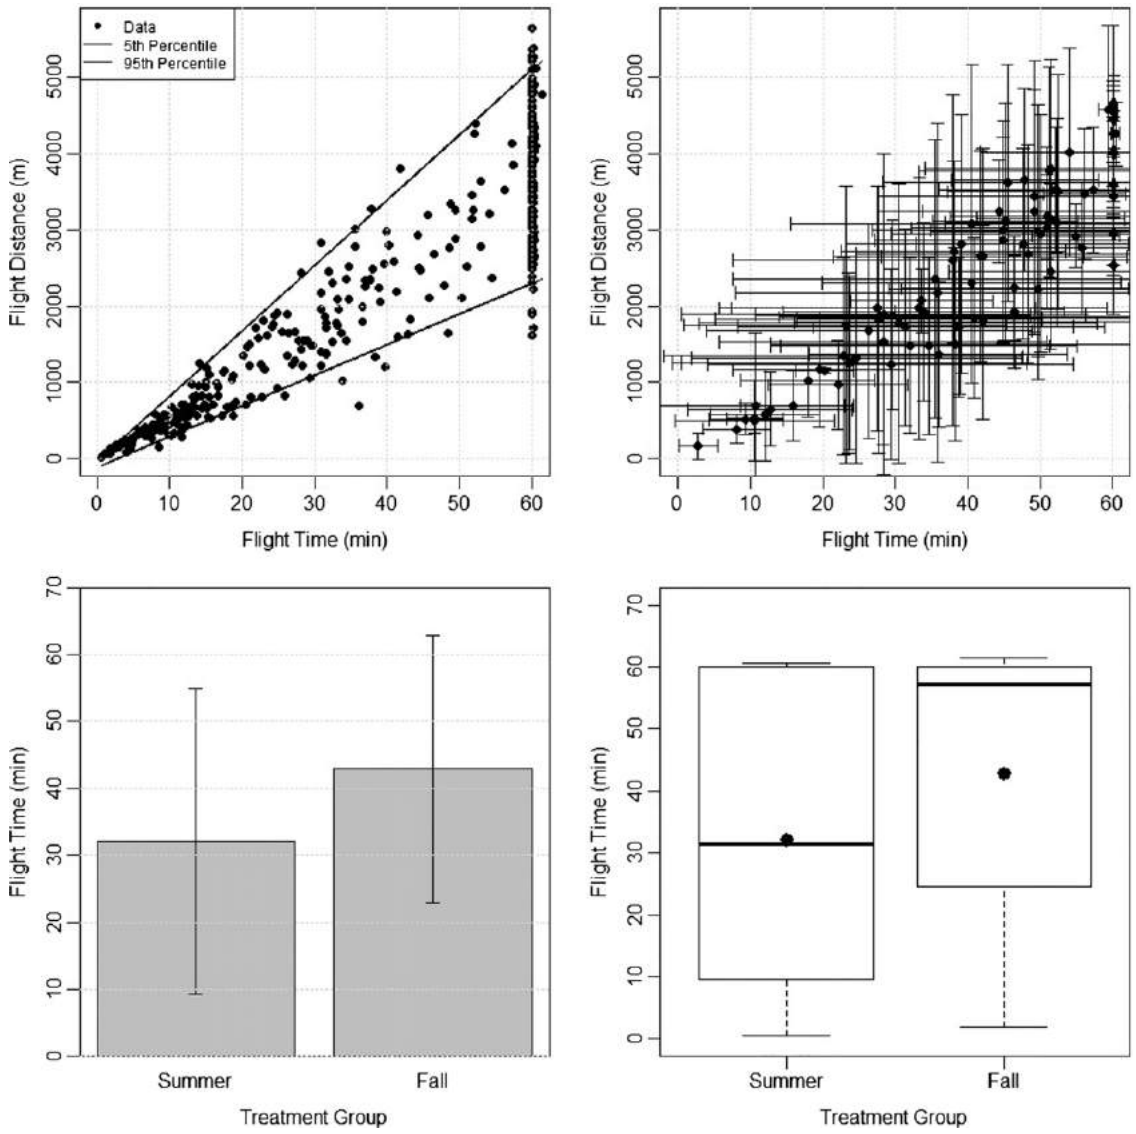

Fig. 2 Visualization of experimental results for monarch butterfly (*Danaus plexippus*) flight trials (McKay *et al.*, 2017a): (top-left) flight data from individual trials with a quantile regression bracketing outcomes, (top-right) flight data summarized by individual butterfly across multiple trials, (bottom-left) bar plot summarizing mean flight duration $\pm$ one standard deviation by treatment, and (bottom-right) a boxplot summarizing the effect of an experimental treatment across the entire sample population where the black point is the mean, black line is the median, box extent is the interquartile range, and whiskers represent maximum and minimum values.

Kjelland *et al.*, 2015). Conversely, the time series visualization methods described above were used to present a set of water management simulations to inform local officials of the magnitude of hydrologic change associated with a municipal water supply (bottom row). While ecological models are often system- or question-specific, visualization methods are agnostic to application, but selecting an appropriate visualization requires careful consideration of the step of the modeling process, goals of the visualization, and structure of the ecological output.

Informing Management Decisions

Visualization methods inform not only the ecological analyses themselves, but also the communication and condensation of those data for management and policy decision-makers (McInerny *et al.*, 2014). For example, an interagency team of federal, state, local, and nonprofit groups is partnering to restore the highly urbanized Proctor Creek watershed in Atlanta, Georgia. Visualization methods have served a vital role in facilitating knowledge transfer between the partners, and here two particular applications are highlighted that benefited from the visualization tools discussed in the article (**Fig. 4**). Urban watersheds represent diverse landscapes with many competing social, ecological, and economic objectives, and stakeholders often hold different relative value across those objectives. In this project, structure decision-making methods are being applied to examine the relative difference in

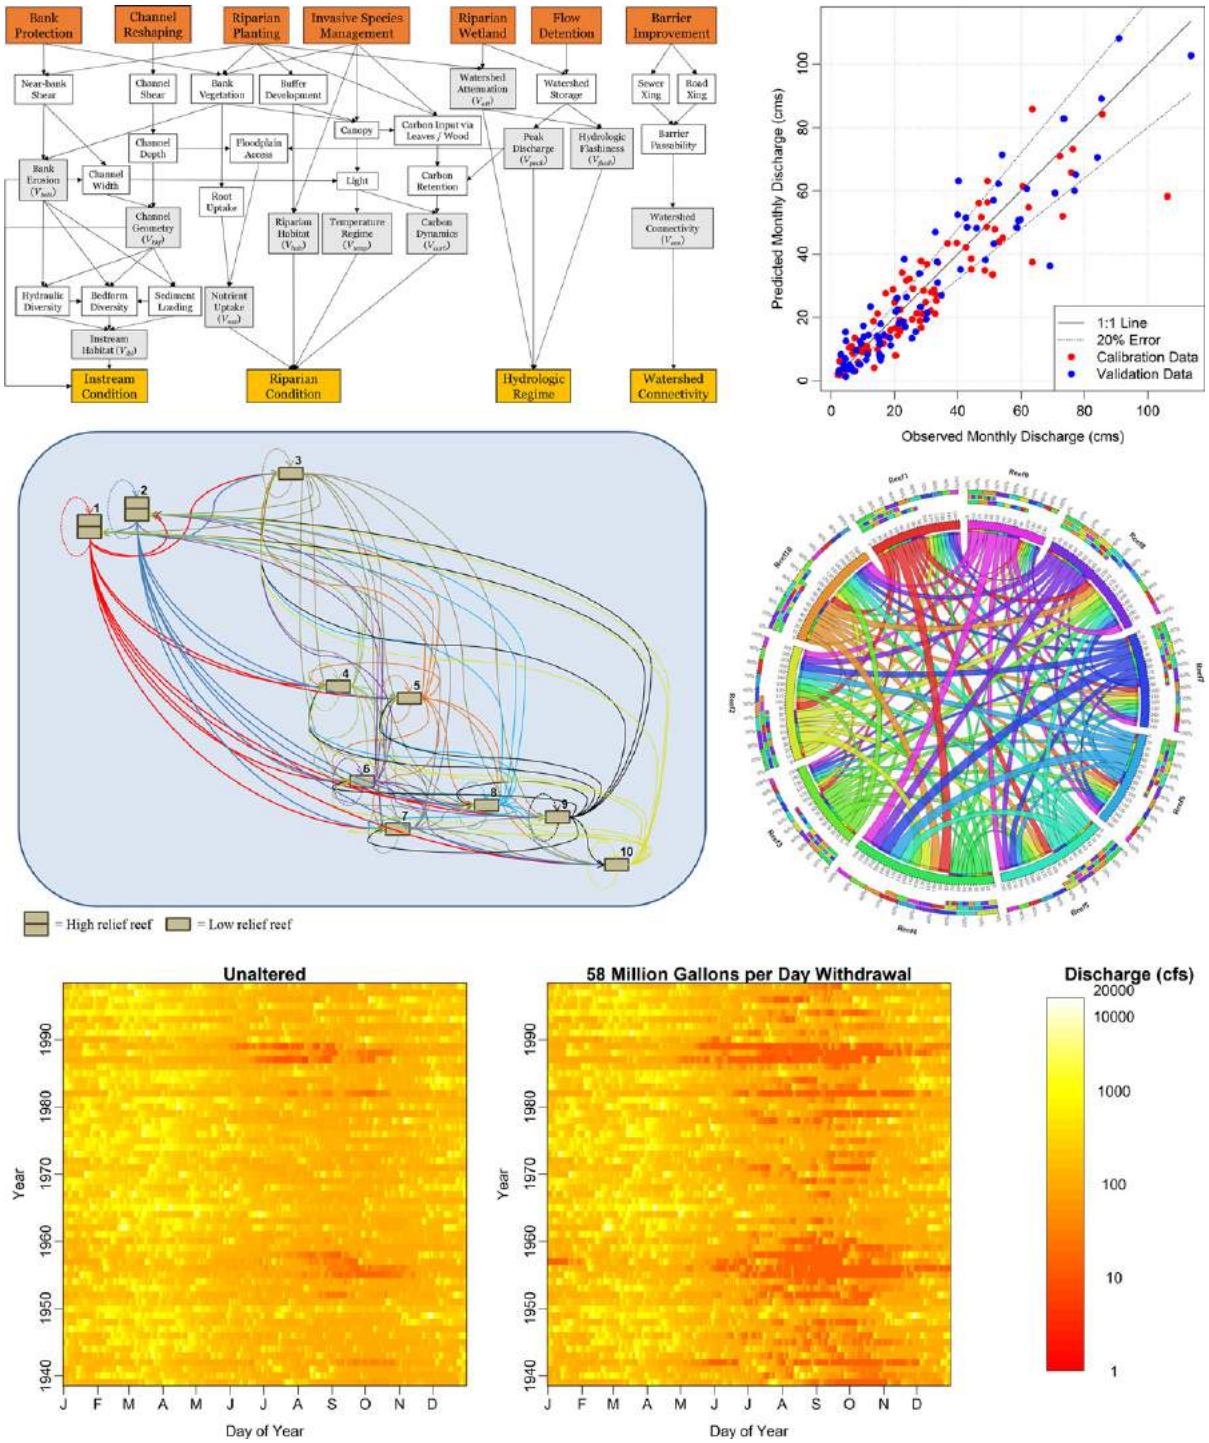

Fig. 3 Visualizations of ecological model results informing all aspects of the modeling process: (top-left) conceptual model of a multivariate model for stream restoration used in Proctor Creek, Atlanta, Georgia, (top-right) hydrologic model outcomes for both calibration and verification analyses (Shrestha, 2016), (middle) Oyster reef larvae dispersal network for a given year in a metapopulation dynamics model illustrating proportion of larvae originating from a given reef and going to other reefs, as well as the proportion of larvae from other reefs going to a given reef (Kjelland *et al.*, 2015), and (bottom row) raster-based time series of river discharge with and without water withdrawal.

stakeholder values across eight primary objectives. While not explicitly ecological data, the family of visualization methods presented in this article were used to summarize these data for communication among these divergent groups. Over 85 stakeholders were asked to distribute 100 "points" across each of the eight objectives, which were subsequently summarized in visualizations which show each stakeholder's values individually (top-left) as well as the aggregate value of all stakeholders (top-

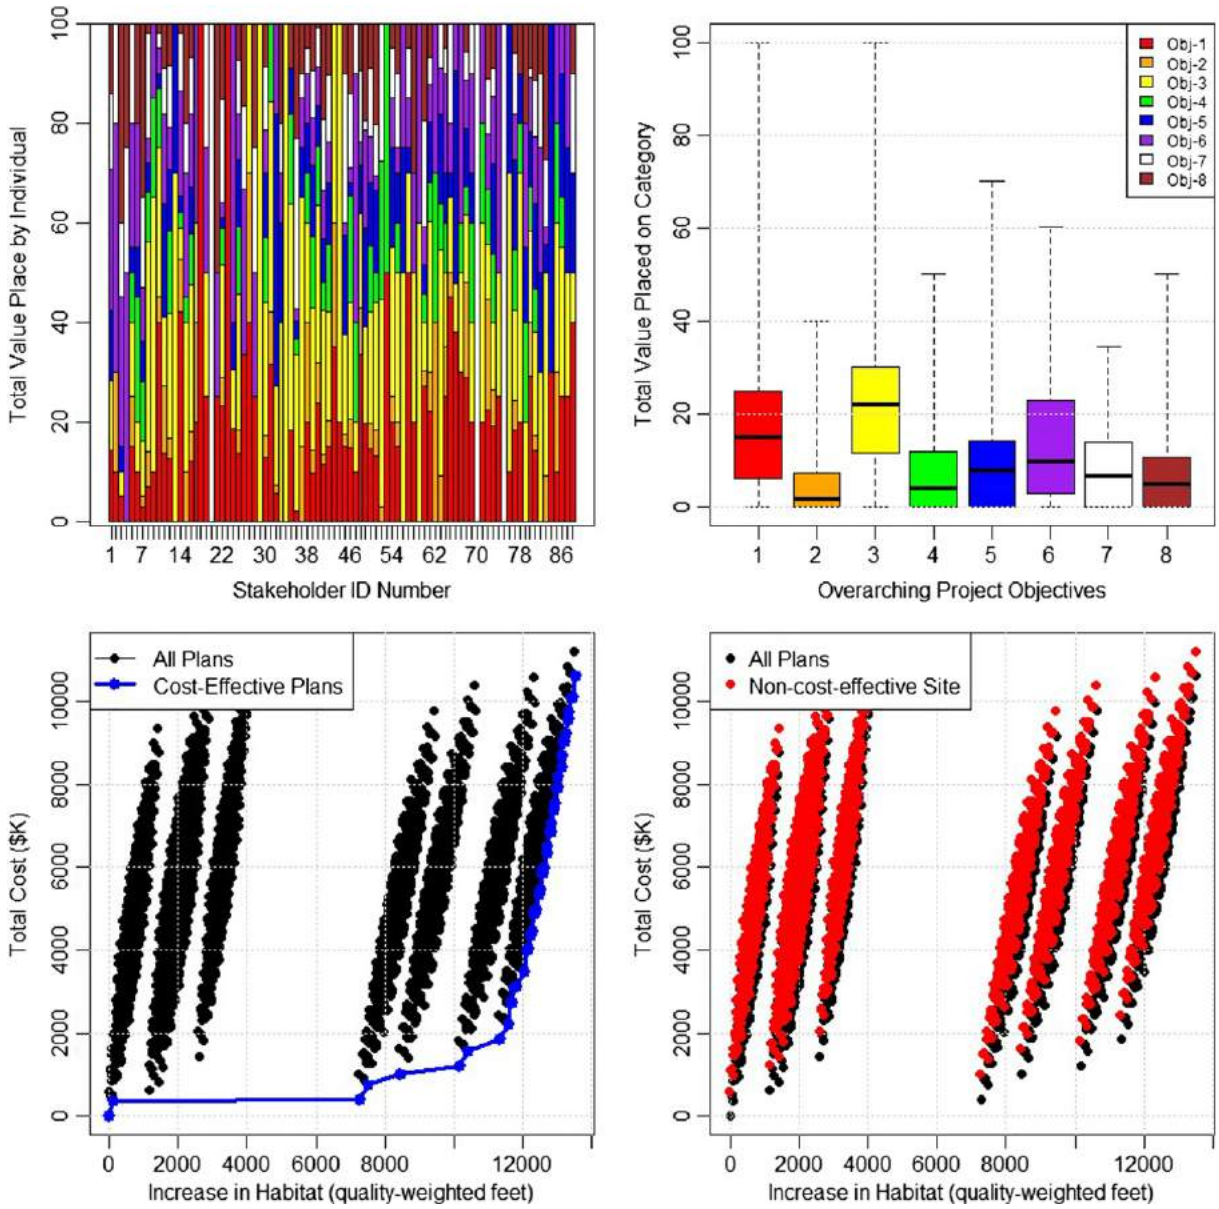

Fig. 4 Sample visualizations used to inform stream restoration decision-making in Proctor Creek, Atlanta, Georgia, United States: (top-left) distribution of values across 8 management objectives for 88 staekholders, (top-right) summary of the distribution of stakeholder values across objectives, (bottom-left) trade-off diagram highlighting sets of restoration actions that provide the most cost-effective restoration schemes, and (bottom-right) trade-off diagram highlighting plans including a particular site which shows that all sets incorporating this location are suboptimal (i.e., there are black points below and to the right of all red points).

right). In these figures, color is used to call information to the eye of the user and create a visual summary of the data (Healey and Enns, 2012), while still showing the range of values. For one of these objectives, an ecological model was developed to quantify the expected change in stream condition for a variety of potential restoration actions at 13 locations (8192 combinations of restoration actions watershed-wide). Model outputs were condensed into trade-off diagrams for decision-makers (bottom row), but the figures were then used to highlight particular aspects of the decision. For instance, suites of restoration actions were identified that were cost-effective (i.e., maximum habitat gain per cost and minimum cost per habitat gain), and color was used to call attention to these for decision-makers (bottom-left). Conversely, restoration sites were identified that were never included in cost-effective actions, which were also summarized with visualization (bottom-right). In communicating for decision and management, visualization must be careful to accurately represent information without imposing a judgment (McInerny *et al.*, 2014). For instance, color selection often implies preference, which can be used appropriately to guide decision-makers away from ineffective actions based on ecological evidence, but analysts must be careful not use visualization to impose their judgment on complex environmental decisions.

Selecting a Visualization Method

The vast array of options for data visualization can make choosing a technique challenging. The following questions are proposed to help ecologists navigate these methods. These questions are merely intended to structure thinking on method selection and are presented in an approximate priority of importance based on the key issues visualization (Aigner *et al.*, 2007, 2011; Kelleher and Wagener, 2011). Importantly, multiple methods can (and should) be applied simultaneously to explore a data set, emphasize specific components of those data, highlight different elements of variability, and guide quantitative analyses.

(1) What is the best method for communicating a message? Purpose and objectives should always drive the selection of a visualization method (Kelleher and Wagener, 2011). For instance, a simple line plot may be sufficient for communicating the time of sampling relative to recent environmental disturbances. However, a pixel-based approach might be more effective for communicating long-term trends (e.g., drought periodicity; **Fig. 1**). In particular, methods might change relative to the components of a data set that are of interest (e.g., extremes vs. central tendencies; **Fig. 2**).

(2) What are the relevant scales? Relevant ecological temporal and spatial scales range from minutes to decades and centimeters to thousands of kilometers in both length and interval. For many ecological processes, valuable understanding can be gained from the presentation of data in the historical context of a long-term record or large spatial domain. The resolution of the data relevant to a particular problem also influences the efficacy of a particular visualization method.

(3) How are data distributed? Ecological data often occur over many orders of magnitude (e.g., changes in streamflow, boom-and-bust of a population). Visualization can often be made more effective by rescaling figures, but care should be taken to maintain understandability in units (e.g., natural units of a process, not transformed units; **Fig. 1**).

(4) What are the constraints of the visualization environment? Selection of methods is influenced by not only the need to present data effectively, but also the limits of the presentation medium (Aigner *et al.*, 2011). The spatial extent, resolution, and use of color in a figure are often limited by screen or page size and the medium of interest (e.g., journal article vs. presentation vs. interactive on-line infographic). This article has focused on static presentation of a single time series, but the capacity to animate or interact with figures can increase visualization options significantly.

(5) What tools and expertise are available? A large variety of software is available to visualize data (e.g., Microsoft Excel, MATLAB, R Statistical Software, Geographic Information Systems). While all of these tools can present data in multiple formats, not all visualizations are easily conducted in all programs. In addition to availability and capability of the software, there may be personnel limitations in terms of expertise or time availability, which should not be overlooked. Herein, the freely-downloadable, R statistical software package was used to develop all figures (R Development Core Team 2016 Version 3.3.2), and code is available upon request from the author.

Conclusions

As ecological analysis has increased in sophistication and rigor, so too have visualization approaches (Kelleher and Wagener, 2011). However, broad adoption of many visualization methods has lagged. Large data, complex, and long-term data sets are becoming increasingly common in ecology (Michener and Jones, 2012). Using a variety of case studies, this article has highlighted a few (of many) techniques for visualizing ecological data and provided a set of criteria for guiding analysts to an appropriate technique. Visualization cannot substitute for rigorous quantitative analyses, but it can inform the analyst, guide the analyses, and facilitate communication (McCormick *et al.*, 1987).

Watershed Models☆

Vojtech Novotny, Northeastern University, Boston, MA, United States

Introduction

Since 1960s computerized watershed models have been used by scientists to simulate the hydrological erosion and deposition throughout the watershed and nonpoint pollution loads from the watershed. Recently, ecological watershed models and applications have been developed and are finding their way into practice. The term "watershed modeling" implicitly describes a category of geographical models that simulate movement of water and associated processes that change the quantity and quality of water. This type of modeling may differentiate from other geographical ecological modeling such as the models of forest ecology, impact of drought conditions on crops and crop yields, habitat suitability for fauna and flora, etc.

A "watershed" is a geographical unit contributing flow to a location on a receiving water body. The watershed is bordered by a "watershed divide" that surrounds the watershed, connecting the highest points. The area behind the divide contributes surface and shallow groundwater flows to another receiving water body. However, in many watersheds deeper groundwater flows may not follow the surface geography of the watershed and groundwater contribution to flow may originate from recharge areas beyond the divide, or the groundwater flow originating within the watershed may discharge into another water body.

The category "ecological watershed modeling" includes mostly mathematical computer models. Fig. 1 presents general categories of models for watershed modeling. Physical watershed models, common in the 1940s, still do exist and are used by laboratories but will not be extensively covered herein. In most cases these models have small ecological relevance and have been primarily used for scaled-down development, testing, and simulation of floods, overland flow, rainfall/runoff transformation, and erosion. The largest physical model covering an area of many hectares was built during the 1940s in Vicksburg (Mississippi, USA). This model represented the Mississippi River Valley watershed from Minneapolis to New Orleans and was used for predicting flood flows and flood propagation. Smaller "watershed" models, as small as a platform (Fig. 2), were built and are still used by scientists to study overland flow, washoff of particulates that accumulate on impervious surfaces, and erosion and elutriation of pollutants from soils. Physical model categories are distinguished from physically based models which is a model category synonymous to deterministic–mechanistic computer models.

Distinction between small physical watershed models and small pilot watershed plots may be sometimes fuzzy but one can presume that the former physical models are built in laboratories and are detached from the natural systems while the latter are a part of nature equipped by monitoring instrumentation. Analog models are rare and have been typically used for modeling groundwater aquifer processes.

Today, watershed models are mathematical computer models and range from the typical desktop or laptop computers to high-speed large computers. However, the capacity of the current desktop or laptop computers can accommodate most watershed models. Ideally, ecological models should include three spheres: (1) atmosphere; (2) terrestrial, including shallow underground and riparian zones; and (3) aquatic freshwater and oceanic systems (Fig. 3). In this article the focus is on modeling terrestrial processes that affect water quality and biotic integrity of aquatic systems.

Types of Models

The computer watershed models can be separated into two distinct categories (Fig. 1):

1. deterministic, also called mechanistic, models and

2. indeterministic models that include probabilistic models and artificial intelligence (e.g., artificial neural net or genetic algorithm models).

Deterministic (mechanistic) models are generically a priori developed from an assembly of known processes, for example, hydrologic processes included in rainfall/runoff transformation, accumulation of pollutants in the watershed, vegetation growth, and hydrological and pollution impact, etc. The model components are then tested by special field monitoring and in the final stage the entire model is then calibrated and verified by field data for modeling a specific watershed. Indeterministic models are typically developed a posteriori from measured data. The data assemblies should be large enough because the basic premise of these models is that the models are developed from the data (data mining) and the previous knowledge about the processes is only basic. Hybrid models, however, combine the knowledge-based deterministic features with data mining and model creation by artificial intelligence models. Stochastic models yield both the mean and probability distribution of outputs. The most common stochastic modeling is Monte Carlo application, where a deterministic model is run thousands times with randomly generated (based on their probability distribution) inputs and model parameters to yield a probability distribution of the model output.

Deterministic models do not consider random variables and for each unique set of input data they produce fixed repeatable results. A mechanistic model is a representation of the physical, biological, or mechanistic theory governing the system; in contrast, a statistical model accounts for the statistical fitting of equations to the available data. Stochastic models use distribution for each variable and parameter to generate random variables of model inputs and system parameters.

Every watershed model can be represented by a box (the watershed) concept (Fig. 4). The term "black box" signifies that not much is known a priori about the system and the model is developed from the monitored data.

Deterministic (Mechanistic) Watershed Models

Watershed Loading Models

Since the 1960s, scientists focused on putting the knowledge of hydrological processes constituting rainfall–river flow transformations into a watershed hydrological model. The most known and the first comprehensive watershed model was the Stanford Watershed Model conceived by Professor Linsley and his graduate students. The model was sound and the concepts and the basic structure of the model are valid today and incorporated into modern hydrologic watershed models. Hydrology and hydrological processes are the backbone of all deterministic watershed models. However, ecological models represent and simulate more than hydrology and have been developed and are used for simulating erosion and sediment movement, pollutant loads, crop and forest growth and resulting loads of nutrients, spread of forest fires, surface–groundwater interactions, drainage, etc.

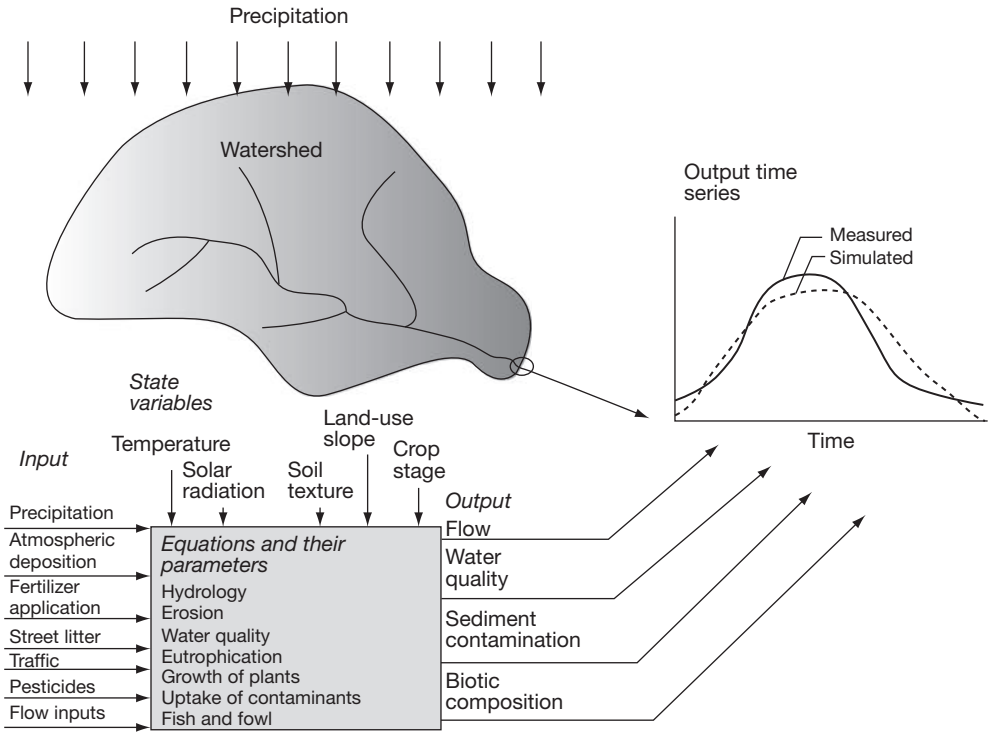

Fig. 4 Black box representation of watershed models.

A detailed deterministic or stochastic ecological model has five components: (1) inputs or forcing functions, (2) state variables, (3) mathematical equations, (4) parameters of the models, and (5) constants. Inputs can be controllable or uncontrollable. The model, like the real system, produces outputs to various inputs and the outputs also reflect the changes in the system itself. The variables describing the system are called "state variables." The distinction between inputs and state variables is sometimes fuzzy but, typically, watershed size, soil composition and erodibility, land-use distribution, watershed configuration with slope are examples of state variables while rainfall, atmospheric deposition, temperature, humidity, and solar radiation are inputs. Most watershed models are driven by precipitation which is an uncontrollable input, while fertilizer application is a controllable, managerial input. The foundation of the model is in equations that describe the input to output transformation. The parameters of each equation may have ranges and the proper value of the parameter must be typically established by calibration and verification of the model. The equations also contain constants and thresholds. A threshold is a constant that activates or terminates a process described by a particular equation or a submodel. For example, many biodegradation processes cease when the temperature is near or below freezing or a priority pollutant is not toxic below a certain concentration.

There are two approaches to modeling watershed processes: "lumped parameter" and "distributed parameter models" (Fig. 5). Lumped parameter models can be both stochastic and deterministic. Distributed parameter models are mostly deterministic. The lumped parameter models treat the watershed (subwatershed) as a homogenous unit. Because of a significant variability of the parameters, even within a relatively small area (e.g., less than 1 ha), the various characteristics of the watershed are lumped together by an empirical equation, and the final form and magnitude of the parameter are simplified to represent the computational watershed as one homogenous unit. The computational units can be vertically compartmentalized to represent surface–ground zones interactions. Water and mass flow from one compartment can overflow into another adjoining compartment. For lumped parameter models the input–output relationship can be represented as

$$\mathbf{Y} = \mathbf{\Phi}(\mathbf{X}) \tag{1}$$

where **X** is the input vector or matrix (single or multidimensional), **Y** is the output vector or matrix (single or multidimensional), and Φ is the multidimensional transfer function.

According to this definition, a lumped watershed model is a multidimensional transfer function. The transfer function Φ does not represent a simple multiplication. In most general terms, a transfer function is a functional response of the system to a pulse (in dynamic models) or a step (in steady-state models) input. A well-known unit hydrograph incorporated in many lumped parameter

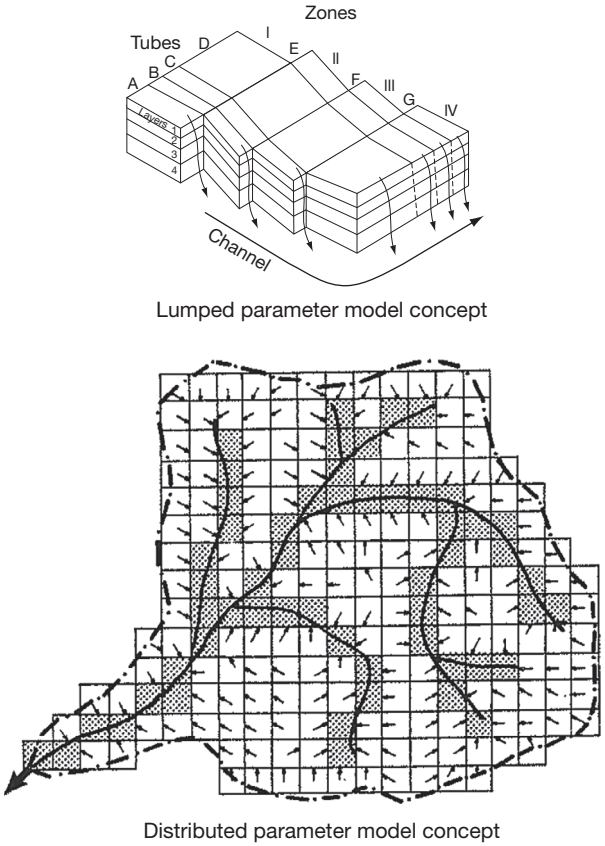

Fig. 5 Lumped (vector) and distributed (raster) parameter concepts for watershed modeling.

hydrologic models is a watershed flow response to a short duration (pulse) unit rainfall while the "rational (Lloyd–Davies) formula" is the watershed flow response to a step (continuous after initiation) uniform.

In the distributed parameter models the watershed is divided into computational subunits that are much smaller than those of the lumped parameter. The size of the subunits may range from 1 ha to more than 1 km^2. The subunit shapes are either rectangular (square) or triangular or they may follow some morphological or hydrological feature of the watershed. Each unit may receive external and internal (from surrounding units) input and is homogenous. The general mass-balance equation for any component within the computational unit is

$$\frac{dS}{dt} = X - Y \pm G \tag{2}$$

where S is the mass storage of the compound in the computational element, G is the sinks (losses) and gains of the compound within the element, X is the external input to the element, and Y is the output.

The major difference between the lumped parameter and distributed parameter models is the mathematical formulation of the mass balance in each unit that for distributed parameter models is generally expressed by a differential mass-balance equation. The differential mass-balance equations for each computational unit are then solved simultaneously in a small computational time interval, Δt, which ranges from minutes for the hydrologic calculation of a small watershed, to a day or more for quality constituents or crop modeling in larger watersheds. Another difference between the lumped and distributed parameter models is the availability of the output. In lumped parameter models the output is available only at the watershed or subwatershed outlet. In distributed parameter models, results are available for each computational unit which makes distributed parameter models attractive for multidimensional displays in the raster geographical information systems (GIS) modeling environment.

Watershed computer models come in all sizes, from 1 ha uniform experimental modeling plots or hydrological subunits to regional large models with a size of thousands of km^2. Large watershed models are dominated by channel storage while smaller watersheds are sensitive to precipitation events and are dominated by overland flow.

Models can be designed or run on an "event or continuous" basis. Event models simulate the response of a watershed to a single large rainfall or another major input (e.g., forest fire). The output from event models is a hydrograph of loads of a constituent from the watershed. The principal advantage of event modeling over continuous modeling is that it requires less meteorological data. The disadvantage of even modeling is that it requires a definition of the "design" storm and antecedent state of the system prior to the event.

Continuous (dynamic) process modeling sequentially simulates processes such as precipitation, water and pollutant storage and movement within the watershed toward the watershed outlet, runoff components, evaporation and transpiration, uptake of pollutant and nutrients by vegetation and their release into aquatic systems, and erosion. The output is the time series of flow and quality constituents from the watershed. Continuous modeling provides time series of the output (flow, concentrations, soil and vegetation contamination). These time series can be statistically analyzed but with caution and warning. The simulated time series are not the "true" time series because the deterministic model inherently does not include random components contained in every time series of natural data. The models are calibrated to simulate local means but not extremes. Thus the statistics of exceedances or comparisons of the time series of outputs generated by deterministic models with ambient standards could be misleading. This problem could be overcome with Monte Carlo modeling methodology which would then categorize such applications as stochastic modeling.

Traditional deterministic watershed models are mostly linear. Linearity means that the equations in the model compartments are either algebraic or differential linear equations. If the mathematical formulation describing the process is nonlinear, it is often linearized within the short computational interval. Under the assumption of linearity, the principles of proportionality and superposition apply. The principle of proportionality implies that if the input is multiplied by a constant the output is also multiplied by the same constant. The superposition means that if two separate inputs to the model are added, the output of the model is the addition of the separate outputs. At the end of twentieth century and thereafter the focus of model developers shifted to development of nonlinear models.

Components of the Deterministic Watershed Ecological Models

Deterministic watershed models are compartmental models, that is, they describe and simulate the transfer of water and biomass from one compartment of the ecosystem to another. The ecological models are almost always dynamic; they calculate mass balances in specific time intervals that do not have to be identical for each compartment. For example, water balance and overland water routing can be done in time intervals of an hour or less, while the growth of plants or mass balances of water quality and algae in a receiving lake can be accomplished in time intervals of weeks or months. The models simulate the fate of water and its quality (chemical) constituents and also their direct and indirect effects on the resident organisms. The mass balance can be calculated sequentially or concurrently. Watershed ecosystem models employ a compendium of submodels (Fig. 6).

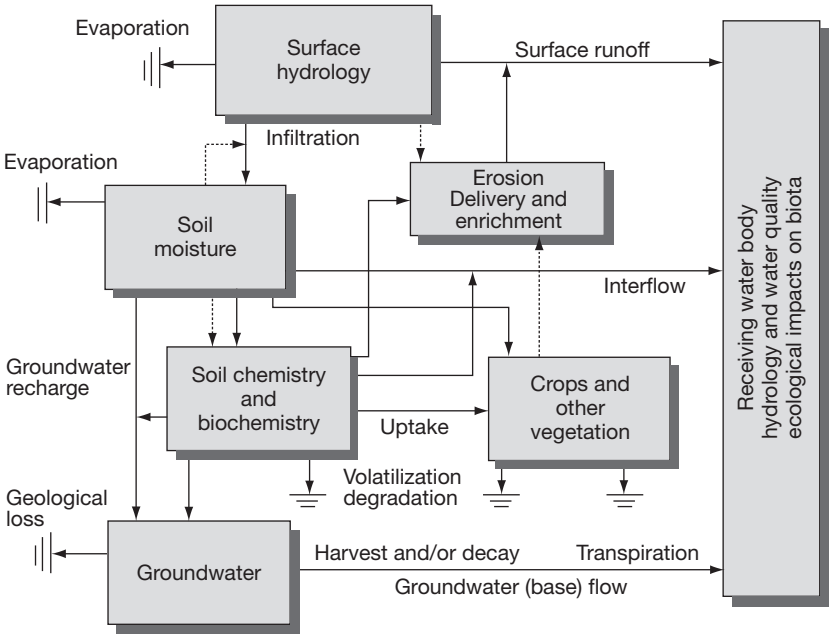

Fig. 6 Suite of basic submodels in watershed modeling. *Solid line arrows* represent transport processes for water and contaminants (including sediment and nutrients), *dot arrows* are impact effects.

Hydrological Component

This component is the backbone of most deterministic watershed ecological models that perform transformation of precipitation into water flow. The watershed water-balance models are either built in a "lumped subwatershed format" (vector representation in GIS) where computational subunits have more or less uniform characteristics or in a "distributed format" (raster representation in GIS) (Fig. 5). The water movement throughout the watershed is calculated in the Lagrangian coordinate system of fluid mechanics in which Z is vertical, and X and Y are lateral axes. X is in the main directions of flow, that is, it may not be perfectly horizontal. The hydrological mass balance is carried out vertically in three zones: (1) on the surface, (2) in the top soil, and (3) in the groundwater zone. Each zone represents a storage component and the mass balance according to Eq. (2). There are many literature sources dealing with hydrology and hydrological modeling (see section on "Further Reading").

The "surface hydrology" modeling component performs the following calculations:

Snowmelt calculation. Based on the ambient temperature, this component makes a decision whether the precipitation is in a form of liquid rain or snow. It then calculates snow accumulation and melting.

Initial subtraction from rain or snowmelt. Water that is intercepted by vegetation, surface roughness, or terrain is returned back to the atmosphere by evaporation.

Infiltration: Infiltration into soil depends on the top soil texture, moisture content, and freezing.

Excess or net rain. This occurs when the precipitation (rain or snowmelt) at the soil surface exceeds the sum of infiltration and surface subtraction. The surface water component accepts solids with associated contaminants liberated from top soil by erosion and leaching. Surface runoff is excess rain transformed by overland routing. Surface runoff is the most polluted component of flow in the receiving water bodies.

Top soil layer water balance. This has infiltration as input and evaporation, vegetation water uptake (transpiration), and groundwater recharge as outputs. Groundwater recharge depends on saturation permeability of subsoil. 'Interflow' in the top soil occurs when the top soil layer is saturated and infiltration exceeds the downward movement of water through the subsoil.

Groundwater recharge. This is a residual of infiltration into top soil storage evapotranspiration. 'Groundwater flow' is a near-horizontal gravity movement of water from the recharge area to surface outlets into the receiving waters. A smaller portion of groundwater is lost to deep groundwater zones and to anthropogenic withdrawals.

Interaction of Contaminants With Soils and Surface Vegetation

This component simulates retention and attenuation of chemicals on soil particles of top soil and on dust and dirt particles that accumulate on impervious surfaces of street gutters and other impervious areas. Chemical contaminants are either hydrophilic that are mostly dissolved or dissociated in pore water of the soil and in groundwater, or hydrophobic that have a high affinity for adsorption on soil particulate matter or precipitate in soil. Nitrate ((NO_3^-)) is an example of a strongly hydrophilic compound that moves readily with soil water into groundwater recharge and with groundwater. Many pesticides and phosphate fertilizers are mostly hydrophobic and remain adsorbed onto soil particles or precipitate into solid forms, such as most toxic metals at a higher

pH. However, a small portion of these pollutants can exist in the dissolved form in the soil pore water. The relationship between the concentration of the chemical in pore water of soil and the total concentration is

$$C_s = \frac{C_T}{\theta + \Pi m_{ss}} \tag{3}$$

where C_s is the concentration of the soluble contaminant fraction in the pore water of soil ($\mu g\, L^{-1}$), C_T is the total contaminant concentration in the soil volume, ($\mu g\, L^{-1}$), θ is the volumetric water content of the soil, Π is the partition coefficient of the contaminant on soil particles ($1\, g^{-1}$), and m_{ss} is the soil density in $g\, L^{-1}$.

Other isotherms used in modeling specific pollutants are Langmuir isotherm for phosphorus or Freundlich equations for some toxic compounds.

The soil component separates the contaminants into dissolved and adsorbed (precipitated) fractions. Also some contaminants can undergo biochemical transformation (e.g., nitrification, biochemical breakdown) that often depends on the redox status of the soil which is affected by soil moisture.

Crop/vegetation growth: This component is important for agricultural or forest growth models. Plants withdraw soil moisture, use for buildup of organic plant matter and release some of the moisture to the atmosphere as transpiration. The withdrawal is limited by the wilting point which is soil moisture content held by soil so tightly that plants cannot overcome it by their suction. With water, plants can get their nutrients and also pick up contaminants. Plants can only take up the dissolved mobile fraction. The adsorbed immobilized fraction is not available for uptake.

Soil Erosion Component

Erosion moves sediment and contaminants adsorbed on or associated with the sediment from the source area to the receiving water body. In modeling, sediment is routed overland by surface runoff; however, not all eroded sediment will reach the receiving water body. The attenuation of the sediment loads and associated contaminants during overland flow is expressed by a fuzzy parameter called the delivery ratio, DR, or

$$Y = \sum_{i=1}^{N} DR_i E_i A_i \tag{4}$$

where Y is the total sediment yield from the watershed, E_i is the erosion rate from the segment I, and A_i is the area of the segment.

Erosion rate depends on the energy of the rainfall to dislodge soil particles from the soil. In addition, erosion is activated only when excess rain is generated that will become surface runoff. Hence, erosion is linked to the surface hydrology component. The most widely used erosion model was developed by Wischmeier and Smith. The model is more than 40 years old and has been modified several times but the fundamentals are sound. The erosion equation is

$$E = (R)(K)(LS)(C)(P) \tag{5}$$

where E is the calculated soil loss in $t\, ha^{-1}$ for a given storm or season or a year, R is the rainfall energy factor that has the same units as R, K is the soil erodibility factor, LS is the slope/length factor, C is the cropping management or vegetation cover (protection) factor, and P is the erosion control factor.

The magnitude methods of calculating the factors are presented in many publications. The "universal soil loss equation" considers the impact of "best management practices" on the loads sediment and associated pollutants.

Examples of Watershed Loading Models

HSP-F. This lumped parameter model evolved from the Stanford Watershed Model. It is now included in the US EPA's watershed modeling suite "BASINS" (better assessment science integrating point and nonpoint sources). The model has several components. The components used for modeling hydrology and pollutant loadings are "the agricultural runoff management model" (ARM) and urban nonpoint simulator (NPS). Both are driven by the hydrological component and the main difference between the two submodels is the soil and groundwater modeling in ARM, and impervious surface hydrology, pollutant accumulation, and washoff incorporated in NPS. By including a channel component (RCHRES) HSP-F has a capability of integrating the land and receiving water quality modeling. The result of the modeling is a time history of flow and water quality at any point in the watershed.

Agricultural nonpoint source pollution model (AGNPS). This was developed by the US Department of Agriculture. The primary emphasis of the model is on nutrient and sediment, and on comparing of various best management practices on the pollutant loading.

Soil and water assessment tool (SWAT). This is a distributed parameter version of previous models "CREAMS" developed by a team of agricultural researchers lead by Knisel and a follow-up model with a groundwater component "GLEAMS." SWAT is spatially distributed, up to several hundred of subbasins, and the subbasins can interact. The SWAT hydrology is based on the water-balance equations and uses National Resources Conservation Service (formally soil conservation service) runoff equation expanded to also consider soil and groundwater movement. It can also simulate irrigation and channel transmission. Erosion is calculated by the

modified universal soil loss equation (MUSLE) developed by Williams and includes overland and channel sediment routing. Arnold incorporated into SWAT model GIS linkage, advanced visualization tolls, and statistical analysis of outputs.

Receiving Water Quality Models

In deterministic ecological watershed modeling, each compartment should be described by a model. Models of hydrology, contaminant transformation, and movement throughout the watershed provide estimates of the water and contaminant loads to the receiving water body. The format of the loads is time-variable hydrographs or histograms of the contaminants (plots of the pollutant contaminant concentrations vs. time), daily loads, or seasonal (annual) loads for larger impoundments with a longer residence time. A riparian zone model can be also considered to provide information on attenuation of pollutant loads (Fig. 7).

Because the endpoint of the modeling effort is the ecology of the water body that receives the loads from the watershed and from the point sources, a receiving water quality model should be the last component of the modeling effort. Fig. 7 shows a schematic of the ecological receiving water body model. Typically, the receiving water model is a stand-alone model which receives the inputs from the watershed loading model by the file transfer, or the receiving water body model is a part of the overall modeling package (e.g., HSP-F, BASINS).

In, general, an ecological model is an expanded version of a deterministic water quality model with added flora and fauna components. The first ecological models linked with water quality were models simulating growth of algal population which signifies eutrophication. These models can be steady state such as QUAL 2-E and its derivatives, or dynamic, such as WASP4. Deterministic modeling of aquatic flora is more demanding, more complex, and less reliable. An extensive review of models for receiving waters and wetlands is in a publication by Straškraba listed in the section on "Further Reading."

The key water quality components depicted on Fig. 6 that impact the aquatic flora and fauna are "organic matter" (both particulate and dissolved), "suspended sediment," "nutrients" (nitrogen and phosphorus), "toxic (priority) pollutants," and "dissolved oxygen." Nutrients and toxic compounds in the water column are both particulate (part of suspended sediment) and dissolved. Only dissolved and dissociated nutrients and contaminates are available for uptake by flora and fauna populations.

An important component of the ecological receiving water model is benthic sediment. Legacy pollution is stored in the sediments as well as organic matter that is slowly anaerobically decomposed. The benthic decomposition releases methane, ammonium, and phosphates. The rate of release depends on the redox status of the interstitial sediment–water layer. If this layer is aerobic, oxides reduce the release of phosphorus, and ammonium is oxidized to nitrate and methane to carbon dioxide. DïToro with coworkers proposed a "sediment oxygen demand" (SOD) model that considers oxidation of methane and ammonium in the interstitial layer. Nitrate, on the other hand, because of its concentration gradient, infuses partially back to the lower anoxic layers of the sediment where it is reduced to nitrogen gas. This simultaneous nitrification/denitrification results in a loss of nutrient nitrogen from the water body.

The processes described and simulated by the ecological models are numerous and described throughout the encyclopedia. They include biodegradation of organic matter imposing demand on oxygen resources in the water body, adsorption–desorption equilibriums of toxic compounds with the particulate organic matter and suspended sediment, uptake of dissolved nutrients and toxics by flora and fauna that impacts their growth, growth and dieoff modeling for flora and fauna, dissolved oxygen-balance

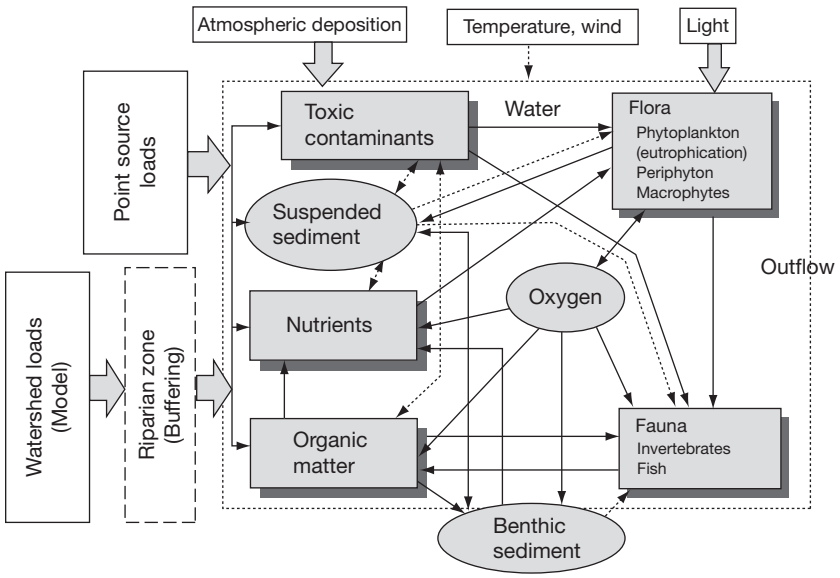

Fig. 7 Schematics of the water–sediment ecological model.

model, settling and scour of cohesive sediments, and nitrification. Many reactions and processes are temperature dependent. There are several links of water quality constituents to the flora and fauna that are not yet quantitatively understood. For example, one of the parameters that most affect the integrity of fish and the macroinvertebrate population is "embeddedness" which describes the amount of clay embedding the gravel and rocks in the bottom substrate. High embeddedness interferes with spawning of fish. This parameter is observational, that is, predictive models were not available at the time of writing this article. It is related to the amount of suspended solids load of the receiving water body and its geomorphic and hydraulic parameters.

Example of Ecologic Water Body Models

AQUATOX is the latest in a series of models developed by Richard Park, starting with the aquatic ecosystem model CLEAN that was subsequently improved and released by the US Environmental Protection Agency in 2005. AQUATOX simulates transfer of biomass, energy, and chemicals from one compartment of the ecosystem to another in daily intervals. The model includes several interrelated components of aquatic ecosystems, including multiple species of phytoplankton, periphyton, and submerged aquatic vegetation, planktonic and benthic algae, forage, game and bottom fish, nutrients and dissolved oxygen, organic and inorganic sediments, and toxic organic chemicals. AQUATOX is now an extension of US EPA's BASINS model that provides linkages to GIS data, HSP-F, and SWAT simulation models.

Regression-Based Statistical Models

Regression allows modeling the dependence of (usually) one response variable on one or more predictor variables. The simple models are based on a stepwise progression of univariate and multivariate analysis. Simple linear regression involves discovering the equation for a line that best fits the given data. These models are easier to test in replication and cross-validation studies. Furthermore, they are less costly to put into practice in predicting and controlling the outcome in the future. In watershed ecological modeling, multiregression models have been used to find relationships between the key chemical (e.g., nitrate concentrations in the receiving water bodies) or biotic (e.g., indices of biotic integrity (IBI), diversity indices) and key watershed stresses such as percent of polluting land uses (imperviousness, agriculture), landscape parameters (slope), habitat quality, etc. A growing number of studies have established relationships between some landscape metric and a biological endpoint.

Principal Component Analysis Multiregression Models

More recent improvements of multiregression statistic such as "principal component analysis" (PCA) can alleviate problems with cross-correlations between multiple inputs. PCA enables grouping of a large number of multiple input parameters that may be cross-correlated into fewer independent variables. The work and paper by Yuan and Norton described extraction of a multi-parameter model from measured biotic integrity (response endpoint) and physical/habitat and chemical stressors (inputs) in watersheds in western Ohio.

As any multiple-regression method, PCA can only analyze single-parameter output matrix, for example, an overall IBI value or a single nutrient concentration versus multiple-parameter input vectors. However, IBI (fish, macroinvertebrates) are composites of and calculated from multiple metrics. Extracting simultaneously knowledge on the metrics relation to the input parameters and to the overall IBI would be very tedious and would have to be done individually, metric by metric.

Canonical Correspondence Analysis

Canonical correspondence analysis (CCA) and similar correspondence analysis models are also special cases of multivariate regression described extensively in a monograph by P. Legendre and L. Legendre (see the section titled "Further Reading"). CCA is a direct gradient technique that can, for example, relate species composition directly and intermediately to the input environmental variables. CCA combines correspondence analysis (CA) with multiple regression, whereby the measured endpoints (dependent parameters) are related to measured environmental, landscape, and habitat stresses as shown in works of Ter Braak and Palmer. CCA and CA are weighted-average ordination techniques that provide simultaneous ordering of sites and species, rapid and simple computation, and very good performance when species have nonlinear and unimodal relationships to environmental gradients. CCA allows simultaneous plotting of output species variables and their site scores in an ordination diagram known as joint plot. Fig. 8 shows the two-axis plot of the 25 variables affecting the IBI in Ohio streams. The plotting of variables when appropriate scaling is used is represented by an arrow (vector) in the direction of the output variables or clusters and the length of the arrow represents a measure of significance of the variable. Furthermore, the direction of the arrows indicates not only how closely the input variable is correlated with the output species variable, but also how closely the input variables are correlated to each other. For two arbitrarily chosen input variables, if their arrow vectors are close to each other or on the same line they are closely correlated. If they are normal (90 degree angle) to each other they are uncorrelated. CCA is a powerful method for the multivariate exploration of large-scale data. CCA preserves the chi-square (χ^2) distance between the rows and columns of the contingency table. Palmer documented that CCA is a weighted-average ordination technique that provides simultaneous ordering

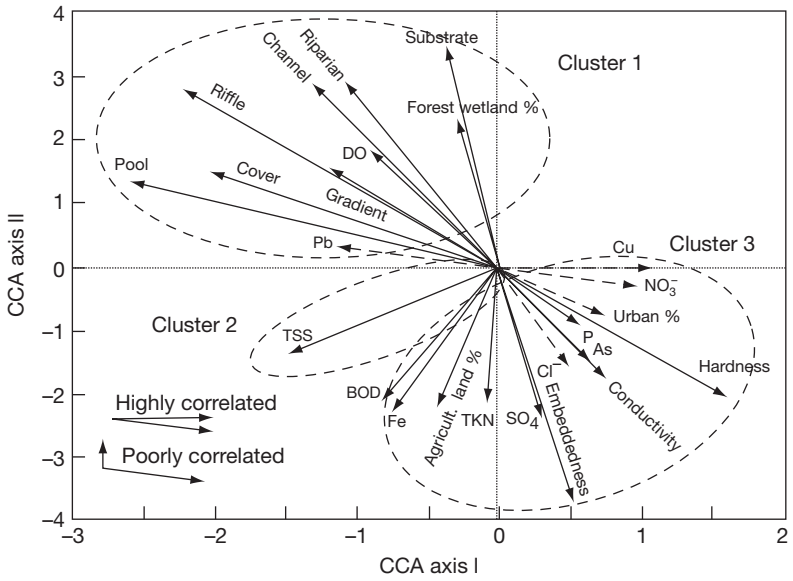

Fig. 8 CCA two-axis plot of the watershed stressors on the metrics of the index of biotic integrity (IBI) derived from the data collected in Ohio. Cluster 1 contains sites with good integrity, Cluster 2 is intermediate, and Cluster 3 has inferior sites. The *arrows* represent the cluster-dominating parameters. The two axes represent about 50% of variability. Replotted from Virani, H., Manolakos, E., and Novotny, V. (2005). Self-organizing feature maps combined with ecological ordination techniques for effective watershed management. *Technical Report # 4*. Boston, MA: Center for Urban Environmental Studies, Northeastern University. http://www.coe.neu.edu/environment.

of sites and species, rapid and simple computation, and very good performance when species have nonlinear and unimodal relationships.

The vectors of stressors on Fig. 8, taken from the work by Virani and coworkers, were combined with the clusters of metrics of the IBI to determine the cluster-dominating parameters. Clustering of metrics was accomplished by "self-organizing mapping" (invented in Finland by Kohonen) by the unsupervised learning of the ANN modeling. It can be seen that the inferior Cluster 3 sites were dominated by pollution caused by pollutants while the superior quality Cluster 1 sites were dominated by habitat parameters.

The explosive growth of information technology has given a major boost to the development and implementation of modeling strategies in watershed management and restoration. GISs are becoming important components of simulation models and decision systems, increasingly being used to store both georeferenced data and associated attributes. GIS technology has played critical roles in all aspects of watershed management, from assessing watershed conditions through modeling impacts of human activities on water quality and to visualizing impacts of alternative management scenarios. GIBSI is one such integrated modeling system comprising of physically based simulation models (hydrological, soil erosion, agricultural–chemical transport, and water quality), a relational database management system and a GIS.

21st Century Developments in Watershed Modeling

Novel techniques such as fuzzy logic, artificial neural networks, genetic algorithms, or ABM are increasingly tested against ecological data. The advantage of these approaches is the self-selection of the critical model inputs based on their data-driven approach.

The "land transformation model" (LTM) described by Pijanowski and coworkers employs GIS and ANNs to describe the influence of landscape changes on ecosystem integrity of large areas. The LTM currently employs a multiplayer perceptron (MLP) neural net topology with one or two hidden layers; each layer has at least the same number of nodes as the number of input vectors. ANNs are used to learn the patterns of development in the region and test the predictive capacity of the model, while GIS is used to develop the spatial, predictor drivers and perform spatial analysis on the results.

Guertin and coworkers have been developing new tools such as global positioning systems (GPS) and remote sensing to inventory and monitor watershed characteristics. The tools ArcPad, developed in the ArcPad environment, implements GISs, mobile computing systems, satellite and aerial images, and network interconnection in the frame of standard ecological methodology. All these tools provide a better understanding of how ecological systems are managed on various levels of the ecological research.

Hybrid ABMs recognize the fact that organisms, including humans, do not behave in an ecological system uniformly *en masse* but their growth, movement, and dieoff are a result of outside stimuli, system thresholds, and their own individualities that have a great degree of randomness. Such models can trace animals, algal species, fish, etc. Because of the large number of individuals (e.g., the

number of cyanobacteria in an algal bloom is 10^4–10^4 mL^{-1}), a "superagent" represents thousands of similar species who are followed by the model throughout their life cycle.

The reasons for the new look at watershed modeling and the new direction of modeling development are

1. Key processes of hydrological and ecological systems to be modeled are nonlinear while the current deterministic watershed models are mostly linear (described by linear differential equations) or the equations that originally were not linear were simplified to linear representations. While a nonlinear watershed model can be deterministic, the nonlinearity complicates the model structure and solutions of the equations.
2. The typical impacts of contaminants and other stressors on flora and fauna have thresholds, that is, a minimal or even beneficial (e.g., nutrients, some metals) concentration effect on the biota below the threshold limit and nonlinear detrimental effect on biota beyond the toxicity threshold. This leads to sudden shifts in species occupying the terrestrial and aquatic environments and clustering. Ecological clustering describes a similar and steadier response (resilience in species population or diversity) of the aquatic and terrestrial biota to smaller perturbation in input stresses. Clusters may also be sensitive to different stressors as shown in Fig. 8 for the metrics of the fish IBI. Most deterministic models, as stated before, are proportional, that is, they result in a corresponding change in populations when any input changes unless a threshold (an "if–then") block is incorporated into the model.
3. Large databases of ecological (e.g., fish, macroinvertebrate, phytoplankton, periphyton numbers, composition, and IBI), chemical, and habitat quality data have been collected by the many agencies. The mega databases containing hundreds of thousands of measurements over larger, often multinational regions cannot be modeled by classic deterministic models that are mostly suitable for smaller watersheds. The models and the relationship must be retrieved by "data mining."
4. Complex interdisciplinary and interuniversity collaborative monitoring and model development projects are being promoted by funding agencies both in the US and European Community. In the US, the National Science Foundation program CLEANER (Collaborative Large-scale Engineering Analysis Network for Environmental Research) and CUAHSI (Consortium of Universities for the Advancement of Hydrologic Sciences, Inc.) plan developing a dual purpose Water and Environmental Research Systems (WATERS) Network which will consist of highly instrumented field facilities for acquisition and analysis of environmental data. The system will also provide environmental cyberinfrastructure for data archiving and networking among community members, and information technology for engineering modeling, analysis, and visualization of data.

Acidification

A Lükewille, Norwegian Institute for Air Research (NILU), Kjeller, Norway
C Alewell, University of Basel, Basel, Switzerland

Introduction

Acidification processes in soils, freshwaters, and oceans are natural processes in geological time frames. However, anthropogenic activities on planet Earth have considerably accelerated acidification by enhancing natural processes as well as by changing dynamics, balances, and pathways.

Acidifying substances can have ecosystem external natural sources such as volcanism, dimethyl sulfide (C_2H_6S) emissions from oceans, or, to a minor extent, sulfide emissions from freshwater wetlands. However, most important are anthropogenic emission sources, mainly fossil fuel combustion processes (e.g., public power plants, industry, and traffic) and agriculture. Emissions of SO_2 and NO_x to the atmosphere increase the natural acidity of rainwater due to the formation of H_2SO_4 and HNO_3, both being strong acids. Furthermore, NH_3 emissions mainly from agricultural activity (volatilization from fertilizers and animal liquid manure) trigger acidification processes in soils. After deposition to ecosystems the conversion of NH_4^+ to either amino acids or to NO_3^- in soils is connected to the production of acidifying H^+ ions.

Since the end of the nineteenth century, industrialized regions of the world have been confronted with the consequences of acidic atmospheric deposition, `acid rain'. There was, and still is, substantial concern about the environmental impacts of air pollution at the local, regional, and global scale. `Acid rain' has threatened vegetation, wildlife, soil biology, and human health, caused damage to materials, and changed the chemistry of soils and waters.

Anthropogenic land-use changes and use of fossil fuels have further led to dramatically increasing atmospheric CO_2 concentrations worldwide. CO_2 is absorbed by oceans and reacts with seawater to form H_2CO_3. Acidification of oceans has adverse effects on marine organisms using $CaCO_3$ in seawater to construct their shells and skeletons (e.g., corals and calcareous phytoplankton).

Acidifying compounds can be carried by winds over long distances and affect ecosystems in pristine areas located hundreds or thousands of kilometers away from pollutant sources. Terrestrial and freshwater ecosystems affected by acidification are usually located in regions where precipitation inputs exceed evapotranspiration, that is, where water percolates through the soil and bedrock.

Acidification is the result of a sensitive (un-)balance between ecosystem internal and external H^+ sources and internal H^+ sinks of different capacities and reaction rates. Acidification processes in terrestrial and aquatic ecosystems can have natural and/or anthropogenic causes; natural internal or external activities can drive these processes in the ecosystem. These processes and their consequences are discussed in this article.

Acidification Processes in Soil and Bedrock

An acid is a compound which has the capability to release H^+ ions (**Box 1**). High concentrations of H^+ (low pH values) can attack natural materials such as limestone, soil minerals, and living tissues or man-made materials or artwork such as cement, concrete, metal surfaces, or sculptures.

Acidification of soils is a natural process on geological timescales. In general, soil acidification can be described as a two-step process:

1. The slow gradual depletion of nutrient cations, that is, the leaching of Ca^{2+}, Mg^{2+}, K^+, bases (HCO_3^-, CO_3^{2-}, etc.).
2. Their replacement by `acidic' $H^+$, Al, Fe, and Mn ions or complexes. While $H^+$ is mainly supplied by internal ecosystem processes or by atmospheric deposition, the `acidic' metal cations are released from the bedrock by mineral weathering.

Intensive agriculture and forestry can lead to high ecosystem internal H^+ production (see below). Many man-made landscapes originate from extensive land-use activities. One example is the heath lands in northwestern Europe, where human pasture, field, and forest

Box 1 H^+ ion concentration or pH The pH scale is logarithmic, neutral water has a pH of 7.0. In the absence of strong acid anions such as SO_4^{2-} and NO_3^-, pure rainwater has a pH of 5.6–5.7. This means that `clean' rain in equilibrium with atmospheric carbon dioxide (CO_2) is acid.

Each whole unit on the pH scale represents a multiplication factor of 10. Thus, water with a pH of 5.0 is 100 times more acidic than water with a pH of 7.0.

 doi:10.1016/B978-0-444-63768-0.00251-1

management over centuries have led to soil acidification and erosion. Plant material was removed by grazing. Sparsely growing trees were used in salt refineries and as firewood. The humus layer including the ground vegetation was removed and interspersed in stables. The mixture of soil and dung was used for manuring fields at locations different from the areas where organic material had been removed.

Application of dung, liquid manure, or compost can compensate (part of) nutrient losses. Agriculture and partly also forestry often apply multinutrient mineral fertilizers containing lime (H^+ buffering $CaCO_3/MgCO_3$).

Most crystalline shields and noncarbonated sedimentary rocks can be considered as being sensitive to acidification by `acid rain'. Areas where acidification has been an issue are major parts of northern Europe, northeastern USA, eastern Canada, and parts of China. Due to rapid increases in acidifying emissions potential future problem areas could be Nigeria, India, Venezuela, Southern Brazil, and Southeast Asia.

Hydrogen Ion (H^+) Sources to Soils

Several biologically mediated processes lead to ecosystem internal H^+ production ($=H^+$ sources), while atmospheric deposition or mineral fertilizer applications are external H^+ sources.

Nutrient cation uptake and the consequences of biomass export

The majority of nutrients needed for plant growth exist as cations (Ca^{2+}, Mg^{2+}, K^+, Na^+, NH_4^+, Fe^+, etc.). Fewer nutrients and their less amounts are taken up as anions (NO_3^-, HPO_3^-, SO_4^{2-}, etc.). The latter implies that vegetation assimilates an excess of non-N nutrient cations over anions. To compensate for electroneutrality, plants release either weak organic acids or H^+ to the soil solution for each positively charged ion taken up by the roots (e.g., one H^+ in the case of K^+ uptake and two H^+ for each Mg^{2+} ion). As a result the pH of the soil solution near the root surface (the rhizosphere) can drop considerably during the growing season. However, if no plant material is removed from the system, nutrient cations return to the soils during decomposition, which is an H^+-consuming process. Thus, without biomass export, plant uptake has no long-term effect on acidification.

In a growing forest the consequence of nutrient cation uptake poses a net production of H^+ in the soil solution over decades, because nutrients can be stored in the biomass and humus layer for a relatively long time periods (Fig. 1). However, organic matter in natural ecosystems is usually exchanged in cycles, that is, when a forest or part of a forest dies, assimilated nutrients are released again via decomposition.

Thus, excess uptake of positively charged nutrients by plants affects soil acidity in the long term only if plant material is removed (Fig. 2). This removal can be driven by harvesting grain crops in agriculture, by removing cattle, which have converted part of the plant material they have eaten into body tissue, or by using timber and firewood in forestry.

Decomposition, root respiration, and the production of carbonic acid

Microbial degradation (decomposition) of organic material and root respiration lead finally to relatively high CO_2 concentrations in the soil air (high CO_2 partial pressure). A greater part of this CO_2 resolves in soil water and forms carbonic acid (Box 2). A consequence is that waters percolating through soils (or bedrocks) contain usually substantially higher concentrations of H_2CO_3 than rainwater or surface waters. The major anion produced by H_2CO_3 dissociation is HCO_3^- (Box 2).

Under natural conditions, the deprotonation of H_2CO_3 is the most significant H^+ source in acidifying soils down to pH $\geq$ 5 (note that the pK_a of H_2CO_3 is 6.46 preventing a decrease of pH below 5). Thus, CO_2 is the major agent of CO_3^{2-}, mineral

Table 1 pK_a values of some important inorganic and organic acids

Acid	*Formula*	pK_{a1}	pK_{a2}	pK_{a3}
Sulfuric acid	H_2SO_4	−3	1.92	
Nitric acid	HNO_3	−1.32		
Oxalic acid	$(COOH)_2$	1.23	4.19	
Phosphoric acid	H_3PO_4	2.12	7.21	12.67
Formic acid	HCOOH	3.75		
Acetic acid	CH_3COOH	4.75		
Carbonic acid	H_2CO_3	6.46	10.25	
Humic and fulvic acids	Complex organic molecules in soil solution and freshwaters; pK_a between 3 and 8			

weathering, and natural acidification (see the section entitled `Hydrogen ion (H^+) sinks'). Below pH 5, production organic acids drive natural acidification.

Soil organic matter and the production of soil organic acids

Soil organic matter consists of carbohydrates, which contain acidic groups (e.g., carboxyl, carbonyl, or hydroxyl). An increase in soil organic matter is in itself a potential source of acidity, as also the application of dung or liquid manure. However, organic matter contains only weak acids, that is, in contrast to strong acids such as H_2SO_4 they do not dissociate completely but release only a portion of their H^+. This proportion varies according to the H^+ concentration in the solution. The lower the pH, the fewer the H^+ ions released (and the more the acid groups protonated).

The deprotonation of dissolved organic acids can be described by dissociation constants (pK_a values). The lower the pK_a, the stronger is the acid (**Table 1**). Dissolved organic acids are ubiquitous in soils and can deprotonize depending on the pH values.

Transport of organic anions causes soil acidification in deeper soil horizons (a process called podsolization) and waters. In general, organic anions can be rapidly degraded to CO_2 by microbial activity and they are important components of groundwater or stream water acidification only in fens or bogs.

H^+ turnover within the nitrogen cycle

The N cycle (**Fig. 3**) is connected to major H^+ turnover processes in soils. Nitrogen is one of the major nutrients, and N turnover exceeds the turnover of all other nutrients and trace elements quantitatively, with the exception of carbon. Because inorganic N can occur as a cation or an anion in soils, the influence on H^+ budgets caused by N turnover is complex (**Box 3**).

Decomposition of N-containing organic material is usually followed by the oxidation of NH_4^+ (nitrification), which is connected to the production of 2 mol of H^+ for each NH_4^+ molecule (**Box 3**).

Nitrogen is an important nutrient as it is part of proteins and nuclides in living organisms. The assimilation of NH_4^+ during the production of amino acids produces 1 mol of H^+ per mole of NH_4.

$$NO_3^- + H^+ \rightarrow N_{org} \quad [4]$$

NH_4^+-uptake and assimilation:

$$NH_4^+ + R-C-OH \rightarrow R-C-NH_2 + H_2O + H^+ \quad [5]$$

Nitrification:

$$NH_4^+ + 2O_2 \rightarrow H_2O + NO_3^- + 2H^+ \quad [6]$$

NH_3-volatilization:

$$NH_4^+ + OH^{-a} \rightarrow NH_3 + H_2O \quad [7]$$

[a]Note that consumption of OH^- is equivalent to production of H^+ and vice versa.

Adding N as NH_4^+ fertilizer will cause acidity ($(NH_4)_2SO_4$ or NH_4NO_3). If the NH_4^+ added is converted to NO_3^- and leached out of the soil, then a very rapid rate of acidification occurs. If plants take up the NH_4^+, then an intermediate rate of acidification occurs. Fertilization with NH_3 can actually be a neutral process (**Box 4**). However, fertilizing NH_3 is bound to extreme rates of volatilization and will increase local and regional N deposition dramatically.

Another way for N into the ecosystem is the fixation of N_2 from the atmosphere by bacteria. While there are only few free living species, most N-fixing bacteria live in a symbiosis with plants, for example, within a legume nodule where the very stabile molecular N_2 is converted into a form available for plants to use. N_2 fixation involves no H^+ transfer. Only after ecosystem internal mineralization of organic N to NH_4^+ or NO_3^-, will fixed N_2 become involved in H^+ transfer. If N accumulates in the ecosystem, it usually does so in soil organic matter. Besides leaching and harvest as an N loss to ecosystems, N can volatilize into the atmosphere as gaseous N compound via denitrification (bound to consumption of H^+) or volatilization (production of H^+).

To conclude, a disruption of the N cycle by either biomass export (harvest) or fertilization has major consequences concerning the H^+ balance and thus the acidification of soils.

Box 4 Acid production due to nitrogen fertilization (negative for H^+ consumption, positive for H^+ production)

Application of ammonium (e,g., as$(NH_4)_2SO_4$)
NH_4^+ uptake and assimilation: $+1$ mol H^+ per NH_4^+
Nitrification: $+2$ H^+ mol H^+ per NH_4^+
If produced NO_3 is taken up by plant: -1 mol H^+ per NO_3^-
Application of NH_4NO_3
NH_4^+ uptake and assimilation: $+1$ mol H^+ per NH_4^+
Nitrification: $+2$ H^+ mol H^+ per NH_4^+
If produced or applied NO_3 is taken up by plant: -1 mol H^+ per NO_3^-
Application of Ammonia (NH_3)
Dissolution (re-volatilization): -1 mol H^+ per NH_3
Nitrification of produced NH_4^+: $+2$ H^+ mol H^+ per NH_4^+
If produced NO_3^- is taken up by plant: -1 mol H^+ per NO_3^-

Oxidation of reduced compounds

Increasing water saturation promotes anoxic conditions in soils, and microorganisms can use NO_3^-, SO_4^{2-}, Fe, Mn, and CO_2 as electron acceptors instead of O_2. During such reduction processes, H^+ is consumed and alkalinity is generated. Up to 70% of the impacted acidity can be neutralized in forested freshwater wetlands by Fe and SO_4^{2-} reduction alone.

Conversely, during the oxidation process of (prior) reduced compounds, H^+ is released. For example, if soils or waters contain a substantial amount of reduced Fe and have a low buffering capacity, the pH of the solution may fall from a value of about 6–7 to 2–3 caused by the oxidation of formerly reduced Fe compounds. Concerning SO_4^{2-} reduction, FeS and FeS_2 are the most important products. If conditions stay anoxic over a longer time period, reduced S species might be incorporated into the organic substance and thus stored long term, resulting in an equally long-term alkalinity generation.

Drainage of valley floors and thus exposure to air (O_3) causes reduced compounds to re-oxidize and release substantial amounts of acid. In contrast, wetland soils and riparian zones may act as long-term sinks for deposited H^+, SO_4^{2-}, and NO_3^-, depending on soil characteristics, climatic parameters, and the composition of the soil microbiota.

Atmospheric deposition of acidifying compounds

Acidifying pollutants are deposited into ecosystems as follows:

1. directly as gases and aerosols to vegetation or other surfaces (dry deposition, especially NH_4^+);
2. as rain or snow (wet deposition); and
3. via impaction and sedimentation of fog or droplets to various surfaces (occult deposition).

High acidification rates occur in forested coniferous sites (compared to deciduous sites) due to more efficient scavenging of acidifying pollutants from the atmosphere especially during wintertime. The acidification rate caused by acid deposition is in the range 0.8–7 kmol ha^{-1} yr^{-1} due to the combined effects of HNO_3, H_2SO_4, HCl, and NH_4 deposition.

Hydrogen Ion (H^+) Sinks

In natural ecosystems weathering of minerals counteracts acidification, that is, acts as H^+ sink. Thus, main sinks in ecosystems are geochemical buffering reactions in soils and bedrocks, and only a minor fraction is buffered in waters. The so-called acid neutralization capacity in soils and bedrock (ANC_{solid}) can be defined as the sum of all unprotonated buffering substances. Thus, acidification is always accompanied by a decrease in ANC_{solid} over time. It is important to note that this decrease in ANC_{solid} is irreversible (against the background of our human calculation of times).

Besides the capacity, that is, the total buffering pool of a soil or bedrock, the geochemical reaction rate of the buffering substances are a crucial factor determining how much of the acidifying compounds are neutralized over a certain period. This rate can, for example, be estimated as kilomole charge per hectare per year ($kmol_c$ ha^{-1} yr^{-1}).

Ecologically effective are, last but not the least, the concentrations of certain ions in the soil/bedrock solution or freshwaters. Such intensity parameters can be measured as concentrations (e.g., pH, Mg^{2+}, or Al^{3+}; in mol_c per liter) or as base cation saturation of exchanger complexes in soils (in %).

In theory, many of the geochemical buffering processes are equilibrium reactions. However, the loss of ions with percolating water leads to permanent disequilibria. The latter has important implications for the expected reversibility of soil acidification under decreasing deposition regime. In North America and Europe, soil acidification is irreversible as long as the supply of weathering products from bedrock is smaller than the loss of weathering products due to the combined effects of natural and anthropogenic acidification processes. It is highly unlikely that the latter two will become smaller than the supply by weathering products because natural acidification processes already exceed buffering by weathering processes in most systems.

Box 5 Dissolution of calcium carbonate

$$CaCO_3 + H^+ \Rightarrow HCO_3^- + Ca_2^+ \quad pK_{a1} = 6.46$$
$$HCO_3^- + H^+ \Rightarrow CO_2 + H_2O \; pK_{a2} = 10.25$$

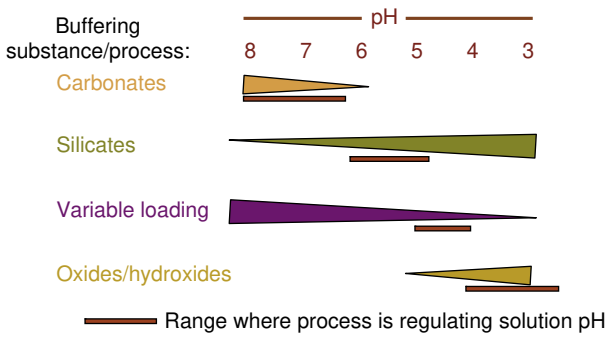

Fig. 4 Buffering systems.

Carbonate dissolution

The H^+ ions are buffered via the dissolution of Ca(or Mg)CO_3 in soils and bedrock (**Box 5**) as long as soils or bedrocks contain accessible carbonate.

The pH values in the soil solution are quasiconstant and stay above pH 6.2 (**Fig. 4**). The buffering rate is high, for example, 2 $kmol_c\ ha^{-1}\ yr^{-1}$ at a water percolation rate of 200 $l\ m^{-2}$ and a CO_2 partial pressure of 0.3 kPa CO_2. The CO_3^{2-} buffering is usually an irreversible one-way reaction resulting in the loss of Ca^{2+} and HCO_3^- from soils and bedrock.

Silicate weathering

The H^+ ions are buffered by the (relatively slow) weathering of primary silicate minerals (e.g., **Box 6**). The soil solution stays in the pH range of 6.2–5.0 (**Fig. 4**), and the rate lies between 0.2 and 2 $kmol_c\ ha^{-1}\ yr^{-1}$. Compared to the accumulated H^+ production or input rates in ecosystems affected by acid deposition (see the section titled `Hydrogen ion (H^+) sources in soils') this rate is rather low.

Silicate weathering results usually in the irreversible destruction of clay minerals, the release of exchangeable cations, and Al ions to the soil solution. Dominant anions in the solution are HCO_3^- and organic anions.

Further, some clay mineral crystals can dissolve completely, leading to high Al concentrations in the solution (**Box 7**).

Exchanger with variable loading

The H^+ ions exchange against base cations bound to clay minerals and oxides or organic matter (pH range 5–4.2; **Fig. 4**; **Box 8**).

Exchangeable cations are lost with the percolating water. The buffering capacity depends on the absolute cation exchange capacity and on the percentage of saturation of the exchanger complex with base cations. The buffering rate is very high (fast reaction). The Ca^{2+} ion is usually the dominant cation. In systems influenced by `acid rain', HCO_3^- is replaced by the anions SO_4^{2+} and NO_3^-. In naturally acidic ecosystems, for example, in bogs, organic anions are dominant.

Amorphous hydroxides or oxides of aluminum and iron

The so-called Al and Fe buffer ranges can be described by the equilibrium reactions shown in **Box 9**.

The H^+ ions are bound in water (H_2O), and soluble Al (or Fe) ions (ion complexes) emerge in the soil solution. The neutralization capacity depends on the reactive amount of Al or Fe (hydr)oxides. Buffering rates are high, and Al ions (or Fe ions) become the predominant cations in the soil solution. In ecosystems affected by acid deposition, SO_4^{2-} and NO_3^- are the predominant anions.

Acidification of Groundwater, Freshwaters, and Oceans

Acidification and Buffering in Ground- and Freshwaters

In the absence of strong acid anions such as SO_4^{2-} and NO_3^-, pure rainwater has a pH of 5.6–5.7. The latter is caused by the equilibrium with atmospheric CO_2 (see the section titled `Introduction').

Box 6 Weathering of primary silicate minerals

$$-\mathrm{SiOM} + \mathrm{H^+} \Rightarrow -(\mathrm{SiOH}) + \mathrm{M^+}\,(\mathrm{M^+} = \text{exchange ablemetal cation})$$

Box 7 Complete dissolution of clay mineral crystals

$$\underset{\text{(feldspar)}}{\mathrm{KAl_3Si_3O_{10}(OH)_2}} + 10\mathrm{H^+} \Rightarrow \mathrm{K^+} + 3\underset{\text{(silica)}}{\mathrm{Al^{3+}}} + 3\mathrm{H_4SiO_4}$$

Box 8 Exchange of H^+ ions against base cations (clay minerals, oxides, organic matter)

$$\mathrm{M^+(soil)} + \mathrm{H^+} \leftrightarrow \mathrm{H^+(soil)} + \mathrm{M^+}$$
$$(\mathrm{M^+} = \text{exchangeable metal cation})$$

or

$$\mathrm{R-COO-M^+} + \mathrm{H^+} \leftrightarrow \mathrm{R-COOH} + \mathrm{M^+}$$
$$(\mathrm{p}K_\mathrm{a}\text{dependent; p}K_\mathrm{a}3-8)$$

Box 9 Aluminum hydroxides, iron oxides and hydroxides

$$\mathrm{Al(OH)_3} + 3\mathrm{H^+} \leftrightarrow \mathrm{Al^{3+}} + 3\mathrm{H_2O} \quad \text{pH range : } 4.2-3.2$$
$$\mathrm{FeOOH} + 3\mathrm{H^+} \leftrightarrow \mathrm{Fe^{3+}} + 2\mathrm{H_2O} \quad \text{pH range :} < 3.2$$

Box 10 Acid neutralization capacity in freshwaters – ANC_{aqua}

$$\mathrm{ANC_{aqua}} = 2\mathrm{CO_3^{2-}} + \mathrm{HCO_3^-} + \mathrm{OH^-} - \mathrm{H^+} - \mathrm{Al^{3+}} - \mathrm{Al(OH_x^{y+})}$$

Constraint of electroneutrality:

$$\mathrm{HCO_3^-} + \mathrm{OH^-} + \mathrm{Cl^-} + \mathrm{NO_3^-} + 2\mathrm{SO_4^{2-}} = \mathrm{H^+} + \mathrm{Al^{3+}} + \mathrm{Al(OH_x^{y+})} + 2\mathrm{Ca^{2+}} + 2\mathrm{Mg^{2+}} + \mathrm{K^+} + \mathrm{Na^+}$$

or:

$$\mathrm{HCO_3^-} + \mathrm{OH^-} - \mathrm{H^-} - \mathrm{Al^{3+}} - \mathrm{Al(OH_x^{y+})} = 2\mathrm{Ca^{2+}} + 2\mathrm{Mg^{2+}} + \mathrm{K^+} + \mathrm{Na^+} - \mathrm{Cl^-} - \mathrm{NO_3^-} - 2\mathrm{SO_4^{2-}}$$

Reuss' and Johnson's definition of ANC_{aqua} (easy to measure):

$$\mathrm{ANC_{aqua}} = 2\mathrm{Ca^{2+}} + 2\mathrm{Mg^{2+}} + \mathrm{K^+} + \mathrm{Na^+} - \mathrm{Cl^-} - \mathrm{NO_3^-} - 2\mathrm{SO_4^{2-}}$$

A major part of rainwater reaching the groundwater and/or surface waters percolates through soils and bedrock. A small portion of (acidified) rainwater is directly deposited into lakes and streams. Areas highly affected by water acidification are small watersheds with shallow soil cover, rapid flushing rates, and slowly weathering bedrock, such as granite and quartzite. These types of soil and bedrock do not contain unstable or readily soluble minerals such as $CaCO_3$ and $MgCO_3$, which are very effective in neutralizing the acids (see the section titled `Carbonate dissolution').

The natural buffering system in surface waters is provided by HCO_3^-, released by the weathering of soil/bedrock minerals, and by the balance between dissolved atmospheric CO_2 and CO_2 from respiration/decomposition processes (**Box 2**). As for soils, freshwater and groundwater acidification can be defined as a decrease in acid neutralization capacity (ANC_{aqua}). Because of the electroneutrality constraint in solutions, ANC_{aqua} can also be defined as the sum of all `base' cations minus the sum of all `strong' acid anions (**Box 10**).

In acidified surface waters, the pH and/or ANC_{aqua} have fallen significantly below pre-industrial levels ($ANC_{aqua} < 0.10$ $mmol_c$ of HCO_3^- per liter). Elevated levels of Al compounds and low pH values usually accompany low ANC_{aqua}. One visible sign of acidification is that the water becomes clearer because humus substances that normally color the water precipitate out together with Al (or Fe) compounds. Biomass production (algae and bacteria) and decomposition slow down, and organic matter such as leaves often collect on the lake or riverbeds.

Acidification of Oceans

Of all CO_2 emitted globally due to land-use changes, fossil fuel burning, and cement production in the past 200 years, only about half has remained in the atmosphere. Besides terrestrial plants, oceans have taken up considerable parts of it. A concern of many scientists is that rising levels of atmospheric CO_2 are causing an increasing acidification of oceans. The latter is due to the equilibrium between atmospheric CO_2 and the CO_2 dissolved in seawater. Dissolved CO_2 forms H_2CO_3 (**Box 2**), leading to increasing acidity. H^+ reacts with the CO_3^{2-} ion to form HCO_3^-, that is, there is also a carbonate buffer in seawater.

CO_2 is absorbed at the sea surface, which is thus most affected. Marine organisms that produce $CaCO_3$ shells live above the so-called `saturation horizon', where $CaCO_3$ does not readily dissolve. Increasing CO_2 concentrations decrease the saturation state of $CaCO_3$ making structures of $CaCO_3$ vulnerable to dissolution.

Organisms containing shells or plates of $CaCO_3$ fall to the sea floor when they die. $CaCO_3$ is thus abundant in sediments and interacts with seawater. Slow mixing throughout the oceans, mixing necessary to bring up compounds from the oceans' sediments to buffer the increased ocean surface chemistry, causes a delay in $CaCO_3$ dissolution. Warming of oceans as a consequence of global warming may even further reduce this mixing rate with deeper waters.

Consequences of Acidification

The effects of natural acidification processes and the acceleration by human land use and `acid rain' are not the main focus of this article. However, the most serious consequences are summarized in the following sections.

With decreasing acid deposition since the 1980s in Europe and North America, the impacts of acidification and eutrophication are foreseen to show a decrease, as a consequence of biodiversity showing some recovery. However, a full return to pre-pollution conditions is not to be expected, because of changes in competition patterns and distribution of species. The introduction – whether voluntary or accidental – of species alien to European ecosystems or to other regions of Europe represents an increasing risk, favored by globalization of trade, exchange, and transports. Thus, even if chemical parameters (e.g., nutrient status, acidity) return to pre-pollution condition, indigenous species might not be successful in competing with well-established alien species.

Consequences of Soil Acidification

The monitoring of soil acidification induced by `acid rain' is difficult because of the long time frames involved and the parallel development of natural acidification processes. Both natural and anthropogenic-driven soil acidification can result in extremely low base saturation, low pH, and low ANC_{aqua}. Anthropogenic soil acidification due to `acid rain' is characterized by high soil solution concentrations of SO_4^{2-} and NO_3^-. In contrast, the anions responsible for H^+ and aluminum leaching during natural acidification processes are organic anions and HCO_3^-. High N and/or SO_4^{2-} deposition have resulted in N and SO_4^{2-} accumulation in forest soils, decreases in forest soil pH, and leaching of base cations.

Despite the lack of evidence for direct effects, there is no doubt that 'acid rain' has complex negative effects on forest ecosystems in central Europe and northeastern America. More recently, serious effects have also been recognized in China, particularly in the industrialized regions such as the Sichuan Province now exploiting nearby extensive coal deposits of high S content.

In many areas, leaching of base cations from soils has led to nutrient deficiency, especially of Mg^{2+} and K^+. Today, many forest soils of central Europe have low base saturation and low pools of exchangeable nutrient cations. The Mg-deficient nutrition of trees (yellowing of needles) is a widespread phenomenon and has been related to decreased concentrations of Mg^{2+} in the soil solution.

Besides loss of nutrient cations, the buffering of H^+ from deposition causes increased levels of Al in soil solutions, which might have detrimental effects on tree root growth and nutrient uptake. In water culture experiments, the ratio of Ca/Al and Mg/Al, rather than the Al concentration itself, largely determines the deleterious effect on roots.

Consequences of Freshwater Acidification

Acidification is largely a problem in naturally nutrient-poor lakes and streams. Some organisms are directly sensitive to low pH values, for example, shell-bearing organisms such as mollusks, mussels, and many crustaceans, including crayfish (dissolution of $CaCO_3$). Acidification and the elevated levels of dissolved Al ions in water can have direct harmful effects on the eggs and fry of many fish species (e.g., salmons, trout, and perches). Further, the number of phytoplankton species falls dramatically in acidified waters.

Al compounds can precipitate in the gills of adult fish and lead to suffocation (mainly `mechanical' effect). The disappearance of fish species or other animals can have an influence on the food chains in a river or lake, and can thus have dramatic effects on the ecosystem structure as a whole. Fish-eating birds, such as divers, merganser, and osprey, are put under pressure, while insect-eaters, such as goldeneye, are favored.

Another effect can be shifts in plant communities. Certain mosses are favored by acidification. In nutrient-poor lakes, plant species such as shore weed or water lobelia, living in shallow waters close to lake shores, are overgrown by bog mosses.

Last but not the least, `acid rain' can also have negative effects on human health, either directly (e.g., SO_2) or indirectly through ground-level ozone formation followed by NO_x emissions. Further, the acidification of groundwater and drinking water supplies can be a direct human health hazard through high NO_3^- concentrations or indirectly through metals (Al, Cd) released from the soils and/or water pipes.

Consequences of Eutrophication in Ecosystems

Atmospheric N deposition very often leads to an excess of N in terrestrial and aquatic ecosystems, leading in general to increased growth. However, imbalances can be the consequence: tree crowns can grow faster than the root systems (increased risk of desiccation). Furthermore, depletion of other nutrients such as Mg^{2+} or phosphorous in acidified soils can counteract plant growth enhanced by excess N supply or can lead to nutrient imbalances and plant instability in spite of enhanced growth. Excess N input in forest ecosystems can change the occurrence of mycorrhizal fungi living in symbiosis with trees and support nutrient uptake by plant roots.

In some relatively nutrient-rich freshwaters atmospheric N deposition can contribute to eutrophication. However, usually phosphorus is the nutrient that limits growth in freshwater ecosystems.

Consequences of Ocean Acidification

Ocean acidification could have profound effects on ocean ecosystems' structure, food chains, population dynamics, and nutrient cycles. It is so far unknown how, for example, tropical and subtropical coral reefs and fisheries will respond to this man-made acidification. Corals, calcareous phytoplankton, mollusks, and other marine organisms use $CaCO_3$ in seawater to construct their shells and skeletons. Some shallow-water animals, which play a vital role in releasing nutrients from sediments, also calcify. In a more acidic environment, it becomes difficult to secrete $CaCO_3$, leading to slower growth rates and more fragile skeletal structures. How this will affect ecosystem community structure and the marine food web is unclear at present.

Allometric Theory: Extrapolations From Individuals to Ecosystems

George B Arhonditsis, Yuko Shimoda, and Noreen E Kelly, University of Toronto Scarborough, Toronto, ON, Canada

Abbreviations

AIC	Akaike information criterion
c	Abundance of consumers/predators
E	Activation energy, eV (electron volts, 1 eV = 23.06 kcal mol^{-1}, = 96.49 kJ mol^{-1})
ES	Ecological stoichiometry
F	Consumer per capita feeding rate
hr	Hour
h	Handling time that predators require to digest resources, s (expressed in seconds)
I	Individual metabolic rate
ind	Individual organisms
k	Boltzmann constant, 8.62×10^{-5} eV/K (see also activation energy)
KH_p	Parameter that represent half saturation constant for phosphorus uptake by primary producer, μmol P L^{-1}
M, m	Mass of organisms, g or kg
MTE	Metabolic theory of ecology
N	Resource abundance in individuals
NH	Parameter represent that half saturation constant for nitrate uptake by primary producer, μmol N L^{-1}
PPMR	Predator-prey mass ratio
QP_{max}	Maximum internal phosphate cell quota, fmol P $cell^{-1}$
QP_{min}	Minimum internal phosphate cell quota, fmol P $cell^{-1}$
R	Rate of metabolism, such as rate of respiration, excretion
r	Abundance of resource/prey
SA	Surface area of microorganisms cell, μm^2
$SA{:}V$	Surface area to cell volume ratio of individual organism's cell, μm^{-1}
T	Temperature, K
V	Body size as volume, cell volume μm^3
VP_{max}	Maximum phosphorus uptake rate by primary producer, μg P μm^{-3} h^{-1}
W	Organism body size, such as body mass, weight, volume, body length or height and surface area (SA)
wR	Mass specific rate of metabolism
Y	Biological attributes, such as growth rate, metabolic rate, physiological rate
μ_{max}	Parameter that represent maximum growth rate of organisms, day^{-1}

Glossary

Ecosystem model A mathematical representation of the interactions among biological, chemical and physical components in an ecological system.

Epilimnion The upper most layer of lakes when the difference in density due to the warmer surface water create stratification in the water column.

Eukaryotes Eukaryotes whose cells have a nucleus and organelles enclosed within membrane, whereas prokaryotes are unicellular organisms with no membrane-bound organelles.

Functional groups A specific group of organisms (or chemical compounds) that share similar attributes.

Half saturation constant for nutrient uptake The nutrient concentration at which uptake rate of a nutrient is half of the maximum potential rate.

Harmful algal blooms Excessive growth of phytoplankton bloom in aquatic environments dominated by species that cause toxic or harmful effects on people, fish, shellfish, marine mammals and birds.

Homeotherm An organism that maintains their thermal homeostasis. Some rely on internal metabolic processes as a heat source (endotherms), while others maintain their body temperature by behavioral thermoregulation.

Kleiber's rule A rule defining that organism's metabolic rates scale to the ¾ power of the animal's mass.

Lotka-Volterra models A model that describes predator-prey relationships with a pair of differential equations as function of growth rate of prey, mortality of prey and predator, predator's search/handling efficiency of prey and time.

Meroplankton Organisms that spend only part of their life (early stage, larval) drifting in pelagic environment and spend their adult life in the benthic community.

Parameterization The process of deciding and defining the parameters necessary for a defensible specification of a model.

Poikilotherm An organism whose internal temperature varies considerably as a consequence of variation in the ambient environmental temperature. Many ectotherms, organisms in which internal physiological sources of heat are of relatively limited importance in controlling body temperature. Such organisms rely on environmental heat sources, which permit them to operate at optimal metabolic rates.

Ecological stoichiometry The balance of multiple chemical elements (mainly carbon, nitrogen, phosphorus) and energy in ecological interactions. It particularly deals with the disequilibrium existing between the nutrient requirements of a consumer and the nutrient availability present in their resources (either mineral for autotrophic organisms or organic for heterotrophic organisms).

 doi:10.1016/B978-0-12-409548-9.10576-7

Occam's Razor Occam's (or Ockham's) razor is a principle attributed to the 14th century logician and Franciscan friar William of Ockham. The most useful statement of the principle for scientists is "when you have two competing theories that make exactly the same predictions, the simpler one is the better."

Fatty acids A fatty acid is a long hydrocarbon chain with variant length and degrees of unsaturation that terminates with a carboxylic acid group. Fatty acids with more than one double bonds are referred to as polyunsaturated fatty acids (PUFA); PUFAs with more than 20 carbons are referred to as highly unsaturated fatty acids (HUFAs). HUFAs are nutritionally critical molecules that animals cannot synthesize but can obtain them through intake of plants.

Introduction

Allometry, also known as biological scaling, describes the dependence of a biological variable on an organism's body mass, size, or shape. Originally used to describe the scaling relationships between body size and metabolic rates, allometric relationships can be expanded into a broader context to include morphological (e.g., total body length with body mass of invertebrates), physiological (e.g., metabolic rates with body size among mammals) or ecological traits (e.g., egg size with survival rates of immature stages in butterflies). Allometry offers the foundation for the development of scaling relationships that capture the variation in physiological mechanisms, individual behaviors such as locomotion or dispersal, as well as spatial distributions, population dynamics, and evolutionary patterns. In principle, allometric relationships stipulate that an easily identifiable predictor, the body size, can provide a reliable estimate of a given biological parameter (Fig. 1).

Most allometric relationships are presented as a simple power function of the form:

$$Y = aW^b \tag{1}$$

where W is the organism's body size, Y is a biological attribute, a and b are the experimentally derived constant and scaling exponent, respectively. Often log-log transformation is used to linearize the relationships, and empirically derive values for the coefficients. The logarithmic-scaled equation is thus:

$$\log Y = \log(a) + b \bullet \log W \tag{2}$$

Numerous allometric equations have been developed to estimate biological attributes as a function of body mass/size, or other morphological features, such as length (L), volume (V), surface area (SA), carbon content, or length: height ratio. The selection of the predictor is generally limited by its measurement precision and practicability for a particular organism. For example, the cell volume of microalgae is relatively easy to measure but the vacuoles may occupy most of the cell volume, thereby introducing considerable discrepancy from the actual algal biomass. While fresh biomass is the critical input for the majority of existing

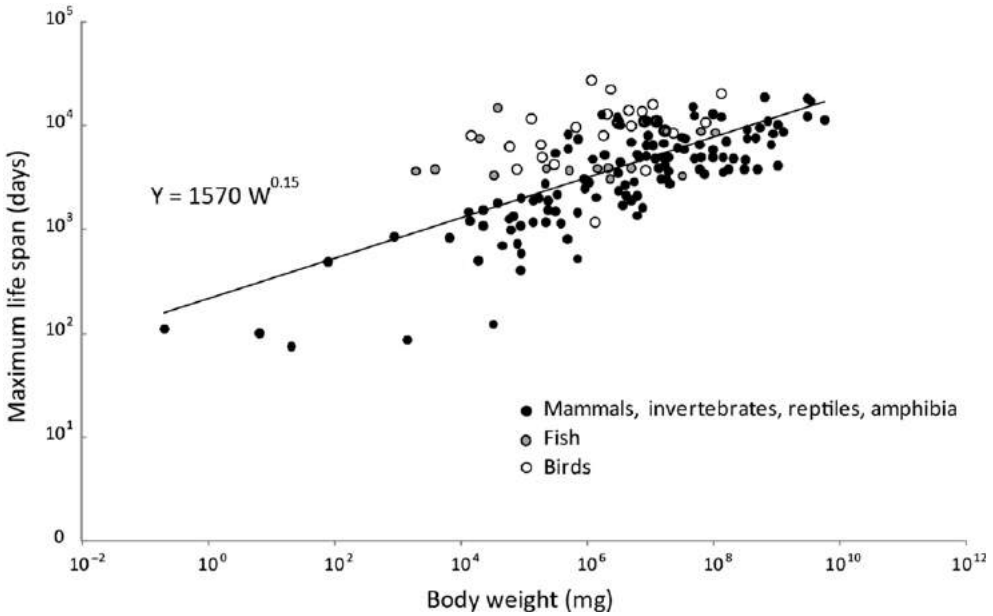

Fig. 1 Maximum life span for a range of animals against adult body weight (mg). Modified with permission from Blueweiss, L., Fox, H., Kudzma, V., Nakashima, D., Peters, R., Sams, S., (1978). Relationships between body size and some life history parameters. *Oecologia* 37, 257–272. https://doi.org/10.1007/BF00344996.

allometric equations, it is often difficult to obtain reliable measurements for many microorganisms. Other allometric relationships are based on the length as a proxy variable of the body size to estimate other morphological characteristics (e.g., stem basal diameter for the below-above ground tree biomass, the length-weight relationships of zooplankton) or organismal size-at-age (e.g., size at maturity). Surface area is often used in the allometric equations of nutrient kinetics and toxicology to quantify the transport of compounds through the cell membrane. In some cases, the ratio to the cell volume (*SA*:*V*) has also been used to account for the effects of morphological traits of unicellular organisms. For example, the uptake of chemical compound is largely regulated by the number of uptake receptors at the cell membrane relative to its cell volume, i.e., species with higher *SA*:*V* demonstrate higher nutrient uptake rates and therefore obtain an advantage when competing for a limiting resource.

Examples of Allometric Principles

Metabolism collectively represents the set of processes in living cells by which energy is provided for vital processes and new material is assimilated in order to maintain life. Metabolism thus determines the demands that organisms place on their environment for all resources. The overall rate of these metabolic processes (often measured as respiration rate; **Table 1**) sets important constraints on the allocation of resources to all components of fitness. Different facets of metabolic activity can be expressed through this strategy. The most common is the basal metabolic rate, which reflects the rate of a fasting, inactive individual; the field metabolic rate characterizing the rate of a free-living individual in its environment; the maximal metabolic rate describing the metabolism of an individual at maximum aerobic activity.

Early research demonstrated that metabolic rate (R, in Watts) could be predicted from fresh body mass (W, in kg) for vastly different groups of organisms (**Fig. 2**A). The fitted allometric relationships for each group all scaled to the ¾ power:

$$R_{homeotherms} = 4.1W^{0.751} \tag{3}$$

$$R_{poikilotherms} = 0.14W^{0.751} \tag{4}$$

$$R_{unicells} = 0.018W^{0.751} \tag{5}$$

The common power in Eqs. **(3)**–**(5)** implies that the allocation of energy and materials to metabolism follow a similar pattern across most organisms. The positive exponent demonstrates that larger organisms within each metabolic class have a higher metabolic rate than do smaller organisms, while a value <1 predicts that metabolic rate rise more slowly as the body size increases. Adjusting these allometric relationships to be expressed as *mass-specific* metabolic rates (wR, in Watts kg^{-1}) yields scaling exponents of the $-¼$ power:

$$\begin{aligned} wR_{homeotherms} &= R_{homeotherms}/W \\ &= 4.1W^{0.751-1} \\ &= 4.1W^{-0.249} \end{aligned} \tag{6}$$

$$wR_{poikilotherms} = 0.14W^{-0.249} \tag{7}$$

$$wR_{unicells} = 0.018W^{-0.249} \tag{8}$$

Thus, the rate of energy expenditure per unit mass declines with increasing body size, while the cost of maintaining a given biomass is less for larger animals than smaller ones.

Subsequent research using this simple allometric equation has been successful in describing the relationship between metabolic rate and body mass for diverse groups of organisms, all characterized by scaling exponents of $\sim$¾. This recurring relationship was adopted as *Kleiber's rule* and its wide applicability suggested that it may be a rare example of a general biological law. However, despite the presence of plausible theoretical explanations for its ubiquity (e.g., processes that control chemical reactions within cells and/or designs of resource distribution networks with functional similarities to all organisms), the debate whether the true value of the scaling exponent b should be set at ¾, ⅔, or whether it is variable, has continued. For example, a recent survey of 642 published regressions of (laboratory-measured) metabolic rates in marine invertebrates found a wide range of scaling exponents for metabolic rates (**Fig. 2**B), with similar species exhibiting scaling exponent values from 0.75 up to (or greater than) 0.9. This finding suggests that the ¾ power law is not universal. While *Kleiber's rule* is a valid statistical generalization, it is important to note that $b = ¾$ is an approximation, rather than the "true" value of the scaling exponent for all allometric equations of metabolic rates.

As metabolism represents the total energetic cost of an organism's biological processes, size-related changes in most other biological functions should parallel the scaling of metabolism. To illustrate this scaling for physiological, morphological, and life-history rates, a series of allometric relationships is presented in **Table 1** for various groups of marine and freshwater zooplankton. Zooplankton is considered as an ideal organism to develop allometric relationships, due to their numerical abundance and ease of sampling in aquatic environments, while their relatively short generation times are conducive to laboratory studies. Furthermore, the trophic linkages between primary producers and zooplankton are arguably the most important in aquatic food webs, as their interactions control the flow of energy to higher trophic levels.

Grazing (ingestion) sets an upper limit to all other physiological rates, and is one of the most significant interactions between an organism and the surrounding environment. Zooplankton grazing can exert significant control on phytoplankton biomass and

Beyond the "3/4-power law": Variation in the intra- and interspecific scaling of metabolic rate in animals. *Biol. Rev.* **80**, 611–662. https://doi.org/10.1017/S1464793105006834.

species composition. The allometric scaling of ingestion (measured as ingestion, filtration, or clearance rates) with zooplankton body size (measured as body length) suggests that larger zooplankton graze particles at a higher rate than smaller ones (**Table 1**). Similarly, a unit increase in zooplankton body size results in 2.4–2.8 increase in ingestion rate (**Table 1**), and therefore larger zooplankton have a greater impact on energy transfer through the food web.

In aquatic ecosystems, zooplankton regenerate mineral nutrients (e.g., nitrogen, phosphorus) via their excretion; thus, changes in the rate of materials recycled can directly impact the abundance and composition of primary producers. Body size has a large effect on excretion rates in zooplankton, where scaling exponents <1 indicate that larger zooplankton excrete at a lower rate for their size than smaller taxa (Table 1). The less than proportional increase in excretion rate is linked to metabolism. Interestingly, the scaling exponents can be higher or lower than ¾ depending on the nutrient recycled, as nitrogen excretion rates scale to the 0.67–0.84 power of body mass, while phosphorus excretion rates can be slightly lower ($b = 0.54$–0.70) (Table 1).

The measurement of zooplankton biomass, together with the productivity assessment, is an important component for estimating standing stocks, as well as community structure and dynamics. Only two quantities are required to calculate the production of a population, since multiplying the number of individuals by their average mass yields an estimate of the total population biomass. The production rate is then the amount of biomass accumulated by a population per unit of time. The most common way to estimate average mass of zooplankton involves prediction of animal weight from body length with allometric equations (Table 1). These relationships suggest that there is a greater than proportional increase in zooplankton weight with a corresponding increase in body size. The variation (in scaling exponents) among allometric regressions may relate to environment influences at the study site in question, such as latitude, temperature, and/or food availability.

Body size imposes constraints on the life-history (e.g., growth, fecundity, survival) of organisms. Quantifying the variation of the relationship between life-history processes and body size can offer insights into the natural selection pressures. For example, examining rates of fecundity, mortality, and developmental time as a function of (adult) body mass is critical for understanding zooplankton evolution. Generation time (time span from egg to maturity) is a critical determinant of the rate of population growth in zooplankton, and scales positively to body mass close to the ¼ power (Table 1).Weight-specific fecundity rates scale close to the $-¼$ power for both broadcast and sac-spawning marine copepods, although the intercepts differ, suggesting that weight-specific fecundities are $\sim$2.5 times greater for broadcast spawners than sac-spawners, which in turn may relate to their different life-cycle strategies (Table 1). Maximum specific growth rates appear to scale to the $-¼$ power, declining with increasing body volume across a wide range of marine and freshwater zooplankton groups (e.g., dinoflagellates, other flagellates, ciliates, rotifers, meroplankton larvae, cladocerans, and copepods), suggesting that small zooplankton have higher mass-specific metabolic rates and grow faster than large ones (Table 1).

The predictive power of scaling laws to life-history processes depends on whether natural selection can alter the scaling exponent value. If the scaling exponent varies with environment, then this reflects the strong role of selection on this exponent. Returning to the large survey of allometric scaling exponents presented earlier, pelagic (open-water) species had significantly greater mean scaling exponents ($b = 0.947$) than those of nonpelagic species ($b = 0.744$) (Fig. 2B). While sampling error can explain some of this variation, it may also reflect real biological differences in metabolic rates across taxa with diverse body characteristics and widely separated phylogenies.

Recent Advances in the Application of Allometric Principles

Metabolic Theory of Ecology

Metabolic and other process rates are strongly affected by both body size and temperature. More recent theoretical advances have combined first principles of allometry and biochemical kinetics to develop the metabolic theory of ecology (MTE). MTE uses scaling functions to incorporate the effects of body size and temperature on individual metabolic rates, which in turn modulate the performance of individual organisms and subsequently the ecology of populations, communities, and ecosystems. The joint effects of body mass (M), and temperature (T, in K) on individual metabolic rate (I), is given as:

$$I = i_0 M^{3/4} e^{-E/kT} \tag{9}$$

where E is the activation energy (0.6–0.7 eV), k is the Boltzmann constant (8.62×10^{-5} eV/K), and i_0 is a normalization constant independent of body size and temperature. Across diverse groups of organisms (from unicellular microbes to the largest vertebrates and trees), this relationship predicts a 100,000-fold variation in metabolic rates over 20 orders-of-magnitude in body size, while temperature predicts a $\sim$30-fold variation in metabolic rates over the temperature range of normal activity for most organisms (0°C–40°C). The dependence on mass may be a consequence of the scaling of resource supply and exchange surfaces in branching hierarchical networks, while the dependence on temperature reflects its impact on biochemical reaction rates. For ectotherms, this is equivalent to ambient temperature, while for endotherms, this temperature is high (35°C–40°C) and mostly temperature independent.

Taking the logarithm of both sides and rearranging terms yields a linear relationship:

$$\ln\left(IM^{-3}/4\right) = -E(1/kT) + \ln(i_0) \tag{10}$$

By incorporating the logarithm of mass raised to the ¾ power, the metabolic rate has been "mass-corrected," and the predicted scaling is incorporated into the y-axis of bivariate plots. This mass-corrected relationship predicts that the (natural logarithm of) whole-organism metabolic rate is a linear function of inverse absolute temperature; the slope gives the activation energy of

metabolism, E, while the intercept represents the (natural logarithm) normalization constant, $\ln(i_o)$. To isolate the effects of body mass, metabolic rates can be "temperature-corrected" using the Boltzmann-Arrhenius factor ($e^{-E/kT}$), to yield:

$$\ln\left(Ie^{E/kT}\right) = \left({}^{3}/_{4}\right)\ln\left(M\right) + \ln\left(i_0\right) \tag{11}$$

This equation predicts a linear relationship between the (natural logarithm) temperature-corrected metabolic rate and (natural logarithm) body mass. Comparing these relationships to empirical data collected from a wide variety of taxa (e.g., endotherms, fish, amphibians, reptiles, invertebrates, unicellular organisms, and plants) demonstrated that the observed slope of mass-corrected metabolic rates for all groups fell within the predicted range of 0.6–0.7 eV (Fig. 3A). In comparison, temperature-corrected metabolic rates for all groups clustered closely around a common allometric scaling relationship with an exponent of 0.71, which is close to the ¾ power predicted from theory, although the intercepts (normalization constants) vary among groups (Fig. 3B).

By isolating the effect of mass (or alternatively temperature), the MTE can be used to investigate other biological rates, which are predicted to scale as $M^{-1/4}$, and biological times, which are expected to scale as $M^{1/4}$. For example, the MTE has been used to predict ontogenic development as a function of body mass and temperature. Using zooplankton eggs reared in the laboratory and fish eggs collected from the field, plots of temperature-corrected hatching rate (day^{-1}) versus body mass (g) were well fit by straight lines with similar slopes very close to the predicted $-¼$ power (-0.26 and -0.22, respectively). The MTE has also been incorporated into allometric modeling to predict excretion rates of invasive fish species at different temperatures. Accounting for the role of temperature is critical when predicting seasonal excretion rates in freshwater ecosystems. Consistent with the MTE, mass-specific nutrient excretion rates decreased with increasing fish size, such that smaller fish generally excreted more nutrients per gram of body mass than larger fish, and were greater in summer than winter.

The MTE framework has been extended to enable predictions regarding population growth. Metabolic rates of organisms determine their rates of growth and reproduction, which in turn fuels population growth. Population growth rate is often measured as net outcome of the maximal growth rate (the capacity of a population to reproduce at maximum rate when resources are not limiting), and the rate of turnover at steady state (where the total number of individuals in the population does not change over time). Allometric scaling relationships of temperature-corrected maximal growth rate as a function of body size for a wide variety of taxa, from unicellular eukaryotes to vertebrates, are suggestive of a single line with a slope of -0.23, across 12 orders-of-magnitude of variation in body size. The rate of population turnover, and thus birth and death rates, scaled similarly. For example,

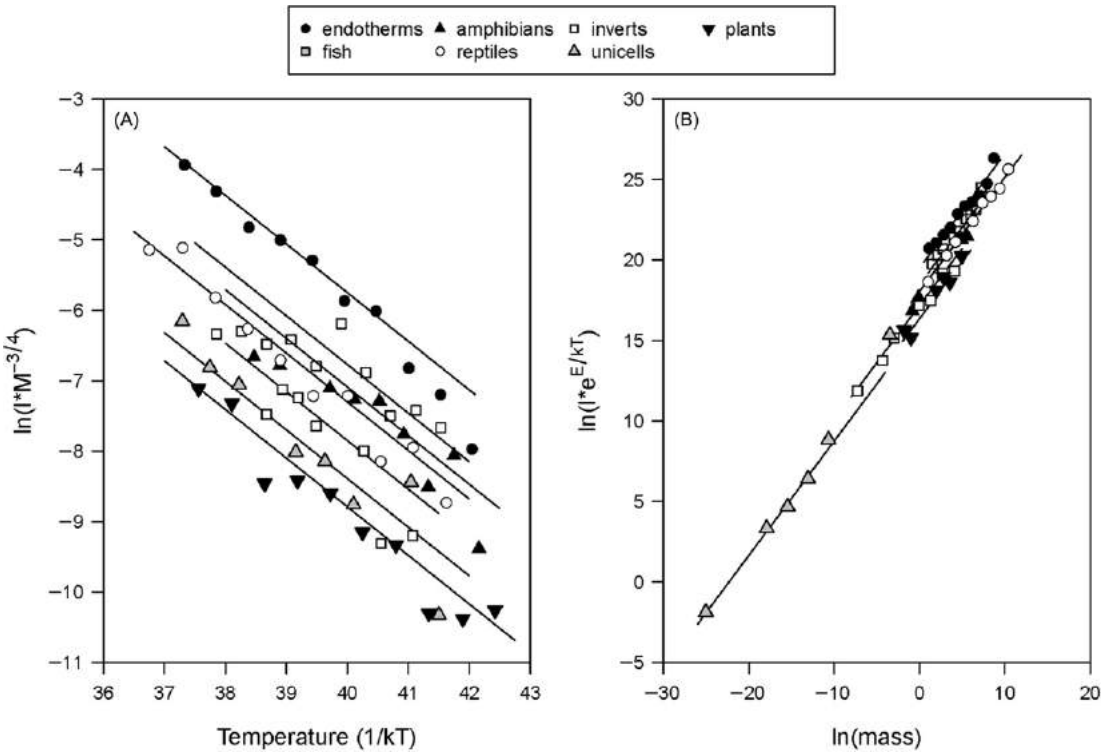

Fig. 3 Allometric scaling relationships of (A) mass-corrected metabolic rate, $\ln(I \cdot M^{-¾})$ (in Watts $g^{-¾}$), or (B) temperature-corrected metabolic rate, $\ln(I \cdot e^{E/kT})$ (in Watts), as a function of body mass, $\ln(M)$ (in grams) for endotherms, fish, amphibians, reptiles, invertebrates, unicellular organisms, and plants. k = Boltzmann constant; T = absolute temperature (in K); E = activation energy (in eV). Modified with permission from Brown, J. H., Gillooly, J. F., Allen, A. P., Savage, V. M. and West, G. B., (2004). Toward a metabolic theory of ecology. *Ecology*, **85**, 1771–1789. https://doi.org/10.1890/03-9000.

an allometric equation predicting temperature-corrected instantaneous mortality rate for marine fish in the field yields a straight line and a scaling exponent of -0.23, statistically indistinguishable from the predicted $-¼$ power.

The MTE framework has also been extended to link the processing of energy and elements at the individual level to the flux, storage, and turnover of these elements at the ecosystem level. For example, the constraints that body size and temperature place on C dynamics at all levels of biological organization (e.g., cellular organelles to the biosphere) can be combined to create a model that relates the global C cycle directly to the C flux, storage, and turnover in individual organisms. Compilations of data from major biomes that include forests, grasslands, tundra, and oceans, have demonstrated that allometric relationships between C storage in plant communities as a function of average plant size scale as a 0.24 power, while C turnover expressed as a function of average plant size yielded scaling exponents of -0.22. Both empirically-estimated scaling exponents were very close to their predicted quarter-power scaling values.

To recap, energy and mass are not distinctly different ecological currencies that operate independently of each other to shape ecosystem structure and dynamics. At all levels, from individual organisms to ecosystems, fluxes, reserves, and transformations of energy and materials are constrained by the biochemical and physiological constraints of metabolism. Within this context, the metabolic theory appears to explain much of the variability in process rates and somatic reserves. However, it is important to note that although metabolism is one of the most integrative processes in biology, building connections from molecules to ecosystems, metabolic theory cannot account for all important patterns and processes. The existence of residual variation around the predictions of the metabolic theory underscores the importance of other variables and processes not considered by the contemporary paradigm.

Ecological Stoichiometry and Metabolic Theory of Ecology

Ecological stoichiometry (ES) theory aims to quantify how variations in the balance of biologically important elements impact, and in turn are impacted by, organisms and their environment. Integration of the theory of ES with MTE may offer a useful framework to link the dynamics of energy and mass across different levels of biological organization. The ES and MTE models are founded upon a series of principles that link the energetics and stoichiometry at the level of cellular organelles with individual-level energetics and stoichiometry, and ultimately with higher-order ecosystem processes. The four major principles proposed state that:

1. Links between the fluxes of energy and materials are based on the kinetics and elemental compositions of processes and subcellular structures;
2. Biomass is comprised of metabolic and structural pools, which can have distinct allometric and elemental signature;
3. Metabolic rate (and its determinants) govern the fluxes of energy and elements at the organismal level;
4. The storage, flux, and turnover of energy and mass in a biological community can be estimated by summing across individuals within that community.

Patterns in rates of consumption by herbivores across freshwater, marine, and terrestrial ecosystems, at the individual and population level, have been used to validate joint ES–MTE predictions. Under the combined ES–MTE theory, per-capita rates of herbivory are expected to:

a. increase with body size;
b. increase with ambient temperatures for ectotherms, whereas for endotherms, either be independent of temperature or decrease with increasing temperature if high metabolic costs occur at low temperatures; and
c. increase with increasing stoichiometric mismatch.

In contrast, population-level rates of herbivory are expected to:

d. be independent of body size;
e. increase with increasing ambient temperature for both *endo*- and ectotherms; and
f. decrease with increasing stoichiometric mismatch.

Empirical data have rendered support to the predicted metabolic and stoichiometric constraints on herbivory at individual and population levels (**Fig. 4**). At the individual level, the body size of herbivores appears to be an important factor of the per-capita consumption rates for large gradients of body size, ranging from small zooplankton to large mammalian herbivores, with larger species consuming more biomass per-capita. Consumption rates in individual endotherms declined at high ambient temperatures, but increased for individual ectotherms. Stoichiometric mismatch had a small, positive effect on per-capita consumption rates. At the population level, consumption rate was invariant with body size, increased with ambient temperature for both ectotherms and endotherms, and declined with increasing stoichiometric mismatch (**Fig. 4**). Interestingly, examining per-capita consumption rates within ecologically similar groups (e.g., taxa with similar sizes and ecological roles) reduced the explanatory power of body size, while stoichiometric mismatch emerged as a more influential factor. Furthermore, MTE-related variables (body size, temperature) are more closely related to per-capita consumption rates, while ES-related variables (stoichiometric mismatch) appear to shape population-level rates. Overall, these results suggest that the integration of ES-MTE theories offer a microscopic-to-macroscopic strategy that can explicitly relate the energetics and stoichiometry of individuals, communities and ecosystems to subcellular structures and processes.

Herbivore metabolism and stoichiometry each constrain herbivory at different organizational scales across ecosystems. *Ecology Letters*, **12**, 516–527. https://doi.org/10.1111/j.1461-0248.2009.01304.x.

Food-Web Interactions

The allometric approach has been primarily considered in the context of organismal physiology and less so to elucidate ecosystem processes. More recently, there has been a growing emphasis on the idea that functional traits, as developed through natural selection, can directly affect the intra-specific variations and may ultimately determine demographic performance, spatial distribution (i.e., ecological niche), population dynamics, and food-web organization. In particular, the body size is one of the most fundamental functional traits that shapes predator-prey interactions and may conceivably modulate other ecological processes (e.g., sedimentation, nutrient recycling, foraging, and migration).

Consumer-resource foraging interaction has long been identified as one of the dominant forces that connect individual ecosystem components (i.e., species, populations, trophic groups). Foraging interactions are traditionally characterized by two types of functional response curves: hyperbolic (type II) and sigmoid (type III) curves, where a consumer's per capita feeding rate (F) increases with the resource abundance (N). Originally established by Holling (1959), foraging ecology has yielded many variations of the functional response models. One of the generalized models describes consumer's feeding rate as:

$$F = \frac{bN^{1+q}}{1 + bhN^{1+q}} \tag{12a}$$

Per capita feeding rate is regulated by the time required to kill, ingest, and digest a resource (handling time, h), as well as the hunting efficiency representing the rate that a resource is captured by a consumer (bN), where b is a coefficient for hunting efficiency. The scaling exponent (q) dictates the response curve type, whose value switches from the hyperbolic type II ($q=0$) into the sigmoid type III ($q>0$) functional response. Although this simple concept around the functional response models has provided mechanistic understanding of consumer-resource interactions, it has failed to characterize more dynamic interactions in natural communities. For example, a predatory spider in central Europe did not follow any of the expected response curves, displaying nonlinear and/or nonmonotonic patterns under conditions of abundant food availability.

In recent years, a size-based perspective has been increasingly recognized as an alternative approach to estimating density-dependent foraging interactions. In size-based functional response models, handling time and/or capturing rate (i.e., hunting efficiency) are expressed as a function of the consumer's body size. For example, handling time (h) in Eq. **(12a)** can be replaced by:

$$h = h_0 m_r^{\alpha_r} m_c^{\alpha_c} \tag{12b}$$

where h_0 is a constant, m_c, m_r and α_c and α_r are body masses (m) and allometric exponents (α) of consumer/predator c and resource/prey r, respectively.

Originally considered as a constant in functional-response models, capture rate, also known as attack rate, is known to have its own unique body-size dependency. Predator-prey mass ratio (PPMR) has been identified as an indicator to depict body size constraints on the capacity of predators to efficiently utilize excessively large prey. On the other hand, a predator does not fully benefit by targeting excessively small prey because of its limited nutritional value relative to the energy expense for the consumption or handling of the prey. PPMR has been used to measure the strength of the trophic interaction between predators and prey, and to illustrate potential shifts in the energy flows and the reliance on specific resources. In general, capturing rate has a hump-shaped response pattern with PPMR, maximizing at intermediate/moderate PPMR, while energy flows at high and low PPMR may not sustain the predator's biomass or could even risk their survival (**Fig. 5**). This hump-shaped relationship between capture rate and PPMR is consistent with optimal-foraging and niche theory, and has broad generality across different species in various habitats.

To accommodate body-mass constraints on the capture rate, hump-shaped relationships with PPMR can be further expressed as a combined equation comprising a power-law relationship with prey body mass and an exponential Ricker function for the optimal foraging body-mass ratio. The capture coefficient (b) in Eq. **(12a)** is then replaced by an allometric scaling relationship, where b_0 is a constant, β_r the exponent for the scaling of m_r, and ϵ is a constant for the range of the optimal foraging body-mass ratio:

$$b = b_0 m_r^{\beta_r} \frac{m_c}{m_r} e^{\epsilon \frac{m_c}{m_r}} \tag{12c}$$

Efforts to develop a generalized functional-response modeling framework have further advanced our mechanistic understanding of consumer-resource interactions in natural food-web dynamics. Counter to early consumer-resource models, such as the Lotka-Volterra models, where all parameter sets are independently assigned only to fit data points, allometric scaling models ensure that parameters lie within biologically plausible ranges based on their size related capacity. Size-based functional response models highlighted that the coexistence of consumer-resource is restricted within specific body-mass ranges, which in turn regulates the resilience of consumers in the food-web and the broader stability of biotic communities. The consideration of body-mass ratio can also be useful in parameterizing more complex population models. Nonetheless, like any other type of models, allometric scaling models require caution in their use; as the definitions of certain facets of trophic interactions, like the hunting efficiency, are somewhat ambiguous and their complex characteristics (i.e., multiple food-sources, mobility of organisms) are essentially habitat/community-specific.

Ecosystem Models

Ecosystem models extend the application of consumer-resource interactions to community-level processes, whereby ecologists attempt to reproduce the interplay among organisms and their surrounding physico–chemical environment. Integration of size-based characteristics into ecosystem models may refine the description of community-level processes, such as species seasonal succession and flow of energy and/or matter across trophic levels. Body-size patterns may be more important, or at least more obvious, in aquatic ecosystems than in terrestrial habitats for several reasons. The majority of autotrophic organisms in aquatic ecosystems are very small and grazed by larger consumers, and thus the relative size ratio of consumer to resource more consistently manifests itself than in terrestrial environments. There are significant operational and technical advantages in the collection of datasets from aquatic environments. Reflecting upon these factors, there are a number of allometric equations developed for aquatic organisms and (not surprisingly) many of the existing size-based ecosystem models have been developed for aquatic environments.

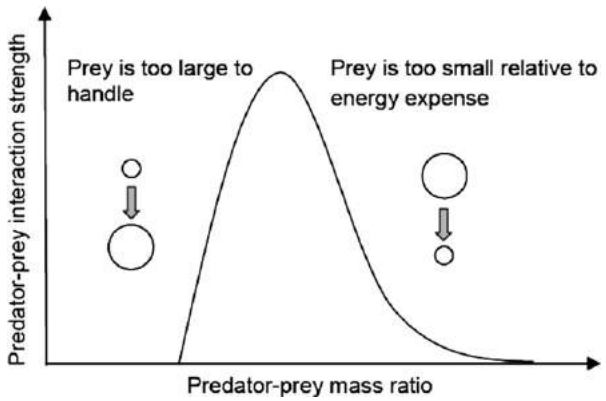

Fig. 5 Conceptualization of the relationship between predator-prey mass ratio and strength of their interaction. Circles represent the relative mass of predators (top) to the mass of prey (bottom). Modified from Nakazawa, T. (2017). Individual interaction data are required in community ecology: A conceptual review of the predator–prey mass ratio and more. *Ecological Research* **32**, 5. https://doi.org/10.1007/s11284-016-1408-1.

The basic concept of size-based ecosystem modeling is that the functional characteristics of the biological components of the studied system can be described by allometric equations. That is, model parameters associated with organismal physiological rates, such as maximum growth rate, nutrient kinetics, and basal metabolism, are determined by the empirically-derived relationships with their body size (i.e., mass, volume, length). Shimoda *et al.* (2016) employed several allometric equations in an existing aquatic biogeochemical model to describe the physiological processes of multiple phytoplankton functional groups, and thus predict how can the morphological features (i.e., cell volume, surface-to-volume ratio, and shape) influence the response to external perturbations, interspecific competition, and ultimately the seasonal composition of algal assemblages (Fig. 6A). For example, maximum growth rate μ_{max} (day^{-1}) was replaced by $\mu_{max}=10^{0.54}V^{-0.15}$, where V denotes algal cell volume (μm^3) (Fig. 6B). Nutrient kinetics were also replaced by several allometric equations such as: half saturation constant for nitrate uptake (NH:$\mu mol\ N\ L^{-1}$), $NH=10^{-0.72}V^{0.52}$, half saturation constant for phosphorus uptake (KH_p:$\mu mol\ P\ L^{-1}$), $KH_p=10^{-1.5}V^{0.53}$ (Fig. 6C), maximum phosphorus uptake rate (VP_{max}:$\mu g\ P\ \mu m^{-3}h^{-1}$), $VP_{max}=10^{-10.7}SA/V^{1.7}$ where SA/V denotes algal cell surface-to-volume ratio (μm^{-1}), maximum internal phosphorus quota (QP_{max}:$fmol\ P\ cell^{-1}$), $QP_{max}=10^{-0.29}V^{0.767}$, minimum internal phosphorus quota (QP_{min}:$fmol\ P\ cell^{-1}$), $QP_{min}=10^{-1.04}V^{0.714}$.

The allometric configuration of the process-based model allowed to realistically reproducing the observed phosphate, total phosphorus, nitrate, total ammonia, total nitrogen, chlorophyll *a*, and total zooplankton biomass patterns in the Hamilton Harbor, Ontario, Canada. Consistent with empirical evidence, the allometric-scaled ecosystem model showed that small algal species have a distinct competitive advantage in summer epilimnetic environments across the range of cell volume and nutrient loading conditions examined; especially, when they are characterized by higher optimal temperature for growth. The same study

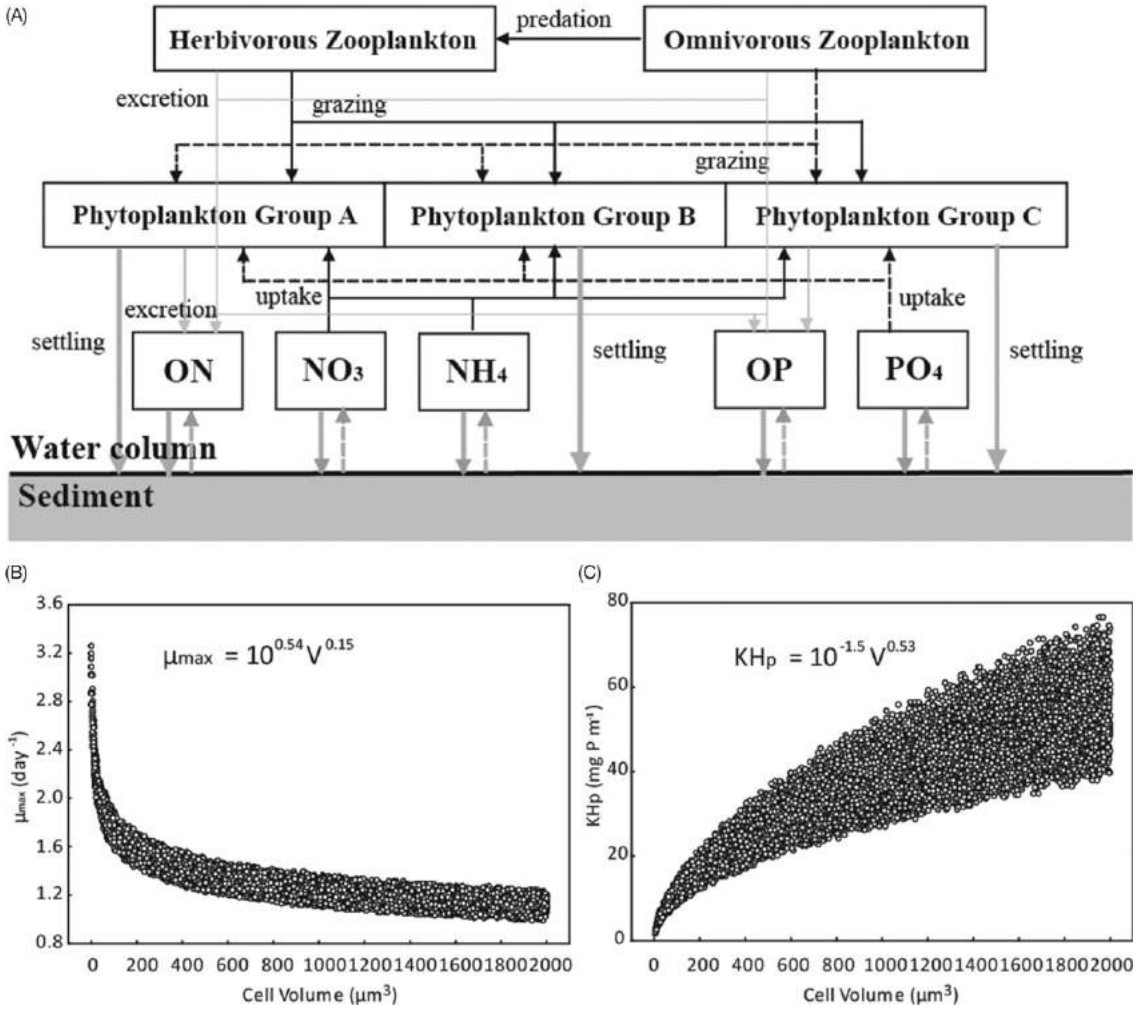

Fig. 6 (A) Conceptual diagram of an aquatic ecosystem model. Parameter values were calculated with allometric equations linking phytoplankton (B) maximum growth rate and (C) half saturation constant for phosphorus uptake with the cell volume. In Shimoda *et al.* (2016), the cell size variability for a given functional groups was assigned a range between 0.1 and 2000 μm^3 (*x*-axis). The parametric uncertainty (as seen in the distributed dots in B and C) of the allometric regressions can be propagated with Monte Carlo simulations through the ecosystem model. (B-C) Shimoda, Y., Yerubandi, R., Watson, S., Arhonditsis, G.B. (2016). Optimizing the complexity of phytoplankton functional group modelling: An allometric approach. *Ecological Informatics* 31, 1–17.

also showed that intense herbivory rates act as a "safety valve" and effectively control the standing biomass of phytoplankton species that can otherwise realize high growth rates under the conditions typically prevailing in the end-of-summer epilimnetic environments. By contrast, when the summer community is released by the zooplankton grazing, the exceedance of critical phytoplankton biomass levels and the likelihood of harmful algal blooms are determined by the multitude of factors that shape inter-specific competition patterns (e.g., relative abundance of competing species, nutrient uptake kinetics). One of the future challenges associated with the allometric approach to plankton modeling involves the characterization of dependence of prey-predator relationships as a function of the interplay among prey morphology, nitrogen, phosphorus, highly unsaturated fatty acids, and other potentially important metabolic congeners through the grazers' digestive tracks.

From a technical standpoint, one of the benefits of the allometric approach to ecosystem modeling is that the characterization of simulated biotic compartments is no longer based on adjustable parameters, often treated as "properties of convenience" for fitting models to the observed data, but instead their morphological features are treated as the common denominator that influences the corresponding physiological rates. In a broader context, this practice may be one of the ways to address the problem of complex over-parameterized models and improve our ability to set quantitative (or even qualitative) constraints while ensuring satisfactory model performance. Model parametric uncertainty is more effectively delineated; namely, the literature-based ranges typically assigned to the calibration parameters can be replaced by the parameter standard error values and/or the estimates of residual variability of allometric equations, which in turn collectively reflect how well does the regression line match the original empirical physiological rates, the variability of the predictor (morphological) variable used to develop the allometric equation as well as the sample size. Using suitable uncertainty analysis techniques, these error estimates can then be propagated through our ecosystem models, whereby we can effectively quantify the degree of confidence in model predictions (**Fig. 6**C).

The allometric approach to ecosystem modeling also offers a different perspective on the optimization of future data collection. Model calibration is not solely perceived as a typical inverse solution exercise, constantly inviting the collection of data on model outputs and subsequently readjusting the parameters to match measurements and predictions. Instead model parameter estimation requires a more robust experimentation focused on the development (or further refinement) of the causal description of model parameters based on the morphological features of the biotic components modeled. Moreover, depending on the nature of the dataset used for the allometric regressions (e.g., marine vs. freshwater algae), the proposed method allows the potential users to delineate the application domain more easily and determine to what extent a particular model has local or universal use.

Cautions, challenges, and future prospects

Allometric theory meets a series of fundamental criteria to be considered as a "good theory." It is extremely simple, quantitative, and most of the dependent and independent variables are easily defined. Empirical relations capture the characteristics of a wide range of organisms, and provide reasonably accurate predictions of many biological processes. Thus, allometric equations have been used to describe biological and ecological processes, ranging from the micro- to macroscale, such as the effects of drugs and other substances on the physiological responses of humans/animals, the estimation of fish stocks, and the prediction of life-stage specific population size in ecosystems, to name a few.

The popularity of the allometric theory, however, appears to have slowed down after its peak around 1970–1980s and much less development and examination of the corresponding equations has been seen in recent literature. It has been argued that its simplicity and generality (supposedly criteria for a good theory) paradoxically represent a "double-edged sword" making it less appealing for research, because any new regressions merely provide validation of the theory. There are also a number of critical viewpoints presented in the literature. First, the precision of the empirical relations is compromised by our desire to achieve generality. It is obvious that capturing the entire range of a physiological characteristic using a regression with only two parameters is nearly impossible. Even though the development of taxa-specific allometric regression models is logical, as phylogenetically neighboring taxa share common physiological traits, other important factors, such as resource availability, may not yield commonality in response to similar selective pressures. For example, the distribution patterns of maximum potential growth rate of phytoplankton vary not only among genera, but also by habitat type (**Fig. 7**). There is still significant space for advancing allometric theory using scientific creativity and technological innovation.

One of the most significant, yet not frequently explored facets of allometry, involves the scatter around each regression (e.g., model residuals) representing the variability among organisms, missing ecological functions (i.e., adaptation), and measurement errors. Many of the empirical equations used are based on small sample sizes (low degrees of freedoms) and/or capture a fairly narrow range of body/cell sizes typically encountered in natural ecosystems. All these factors inflate the magnitude of the uncertainty (confidence, predictive) bands of allometric equations. Rather than perceiving this error as a weakness of the allometric approach, recent viewpoints claim that it offers an excellent piece of information to conduct rigorous uncertainty analysis in complex process-based models and a solid foundation to draw probabilistic inference on important ecological questions.

Many of the existing equations have been derived in experimental controlled settings (i.e., laboratory, mesocosms), and do not necessarily represent the response of organisms that may be observed in the natural world. Unless allometric equations predict maximum potential metabolic/physiological rate under resource saturated environment, more accurate representation of biological traits must be tested with free-living organisms. Although validation of theoretical relationships and existing models is an integral part of science, few studies have attempted to provide a comprehensive review of the existing allometric equations. Often many equations that describe the same phenomenon exist, but objective comparison of these equations has been rarely performed. Further development of new, taxon-specific allometric relationships, expansion of size range for the existing relations may improve their credibility and predictive power.

While Occam's razor is (and should be) the cornerstone of any ecological modeling activity, the integration of process-based models and empirical parameter specification, founded upon the basic allometric concepts, offers an appealing prospect. The development of predictive ecological frameworks that are based on our best mechanistic understanding of biotic processes and ecosystem feedback loops, yet remain within the bounds of data-based parameter estimation and therefore can accommodate rigorous error analysis has both methodological and ecophysiological advantages. Size structure of biotic communities is an important regulatory factor of the biogeochemical fluxes and energy transfer via the food webs that ultimately affects system productivity. The improvement of empirical description of ecological parameters could reconcile the debate regarding the need to balance between simplicity and realism in predictive ecology.

Ammonification

Nicolas Romillac, Université de Lorraine, Laboratoire Agronomie et Environnement, Vandoeuvre Cedex, France

Nomenclature

DON Dissolved organic nitrogen

MIT Mineralization immobilization turnover

µmol L^{-1}
Micromole per liter

µgN-NH_4^+ h^{-1} g dry $soil^{-1}$
Micrograms of ammonium nitrogen produced per hour per gram of dry soil

Glossary

Aquaporin Membrane proteins facilitating the transport of water through the membrane.

Deamination Reaction of liberation of an amino group ($-NH_2$) from an organic molecule.

Dissimilatory nitrate reduction Biological reduction of nitrate (NO_3^-) to ammonium (NH_4^+).

Nitrification Biological oxidation of ammonium (NH_4^+) to nitrate (NO_3^-).

Rhizodeposition Release of organic and mineral compounds by plant roots in the soil (or other environment).

Transamination Reaction of transfer of an amino group ($-NH_2$) from an amino acid to a ketoacid.

Introduction

Ammonification is the process by which microorganisms present in soil, sediment, or water mineralize low molecular weight, dissolved, organic molecules presenting amine or amide groups (of general formula R-NH_2) and produce ammonium (NH_4^+). Ammonification is the last step of the nitrogen cycle involving an organic compound, and is the intermediary step between the depolymerization of large organic molecules and the nitrification step (**Fig. 1**).

In marine ecology, ammonification is also referred to as ammonium regeneration and ammonium recycling. The term "nitrate ammonification" is sometimes used to refer to the dissimilatory reduction of nitrate to ammonium (e.g., Rysgaard et al., 1996). Nitrate ammonification is beyond the scope of this article.

One should distinguish between gross ammonification, the amount of mineralized organic molecules, ammonification activity, the activity of microbial enzymes responsible for ammonification in a given environment, and net ammonification, the release of NH_4^+ in the environment. While gross ammonification and ammonification activity are well correlated, they are not necessarily correlated to net ammonification, as net ammonification is the result of the co-occurring processes of ammonium uptake and release from microbial cells after ammonification.

Dissolved Organic Nitrogen as a Substrate for Ammonification

Dissolved organic nitrogen (DON), in soils, sediments, seawater, and freshwater, is a mixture of diverse molecules, of which a great part is of unknown chemical structure. DON is composed of both labile and recalcitrant, high molecular weight and low molecular weight molecules (Neff et al., 2003; Jones et al., 2004a).

Only the low molecular weight molecules can be the substrates of ammonification. They include amino acids, urea, amino sugars, and nucleotides. Of these substrates, amino acids are the best studied, and are generally considered as the model substrates for ammonification. An important characteristic of amino acids is their solubility in water or in soil solution, which make them an easily accessible source of carbon and nitrogen for microorganisms (Jones and Kielland, 2012).

Amino acids originate from various sources. They can be released from cells after cell lysis (Miltner et al., 2009), rhizodeposited by plant roots (Jones et al., 2004b), or released by microorganisms in order to adapt their osmotic pressure to a fluctuating

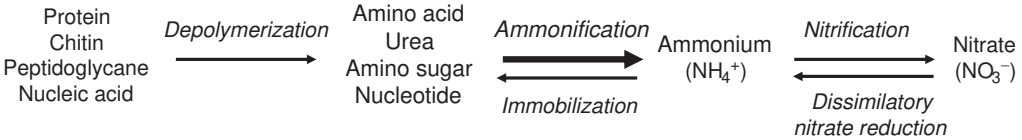

Fig. 1 Ammonification positioned in the nitrogen cycle.

 doi:10.1016/B978-0-12-409548-9.10889-9

environment (Halverson et al., 2000). In water, they can be trapped by humic substances and subsequently released by the action of UV, in a photochemical reaction (Moran and Zepp, 1997).

Free amino acids in soil solution, sea, and freshwater are relatively scarce, as they are rapidly uptaken or mineralized by plants and microorganisms. As an example, Jones et al. (2005) found a half-life of 3.5 h for amino acids in agricultural soils, and Fuhrman and Ferguson (1986) found a turnover of 6 h in winter and 1 h in summer for amino acids in temperate seawaters. In soil solution, amino acids represent 10%–40% of DON and their concentrations range from 0.1 to 50 $\mu mol\ L^{-1}$ (Jones et al., 2002). Amino acids represent 0.3% of the dissolved organic matter in the equatorial Pacific Ocean (Lee and Bada, 1975), and concentrations inferior to 1 $\mu mol\ L^{-1}$ are frequently observed in oceans and estuaries water (Lee and Bada, 1975; Fuhrman and Bell, 1985; Fuhrman and Ferguson, 1986; Coffin, 1989; Pomeroy et al., 1990).

Urea originates from mammal urine and from excretion of uric acid by birds, reptiles, or arthropods. It can be excreted by heterotrophic bacteria, zooplankton, and phytoplankton. It is also a product of the degradation of the amino acid arginine, and a major fertilizer. Urea can move from ecosystems to ecosystems, and thus can leach from soils to fresh and coastal waters, be released in the water from sediments, and originate from atmospheric deposition (Glibert et al., 2006; Geisseler et al., 2010; Solomon et al., 2010).

Amino acids, amino sugars, and nucleotides can also be released from the depolymerization of macromolecules (respectively, proteins and peptides, chitin and peptidoglycane, and nucleic acids) by the action of microbial enzymes (proteases and peptidases, chitinases and *N*-acetylglucosamidase, and nucleases) (Jones et al., 2004a; Roberts and Jones, 2012; Isobe and Ohte, 2014).

Biochemical Pathways of Ammonification

Ammonification can be either extracellular or intracellular (Geisseler et al., 2010). In the extracellular pathway, the breakdown of organic compounds is realized by free extracellular enzymes or by enzymes bound to the outer cell membrane. The released ammonium is subsequently uptaken by the microbial cells. This is classically called the mineralization immobilization turnover (MIT) route. Extracellular enzymes involved in this process are poorly known, with the exception of urease (EC 3.5.1.5) and amino acid oxidases (EC 1.4.3.2).

Urease catalyzes the formation of ammonia (NH_3) and carbamate. Carbamate spontaneously decomposes to NH_3 and carbonic acid. Ammonia then dissolves to form ammonium (NH_4^+), in an equilibrium between ammonia and ammonium controlled by pH.

Microbes can synthetize urease constitutively, but its synthesis is more often regulated by N availability. In this case, the synthesis is repressed by ammonium and activated by presence of urea and by N starvation (Mobley et al., 1995).

Approximately 45%–60% of the soil urease activity is extracellular, while the remaining activity is intracellular (Geisseler et al., 2010). Extracellular ureases are probably bound to soil organic matter, which protects them from degradation by soil proteases. The greatest part of the extracellular ureases in soil appears to derive from the release of intracellular ureases by cell lysis and not from a secretion by living organisms.

Amino acid oxidases are bound to the outer cell membrane of microorganisms and catalyze the deamination of amino acids and produce ketoacids, NH_3 and H_2O_2. They have either broad or strict substrate specificity. In soils, enzymes with a broad substrate specificity seem to be dominant (Nuutinen and Timonen, 2008). Their synthesis is repressed by ammonium, and induced by N starvation and by amino acids in the presence of a carbon source.

On the other hand, microorganisms can also uptake low molecular weight organic compounds, such as amino acids, and mineralize them to ammonium inside the cell. Ammonium can be subsequently excreted from the cell, if in excess. This is called the direct route. This metabolic pathway includes an active transport through the membrane and deamination or transamination of the molecule inside the cell, in order to release ammoniac and ammonium.

In the case of amino acids, the transport systems are located in the cytoplasmic membrane and are usually specific to a group of structurally similar amino acids. Bacteria possess relatively specific transport systems, and up to 12 different transport systems can be found in a cell. Fungi have transport systems with a broader specificity and present fewer different transporters than bacteria (Geisseler et al., 2010). Some transport systems can be constitutively synthetized, but the majority of the systems are regulated by N availability. Ammonium and intracellular amino acids repress the synthesis while starvation of C, N, or S induces the synthesis.

Furthermore, microbes can possess active transport systems for small peptides, up to 600 Da, corresponding to a peptide made of five or six amino acids (Payne and Smith, 1994).

Transport systems for amino sugars are less well known. They are repressed by glucose and induced by their substrate (Geisseler et al., 2010).

In marine waters, urea uptake can contribute to more than 50% of N uptake by phytoplankton (Glibert et al., 2006). In a cell, high affinity active transporters and low affinity passive transporters for urea can coexist. Urea can also enter a cell through aquaporines and urea/amides channels. The synthesis of transport systems for urea is induced by N starvation and is repressed by ammonium (Solomon et al., 2010).

Once in the cell, ammonium can be released from the organic compounds by a great variety of enzymes pertaining to the hydrolases and lyases groups. These include, in the super-family of the amidohydrolases, L-asparaginase (EC 3.5.1.1; substrate: asparagine), L-glutaminase (EC 3.5.1.2; substrate: glutamine), amidase (EC 3.5.1.4; substrate: monocarboxylic acid amides), and urease. The groups also include the hydrolases arylamidase (EC 3.4.11.2; substrate: amides and arylamides), L-arginine deiminase

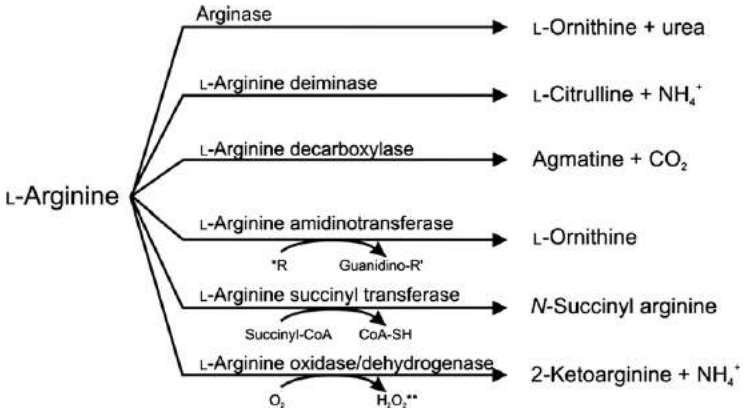

Fig. 2 Pathways of L-arginine degradation in bacterial cells. The arginase, the L-arginase deiminase, the L-arginine oxidase/dehydrogenase and, putatively, the L-arginine decarboxylase pathways, lead to the release of ammonium inside bacterial cells. Reproduced from Schriek, S., Rückert, C., Staiger, D., Pistorius, E. K. and Michel, K. (2007). Bioinformatic evaluation of L-arginine catabolic pathways in 24 cyanobacteria and transcriptional analysis of genes encoding enzymes of L-arginine catabolism in the cyanobacterium Synechocystis sp. PCC 6803. *BMC Genomics* **28**, 1–28.

(EC 3.5.3.6; substrate: arginine) and arginase (EC 3.5.3.1; substrate: arginine), and the lyases L-aspartase (EC 4.3.1.1; substrate: aspartate) and L-histidase (EC 4.3.1.3; substrate: histidine). As an example, at least six pathways are known for the degradation of the arginine, of which at least three lead to the release of ammonium (**Fig. 2**; Schriek et al., 2007).

Microbial Choice Between MIT and Direct Route

The direct route presents the advantage of fulfilling the C and N requirements of the microorganisms at the same time, as the carbon skeleton of the amino acid can be metabolized after deamination, and serve as a source of energy. Amino acids can also be directly incorporated into microbial proteins. On the other hand, the direct route requires the synthetizing of a diversity of amino acid transporters (while ammonium transporters are more likely to be present already in a cell), amino acids profile into the environment does not necessarily matches the microbial needs, and the deamination process can create toxic byproducts. The production of H_2O_2 in the MIT route can also have a role in suppressing other microbial strains. All those elements can favor the MIT route.

Geisseler et al. (2010) developed a conceptual model in order to understand which route will be predominant in soils. According to their analysis, based on the mechanisms of regulation of the two pathways, the MIT route should be favored over the direct route (**Fig. 3**):

- when the N availability is high relatively to the C availability;
- when the availability of ammonium is high relatively to other sources of nitrogen (i.e., amino acids and amino sugars); or
- when the availability of carbohydrates is high relatively to organic compounds rich in nitrogen (amino acids and amino sugars).

Net Ammonification

The net ammonification, that is, the release of ammonium in the extracellular environment, is not directly correlated to gross ammonification, as it is influenced by the degree of retention, uptake, and excretion of ammonium by microbial cells after ammonification. The balance between retention/uptake and excretion of ammonium is likely to be influenced by the N nutritional status of the microbial community (starvation or nitrogen excess), the C:N ratio of the microbial population, and the quantity and chemical composition of dissolved organic matter (Jones et al., 2004a). Typically, bacteria will excrete N for a C:N of the dissolved organic N inferior to 12.5 and fungi for a C:N inferior to 30.3 (Hodge et al., 2000).

Organisms Responsible for Ammonification

It is generally considered that the majority of, if not all, microorganisms (bacteria and fungi) are capable of ammonification. Ammonification enzymes and transport systems are shared by widely diverse microbial species. As an example, more than 50 strains of soil bacteria are capable of arginine ammonification (Alef and Kleiner, 1986). Most heterotrophic bacteria are able to uptake amino acids, as well as a few species pertaining to phytoplankton (Fuhrman and Azam, 1982; Jones et al., 2004a). A wide number of marine cyanobacteria and dinoflagellates, as well as some heterokont unicellular algae, are also able to uptake urea (Glibert et al., 2006). Urease is produced not only by bacteria and fungi, including nitrogen-fixing bacteria colonizing legume nodules (Chuntanom and Pongsilp, 2011), but also by plants and unicellular algae (Solomon et al., 2010; Geisseler et al., 2010).

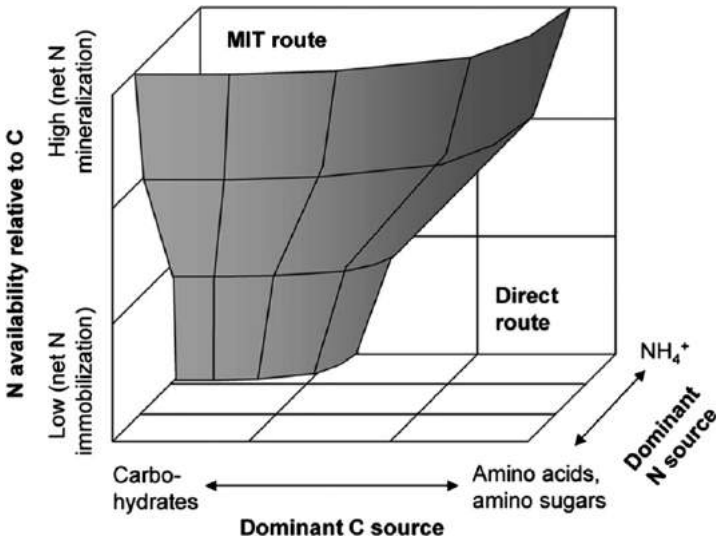

Fig. 3 Conceptual model of the factors affecting the relative importance of the microbial immobilization turnover and the direct route of N uptake by soil microorganisms. Reproduced from Geisseler, D., Horwath, W. R., Joergensen, R. G. and Ludwig, B. (2010). Pathways of nitrogen utilization by soil microorganisms – A review. *Soil Biology and Biochemistry* **42**, 2058–2067. Available at: https://doi.org/10.1016/j.soilbio.2010.08.021, with permission from Elsevier.

Amino acid oxidases are produced by a wide diversity of bacteria and fungi (in both ascomycetes and basidiomycetes phyla, and including some mycorrhiza), found in soil and water, and by some species of phytoplankton (Pantoja and Lee, 1994; Geisseler et al., 2010). This is in contrast, for example, with the enzymes involved in the steps of depolymerization of the nitrogen cycles (proteases, peptidases, nucleases, etc.) which are produced by phylogenetically restrained microbial groups.

Methods to Study Ammonification

Several methods to measure potential ammonification activity have been developed, using L-amino acids as model substrates. The method developed by Alef and Kleiner (1986), based on the arginine amino acid, is the most commonly used, while methods based on histidine (Burton and McGill, 1992), asparagine (Frankenberger and Tabatabai, 1991a), glutamine (Frankenberger and Tabatabai, 1991b), or aspartase (Senwo and Tabatabai, 1996) are also available. Briefly, the arginine method consists of adding a saturating concentration of arginine to a soil slurry, and conducting a short incubation (1–2 h) at normal soil pH and at 22°C. At the end of incubation, soil mineral nitrogen is extracted, using an extractant such as KCl, and ammonium abundance is measured in the extracts. Methods based on other amino acids have similar protocols. Arylamidase, amidase, and urease activity are measured in the same way, using L-leucine, formamide, and urea, respectively, as the substrate (Acosta-Martínez and Tabatabai, 2001; Miller et al., 2001; O'Toole, 1991).

These methods measure the potential activity, that is, the activity of all enzymes in optimal conditions with unlimited substrate amount. However, arginine ammonification is considered a reliable indicator of ammonification, as it is well correlated to the gross N mineralization, measured by isotopic methods (Bonde et al., 2001).

Among other methods, the gross ammonification flux can be measured by isotopic methods using ammonium enriched in ^{15}N (Rosenkranz et al., 2006). Culture media, containing peptone, can be used to count the number of cultivable ammonifying organisms in environmental samples (Chuntanom and Pongsilp, 2011).

Importance of Ammonification for the Nitrogen Cycle

Overall, ammonification does not appear to be a limiting step of the nitrogen cycle in soils. Indeed, the rate of ammonification appears to depend on the rate of depolymerization of macromolecules such as proteins, chitin, and nucleic acids. Depolymerization is probably the limiting step of the nitrogen cycle (Jan et al., 2009). This is consistent with the rapid mineralization of amino acids in agricultural topsoils (average half-life 3.5 h; Jones et al., 2005), in boreal forest soils (half-life 1–6 h; Kielland et al., 2007), and in marine waters (turnover of 1–6 h; Fuhrman and Ferguson, 1986).

The ammonium produced by ammonification is the substrate of the nitrification process, probably the most studied step of the nitrogen cycle. As a consequence, the rate of ammonification tightly controls the rate of nitrification in estuaries and oceans (Ward, 2008; Flindt et al., 1999), and, even if the evidence is scarcer, in some soils (e.g., Papen and Butterbach-Bahl, 1999).

Sensitivity to Environmental Factors

Because of the widespread ability to perform ammonification among bacteria and fungi, ammonification activity does not depend on the composition or diversity of the microbial community. However, it depends on the activity and abundance of the whole community. Arginine ammonification activity is well correlated to indicators of microbial activity, such as respiration (Alef and Kleiner, 1987), dehydrogenase, protease, phosphatase, and β-glucosidase activities (Graham and Haynes, 2005; Dilly et al., 2007; Stark et al., 2008), and indicators of microbial abundance such as microbial biomass C (Lin and Brookes, 1999) or microbial biomass N (Pajares et al., 2009). Then, all factors affecting microbial activity, microbial abundance, and C and N availability should modify the ammonification activity. Furthermore, every perturbation destroying microbial biomass, such as freeze-thawing, drying-rewetting, or grazing by predators, is susceptible to release amino acids from lyzed cells, thus increasing the rate of ammonification (Schimel and Bennett, 2004).

Arginine ammonification is the standard method to measure ammonification activity. As the measurements of arginine ammonification are scarce in waters and sediments, below is a summary of knowledge on the response of soil arginine ammonification to environmental factors, particularly in agricultural soils. In soil, typical values for arginine ammonification range from 1 to 5 $\mu gN\text{-}NH_4^+\ h^{-1}$ g dry $soil^{-1}$ (Dilly et al., 2007; Stark et al., 2007; Pajares et al., 2009; Meisner et al., 2011; Romillac et al., 2015), with extreme values up to 15 $\mu gN\text{-}NH_4^+\ h^{-1}$ g dry $soil^{-1}$ under a lupin crop (Stark et al., 2008).

As ammonification is largely determined by microbial activity and abundance, which are themselves determined by substrate availability, arginine ammonification is correlated to soil organic carbon content (Lin and Brookes, 1999; Pajares et al., 2009; Nourbakhsh and Alinejadian, 2009). Thus, all factors influencing soil organic matter content are likely to modify arginine ammonification. Arginine ammonification is higher:

- under permanent grasslands than under temporary grassland;
- in grasslands than in cultivated fields (Milne and Haynes, 2004);
- under reduced tillage than under conventional tillage (Van Capelle et al., 2012);
- under organic fertilization than under mineral fertilization (Mercik et al., 1995);
- under plants than in bare soil (Dinesh et al., 2004).

The activity also decrease with soil depth (Kandeler et al., 1994) and several studies also found higher activity in organic agriculture fields, compared to conventional agriculture (Haynes and Tregurtha, 1999; Gunapala and Scow, 1998; Stark et al., 2008). All these variations of activity can probably be explained by variations of soil carbon content and microbial biomass size.

Arginine ammonification can also be influenced by the plant species (Dinesh et al., 2004) and the climate. A higher activity has been observed under legume litters than under cereal litters, which can be explained by the higher amino acid content of the legume litter (Dilly et al., 2007). The activity decreases linearly with soil water potential (Chen et al., 2011a, b; Tietema et al., 1992; Low et al., 1997), and is thus higher in humid soils and after rainfalls and lower in summer months (Bonde et al., 2001).

Among other enzymes involved in ammonification, amidase, L-asparaginase, L-aspartase, and L-glutaminase activities are positively correlated to microbial biomass C and N (Dodor and Tabatabai, 2003). Amidase and urease activities are higher in grassland than in cultivated fields. Urease activity is higher in soils under organic fertilization and in natural soils, while amidase is higher in soils under mineral N fertilization (Gianfreda and Ruggiero, 2006). In general, those enzymes' activities increase with liming and decrease with soil acidification; L-glutaminase is particularly sensitive to pH and L-aspartase is far less sensitive (Acosta-Martínez and Tabatabai, 2001).

Consequences for Pollution

Ammonium released from ammonification in soils is retained by the soil constituents, preventing its leaching to water. However, it is readily available for nitrification, which quickly transforms ammonium to nitrate, a nitrogen form highly susceptible to being leached. Ammonium can also be volatilized as ammonia (NH_3), a major source of nitrogen pollution and eutrophication through atmospheric deposition, as well as a source of air pollution through the formation of particulate matter. In agricultural systems where urea or animal dejections are used as fertilizer, a significant part of the ammonium produced by the urease activity is lost to the atmosphere by volatilization (Bussink and Oenema, 1998). Habitually, 20%–30% of the N applied as urea is volatilized (Chadwick et al., 2005). Urease activity and volatilization are also of concern during the storage and composting of manure. This has led to important research to find urease inhibitors applicable in the field. Nowadays, some commercialized urea fertilizers contain urea inhibitors in order to prevent this phenomenon by slowing down the rate of ammonification.

Importance for Plant Nutrition

Ammonification produces ammonium and probably controls the rate of nitrate production by nitrification. It is thus likely to be an important process for plant nutrition. However, ammonification has been poorly studied in this context, probably because this activity is widely distributed among microorganisms and because its rate is controlled by upstream depolymerization.

Plants preferentially uptake N under the nitrate form, but are also able to uptake ammonium and amino acids. Thus, ammonifying microorganisms can be both competitors and providers of nitrogen for plants. The role they will play will depend on the importance of the different forms of nitrogen in soil.

In soils of the tundra, taiga, and alpine ecosystems, where mineral nitrogen is present in low amounts, amino acids are usually the main source of nitrogen for plants (Jones and Kielland, 2012). In soils of the wetlands, deserts, and some temperate or boreal forests, ammonium can be an important source of nitrogen for plants, in addition to amino acids (Schimel and Bennett, 2004). In these conditions, intense competition for N should occur between plants and ammonifying microorganisms. In theory, microorganisms should win competition due to faster growth, higher surface-to-volume ratio, and higher substrate affinities than plants (Hodge et al., 2000). However, plants can obtain N due to the presence of N-rich microsites where nitrogen mineralization is higher than nitrogen retention by microorganisms. Nitrogen can then leak from those microsites and be captured by plants. Another mechanism explaining the success of plants in the face of microbial competition is the longer lifespan of roots compared to microorganisms. The high turnover of microbial cells, which die from predation, starvation, freeze-thawing, or drying-rewetting, releases nitrogen, making it available for plants. Nitrogen acquisition via mycorrhiza can also permit plants to obtain more nitrogen (Hodge et al., 2000; Schimel and Bennett, 2004).

In soils where substantial amounts of nitrate are present, such as agricultural soils and tropical forests, plants are hypothesized to uptake preferentially nitrate; thus ammonifying microorganisms are no longer competitors, but providers of mineral nitrogen (Schimel and Bennett, 2004). In some cases at least, plants growing in those conditions can increase ammonification activity at times when their N requirements are the highest (Romillac et al., 2015).

Apart from competition, plants and ammonifying microorganisms can maintain a relationship of the mutualistic type: plants rhizodeposit significant amounts of amino acids (Jones et al., 2004b), which are substrates for ammonification and can help microorganisms to fulfill their carbon and nitrogen requirements. Rhizodeposition increases the abundance and activity of microorganisms, resulting in higher ammonification and nitrogen mineralization rates, which prove beneficial for plants' nutrition. This is called the "rhizosphere priming effect." The detailed mechanisms of the rhizosphere priming effect are yet to be discussed (Dijkstra et al., 2013; Cheng et al., 2014). In the microbial mining hypothesis, the rhizosphere priming effect results from an increase in the production of extracellular enzymes responsible for depolymerization, the step ahead of ammonification in the nitrogen cycle (Fontaine et al., 2011). In the microbial loop hypothesis, the increasing predation by protozoa and nematodes on the increased microbial biomass accelerates the turnover of microbial organic nitrogen and liberates ammonium available for plants (Clarholm, 1994). Thus, the link between plant rhizodeposition and ammonification rate would be an indirect one.

Conclusion

Ammonification activity is a widely shared activity among bacteria, fungi, and even unicellular algae, making ammonification a quick and non-limiting step of the nitrogen cycle. Therefore, ammonification rate is mainly controlled by the size and activity of the microbial community, and by the availability of DON. It responds quickly to the modification of these parameters, and in particular to modifications of the rate of depolymerization of macromolecules such as proteins, chitin, and nucleic acids.

Biological Nitrogen Fixation☆

N Rascio and N La Rocca, University of Padua, Padua, Italy

Introduction

Nitrogen is a key element present in many biochemical compounds (such as nucleotide phosphates, amino acids, proteins, and nucleic acids) of living cells. Only oxygen, carbon, and hydrogen are more abundant in the cell. The entry of organic nitrogen in the food chains of natural ecosystems is essentially due to the activity of photoautotrophic organisms (cyanobacteria, algae, and terrestrial plants). These primary producers take up nitrogen from the environment mainly as nitrate, reduce it to ammonia, and then assimilate ammonia into organic compounds to form amino acids. However, this process of assimilatory reduction of nitrate is not the only change that nitrogen undergoes.

In the biosphere nitrogen passes through many forms, ranging from the most reduced, NH_3 (or NH_4^+), to the most oxidized, NO_3^-, in a biogeochemical cycle whose steps depend on both physical and biological events. The processes that involve living organisms (Fig. 1) include the following:

- ammonification, carried out by saprophytic bacteria (e.g., *Clostridium* spp.) and fungi that detach NH_3 from organic nitrogenous compounds and release this reduced form of inorganic nitrogen into the environment;
- nitrification, carried out by chemosynthetic bacteria that draw energy from oxidation of ammonia to nitrite (e.g., *Nitrosomonas* spp.) and of nitrite to nitrate (e.g., *Nitrobacter* spp.):

$$NH_4^+ + 3/2\ O_2 \rightarrow NO_2^- + H_2O + 2H^+ \left(\Delta G^{0,} = -66\ \text{kcal mol}^{-1}\right)$$

$$NO_2^- + 1/2\ O_2 \rightarrow NO_3^- \left(\Delta G^{0,\prime} = -18\ \text{kcal mol}^{-1}\right)$$

- assimilatory reduction of nitrate to nitrite and then of nitrite to ammonia by nitrogen autotrophic organisms:

$$NO_3^- + NAD(P)H_2 \rightarrow NO_2^- + NAD(P)^+ + H_2O$$

$$NO_2^- + 6\ \text{reduced ferredoxins} + 8H^+ \rightarrow NH_4^+ + 6\ \text{oxidized ferredoxins} + 2\ H_2O$$

- ammonia assimilation into aminoacids (see the pathway in the Ammonia Assimilation section) that leads to the recovery of organic nitrogen, thus closing the cycle.

Nonetheless, biological pathways of irreversible nitrogen loss also exist. One of them is carried out by facultative aerobic bacteria. These microorganisms (e.g., *Pseudomonas* spp. and *Alcaligenes* spp.) bring about a process of dissimilatory reduction of nitrate, called denitrification. Under anoxic conditions they activate anaerobic respiration by using nitrate and other oxidized forms of nitrogen instead of oxygen as final electron acceptors of the respiratory chain:

$$2\ NO_3^- + 4e^- + 4H^+ \rightarrow 2\ NO_2^- + 2H_2O$$

$$2\ NO_2^- + 2e^- + 4H^+ \rightarrow 2NO + 2H_2O$$

$$2\ NO + 2e^- + 2H^+ \rightarrow N_2O + H_2O$$

$$N_2O + 2e^- + 2H^+ \rightarrow N_2 + H_2O$$

This leads to volatile nitrogen forms (e.g., N_2O or N_2), which are lost to the atmosphere.

Another widespread process which contributes substantially to the loss of fixed nitrogen as N_2 in different natural environments has recently been discovered. This process is the anaerobic ammonium oxidation (anammox) performed by chemoautotrophic bacteria ("anammox" bacteria, such as *Brocadia anammoxidans* and *Scalindua* spp.) that derive energy for growth from oxidation of NH_4^+ to N_2 in complete absence of oxygen using nitrite as electron acceptor:

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O\ \left(\Delta G^{0,\prime} = -86\ \text{kcal mol}^{-1}\right)$$

In natural ecosystems, the recovery of nitrogen, necessary to satisfy the nutritional demands of the inhabiting organisms, occurs through biological nitrogen fixation (Fig. 1). This event is of capital importance and consists in the reduction of molecular nitrogen (N_2) to ammonia (NH_3), providing the Earth's ecosystems with about 200 milion tons N per year. It has been estimated that the 80–90% of the nitrogen available to plants in natural ecosystems originates from biological nitrogen fixation.

	Calotrix

Nitrogen-Fixing Organisms

Nitrogen constitutes almost 80% of the atmosphere, but is metabolically inaccessible to plants due to the exceptional stability of the triple covalent bond (N≡N). The ability to catalyze enzymatic reduction of N_2 to NH_3 is limited to a variety of prokaryotes defined as nitrogen-fixing or diazotrophic microorganisms, which are widely distributed in all ecosystems as either free-living organisms or in symbiotic association with a number of different plants. These N_2-fixing prokaryotes can be anaerobic, facultative aerobic, aerobic, photosynthetic, or nonphotosynthetic (**Table 1**). All carry out N_2 reduction by an enzymatic complex termed nitrogenase.

Nitrogenase and Nitrogen Fixation

The complex of nitrogenase (**Fig. 2**) consists of two distinct enzymes: dinitrogenase reductase and dinitrogenase, neither of which has enzymatic activity by itself (Igarashi and Seefeldt, 2003). Dinitrogenase reductase is a dimeric (α_2) Fe-protein of about 70 kDa with a 4Fe–4S cluster, which binds ATP and transfers electrons to dinitrogenase. The latter enzyme is a tetrameric ($\alpha_2\beta_2$) FeMo protein of about 220 kDa. It contains two Mo–Fe–S clusters and a variable number of Fe–S clusters and binds N_2. Both these enzymes are very sensitive to oxygen, which rapidly inactivates them (Dixon and Wheeler, 1986).

The molybdenum requiring nitrogenase (Mo-N_2ase) is the long-studied enzyme complex found in all diazotrophs. However other two alternative nitrogenases have been identified in some free-living bacteria belonging to the genera *Azotobacter* and

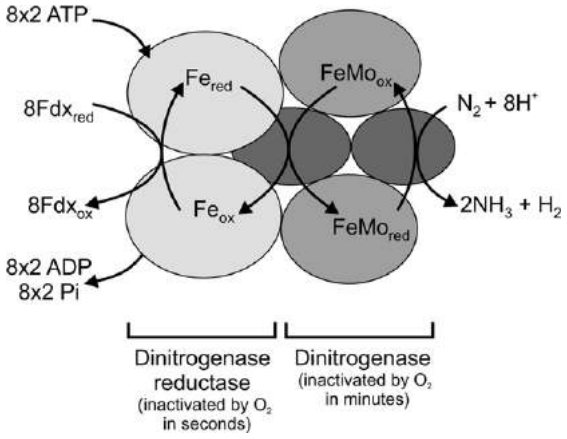

Fig. 2 The enzymatic complex of nitrogenase.

Rhodopseudomonas and in some cyanobacteria. These peculiar diazotrophic organisms can synthesize, in addition to Mo-Fe N_2ase, a vanadium nitrogenase (V-N_2ase) and a nitrogenase which requires only Fe (Fe-N_2ase) (Newton, 2007). The alternative nitrogenases may serve as substitutive pathways for nitrogen fixation in molybdenum deficient conditions. They are structurally similar to the Mo-N_2ase, except for the dinitrogenase components which are composed of $\alpha_2\beta_2\delta_2$ hexamers, they also operate in the same way, have the same requirements for activity and are reactive towards the same range of substrates.

In the nitrogen reduction carried out by the Mo-N_2ase (also referred to as conventional nitrogenase), the oxidized dinitrogenase reductase accepts an electron from a donor (reduced ferredoxin or reduced flavodoxin) and binds two molecules of adenosine 5′-triphosphate (ATP). This binding causes a conformational change of the Fe protein that lowers its redox potential (from -300 to -400 mV). The reduced Fe protein transfers the electron to the oxidized dinitroreductase with concomitant hydrolysis of both ATP molecules. Finally, the FeMo protein carries out the electron (and proton) transfer to the N_2 bound to the MoFe cofactor. Since six electrons are required to reduce N_2 to $2NH_3$, six sequential reduction events occur with the hydrolysis of 2ATP for each electron flowing through the nitrogenase. However, the nitrogenase also recognizes the protons (H^+) in the cell, so that for each N_2 reduced to $2NH_3$, two H^+ ions are reduced to H_2, with the involvement of two additional electrons and the hydrolysis of another 4ATP. Thus, the overall reaction catalyzed by nitrogenase in the diazothrophic organisms is

$$N_2 + 8e^- + 8H^+ + 16ATP \rightarrow 2NH_3 + H_2 + 16ADP + 16Pi$$

Under natural conditions the reduction of protons to hydrogen competes with that of nitrogen to ammonia for the electrons provided to nitrogenase by the donors. This lessens the efficiency of nitrogen fixation and leads to a waste of metabolic energy (ATP). Nevertheless, many nitrogen-fixing organisms have an uptake hydrogenase that reoxidizes H_2 to $2H^+$ and $2e^-$ The activity of this enzyme can greatly increase the efficiency of nitrogen fixation since it leads to ATP recovery by the flow of electrons through a respiratory transport chain, nitrogenase protection against the oxygen poisoning by reduction of O_2 to H_2O, and maintenance of nitrogenase activity by removal of H_2 that inhibits the enzyme.

For nitrogenase to function, low-potential electrons and energy (ATP) are needed. The most common source of electrons is ferredoxin (a small iron–sulfur protein). In phototrophic organisms the reduced ferredoxin can be derived from the photosynthetic electron flow, while in heterotrophic organisms the reduction occurs enzymatically through a pyruvate ferredoxin oxidoreductase that transfers electrons to oxidized ferredoxin from α-ketoacids such as pyruvate and α-ketoglutarate. An analogous reaction, carried out by a pyruvate flavodoxin oxidoreductase, produces reduced flavodoxin, a flavoprotein also used as an electron donor to nitrogenase. Some organisms may generate the required low-potential electrons by other alternative methods.

The source of energy for reduction of N_2 is ATP obtained from different metabolic pathways, according to the diazotrophic organism. In anaerobic phototrophic bacteria, the ATP comes from photosynthesis, while anaerobic heterotrophic organisms gain ATP essentially from fermentations that, due to the scarce oxidative efficiency, force them to consume large quantities of substrates. The aerobic organisms take advantage of the production of ATP through more efficient respiratory processes. Nevertheless, they still require mechanisms that keep oxygen away from the O_2-sensitive nitrogenase. Some of these mechanisms are described in the following sections.

Even if the nitrogen fixation is actually an exergonic process ($\Delta G^{\circ\prime} = -15.2$ kcal mol^{-1}), it has a high demand for energy due to the necessity to overcome unfavorable activation energies. The theoretical cost for reducing one molecule of N_2 with the concomitant reduction of $2H^+$ is 16ATP. However, under natural conditions the cost may be even higher due to the less than perfect efficiency of the process. This high energetic cost makes nitrogen fixation a strictly controlled process, through the modulation of the synthesis and activity of nitrogenase. All the other available forms of nitrogen (such as nitrate, nitrite, or amino acids) inactivate the enzymatic complex and inhibit the expression of the genes (*nif* genes) that code for the nitrogenase components (Helber *et al.*, 1988; Cheng *et al.*, 1999). The reaction products NH_3 and H_2 also cause strong inhibition. Thus, N_2 fixation is an inductive process that diazotrophic organisms activate only in the absence of other more economic nitrogen sources.

Ammonia Assimilation

The assimilation of NH_3 obtained from N_2 reduction occurs principally via the glutamine synthetase–glutamate synthase (GS-GOGAT) pathway (Nagatani *et al.*, 1971). The first enzyme catalyzes the ATP-dependent assimilation of ammonia into glutamine using glutamate as a substrate:

$$\text{Glutamate} + NH_3 + \text{ATP} \rightarrow \text{Glutamine} + \text{ADP} + \text{Pi}$$

The second enzyme catalyzes the reductive transfer of the amide group from glutamine to α-ketoglutarate, forming two molecules of glutamate. The reductants are NAD(P)H or reduced ferredoxin (Fdx_{red}):

$$\text{Glutamine} + \alpha - \text{ketoglutarate} + \text{NAD(P)H (or } Fdx_{red}) \rightarrow 2\text{glutamate} + \text{NAD(P)}^{+} (\text{or } Fdx_{ox})$$

One glutamate serves to keep the pathway going, whereas the other represents the gain in organic nitrogen.

Diazothrophic Bacteria – Plant Symbioses

Nitrogen-fixing microorganisms have been found in roots or other organs of many species of plants with which they establish symbiotic associations. The diazotrophic partners can be aerobic bacteria or, in some cases, cyanobacteria.

Symbiotic associations of current ecological importance for wide diffusion and the large nitrogen supply to the ecosystems are those between N_2-fixing bacteria and roots of higher plants and, in particular, the rhizobia-legume and *Frankia*-dicotyledon symbioses. Another association of particular interest is that established by endophytic diazotrophic bacteria with cereals.

Rhizobia–Legume Symbiosis

Most Leguminosae (about 90%) can establish a symbiotic association with aerobic diazotrophic Gram-negative bacteria commonly referred to as rhizobia. This symbiosis takes place in roots and brings about the formation of nodules in which N_2 fixation occurs. The large contribution made by these symbioses to the nitrogen availability for agronomically important legumes is well known. *Medicago sativa*, for instance, can fix 300 kg N ha^{-1} $year^{-1}$ and *Vicia faba* over 500 kg N ha^{-1} $year^{-1}$. It has been calculated that soybean (*Glycine max*), which is the dominant crop legume, representing 68% of global production, can fix more than 16×10^6 T N annually, corresponding to over 75% of the N fixed by crop legumes (Herridge *et al.*, 2008).

This makes biological nitrogen fixation a major component of sustainable agricultural systems, since it has the potential to greatly limit the use of chemical nitrogen fertilizers.

Numerous species belonging to the family Leguminosae are also abundant in natural ecosystems, such as the forests of tropical regions (e.g., those in Brazil and Guyanas) (Koponen *et al.*, 2003, Kreibich *et al.*, 2006), where they can represent over 50% of all trees. Tropical forests often grow on substrates poor in mineral nutrients, and thus the continuous supply of nitrogen through biological N_2 fixation acquires an essential role to maintain large nitrogen pools in these ecosystems.

The rhizobia forming symbiosis with legume roots belong to five different genera: *Rhizobium*, *Azorhizobium*, *Mesorhizobium*, *Sinorhizobium*, and *Bradyrhizobium*. A given species of bacterium establishes symbiosis with one or few species of legumes (**Table 2**).

This is due to the host-symbiont recognition occurring in the rhizosphere through the exchange of molecular signals. The first event of the root nodule formation is the chemotactic movement of the bacterium toward the root of the host plant in response to chemical attractants, usually specific flavonoids secreted by the root under nitrogen-starvation conditions. Each legume species produces its own particular cocktail of these compounds and this contributes to one of the distinctive characteristics of rhyzobium-legume symbiosis, with a rhizobial species usually infecting a very limited host range (Marks, 2004).

The compounds secreted by the roots induce the expression of host-specific bacterial genes (*nod* genes) coding for Nod factors (lipo-chito-oligosaccharides) that, in turn, induce plant responses and trigger the nodule developmental program (Spaink, 2000).

Root infection starts with the bacterium-induced curling of a root hair, bacterium attachment to the hair surface, cell wall degradation, and formation of the infection thread. This is an internal tubular extension of the hair plasma membrane that carries out the proliferating rhizobia from the root surface into the root cortex. Concomitantly, some cortical cells undergo rapid divisions

Table 2 Some examples of associations between rhizobia and legumes

Rhizobia	*Host plants*
Bradyrizobium japonicum	*Glycine*, *Vigna*
Sinorhizobium meliloti	*Medicago*, *Trigonella*, *Melilotus*
Sinorhizobium fedii	*Glycine*, *Vigna*
Azorhizobium caulinodans	*Sesbania*
Rhizobium leguminosarum biovar. *phaseoli*	*Phaseolus*
Rhizobium leguminosarum biovar. *trifolii*	*Trifolium*
Rhizobium leguminosarum biovar. *viciae*	*Vicia*, *Pisum*, *Cicer*
Mesorhizobium loti	*Lotus*, *Lupinus*, *Anthillis*

that give rise to the nodule primordium. When the branched infection thread reaches target cells within the developing nodule, its tip vesiculates releasing bacteria packaged in a membrane derived from the host cell plasmalemma. The rhizobia undergo some divisions but very soon they stop dividing and differentiate into diazotrophic bacteroids. Bacteroids and surrounding peribacteroid membrane form the symbiosome (**Fig. 3(b)**), which is the site of N_2 fixation. In the mature nodule (**Fig. 3(a)**) specialized structures are developed around the infected tissue: an endodermis and a vascular system continuous with the root stele, and a layer of cells hampering O_2 diffusion to the root nodule interior. Some leguminous species such as soybean, peanut, and bean form spherical determinate nodules with a nonpersistent meristem (**Fig. 3(a)**).

Others, such as pea, clover, and alfalfa, form cylindrical indeterminate nodules with a persistent terminal meristem (**Fig. 4**). The mature determinate nodule contains a homogenous central tissue with cells fully packed with nitrogen fixing bacteroids, whereas in the indeterminate nodule a gradient of developmental states occurs, due to the active meristem that continuously produces cells that become infected with bacteria (Ferguson *et al.*, 2010). At maturity a meristematic zone, an invasion zone with infection threads, a N_2-fixing zone with bacteroids and a senescent zone with degraded bacteroids can be distinguished along the nodule axis (**Fig. 4**).

Different mechanisms take place to obtain the microaerobic environment appropriate for maintaining ATP production in host cells and bacteroids and for preserving, at the same time, nitrogenase activity in N_2-fixing tissue. The first hindrance to the entry of oxygen into the infected cells is the mechanical diffusion barrier in the nodule parenchyma. Moreover, leghemoglobin is synthesized in the cytoplasm of the host cells (Downie, 2005). This oxygen-binding protein plays a major role in delivering oxygen to the bacteroid surface and accounts for the characteristic pink color of N_2-fixing tissue. Efficient bacteriod respiration also restricts oxygen penetration into the cytoplasm and provides nitrogenase with the ATP and reductants required. Finally, in most rhizobia the activity of an uptake hydrogenase is an additional help for protecting nitrogenase against the O_2-poisoning (Ciccolella *et al.*, 2010).

Bacteroids do not have enzymes for the ammonia assimilation. For this reason, the NH_3 obtained from N_2 reduction is released into the root cell where the assimilation occurs via GS-GOGAT pathway (**Fig. 5**). This leads to production of glutamine, glutamate, and, successively, of other nitrogenous transport compounds. Some of these organic compounds are returned to the bacteroids, but most are exported to the plant shoot via xylem.

In order to sustain N_2 fixation, the host plant must supply the bacteroids with a carbon source, which arrives to the root nodule via phloem as sucrose. However, this sugar is metabolized in the host cell and converted to C_4 dicarboxylates, principally malate. The dicarboxylates, in fact, are transported across the peribacteroid membrane, becoming the primary carbon source for the N_2-fixing organisms (White *et al.*, 2007).

Symbiotic nitrogen fixation is crucial to success of legumes, but the plant has to control the number of nodules it forms to balance the nitrogen gains with the developmental costs in order to avoid the severe energy drain that would be imposed by having to many nitrogen fixing nodules. The control of nodule number on the colonized root occurs via a complex systemic mechanism called "autoregulation of nodulation", based on root-derived and shoot-derived signals (Kouchi *et al.*, 2010).

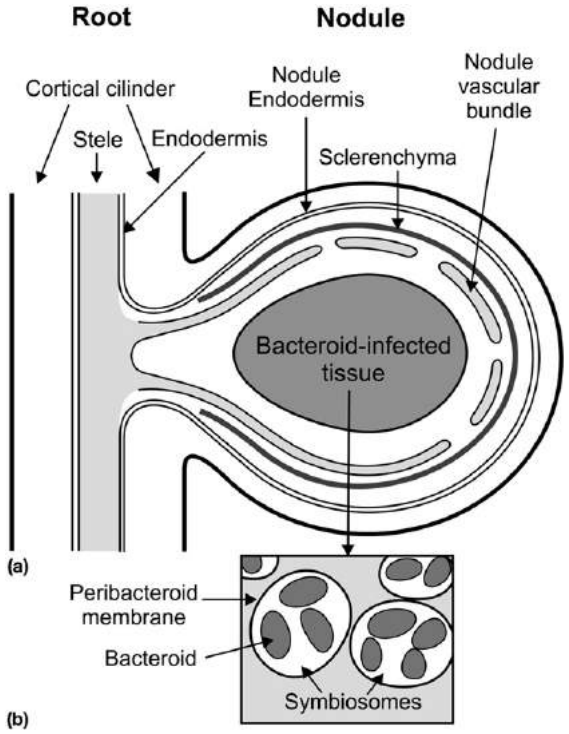

Fig. 3 Schematic drawings of: (a) a determinate root nodule of a rhizobia-legume symbiosis and (b) a part of an infected cell with symbiosomes.

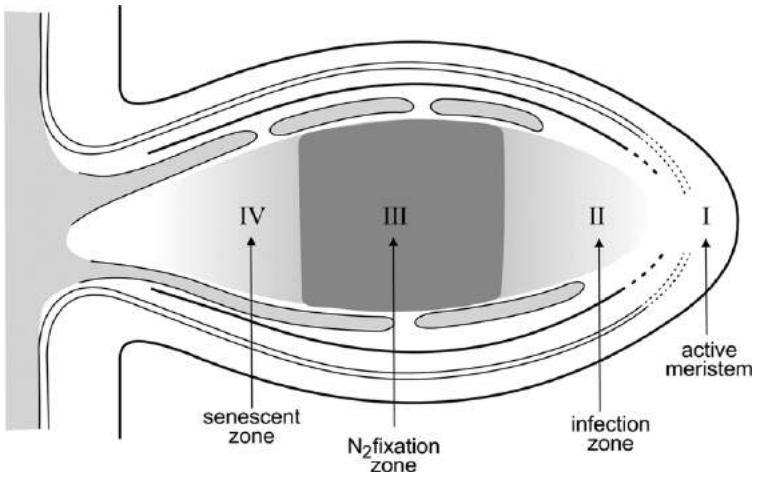

Fig. 4 Schematic drawing of an indeterminate root nodule of a rhizobia-legume symbiosis.

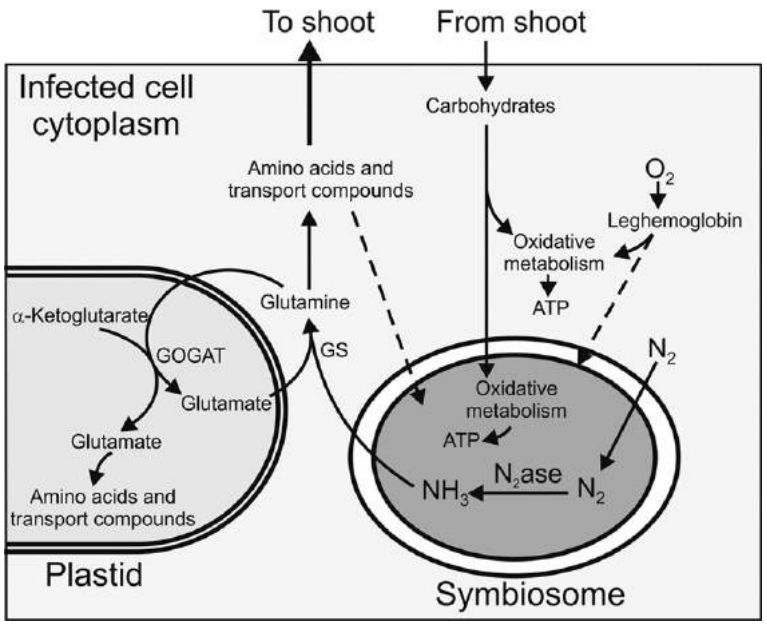

Fig. 5 A simplified diagram showing nitrogen fixation and ammonia assimilation in an infected cell of a legume root nodule. GOGAT, glutamate syntase; GS, glutamine syntetase; N_2ase, nitrogenase.

Furthermore legume regulates the nodule number in response to environmental nitrogen (nitrate or ammonia) availability to preferentially obtain this nutrient from sources energetically favourable relative to the cost of nodulation (Jeudy *et al.*, 2009).

In both determinate and indeterminate nodules bacteroids carry out an optimal N_2-fixation for 4–5 weeks after infection. Beyond this period the bacteroid activity declines and a senescence process occurs in the N_2-fixing zone, leading to degradation of the infected cells. Finally, bacteroids (or some undifferentiated bacteria) are released from decayed nodules to the soil where they can recolonize the rhizosphere resuming the free saprophytic lifestyle.

Frankia-Dicotyledon Symbiosis

The aerobic Gram-positive actinomycetes belonging to the genus *Frankia* are diazotrophic bacteria that are capable of inducing formation of N_2-fixing nodule lobes in roots of many dicotyledonous angiosperms. The plants nodulated by *Frankia* strains are known as actinorhizal plants and include 8 families, 25 genera, and over 200 species, most of which are perennial woody shrubs or trees distributed in all landmasses except Antarctica. The actinorhizal plants share a predilection for marginally fertile soils and the majority are pioneers on nitrogen-poor sites. In addition, many actinorhizal species are able to tolerate environmental stresses such as heavy metals, high salinity, drought, cold, and extreme pH. They inhabit a variety of ecosystems, including coastal dunes,

riparian zones, alpine communities, arctic tundra, glacial tills, and forests. Actinorhizal plants are especially important in high latitude regions, such as Scandinavia, Canada, Alaska, and New Zealand where Leguminosae are absent or rare while actinorhizal plants are abundant and capable of vigorous growth (Wall, 2000). Much of the new nitrogen entering these ecosystems comes from the actinorhizal symbioses that, on the whole, account for over 15% of the biologically fixed nitrogen worldwide.

The filamentous frankiae, besides in symbiotic association with actinorhizal plants, can also occur as free-living diazotrophic organisms (Benson and Silvester, 1993). In pure culture, *Frankia* strains produce extensive hyphae and sporangia. In response to nitrogen deprivation, they also differentiate vesicles, named diazovesicles, which contain nitrogenase and are the site of N_2 fixation. The diazovesicles are encapsulated by a series of laminated lipid layers that are rich in neutral lipids, glycolipids, and hopanoids. This envelope, whose thickness depends on the environmental O_2 concentration, works as an oxygen-diffusion barrier, providing an anaerobic environment for nitrogenase to function inside vesicles (Berry *et al.*, 1993).

The *Frankia* strains that nodulated actinorhizal plants can be phylogenetically distinct in three groups (groups I, II, and III) that infect specific dicotyledon families (**Table 3**).

Actinorhizal plants fall into families of three related orders: Rosales (Rosaceae, Eleagnaceae, Rhamnaceae), Fagales (Betulaceae, Casuarinaceae, Myricaceae) and Cucurbitales (Coriariaceae, Datiscaceae). Together with Fabales (legumes), they form a single "nitrogen-fixing clade" within the angiosperms (Soltis *et al.*, 1995).

In the actinorhizal symbioses, root nodule formation begins with the host-symbiont recognition through the exchange of molecular signals, the knowledge of which is still limited.

However, some findings suggest that the signaling mechanisms of *Frankia*-actinorhizal plants might be similar to those of rhizobia-legumes (Hocher *et al.*, 2011b) and genomic analyses reinforce the hypothesis of a possible single origin for legume-rhizobia and actinorhizal symbioses (Hocher *et al.*, 2011a).

Frankia strains can infect the host root by intracellular or intercellular mechanisms. Intracellular infection, such as that occurring in genera *Myrica*, *Comptonia*, *Alnus*, and *Casuarina*, starts with penetration of bacterial hyphae in a curled root hair. Afterward the hyphae move in cortical cells encapsulated with a layer of plant cell wall material surrounded by host plasmalemma. In intercellular infection, common in genera *Elaeagnus*, *Ceanothus*, and *Cercocarpus*, the bacterial hyphae penetrate between two adjacent rhizoderm cells and progress apoplastically through cortical cells encapsulated in a pectic matrix. Concomitantly, cell divisions induced in the root pericycle give rise to the nodule lobe primordium to which the hyphae move. The mature actinorhizal nodule lobe resembles a modified lateral root with an apical meristem but without a root cap. It shows a central stele with vascular tissues and has *Frankia* hyphae restricted to the cortical cells (**Fig. 6**).

In most actinorhizal symbioses, the N_2-fixing activity of *Frankia* in infected cells is associated with differentiation of diazovesicles whose morphology is strictly controlled by the host plant. As in the free-living frankiae, these vesicles are surrounded by the multilayered lipid envelope and contain nitrogenase. However, in some symbioses (with plants of genera *Myrica*, *Coriaria*, *Comptonia*, and *Casuarina*), the *Frankia* hyphae proliferate without forming vesicles. The mature anatomy of a nodule lobe is reached at about 2 weeks after inoculation while the N_2-fixation can be detected after three weeks (Huss-Danell, 1997).

In infected cells of mature nodule lobes, some mechanisms take place to lower the oxygen tension near the site of the oxygen-intolerant nitrogenase. The first diffusion resistance to oxygen is provided in diazovesicles by the multilayered envelope and a further reduction of the pO_2 is obtained through their high respiration rate. In many nodule lobes devoid of diazovesicles, the infected cells contain high levels of hemoglobins that have homologous sequences to leghemoglobins and are believed to play the same role (Fleming *et al.*, 1987). In these nodules, moreover, a low pO_2 may be maintained by lignification of the host cell walls. Finally, the activity of uptake hydrogenases can also help to protect the nitrogenase against O_2 in both hyphae and diazovesicles of the symbiotic frankiae (Leul *et al.*, 2009). In free-living *Frankia* strains, as in the other free-living diazotrophs, the ammonia produced by N_2 fixation is assimilated by the organism via the GS-GOGAT pathway. On the contrary, these enzymes are differently regulated in the symbiotic frankiae. In diazovesicles of root nodule lobes GS activity is very low and ammonia remains unassimilated (Alloisio *et al.*, 2010). As in rhizobia–legume symbiosis, NH_3 is released into the host cell where its assimilation gives rise to amino acids and other organic nitrogen compounds. Some are furnished to the bacterium, but most of them are transferred to the plant shoot.

Table 3 Association between *Frankia* and actinorhizal plants

Frankia phylogenetic groups	*Plant families*	*Plant genera*
Group I strains	Coriariaceae	*Coriaria*
	Datiscaceae	*Datisca*
	Rosaceae	*Cercocarpus*, *Chamaebatia*, *Dryas*, *Cowania*, *Purshia Ceanothus*
	Rhamnaceae	
Group II strains	Betulaceae	*Alnus*
	Casuarinaceae	*Casuarina*, *Allocasuarina*, *Ceuthostoma*, *Gymnostoma*
	Myricaceae	*Myrica*, *Comptonia*
Group III strains[a]	Elaeagnaceae	*Elaeagnus*, *Hippophaë*, *Shepherdia*
	Rhamnaceae	*Calletia*, *Discaria*, *Kentrothamnus*, *Retanilla*, *Talguenea*, *Trevoa*

[a]Group III strains are more promiscuous and can occasionally inhabit root nodules of Rosaceae, Coriariaceae and *Ceanothus*.

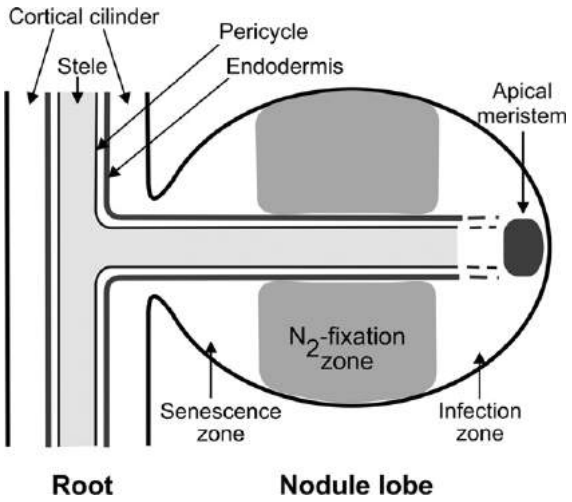

Fig. 6 Schematic drawing of a mature actinorhizal nodule lobe.

The scarcity or lack of GS activity in the diazotrophic symbiont also characterizes the rhizobia legumes as well as some cyanobacterial symbioses such as *Anabaena–Azolla*, showing a remarkable convergence of physiological strategies in the N_2-fixing associations.

The actinorhizal plant must provide photosynthates to the symbiotic bacterium. As in the rhizobia–legume symbiosis C_4 dicarboxylates derived from sucrose metabolism occurring in the host cell are likely to be the carbon sources for *Frankia* strains in actinorhizal symbiosis.

Furthermore, as it occurs in rhizobia–legume symbiosis, the actinorhizal plants can control infection by *Frankia* and regulate number and development of nodule lobes on roots by systemic autoregulatory processes (Wall *et al.*, 2003).

Endophytic Diazotrophic Bacteria–Cereal Association

A recently discovered nitrogen-fixing association is that between grasses, such as sugar cane, maize, rice, wheat, sorghum, and other graminaceous species and endophytic diazotrophic bacteria that can colonize the plant interior without causing symptoms of disease. These bacteria enter the plants at root tips or at the emergence points of lateral roots and penetrate the root cortex, the stelar tissues, and the xylem vessels through which they may migrate toward the shoot (Cocking, 2003). Endophytic diazotrophic bacteria are generally restricted to intercellular spaces and especially to the xylem vessels where the low pO_2 and the high bacterial respiration rate create the microaerobic conditions needed for nitrogenase activity. Some of these diazotrophic microorganisms, such as those belonging to the genera *Acetobacter*, *Herbaspirillum*, *Azospirillum*, and *Azoarcus*, are of extreme interest since they can significantly contribute to the nitrogen requirement of the graminaceous plants (Kennedy *et al.*, 2004). Certain rice varieties, for instance, can obtain over 30% of their nitrogen from these endophytes (James *et al.*, 2002) and some Brazilian sugarcane varieties up to 80%, with a total contribution of more than 170 kg N ha^{-1} $year^{-1}$. (Urquiaga *et al.*, 1992).

Studies of these N_2-fixing associations form a topical field of research whose aim is to explore the possibility of both enhancing the N_2 fixation and extending this efficient system to other cereals. This would greatly reduce the use of nitrogen fertilizers with considerable economic benefits, and, above all, with enormous environmental advantages. Over two-thirds of arable lands, in fact, are dedicated to the growing of cereals, which provide 80% of the food for the world's populations.

Nitrogen Fixation in Free-Living Cyanobacteria

Among the free-living diazotrophs a prevailing interest is that addressed to cyanobacteria. This interest comes from the wide and abundant distribution of these microorganisms in all terrestrial and aquatic ecosystems as well as from their unique photosynthetic metabolism that makes the nitrogen fixation an apparently paradoxical event. Cyanobacteria, in fact, are the only prokaryotes that carry out oxygenic photosynthesis.

A very great number of these microorganisms is able to both fix N_2 under aerobic conditions and produce O_2 by photosynthesis. Filamentous cyanobacteria resolve this oxygenic photosynthesis–diazotrophy paradox by segregating the oxygen-sensitive machinery for N_2 fixation in specialized nonphotosynthetic cells named heterocysts, and by maintaining the oxygen evolving photosynthesis in the neighboring vegetative cells. Thus, the simultaneous operation of the two basically incompatible processes is made possible through their spatial separation.

Nitrogen starvation leads to the appearance at regular intervals along the cyanobacterial filament of heterocysts which function as anaerobic factories for N_2 fixation under external aerobic conditions. The ability to fix N_2 ensues from changes that occur in vegetative cells that differentiate to heterocysts (Fig. 7).

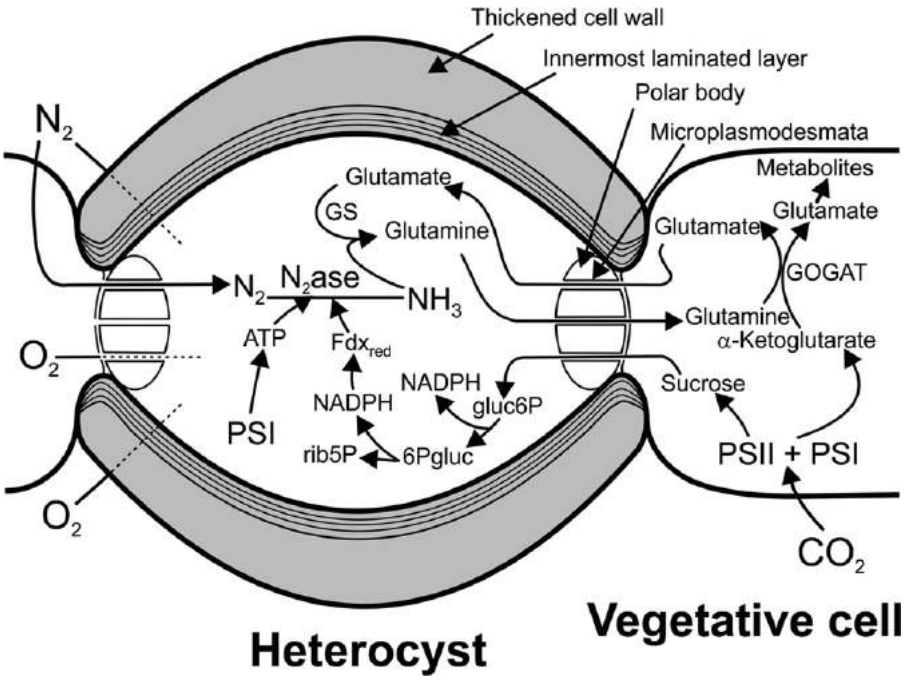

Fig. 7 Schematic drawing of a cyanobacterial heterocyst showing nitrogen fixation and metabolite exchange with the neighboring vegetative cell. Fd_{red}, reduced ferredoxin; gluc6, glucose-6-phosphate; 6gluc, gluconate-6-phosphate; GOGAT, glutamate syntase; GS, glutamine syntetase; N_2ase, nitrogenase; PSI, photosystem I; PSII, photosystem II; rib5P, ribulose-5-phosphate.

First they build up a very thick cell wall with an innermost laminated glycolipid layer, whose function is to provide an O_2 permeability barrier to avoid the inactivation of nitrogenase inside the cell (Nicolaisen *et al.*, 2009). The connections between heterocyst and neighbor cell occur through thin cytoplasmic channels (microplasmodesmata), which traverse the septum separating the two cells and the plag (polar body) of cyanophycin filling the adjacent region (Mullineaux *et al.*, 2008). In addition, the photosynthetic apparatus undergoes a deep reorganization during the heterocyst differentiation: phycobilisomes disappear and the oxygen-evolving photosystem II is totally dismantled, while photosystem I, which produces ATP through cyclic photophosphorylation, persists in thylakoid membranes (Wolk, 1996). The ATP necessary to fulfill the energy demand for nitrogenase activity, in fact, comes in heterocysts from cyclic photophosphorylation, while the reductant for the N_2-fixing enzyme is furnished by neighboring photosynthetic cells probably as sucrose (Cumino *et al.*, 2007). The sugar hydrolysis and glucose oxidation through the pentose phosphate pathway produces NADPH used for ferredoxin reduction.

The heterocysts of free-living cyanobacteria contain high levels of glutamine synthetase (GS), but are deficient in GOGAT that, on the contrary, is active in vegetative cells. Thus, after N_2 reduction, the NH_3 assimilation in glutamine is carried out in the heterocyst while the successive reaction leading to glutamate synthesis occurs in the near vegetative cell into which glutamine moves through microplasmodesmata (Martin-Figueroa *et al.*, 2000).

A major role in protecting nitrogenase against O_2 is played in heterocysts by the thick cell wall which prevents gas diffusion toward the cell. However, it is unlikely that this envelope provides a truly impermeable gas diffusion barrier, since this would also exclude nitrogen from the fixation site. Moreover, gases can reach the heterocyst cytoplasm through the junctions between them and the contiguous vegetative cells which produce O_2 by photosynthesis. Thus, also cyanobacterial heterocysts, as the other aerobic diazotrophic organisms, need systems to remove oxygen that enters the cell. These include enhanced rate or respiration (Valladares *et al.*, 2007), probable presence of hemoproteins in the cytoplasm peripheral region, and activity of an uptake hydrogenase (Tamagnini *et al.*, 2007).

A great ecological interest arose from the unexpected finding that unicellular and nonheterocystous filamentous cyanobacteria are also able to both fix nitrogen and carry out oxygenic photosynthesis. These cyanobacteria, which are very abundant in the phytoplanktonic populations of marine environments, are responsible for most of the photosynthetic organic carbon provided to the ecosystem (Karl *et al.*, 2002), and they may also account for a high percentage of the nitrogen fixed biologically worldwide.

The oxygenic photosynthesis–diazotrophy paradox is resolved by these nonheterocystous cyanobacteria through creative strategies enabling them to separate spatially or temporally the two incompatible processes.

The marine filamentous cyanobacteria of genus *Trichodesmium* fix nitrogen during the light period in a subset of specialized nitrogenase-containing cells, named diazocytes, formed by cell division primarily confined to dark period. In addition, nitrogenase shows a diurnal pattern in which its activity is highest early in the day (Sandh *et al.*, 2009).

A number of unicellular diazotrophic cyanobacteria, such as those of genus *Cyanothece*, exhibit temporal separation of the two physiological processes that should necessarily occur in the same cell. They carry out only the oxygenic photosynthesis during the

day and fix N_2 only during the night, when the photosynthetic O_2 production does not occur. This timing of N_2 fixation is also related to the fact that the nitrogenase is active exclusively during the dark period. Interestingly, the daily oscillation of nitrogenase activity occurs according to an endogenous circadian rhythm (Toepel *et al.*, 2008).

The finding that the nitrogenase of nonheterocystous N_2-fixing cyanobacteria possesses this kind of rhythmic activity was also of great scientific importance since it was the first clearly recognized circadian rhythm in prokaryotic organisms, which led to the backdrop of the former dogma that restricted the biological clocks to eukaryotes (Golden *et al.*, 1997).

Diazotrophic Cyanobacteria–Plant Symbioses

Many species of filamentous N_2-fixing cyanobacteria, in the great majority of cases belonging to the genus *Nostoc*, can form symbiotic associations with a wide range of eukaryotic hosts, among which fungi (cyanolichens), microalgae (diatoms), corals, sponges and numerous plants.

The cyanobacteria-plant symbioses include Bryophyta (liverworts, hornworts, and mosses), Pteridophyta (the genus *Azolla*), gymnosperms (Cycadaceae) and angiosperms (Gunneraceae) as hosts.

The free-living cyanobacteria which can form these symbiotic associations share two major characteristics: they are able to differentiate heterocysts and to produce short motile filaments, known as hormogonia. Hormogonia, which provide a means of dispersal for otherwise immotile cyanobacteria, are the infective agents which enter the host plant tissues (Meeks and Elhai, 2002).

The hormogonia, which are devoid of heterocysts, form in response to chemical signals (HIFs: hormogonia-inducing factors) released from the plant, that also produces chemoatractants to guide them into symbiotic cavities. Subsequent to the infection the host may release signals (HRFs: hormogonia-repressing factors) to prevent formation of further hormogonia and to shift the cyanobiont development towards heterocyst differentiation and N_2 fixation (Rai *et al.*, 2000). The frequency of heterocysts in filaments of the symbiotic cyanobacterium is several folds higher than in the same cyanobacterium in free-living state. However, only a low quantity of nitrogen fixed is retained by the cyanobiont, the remaining being transferred to the host plant as ammonia. Photosynthesis can be highly depresses in cyanobionts, relative to that in free-living strains, but the reduced CO_2 fixation is compensated by sugars derived from the hosts (Meeks, 2003).

Among the numerous cyanobacteria-plant symbioses, particular attention has been paid to that between the cyanobiont *Anabaena azollae* and the leaves of the aquatic fern *Azolla*. The interest for the *Anabaena–Azolla* association is mainly due to the potential use of *Azolla* as fertilizer in rice fields.

Anabaeana–Azolla Symbiosis

Azolla is a small floating fern and is the only known pteridophyte that lives in symbiosis with a diazotrophic cyanobacterium. All the species of the genus harbour in their fronds a filamentous N_2-fixing cyanobacterium until now referred as *Anabaena azollae* (Nostocaceae) (Papaefthimiou *et al.*, 2008).

The *Azolla* sporophyte (generally 0.5–7 cm in lenght but up to 40 cm in *A. nilotica*) consists of a multibranched rhizome generating, on the ventral surface, adventitious roots hanging down into the water to absorb nutrients directly. The rhizome bears small leaves (approximatively 1 mm in length) consisting of an aerial chlorophyllous dorsal lobe and a partially submerged colourless ventral lobe which is cup-shaped to provide buoyancy. Each dorsal lobe contains a specialized cavity housing the cyanobiont permanently.

The mature cavity, ellipsoid in shape, has the interior surface covered by a mucilaginous layer delimited by an envelope, where 2000–5000 cyanobacterial cells are embedded and immobilized. Several trichomes, traditionally called hairs, protrude from the cavity surface into the mucilage layer and create an intimate contact between the symbiotic partners helping in the exchange of metabolites. Thus the leaf cavity can be considered as a natural microcosm with a self organization and an ecological defined structure. It behaves as both the physiological and dynamic interface unit of the symbiotic association where the main metabolic and energetic flows occur (Peters and Perkins, 1993; Rai *et al.*, 2000).

The diazotrophic cyanobacterium *Anabaena azollae* consists of unbranched filaments containing bead-like highly pigmented vegetative cells and lightly pigmented intercalary N_2-fixing heterocysts. In the youngest leaves of the water fern the *Anabaena* filaments lack heterocysts while these gradually increase in frequency, relative to photosynthetic cells, reaching 30%–40% of the cyanobacterial cells in *Anabaena* population of mature leaf cavities. This heterocyst frequency in *Azolla*-associated *Anabaena* (compared to 5%–6% in other free-living species of *Anabaena*) is far higher than necessary to support the fixed N needs of the symbiotic cyanobacterium. Moreover, an overall decrease (up to 70%) in GS activity in the *Azolla* cyanobiont has also been shown, that limits the ammonia assimilation in heterocysts. Thus, some 50%–90% of fixed nitrogen is delivered by *Anabaena* to the fern as ammonia. Translocation of fixed N from the symbiotic environment of mature cavities to other parts of the host plant occurs in the form of amino acids.

Concomitantly with the differentiation of *Anabaena* into a higher proportion of nitrogen-fixing heterocysts, relative to the photosynthetic cells, a reduction of photosynthesis and CO_2 fixation occurs in cyanobacterial filaments, which are supplied with sucrose by the host plant (Chapman and Margulis, 1998).

The *Anabaena–Azolla* symbiosis is perpetual and hereditary and the symbiotic condition can be described as obligate for the cyanobiont whose free-living form is not found in nature.

The symbiosis is maintained during all the life cycle of the pteridophyte throughout both sexual and asexual reproduction without requiring fresh infection from the environment. In contrast with other plant-cyanobacterial symbioses, *Azolla* hormogonium initiation factors (HIFs) are unknown. A colony of *Anabaena* is associated with each fern shoot apex and, as the plant grows, the cyanobacterial filaments are partitioned off into each new leaf.

In the *Azolla–Anabaena* symbiosis, the cyanobiont growth is synchronized with that of the host plant. The growth rates of both partners are highest in the apical parts of the fern and decrease along the axis away from the apex. When growth of *Azolla* stops, cyanobiont cells cease to divide (Lechno-Yossef and Nierzwicki-Bauer, 2002).

The water fern *Azolla* naturally occurs on lake surfaces, slow-moving rivers, canals, ponds, and ditches in warm-temperate to tropical climates, but its world distribution has been enlarged by humans. In fact, the *Anabaena–Azolla* association has been shown to be of major agronomic importance for its potentiality as a biofertilizer to substitute chemical nitrogen compounds. *Azolla* has been used as "green manure" in several countries to fertilize rice paddies and to increase rice yields (van Hove and Lejeune, 2002). *Azolla–Anabaena* is capable of fixing nitrogen at higher rates than legumes and is able to growth successfully in waterlogged habitats having low level of nitrogen. The Asians have recognized benefits of *Azolla* on rice cultivation first, since both rice crop and fern require similar environmental growing conditions. In rice fields, for instance, it can fix over 1 kg N ha^{-1} day^{-1}, providing sufficient nitrogen to allow sustainable rice cultivation. Increase from 14% to 40% in grain yield of rice has been reported with *Azolla* used as dual crop. Moreover, *Azolla* has a high rate of multiplication, which helps in covering very rapidly the surface of water bodies where it is growing. Thus the thick mat produced helps to reduce the volatilization of ammonia in rice fields.

The exploitation of this system in temperate environments is limited due to the *Anabaena–Azolla* sensitivity to low winter temperatures and to alternating day/night temperatures in spring before the rice sowing period (Pabby *et al.*, 2003). Recently, however, *Azolla* strains have been selected as practicable biofertilizer even in the high latitude of the temperate rice areas, such as those of Northern Italy (Bocchi and Malgioglio, 2010).

Besides its extensive use as a N-supplement in rice-based ecosystems, it has also been utilized in other crop cultivations such as taro, wheat, tomato, and banana.

Furthermore, the *Anabaena–Azolla* association is also applied as controlling agent for weeds and mosquitos, due to its ability to cover water surfaces, and for improving water quality for its properties of removing excess quantities of nitrate and phosphorous.

Cyanolichens

Lichens are symbiotic associations between fungi (mycobionts, commonly Ascomycetes) and photosynthetic partners (photobionts) which can be green algae (commonly *Trebouxia* spp.) or diazotrophic cyanobacteria (commonly *Nostoc* spp.). These mycobiont-photobiont symbioses are regarded as mutualistic. The photoautotroph partners provide photosynthetic products and, in the case of cyanobacteria, also organic nitrogen compounds to the fungus. This latter, in turn, provides shelter for the photobionts by enclosing them within the thallus. In this way the photosynthetic organisms, protected from drying and strong sunlight, are allowed to growth in very harsh conditions.

Lichens can tolerate the most extreme environments on Earth. They can live in hot deserts and arctic regions, on steril soils, bare rocks, wood debris and epiphytes on tree trunks, branches and leaves. Recently it has been reported that lichens are able to survive exposure to space conditions and even to adapt to the harsh Mars environment (de Vera, 2012; Raggio *et al.*, 2011). Lichens can reproduce asexually through the dispersal of small fragments of thallus or through propagules (diaspores) tipically containing cells from the symbiotic partners.

Bipartite lichens are symbiotic associations of a fungus with a single photosynthetic partner, which in so-called chlorolichens is a green alga while in lichens defined as cyanolichens is a diazotrophic cyanobacterium. In these latter associations the cyanobacterium may be localized in a distinct layer or dispersed through the thallus. As the sole photobiont, it is responsible for provision of both fixed carbon and fixed nitrogen to the mycobiont. The cyanobacterium maintains high photosynthetic levels and N_2-fixing activity, with heterocyst frequency (7–8%) close to its free-living counterpart.

In tripartite lichens the fungus is associated with both a green alga (phycobiont) and a cyanobacterium (cyanobiont). In these cyanolichens (also referred to as cephalolichens) the phycobiont is widely distributed through the thallus, while the cyanobiont is confined to special structures, named cephalodia. In cephalodia the cyanobiont becomes predominantly heterotrophic and is specialized for nitrogen fixation, as shown by the increase of heterocyst proportion over 30% of cyanobacterial cells. Thus, in these tripartite cyanolichens the fixed carbon is provided to the fungus by the phycobiont, while the cyanobiont supplies it with the fixed nitrogen.

A Swift Ecological Overview of Biological Nitrogen Fixation in Terrestrial and Aquatic Ecosystems

Nitrogen is an essential element for all living organisms and the nitrogen supply is crucial for the ecology and biogeochemistry of terrestrial and aquatic ecosystems. A number of both physical (e.g., the dissolved nitrate exiting with percolating waters) and biological (e.g., denitrification and anammox) processes tend to restrict the biological nitrogen availability in the ecosystems. Apart from a minor contribution by lighting, the biological nitrogen fixation is the process which provides the largest source of new combined nitrogen to natural environments for replenishing the nitrogen losses. However, the fixation rates vary widely

across the different ecosystems where symbiotic and free-living diazotrophic microorganisms can be differently involved in the process. Although the biological fixation is the major nitrogen input into terrestrial and aquatic ecosystems, currently there is only limited understanding about the factors that regulate this process in natural environments.

In arid lands of the world, from arctic ecosystems (Stewart *et al.*, 2011) to hot deserts of Southern Africa (Büdel *et al.*, 2009), much of the nitrogen input via biological nitrogen fixation relies heavily on diazotrophic microorganisms, mostly cyanobacteria, living in biological soil crusts (BSCs). The BSCs, also referred to as cryptogamic crusts, are microbic communities (millimeters to centimeters thick) covering large portions of the dryland soils (more than 70% in untouched deserts of North America). BSCs are composed of fungi, cyanobacteria and microalgae, either as free-living organisms or as partners of lichen symbioses. Also symbiotic cyanobacteria-bryophyte associations can occur in well developed BSCs, which substantially contribute to available nitrogen increase in these extreme environments.

Biological nitrogen fixation is limited in arctic and alpine tundra as well in enormous extended boreal forests of Eurasia and North America. The majority of nitrogen accretion in these environments occurs through cyanobacteria either free-living or symbiotic in cyanolichens or associated with bryophytes. The boreal forests lack significant quantities of plants forming root symbioses with diazotrophic bacteria (referred to as N_2-fixing plants), with the exception of actinorhizal forms, among which species of *Alnus* and *Ceanothus* and of the coushion-forming dwarf shrubs *Dryas*. However, these fast-growing pioneer plants substantially contribute to nitrogen input only in early successional forests that develop after some form of disturbance, such as wildfire, windstorm or logging. In late successional and old-growth forests (more than 100–150 years since the last disturbance), instead, dominant sources of fixed nitrogen are communities of cyanobacteria (*Nostoc* spp.) associated with feather mosses (*Pleurozium schrebery* and *Hylocomium splendens*) that contribute approximatively 2 kg N ha^{-1} $year^{-1}$ (DeLuca *et al.*, 2002). The feather mosses, which account for as much as 95% of ground cover of the boreal forest floor, and their associated cyanobacteria may be the most broadly distributed N_2-fixing association in Earth and are considered the primary source of nitrogen fixation in boreal ecosystems (Gundale *et al.*, 2012) which are the second largest biome in the world.

Many overstory and understory species of N_2-fixing genera (e.g., *Alnus*, *Robinia*, *Ceanotus*, *Myrica*, *Lupinus*) can be present in temperate forests, accounting for high rates of nitrogen input in the environment (even more than 100 kg N ha^{-1} $year^{-1}$). However, like in boreal ones, these plants are prominent only in early successional stage of temperate forests. In mid and late successional forests the N_2-fixer plants become rare, being totally absent in old-growth forests. Failing N_2-fixing plants, the available nitrogen input into the ecosystem relies essentially on epiphytic cyanolichens (Antoine, 2004) and on nonsymbiotic N_2 fixation that can account for over 1 kg N ha^{-1} $year^{-1}$ and increases in magnitude toward mid, late and old-grown successional stages of forest. The nonsymbiotic N_2 fixation is carried out by heterotrophic bacteria living on decomposing leaf litters or woody debris of forest floor, where reduced forms of carbon are available as energy sources for the energetically expensive microbial process (Pérez *et al.*, 2010).

Biological nitrogen fixation rates are very high in tropical rain forests that may fix more N_2 than any other unmanaged ecosystem (even more than 200 kg N ha^{-1} $year^{-1}$). Legumes are abundant in many of these forests, representing in some of them more than 50% of all trees. However, although these plants can be a major source of nitrogen input into the environment, their abundance may lead to overestimate the potential for N_2-fixation. Not all leguminous trees, in fact, are able to establish an effective symbiosis with rhizobia or may not do so under natural conditions (Pons *et al.*, 2007). High legume nodulation levels and N_2 fixation rates occur in recently disturbed forests and in forests subjected to seasonal flooding, which have N-poor soils. Nodulation and N_2 fixation, instead, are virtually absent from N-rich soils of undisturbed late successional and old-growth forests, despite the abundance of N_2-fixing leguminous species. This is due to the ability of many symbiotic legumes to employ a strategy of facultative nitrogen fixation. These plants can induce N_2 fixation in N-poor environments and down-regulate it to low or negligible levels in response to increased soil nitrogen availability (Barron *et al.*, 2011). Therefore, the N_2-fixing trees can act to rapidly redress any local nitrogen deficiencies that develop within tropical landscapes. Despite the lack of nitrogen fixation by tree in N-rich environmental conditions, substantial amounts of nitrogen enter the tropical forest ecosystem through several other diazotrophic organisms. Heterotrophic nonsymbiotic bacteria living on organic litter layers that cover the forest floor can bring about an input of available nitrogen up to 12 kg N ha^{-1} $year^{-1}$. Canopy communities, dominated by autotrophic organisms, such as free-living cyanobacteria, cyanolichens and cyanobacteria-bryophyte associations can also contribute significant fluxes of nitrogen (up to 5 kg N ha^{-1} $year^{-1}$) via biological fixation to the tropical rain forest ecosystems (Reed *et al.*, 2008). Canopy cyanolichens and other epiphyte diazotrophic communities are a source of fixed nitrogen also in tropical dry forests, where the greatest contribution to available nitrogen input is given by actinorhizal tree species (e.g., those of genus *Casuarina*).

Leguminous (e.g., *Mimosa*, *Calliandra*, *Leucaena*, *Prosopis*) and actinorhizal (e.g., *Casuarina*) genera are widespread in xeromorphic and arid woodlands from North and South America to West Africa and *Ceanothus* shrubs are common in European and American mediterranean shrublands. All these N_2-fixing plants can greatly contribute to the nitrogen supply to their ecosystems (Cleveland *et al.*, 1999). However, also in these environments an additional input of fixed nitrogen is provided by other symbiotic and nonsymbiotic diazotrophic communities.

Legumes are not abundant in most grasslands and temperate savannas (from prairies of North America to pampas of South America and steppes of Eurasia) and contribute little available nitrogen to these environments that essentially rely on diazotrophic microorganisms of the soil (cyanobacteria and eterotrophic bacteria) as sources of fixed nitrogen. Conversely, N_2-fixing plants seem to be the largest source of available nitrogen in some tropical savannas. High proportions of legume trees, such as species of *Acacia*, are commonly present in tropical savannas that take up almost the half of the African continent, whereas Cycads (with symbiotic *Nostoc* spp. or *Anabaena* spp. in so called coralloid roots) form large populations in tropical savannas of Northern

Australia. An estimate of biological nitrogen fixation, however, may be difficult in some of these ecosystems, due to the fact that they are often managed and contain N_2-fixing forage plants (Cadish *et al.*, 1994).

Biological nitrogen fixation is an essential process in regulating biological productivity of freshwater and marine ecosystems that are most frequently under N-limited conditions also due to the worldwide presence of anammox bacteria whose activity accounts for up to 50% of the N_2 gas released from these environments (Jetten *et al.*, 2009). The major N_2-fixers in the aquatic ecosystems are cyanobacteria. They are present as planktonic or benthic forms of nonheterocystous filamentous cyanobacteria, unicellular cyanobacteria and free-living and symbiotic heterocystous filamentous cyanobacteria. Recently, a significant role in N_2 fixation has also been assigned to heterotrophic bacteria (Halm *et al.*, 2012).

Nitrogen fixation by planktonic cyanobacteria is rather low in oligotrophic lakes while the process may reach consistent levels in the mesotrophic and eutrophic ones. In these latter ecosystems the N_2 fixation depends on some environmental factors including light intensity and phosphorus concentration. Phosphorus is often the limiting nutrient in lakes and diazotrophic cyanobacteria become abundant in planktonic communities only when phosphorus levels increase, leading to low nitrogen/phosphorus ratios. Benthic diazotrophic cyanobacteria also contribute the input of available nitrogen into lakes. They can develop extensive mats of filamentous species (such as *Anabaena* spp. and *Oscillatoria* spp.) on sediments, or they can occur as epilithic peryphyton forms (such as *Nostoc* spp., *Calothrix* spp., and many others).

Extensive mats of diazotrophic cyanobacteria are also present in N-poor desert streams of western North America (Grimm and Petrone, 1997) which are characterized by warm temperature, high light, slow currents and ample supply of P. These environmental conditions support abundant cyanobacterial populations that can account for very high rates of N_2 fixation (up to 150 mg N m^{-2} day^{-1}).

High current velocity, low light or high turbidity, instead, can limit growth of benthic and planktonic cyanobacteria and N_2 fixation rate in flowing water systems, in most of which these diazotrophic microorganisms do not occur at all. Moreover, great turbulence, low availability of trace elements (in particular molybdenum) and also grazing by zooplankton (that breaks down diazotrophic filaments preventing the accumulation of enough photosynthetic cells to support the energetic requirement by heterocysts) are among the causes that negatively affect growth of cyanobacteria and N_2 fixation in most temperate estuaries (Marino *et al.*, 2006).

N_2-fixing heterotrophic bacteria have never been found in any of these freshwater ecosystems.

Oceans are oligotrophic environments that make up 71% of the Earth's surface. The South Pacific, which is the largest ocean system in the world, and the other tropical and subtropical oceanic gyres are regarded as biological deserts because of the extremely low availability of nutrients and minimum productivity. The only biological source of available nitrogen in all the oceanic ecosystems is the N_2 fixation carried out by different types of cyanobacteria and heterotrophic bacteria (more than 100 million tons N per year).

The most representative diazotrophs of North Atlantic Ocean, also abundant in the Arabian Sea and in the nearby Red Sea, are nonheterocystous filamentous cyanobacteria of genus *Trichodesmium*, which form large surface colonies at water temperature above 25 °C. In North Pacific Ocean and in equatorial Pacific, instead, the dominant diazotrophs are small (<10 μm) unicellular coccoid cyanobacteria (e.g., *Cyanoteche* spp. and *Crocosphaera* spp.) together with heterotrophic bacteria (Halm *et al.*, 2012). Heterocystous filamentous cyanobacteria (e.g., *Nodularia* spp. and *Aphanizomenon* spp.) are the N_2 fixers living in the cooler brackish waters of the Baltic Sea.

Although these free-living cyanobacteria are regarded as dominant diazotrophs in the oceanic environments, other N_2-fixers also deserve consideration. Most notably, cyanobacteria-diatom symbioses capable of high N_2 fixation rates, which are widely distributed through the warm oceans. Some genera of diatoms (e.g., *Rhizosolenia*, *Hemiaulus* and *Guinardia*), which are common members of the phytoplankton communities, form symbiotic associations with heterocystous filamentous cyanobacteria (e.g., *Richelia intracellularis* and *Calothrix* spp.) and represent a significant component of the nitrogen budget in these ecosystems (Foster *et al.*, 2011).

Planktonic diazotrophs are the only N_2 fixers living in open oceans, while in coastal marine environments, such as salth marshers, intertidal zones and coral reefs, benthic filamentous cyanobacteria (e.g., heterocystous *Calothrix* and *Anabaena* and nonheterocystous *Lyngbya* and *Oscillatoria* genera) colonize sediments forming extensive mats that make substantial contributions to nitrogen supply to the ecosystem.

The highest rates of N_2 fixation in coastal environments are exhibited by the coral reef communities. Most of the fixed nitrogen entering the coral reef is provided by both free-living diazotrophs and benthic cyanobacteria that cover large areas of reef substratum. Additionally, several important members of the reef community, including sponges and corals, have also the capability to fix nitrogen through symbiotic associations with N_2-fixing cyanobacteria and eterotrophic bacteria. Corals, in particular, are holobionts, with the coral animals that harbor a variety of microorganisms, including endosymbiotic dinoflagellates (*Symbiodinium* spp.), commonly referred as zooxanthellae, which provide over 95% of fixed carbon to the hosts. In addition, corals harbor endosymbiotic diazotrophic bacteria and cyanobacteria (e.g., *Synechococcus* and *Prochlorococcus* strains) that benefit with fixed nitrogen both zooxanthellae and coral hosts which possess enzymes enabling ammonium assimilation (Yellowlees *et al.*, 2008).

Interestingly, the symbiotic diazotrophic bacteria of many coral reefs, including the Great Barrier Reef, are closely related to bacterial species belonging to the order *Rhizobiales* (Lema *et al.*, 2012). It is still unclear how the coral rhizobia might be protected against high concentrations of oxygen arising from the zooxanthella photosynthesis in host tissues. Possibly the diazotrophic communities are sheltered in oxygen-depleted coral microhabitats.

Decomposition and Mineralization☆

L Wang, Indiana University-Purdue University, Indianapolis (IUPUI), Indianapolis, IN, USA
P D'Odorico, University of Virginia, Charlottesville, VA, USA

Introduction

Decomposition can be considered the inverse process of production, because it is a metabolic degradation of organic matter (such as plant residues, animal tissues and microbial material) into simple organic and inorganic compounds. Decomposition is essentially a process of breakdown of the carbon skeleton existing in the organic compounds with consequent liberation of energy. Decomposition is an important component in global carbon cycle: without decomposition, the atmospheric CO_2 pool could be depleted literally in one decade based on the current annual rates of net photosynthesis (without considering the effect of biological feedbacks). Moreover, soil organic matter is one of the largest and most dynamic reservoirs of carbon in the global carbon cycle. The carbon stored in soil organic matter is 2400 petagrams (Pg, 10^{15} g), which is almost twice as much the combined amount stored in vegetation (550 Pg) and atmosphere (750 Pg). A better understanding of processes involved in the dynamics of soil organic matter is crucial to predict future changes in atmospheric CO_2 concentrations. Decomposition and the subsequent mineralization are also an indispensable process for sustaining life on Earth, as they are the only processes enabling massive recycling of chemical elements in the biosphere. Most nutrients cycle from an inorganic form in the soil solution to vegetation and back to the soil solution through decomposition and subsequent mineralization. Mineralization is the conversion of nutrients and other substances from an organically bound form to a water-soluble inorganic form. Decomposition and mineralization are closely related processes. In fact, mineralization is often considered as part of the decomposition process, however, decomposition does not always lead to mineralization. Decomposition is associated with carbon cycling whereas mineralization with nutrient cycling. Part of decomposition processes such as fragmentation and chemical alteration could be classified as mineralization, if inorganic nutrients or other simple bases (e.g., $-NH_3$, $(PO_4)^{3-}$) are released from the complex organic compounds during these processes. Mineralization is a vital process in ecosystem dynamics since most plant essential nutrients (such as nitrogen, phosphorus and sulfur) are made available to plant uptake through the process of mineralization (Figure 1).

Mechanisms and Processes

Overview

Decomposition is comprised of a series of interacting physical, chemical and biological processes. In general, three major processes are involved in terrestrial decomposition: leaching, fragmentation and chemical alteration. Leaching is a physical process through which ions (such as K^+, Mg^{2+} and Ca^{2+}) and small water-soluble organic compounds (such as sugars, amino acids and amino sugars) dissolve in water and move out of the decomposed organic material. Leaching could happen even from green leaves still

☆*Change History:* March 2013. L Wang and P D'Odorico updated all parts of the text.

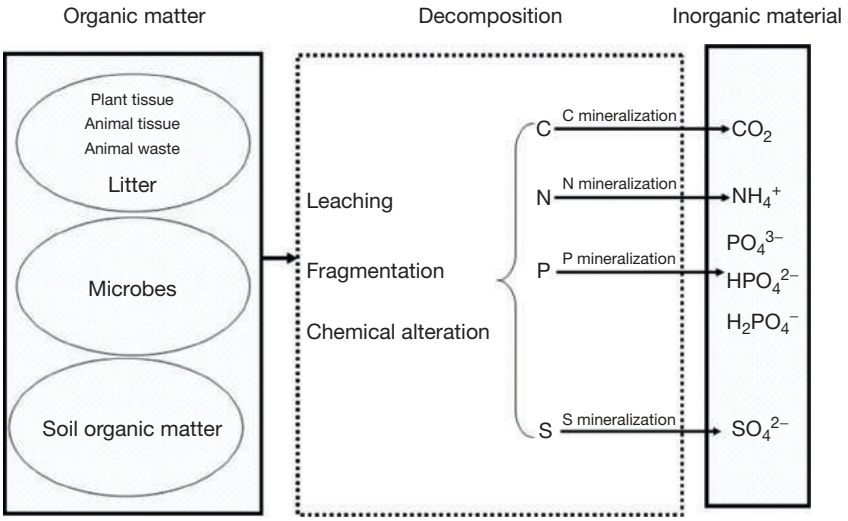

Figure 1 The process of decomposition and mineralization.

attached to the plants. These soluble materials move into the soil matrix where they are taken up by plant roots or soil microbes, adsorbed to soil minerals, or leached and transported through the soil column by water drainage. Leaching losses are greatest in environments with high precipitation and negligible in dry environments. Fragmentation is a physical process through which fresh detritus is broken down into smaller pieces. During fragmentation some chemical bases can break off from organic compounds thereby contributing to nutrient mineralization. Fragmentation also provides more fresh surfaces that can be used by microbial colonization thereby facilitating further decomposition. Biological factors are major contributors of litter fragmentation. Fragmentation is a byproduct of the feeding activities of larger animals and the direct product from the feeding of smaller organisms such as protozoan, potworm and earthworms. Abiotic factors such as freezing-thawing and wetting-drying cycles can also facilitate litter fragmentation. Through chemical alteration, the final stage of the decomposition process, litter fragments are further broken down into simple organic and inorganic compounds. The complete decomposition, i.e., the release of all the energy fixed in organic compounds, may take thousands of years if it happens at all. One of the most commonly known products of incomplete decomposition is fossil fuel, on which our modern societies heavily rely.

Carbon mineralization is about the same as carbon decomposition if we exclude the leaching process. Nitrogen (N) and phosphorus (P) mineralization, however, although related to decomposition, are distinct processes. In particular, P mineralization is less tightly linked to decomposition than N mineralization due to the chemical structure of P-containing compounds. In fact, because the N atoms are directly bonded to carbon skeletons of organic matter (C-N), N is generally released as dissolved organic N (DON) in the breakdown of these skeletons, i.e., in the course of the decomposition process (e.g., during fragmentation or chemical alteration). On the other hand, because P atoms can form ester linkages C-O-P, P can be released (i.e., mineralized) independently of the decomposition of organic matter, i.e., without break down of the carbon skeleton. N mineralization starts with the release of DON associated with decomposition. Both plants (through the mycorrhizal fungi associated with plant roots) and soil microbes can take up DON, although in most cases soil microbes out compete plants for DON uptake. When microbial needs for DON are met, microbes break down the remaining DON – using the energy released by the break down of the carbon skeleton and secrete NH_4^+ to the surrounding soil matrix. This process is known as "N mineralization". When DON is insufficient to meet the microbial N requirement, soil microbes absorb additional N from the pool of inorganic N (e.g. NH_4^+, NO_3^-) in the soil solution, a process known as "immobilization". Immobilization also includes the removal of inorganic N from the soil solution by chemical fixation.

Decomposers

Fungi are an important class of decomposers due to their abundance and ability to decompose rather recalcitrant organic material. In fact, fungi are able to secrete enzymes that are capable of breaking down virtually all classes of plant compounds. Thus, fungi can decompose substrates such as fresh plant litter and some structural materials (e.g. lignin, chitin and keratin) that are initially almost inaccessible to other decomposers. Moreover, fungi account for a large fraction of the soil microbial biomass, as they contribute to about 60–90% of the microbial biomass in forest soils and to 50% in grassland soils. Fungi have extensive hyphae networks, which make it possible to acquire carbon (e.g. from forest litter) and nutrients (e.g. from mineral soil) from different locations. Mycorrhizae are symbiotic associations between plant roots and fungi. Based on conservative estimates, approximately 95% of all vascular plant species have the potential to form this mutualistic association with mycorrhizal fungi. Approximately 70% of all plant families include species, which develop specialized endomycorrhizae called vesicular-arbuscular mycorrhizae (VAM) or just arbuscular mycorrhizae (AM). In these associations, plants receive nutrients from fungi – especially the less mobile groups (e.g.,

phosphates), while providing, in return, fungi with carbohydrates. Mycorrhizal fungi play a role in the decomposition process by breaking down proteins into amino acids. Under certain conditions, mycorrhizal fungi have been found to turn into aggressive decomposers capable of decomposing humus that used to be considered stabilized.

Bacteria are another major group of decomposers. Like fungi, bacteria spores are ubiquitous in air, water, and both dead and live organic matter. There is a wide range of types of soil bacteria. Recent studies have shown that bacteria are able to degrade cellulose/hemicellulose, lignin and even intact fiber walls. Due to their small size and large surface to volume ratio, bacteria are able to rapidly absorb soluble substrates and to reproduce quickly in substrate-rich conditions. In substrate-rich environments such as the rhizosphere or dead animal carcasses, bacteria tend to undergo population "explosions", thereby become the dominant decomposers. These populations collapse as the freely available resources are consumed. Bacteria decomposition seems to be more common in situations where fungi are under stress. Bacteria have also been found to degrade substrates resistant to fungal decay.

Soil fauna can be classified into three categories based on the size – microfauna (less than 0.1 mm), mesofauna (between 100 μm and 2 mm) and macrofauna (between 2 mm and 20 mm), though some researchers adopt slightly different size criteria. Soil fauna used to be considered an important contributor to litter decomposition, however, it was later recognized that, soil microorganisms such as fungi and bacteria are the dominant functional groups of decomposers. In fact, complex organic polymers, such as lignin, can be degraded exclusively by these microorganisms. Soil fauna affect decomposition through the processes of litter fragmentation, bacteria/fungi grazing and soil structure alteration. They graze either directly on microorganisms or on dead organic matter inhabited by bacteria and fungi. At the same time, soil fauna spread the populations and increase the turnover rate of microbial communities, thus enhancing the rates of organic matter decomposition. Therefore, despite its limited direct participation to the decomposition process, the overall influence of soil fauna on the turnover of soil organic matter should not be underestimated.

Temporal and Spatial Patterns

Litter mass decreases exponentially with time in the course of the decomposition process. In general, leaf litter typically loses 30–70% of its mass in the first year and another 20–30% in the following 5–10 years. Only a few of the important chemical changes occurring during decomposition have been completely understood, while most of these reactions still need to be investigated. The organic compounds in plant tissues can be grouped into several broad classes on the basis of their different rates of decomposition. These organic compounds are typically grouped (from fast to slow decomposition) into 1) sugars, starches and simple proteins, 2) crude proteins, 3) hemicellulose, 4) cellulose, 5) fats and waxes, and 6) lignin and phenolic compounds. A three stage model is often used to describe the chemical changes and rate-regulating factors contributing to decomposition. These stages include an early, a late, and a near-humus stage. At the early stage, the decomposition of water-soluble substances and unshielded hemicellulose/cellulose is stimulated by high levels of nutrients; at the late stage, the degradation rate of lignin determines the rate of litter decomposition, while higher N level decrease the decomposition rates; in the near-humus stage, the rate of litter decomposition tends to zero, while the total amount and the lignin content of the residual soil organic material remain constant. An alternative commonly accepted three-phase model of litter decomposition, considers the following phases: 1) leaching of cell solubles; 2) fragmentation and chemical alteration; this second phase occurs slowly and includes most of the fragmentation and alteration of the litter structure; and 3) chemical alteration of litter detritus mixed with mineral soils; in this final phase decomposition occurs at a slower pace.

Climate determines regional patterns of decomposition. In general, regions with higher temperature and water availability tend to experience higher decomposition rates. However, decomposition is limited under water logging conditions typical of wetland environments. At a given location, most decomposition occurs near the ground surface, where soils are substrate-rich, due to the presence of relatively high amounts of leaf and root litter.

Controlling Factors

Decomposition and mineralization rates are controlled by both biotic and abiotic factors. Biotic factors include substrate quantity and quality (i.e., nutrient content) available to decomposers, and the type and size of microbial community; abiotic factors include variables such as soil temperature, moisture, and pH, which determine the soil environmental conditions.

Biotic factors

Substrate quality and quantity

Substrate quantity and quality are major biotic factors controlling the rates of decomposition. Litter quality is determined by three general characteristics: 1) the type of chemical bonds present in the organic compounds, 2) the amount of energy released by their decay, and 3) the size and structure of these compounds and their nutrient content. Glucose and other simple sugars have high carbon quality for microbial decomposer, followed by cellulose and hemicellulose. Lignin a structural compound second only to cellulose in quantitative importance in most plant tissues. Lignin content ranges from 2% to more than 50% in plant dry weight. These polyphenols dramatically slow the decomposition and mineralization rates. The quality of organic matter is generally expressed (especially in biogeochemical models) in terms of the C/N ratios of litter, soil organic matter, and microbial biomass, though the mechanistic role of C/N ratios in the decomposition and mineralization processes is still not completely understood.

Because microbes are generally more N-limited than carbon limited, lower C/N ratios in plant residues usually lead to higher decomposition rates. The C/N ratios of plant residues range from 10:1 to 100:1. The C/N ratios of soil organic matter remain rather constant with a typical value of 10. The C/N ratios of microbial biomass range from 5 (e.g., tropical arable soil) to 10 (e.g., tropical dry forest). Microbial biomass is the most readily decomposable pool of organic material due to the simple structure and high quality of both carbon and nutrients. The microbial decomposition rates are followed by those of plant litter and soil organic matter. In most systems, if the C/N ratio of soil organic matter exceeds about 25:1, net N immobilization (i.e., microbes holding nitrogen instead of releasing it) occurs instead of net mineralization.

Microbial community composition

The composition of microbial communities is another important factor determining the rates of decomposition due to the different type and rate of enzyme production in different microbial communities. These enzymes are major players in break-down of different classes of substrates. In addition, different microbial decomposers have different tolerance to soil moisture and temperature conditions, with consequent effects on the rates of decomposition and mineralization. For example, because fungi are usually less sensitive to water stress than bacteria, they may play a more important role in organic matter decomposition in arid and semi-arid environments.

Abiotic factors

Temperature

Soil temperature may affect microbial activity both directly and indirectly, through its impact on other factors such as soil moisture and litter quantity. Higher temperatures are associated with higher rates of microbial activity. Moreover, changes in soil temperature also affect the microbial community composition. The effect of temperature is also modulated by other factors. For example, in water limited environments higher temperatures do not necessarily lead to higher decomposition rate if the soil is dry. In cold climates temperature fluctuations determine freeze-thaw cycles, which kill soil microbes, release pulses of available nutrients, and lead to higher rates of decomposition and N mineralization in the subsequent growing season.

Soil moisture

Conditions of limited soil water availability reduce the rate of microbial activity due to the emergence of conditions of microbial water stress caused by dehydration, and to the reduction in the size of the water films coating the soil grains. Low moisture contents also limit the mobility and the supply of substrate to the soil microbes by diffusion through the soil solution. In wet soils microbial activity is limited by the low soil aeration and the consequent limitations in the amounts of oxygen available to the decomposition process. Thus, under water-logging conditions typical of wetland soils decomposition is for most part inhibited due to the limited supply of oxygen to the soil microbes and to the limited transport of the CO_2 produced in the decomposition process (soil respiration). The optimal environment for microbial activity is provided by a warm soil that is both moist and aerated soil. These conditions are met with intermediate moisture contents between those of dry and completely saturated soils. The effect of soil moisture is also modulated by other factors: in energy-limited environment, e.g. boreal forest, higher moistures do not necessarily lead to higher decomposition rates. Soil moisture fluctuations, typical of arid and semi-arid environments, are associated with pulses in the rates of decomposition and mineralization, with consequent pulses in the availability of soil mineral nutrients. Other abiotic factors such as solar irradiance, soil pH, and soil physical properties (e.g. clay content) also affect the decomposition rates. For example, it has been found that in arid environments litter decomposition can undergo a process of photodegradation, which provides a shortcut in the cycling of soil carbon.

Dynamics of Selected Ecosystems

Arid and Semi-Arid Environments

Arid and semi-arid lands occupy an increasingly large portion of world's land surface. Decomposition processes in arid and semi-arid environment have some unique characteristics due to the distinct physical environment, e.g. low rainfall and relatively high solar radiation. In these ecosystems 1) leaching is not an important decomposition process as opposed to temperate and tropical environments; 2) fragmentation and chemical alteration may be separated both temporally and spatially; 3) the ultimate location of plant litter is more important than its physical-chemical structure; 4) a variable quantity of the litter input in a desert ecosystem can be buried under the soil surface. The buried litter decomposes more rapidly than surface litter though it goes through the same pathway of chemical transformation as the surface litter; 5) photodegradation may provide an alternative pathway of aboveground litter decomposition. Photodegradation provides a shortcut in the carbon cycle, with a substantial fraction of vegetation carbon being lost directly to the atmosphere without cycling through the soil organic matter pools. Partially due to all the above reasons, compared with wetter environments, the rate of litter decomposition in arid and semi-arid environments is much poorly predicted using abiotic factors such as mean annual precipitation and soil moisture.

Aquatic Ecosystems

Aquatic ecosystems comprise the largest portion of the biosphere and include both freshwater and marine ecosystems. The sources of organic matter in these systems can be both internal (autochthonous) and external (allochthonous). In general, the autochthonous material has higher available N concentration and is structurally easier to decompose than the allochthonous plant residues. Decomposition in aquatic ecosystems follows similar patterns as in terrestrial environments (i.e., it involves leaching, fragmentation and chemical alteration), though with some major differences due to the aquatic environment. A major form of organic matter in aquatic ecosystems is the particulate organic matter (POM). POM can come both from autochthonous and allochthonous sources. The allochthonous sources include terrestrial leaves and small twigs, which are usually colonized by fungi and fragmented by shredders, leading to the formation of POM. Autochthonous POM is derived from the fragmentation of dead organisms and other organic material. POM is partly ingested, digested and mineralized by organisms and micro-organisms before settling on the bottom. The remaining organic matter that reaches the bottom is further broken down by bacteria both through aerobic and anaerobic processes. Another important component of organic matter in aquatic ecosystems is the dissolved organic matter (DOM). Major sources of DOM in the water column are exudates excreted by macroalgae, phytoplankton and zooplankton and autolysis the remains of phytoplankton and zooplankton. DOM is taken up by bacteria and converted into bacterial biomass without undergoing any break-down into inorganic compounds. This bacterial biomass is later consumed by the zooplankton, which, in turn, excretes nutrients in the form of exudates, contributing to a significant portion of the suspended material in the water column. Bacteria, then, take these exudates (even at very low concentration) to obtain both carbon and nutrients, and a new cycle starts. Thus, in contrast to terrestrial ecosystems, bacteria in aquatic systems act as converters rather than as decomposers, whereas phytoplankton and zooplankton play major roles in the release of available nutrients.

Boreal Forests

Boreal forests are among the best studied ecosystems in terms of litter decomposition and mineralization. In these forests – and in forest ecosystems in general – litterfall is the largest source of soil organic material, in that it can account for more than 50% of Net Primary Productivity (NPP). Due to the low energy environment (low temperature and solar radiation), litter decomposition in boreal forests is slow. In these environments the initial leaching from leaf litter is generally slow, while microbial degradation is the major decomposition process. The chemical changes of litter biomass in boreal forests have been well documented. The concentrations of N, P, S, Fe, Pb, Cu and Zn in litter increase with time during decomposition. However, these relationships are empirical and have not been fully explained. The concentration of K normally decreases with time until it reaches a minimum value, and, then, it slowly increases, probably due to the fact that K is the most mobile element among all plant nutrients and its leaching may start as soon as the trees shed their leaves. Mg is another mobile nutrient and its leaching pattern is similar to that of K, though at a slower pace. Ca concentration usually increases in the early stage of decomposition until it reaches a maximum value, and then it decreases. The concentration of Mn, in contrast to most of the other elements, decreases almost linearly throughout the decomposition process.

Anthropogenic Impacts

Human activities significantly modify several aspects of ecosystem function in many environments around the world. Decomposition is unavoidably altered in most ecosystems.

Effects of N Deposition

Dry and wet deposition and fertilization add significant amounts of N both to aquatic and terrestrial ecosystems. In most systems, the increase in soil N content leads to higher levels of foliar N and, hence, to higher litter N contents. The higher substrate quality (high litter and soil N levels) generally result in higher rates of decomposition. In some ecosystems (e.g. Scots pine and Norway spruce forests), however, N fertilization has also been found to increase the amount of lignin in the litter, with consequent reduction in the decomposition rates, suggesting that the effect of N fertilization on decomposition could be complicated and counterintuitive.

Effects of Heavy Metal Pollution

Some heavy metals tend to accumulate in the soil, due to their high affinity both with soil organic matter and with mineral particles. This accumulation eventually exceeds the toxicity threshold tolerable by soil microorganisms and soil fauna – the major drivers of the decomposition process. The direct effect of heavy metal accumulation on plant uptake depends on soil properties: soils with neutral pH and high clay content can immobilize large amounts of heavy metals, while the chemical composition of leaves is not significantly affected by the heavy metals in the soil. However, plants growing on these soils are only temporarily protected against heavy metals until the soil retention potential for these metals is reached. In acidic soils, the low pH increases the solubility of most heavy metals leading to the uptake of heavy metals by vegetation, and to their accumulation in the plant tissues

(e.g., leaves). Because all heavy metals are potentially toxic, there is some concern about the possible increase in heavy metal content in the plant leaves, and its consequent deleterious effects on ecosystem function.

Common Study Methods

Decomposition Methods

The use of litter bags is one of most common field techniques for litter decomposition studies to the point that it has become a sort of standard method in studies on decomposition. This method is used both for the quantitative assessment of litter biomass loss and for studies on its chemical changes. With this method a bag is filled generally with 1–10 g of litter dried at room temperature until a constant moisture level is reached. High temperatures are avoided in the preparation of these litter samples to prevent important changes in microbial community and fiber structure. The bag is first exposed to field conditions for a specific time period, and then it is brought back to the laboratory for reweighing and performing chemical analyses on the remaining litter using techniques such as atomic emission spectrometry (AES), atomic absorption spectrometry (AAS) and inductively coupled plasma spectrometry (ICP). A typical litter bag size is between 10×10 cm and 20×20 cm and it is made of biologically resistant polyester or nylon. Nylon is not used in N studies because this material contains N. Mesh size and incubation time depends on aim of the study and the precision required. Sometimes a certain mesh size is purposely employed to exclude particular groups of soil fauna in order to determine their functional significance to decomposition processes. The number of replicate bags is important for the accuracy in mass loss estimation and the minimum of bags must be sufficient to estimate the decomposition rate constant k adequately. The study methods for woody detritus decomposition are analogous to the litter bags method, though they usually do not use litter confinement. Other methods commonly used to investigate decomposition include microcosm studies, or laboratory and field techniques based on the measurement of concentration and fluxes of soil CO_2 through time. These measurements allow separating the different contributions to soil organic matter loss (e.g., carbon mineralization vs. leaching).

Mineralization Methods

The buried bag technique is a common approach to measure N mineralization. It consists of 1) collecting soil core samples and measuring the initial concentration of inorganic N; 2) reburing subsamples of this core in polyethylene bags for specific period of time, and 3) measuring the inorganic N after incubation. The net rate of N mineralization is calculated by the difference in N concentrations between the two measurements. The buried bag method is relatively simple, cost effective and provides results that can be compared with other studies, due to its widespread use in many different ecosystems around the world. The major problem of this method arises from the disturbance of the soil sample. For example, the method eliminates plant uptake, with a consequent increase in soil inorganic N. In N-limited systems this increase leads to higher microbial N immobilization, which, in turn, results in the underestimation of plant uptake. The mineralization rates of other nutrients essential to plants, such as P and S, can also be measured using buried bags with appropriate adjustments. Several other methods can be used to determine the rates of N mineralization, including the N budget analysis (ideally for large temporal scales), the "super sinks" analysis (e.g. ion exchange resin), the use of substrate analogs, as well as of isotope tracer and dilution measurements. Over the last decade, the general notion of N mineralization has evolved: the concept of N mineralization as the driving process in the N cycle has been replaced by the idea that exoenzyme-driven depolymerization is the rate-limiting step in the generation of bioavailable N. This new N cycling paradigm does not invalidate the traditional methods of net mineralization measurement as fundamental tools in the study of N-cycling, but caution needs to be used in the interpretation of the results. Net mineralization is an indirect indicator of N availability and not the key step of N cycling.

Erosion

EJ Comoss and DA Kelly, Bureau of Facility Design and Construction, Harrisburg, PA, USA
HZ Leslie, Bureau of State Parks, Erie, PA, USA

Outline of Erosion

Erosion could be defined as displacement of solids (e.g., soil, mud, rock) by the agents of currents such as wind, water, or ice by downward movement in response to gravity or by living organisms (i.e., bioerosion) (http://en.wikipedia.org/wiki/Erosion). The degree of erosion is accelerated by various sources. Rainfall (i.e., the amount and intensity of precipitation) is the primary cause of erosion and plays a key role for the other agents to intensify the erosion impact on ecosystems. Rate of erosion depends on various environmental factors such as soil texture, gradient of slope, ground cover (e.g., vegetation, land use), and current velocity of streams (http://en.wikipedia.org/wiki/Erosion).

Due to rapid agricultural/industrial development and mismanagement of natural ecosystems (e.g., overuse of trails in parks), erosion (especially soil erosion) has been a global issue in achieving sustainable ecosystem management. Soil erosion is accelerated by water (e.g., rain detaching, transporting soil; **Fig. 1**), wind (**Fig. 2**), or tillage, and affects greatly agricultural areas and the natural environment. Soil erosion is one of the most serious environmental problems and has both on-site and off-site impacts (Favis-Mortlock 2005 in http://www.soilerosion.net/).

The main `on-site' impact occurs at the place where the soil is detached and is presented as the reduction in soil quality resulting from the loss of the nutrient-rich upper layers, and the reduced water-holding capacity. Loss of soil quality is presently a global problem. Soil erosion's most serious impact may well be its threat to the long-term sustainability of agricultural productivity. The `off-site' problem is caused from soil detachment by accelerated water or wind erosion and occurs wherever the eroded soil ends up. The soils could be transported considerable distances (see **Fig. 3**) and may give rise to the `off-site problems'. The transportation of soil will result in accumulation of sediments and agricultural pollutants in watercourses, leading to the silting up of dams, disruption of the ecosystems of lakes, and contamination of drinking water and downstream watercourses (Favis-Mortlock 2005 in http://www.soilerosion.net/).

An Innovative Control of Shoreline Erosion

In addition to the traditional problems of agriculture-related erosion, erosion control for natural ecosystems (e.g., national parks) has been recently a critical issue. In particular, the border area between land and water (e.g., shoreline, riparian zone) is extremely sensitive to erosion. Proper management of erosion in this type of ecotone is essential for achieving sustainability of ecosystems (e.g., biodiversity, efficiency in energy production) and for obtaining maximum socioeconomic benefit from environmental amenity.

In this article, an innovative control of shoreline erosion is introduced to demonstrate how efficient ecosystem management could be optimized between nature conservation and environmental engineering. Protection of recreational beaches along ocean coasts and inland lakes, bays, and inlets, as well as finding a beneficial use for dredge material, has become a sensitive issue to a diverse public. It is often difficult to find a solution that makes good engineering sense while maintaining environmental responsibility.

Current conventional methods used to retard shoreline erosion include the installation of breakwaters, groins, and jetties. Sand replenishment is often used in conjunction with these methods when shorelines are being extended or restored. These techniques, though often functional, are costly and can detract from the natural environment. Dredge material management was viewed as a `necessary evil' associated with overdevelopment of coastal areas in the past. Through the years, hundreds of metric tonnes of sediment have been dredged annually for commercial and recreational purposes and subsequently discharged into land-based disposal facilities or into oceans, estuaries, rivers, and lakes. As the space for disposal facilities reaches capacity, and discharge into water bodies becomes more of an ecological concern, the problem arises as to what to do with this material.

The purpose of this article is to describe in detail how Presque Isle State Park, located along the shoreline of Lake Erie in Pennsylvania, implemented a unique erosion protection project, which also included the beneficial use of dredge material. This low-cost, innovative demonstration project minimized erosion in the lesser-energy zone of Misery Bay in Presque Isle State Park by utilizing native plants, bioengineering, dredge material placement, and nonconventional erosion practices.

Outline of the Park and Erosion

Presque Isle State Park is a 1295 ha migrating sand spit that juts 11.3 km into Lake Erie and is a major recreational landmark for approximately 4 million visitors each year. The park, a National Natural Designated Landmark, is particularly environmentally

 doi:10.1016/B978-0-444-63768-0.00054-8

sensitive with its constantly evolving shoreline (**Fig. 4**) and the presence of numerous plants recognized as being of exceptional value. Presque Isle is rated as one of the top birding areas in the Northeast, as birds use the distal end of the spit for a resting and feeding area.

Fig. 3 Yangtze River showing the sediment-rich water, the Three Gorges, Hubei Province, China. From http://www.soilerosion.net/.

Protection of the spit has been an ongoing process since 1828. Along the Lake Erie shoreline, a series of conventional erosion control techniques such as groins, bulkheads, seawalls, and beach nourishment have been used with varying degrees of success. Between 1989 and 1992, many of the previous structures were removed and 55 offshore rubble mound breakwaters were constructed. Since completion of the breakwaters, shoreline maintenance has been limited to an annual beach nourishment program. Construction of the breakwaters has decreased sand purchased for annual nourishment by *c.* 85%, from approximately 231 000 m^3 before breakwater installation to *c.* 30 764 m^3 after breakwater construction.

Since 1975, the beaches along the lakeside of the park have been nourished annually; nourishment amounts varied based on fluctuating lake levels and storm severity. The prevailing winds along the lake are from the west, and, as a result, the beach sand is in continual motion as it moves in response to longshore transport. While most of this transient sand is redeposited in offshore bars in the lake, some of the sand is carried around the distal end of the spit into the back bay area. Accumulation of this fine-grained material in the back bay has been a continual problem as these shallow areas become choked with sediment. As a result, the park struggles with the problem of dredging these areas and finding a suitable disposal option for the dredged material.

Historically, protection of the shoreline from erosion had been accomplished along the Presque Isle Bay side of the park by utilizing large stones to riprap the shoreline. Although this process was very effective in preventing shoreline erosion and was quite suitable in the more developed recreational areas of the park, because of its `non-natural' appearance, riprap did not concur with the desired results and appearance specified by the management plan for the low density and natural areas.

As a result of the fragile ecosystem of the spit, specific erosion problems along the bay, and the development of a sand bar within the park's back bay area, the decision was made to seek funds to advance an innovative solution to these problems. With this goal in mind, the Department of Conservation and Natural Resources, Bureau of State Parks – Presque Isle State Park, in conjunction with the Presque Isle Partnership, secured funding via a matching grant from the Great Lakes Commission. The project coordinated efforts between state and federal government units, as well as private, nonprofit volunteer organizations to design, implement, and provide construction services for the project. This project brought forward a concept that provided the park with the protection needed for the infrastructure as well as creating a shoreline appearance that resembled natural shorelines along environmentally sensitive areas of the park. Additionally, the project provided a beneficial use of dredge material from the back bay sand bar.

In order to realize the goals of the project, the decision was made that rather than solely utilizing conventional riprap, the project would incorporate a combination of riprap as well as indigenous vegetation, bioengineering, dredge material, and innovative landscape architecture to retard shoreline erosion along a heavily used multipurpose trail. Completion of this project has provided valuable information to other parks and recreational facilities in the Great Lakes area (especially along bay inlet areas), which are also faced with the challenges of minimizing erosion and sedimentation as well as finding a beneficial use for dredge material.

Problem Areas

There are numerous recreational features within the park. One of these is a 15.4 km multipurpose trail. This trail, designated as a National Recreation Trail, begins at the park entrance and completes a 21.7 km loop throughout the park. This is the most popular trail within the park, and is heavily used by bicyclists, joggers, roller bladers, and is wheelchair accessible. Because of its popularity, protection of the trail from erosion is paramount.

A portion of this trail lies along the southern shoreline of the peninsula within Presque Isle Bay, Misery Bay, Marina Lake, and Thompson Bay; this area had been exhibiting significant erosion. Because this area was adjacent to Presque Isle's ecological reservation area, the standard riprap remedy was not appropriate because it did not match the park's designated management prescriptions for maintaining a natural shoreline appearance.

Fig. 4 Presque Isle State Park. (a) Aerial view of Gull Point and the park from the east. (b) The shore on the bay side, looking north. (a) Photographer: Robert K. Grubbs, http://en.wikipedia.org/wiki/Image:PresqueIsleStatePark.JPG; (b) http://en.wikipedia.org/wiki/Image:PresqueIsleBay-lookingN.JPG.

Another popular tourist attraction is the Perry Monument, dedicated to Commodore Perry. The area surrounding the monument, located along Misery Bay, receives widespread use for shoreline fishing as well as the launching of recreational boats. Normal wave energy along the shoreline of Presque Isle Bay, fluctuating water levels and currents, caused a significant sand bar to develop off the northeast tip of Perry Monument. The sand bar measured approximately 91 m long by 8 m wide by 1.5 m deep (1100 m^3) and severely restricted recreational boat usage. Removal of the sand bar was essential to preserve the recreational activities at the monument.

A small portion of this sand undoubtedly was the beach sand along the Lake Erie side of the spit. The probable source for the remainder of this sand was the erosion of the shoreline around Misery Bay. Historical photos of this area show that the east shoreline of Misery Bay has eroded several hundred feet since the late 1800s. Suitable disposal of this sand would be difficult because of its susceptibility to erosion no matter where it would be placed. Rather than following the standard disposal options of this dredged material, the park wanted to find a constructive use for this sand.

Project Description

The first phase of the project was to remove some of the sand from Perry Monument. After passing the mandated state tests for disposal of dredge material, and in accordance with all applicable permits and regulations, approximately 917 m^3 of material from the sand bar was dredged via a clam shell and placed in an unused gravel parking lot within the park so it could naturally dewater; the water could naturally seep through the gravel into the ground. The remaining sand bar was then graded to provide a suitable launch/mooring area for canoes and shallow boats.

The next phase involved the creation of a stabilized area on the backside of Misery Bay where the multipurpose trail is located adjacent to an ecologically sensitive area of the park (an area where the natural habitat is to be maintained and little to no development is to occur). In this area, significant erosion had occurred, to the point that water was only 3–4.5 m from the trail.

Initially, the project proposed to install 10–25-cm-sized riprap *c.* 7–9 m from the existing shoreline. However, based on design criteria for the worst-case scenario for wave height, which in this area would be 1 m, the decision was made to place 30–61-cm-sized riprap offshore; it was felt that this sized riprap would provide better protection for the shoreline. Placement of this riprap below the water line created an artificial stone shoreline that protected the multipurpose trail by functioning as an erosion/wave energy dissipater.

Once the rock was in place, the third phase began. In this phase, the park placed the dewatered dredge material (sand) over the newly placed riprap, creating a higher-elevation dune line. This subsequently provided a buffer of *c.* 8–9 m between the water and the trail. Next, to enhance the `natural' appearance of the shoreline, randomly spaced downed trees and stumps from the park (25–91 cm in diameter), minus the limbs, were used as timber groins. To function as groins, the tree root bases were anchored behind the riprap in the fill, and the trunks extended out past the riprap and into the water, also serving as sediment catch basins.

After the fill had been placed and prior to planting, the decision was made to use geotextile (comprised of coconut fiber cured to aid in longevity) in conjunction with wattles (poles interwoven with slender branches) in order to augment the vegetative plant rooting and further stabilize the dredged sand. The woven geotextile material is biodegradable, but it was anticipated that the plants should be well established before it decomposed.

Within the fill material, several trenches, parallel to the shoreline, were dug. First, the geotextile was laid in the trench, and then the wattles were placed on top – end to end and parallel to the shoreline, approximately at the average high-water mark. The geotextile was then rolled back over the wattles and staked with live saplings. The wattles and geotextile were then further secured by placing sand on top; the sand helped to anchor the entire apparatus against the wind. The geotextile and wattles provided extra erosion protection to the shore zone area, as well as ensuring a stabilized area in the fine-grained sand for plant rooting.

Prior to planting of the indigenous vegetation, plant community goals were established to ensure that the plants would thrive in the newly created environment. The plant community goals were developed by reviewing historical records of plant community structure in that area, consulting local and regional plant experts, and considering wildlife uses of the site. After the goals were established, a vegetation planting plan was prepared. Final preparation of the site prior to planting included the addition of topsoil to the upper layer of sand, and shaping of the dune line.

The final phase was the vegetative planting. For this phase, local sources of plant material within the park were identified for transplanting onto the dune. These included beach grass (*Ammophilia breviligulata*), Indian sea oats (*Chasmanthium latifolium*), switch grass (*Panicum virgatum*), choke cherry (*Prunus virginiana*), bayberry (*Myrica pensylvanica*), and black oak (*Quercus velutina*). Additionally, driftwood from local sources was collected and was dispersed in the restored area to provide shelter for the young seedlings. Local sources of emergent wetland plants were located, and these were then transplanted into shallow water below the wattle trenches. Transplanted aquatic plants included species that enhanced the establishment of desirable native emergent communities. These species, such as branching bur reed (*Sparganiuma androcladum*), duckweed (*Spirodela oligorrhiza*), and soft-stem bulrush (*Scirpus validus*) were also beneficial to waterfowl by providing a native food source.

After the native species were established, invasive species, such as purple loosestrife (*Lythrum salicaria*) and common reed (*Phragmites australis*), targeted in the Presque Isle Partnership report, were mechanically removed as they were encountered throughout the restored areas. Roundup, a glyphosate, was applied as necessary to eliminate invasive species that could not be controlled by mechanical means. The final objective was to achieve at least 50% vegetative cover in both the shoreline and dune habitats – this goal had been achieved within 6 months of project completion. Annual plane surveys have shown that since project completion, erosion has been reduced by approximately 90%, thus providing protection for the heavily used multipurpose trail.

Summary and Conclusion

Due to rapid agricultural/industrial development and mismanagement of natural ecosystems, erosion has been a global issue in achieving sustainable ecosystem management. Degree of erosion is accelerated by various sources covering rainfall, soil texture, gradient of slope, ground cover, and current velocity of streams. Soil erosion accelerated by water, wind, or tillage affects greatly agricultural areas and the natural environment.

In addition to the traditional problems of agriculture-related erosion, erosion control for natural ecosystems has been recently a critical issue. Especially erosion control in the border area between land and lake such as shoreline is critical for achieving sustainability of ecosystems and for obtaining maximum socioeconomic benefit from environmental amenity.

An innovative control for shoreline erosion was successfully carried out in a state park in the lake area. The dual goal of the project was to combine the beneficial use of dredge material, indigenous plants, and landscaping to reduce sediment loading into Lake Erie, and to protect the recreational aspects of Presque Isle State Park. The completed project has resulted in several additional hectares of stabilized vegetation and has decreased soil and subsequent nutrient runoff from entering Lake Erie. The amount of material removed from the Perry Monument sand bar has facilitated recreational boat usage and shoreline fishing in this area.

Through the years, conventional erosion protection techniques at Presque Isle State Park have been both costly and inappropriate for natural area management. Conversely, this economical project (a total cost of $33 000) has provided a natural and esthetic alternative to conventional shoreline erosion protection. While remaining within standard bureaucratic financial constraints, the project affords a valuable example to other parks and recreational facilities in the similar situations with the challenge of minimizing erosion while maintaining a natural appearance, and finding a beneficial use for dredge material.

Acknowledgments

The authors would like to acknowledge the Great Lakes Commission for awarding a matching grant to accomplish this project. Also, they would like to thank the Buffalo District of the Corps of Engineers for aerial photos, Ernst Seeds for developing the vegetative planting plan, Mercyhurst College in Erie for the actual vegetative plantings, and the Presque Isle Partnership for their volunteer efforts for a variety of tasks related to the project. Finally, thanks are due to the Bureau of Facility Design and Construction engineers and the staff at Presque Isle State Park for their tireless efforts to ensure the success of this project.

Evapotranspiration☆

Jan Pokorny, ENKI, O.P.S., Třeboň, Czech Republic

Introduction

Water is one of the most important limited natural resources. Declining water resources and water quality problems have resulted in dramatic increase in the need for water-conserving methodologies on a field, watershed, and regional scale and this makes efficient use of freshwater resources an obligation of each user. During the 30-year period from 1950 to 1980, the actual level of per capita water supply decreased significantly in many countries due to population increases. It has been projected that in early year 2000 considerably low water availability per capita is anticipated in many regions of the world. As water becomes increasingly scarce and the need becomes more pressing, newer and more complete methods of measuring and evaluating techniques of handling water resources are necessary. In terms of agricultural production, approximately 17% of the cropped area of the world is irrigated and contributes more than one-third of the total world food production. In the United States, about 12% of the cropped area is irrigated and contributes about 25% of the total value of the United States crops. In the United States and around the world, irrigated agriculture uses most of the water withdrawals from the surface and groundwater supplies. Thus, accurate quantification of plant water use (evapotranspiration) is crucial for better management and allocation of water resources.

The process known as evapotranspiration (ET) is of great importance in many disciplines. Accurate quantification of ET in agroecosystems is critical for better planning, managing, and efficient use of water resources, especially in arid or semiarid environments where lack of precipitation usually limits plant growth and yield and negatively affects ecological balances. Quantification of ET is also crucial in water allocation, irrigation management, evaluating the effects of changing land use on water yield, environmental assessment, and development of best management practices to protect surface and groundwater quality.

ET can be defined as the loss of water from the ground, lake or pond, and vegetative surfaces to the atmosphere through vaporization of liquid water. In agroecosystems, ET is the sum of two terms: (1) transpiration, which is water entering plant roots and used to build plant tissue or being passed through leaves of the plant into the atmosphere in the vapor form, and (2) evaporation which is water evaporating from soil and water surfaces, or from the surfaces of plant leaves. Evaporation from buildings, streets, parking lots, etc., after a rain event also contributes to the total ET in the hydrologic cycle.

Evaporation and transpiration processes occur simultaneously and there is no easy method to separate these two processes. Evaporation in the field can take place from crop canopies, from the soil surface, or from a free water surface. When the soil surface is bare, evaporation will take place from the soil directly. In the absence of vegetation, and when the soil surface is subject to radiation and wind effects, evaporation can result in considerable loss of water in both irrigated and nonirrigated agriculture, and other ecological landscapes. In the semiarid and arid western regions of the United Sates, evaporation can be as high as 40% of the total ET.

Transpiration increases with increasing leaf area until complete closure of the canopy occurs. For agricultural crops such maximum transpiration is usually attained at a leaf area index (LAI) of about 3–3.5. In the transpiration process, stomata opening and closure depends on water uptake rate which in turn depends on the density and distribution of roots and their effectiveness to uptake water and nutrients from the soil. Stomata would close when roots cannot uptake water from soil with sufficient rate to keep up with the transpiration. In irrigated agroecosystems, the goal should be decreasing the evaporation component of the total ET for optimum crop production because yield and transpiration are strongly related and evaporation does not have any contribution to the crop growth and yield. Thus, the evaporation falls into the "unbeneficial water use" category.

The ET rate and amount for different vegetation surfaces (i.e., agronomical crops, which are mostly "annual crops" vs. trees and shrubs, which are mostly "perennials") show significant variation from one location to another and are strong functions of climatic, soil conditions, and management practices. For example, the seasonal crop ET for corn (maize, *Zea mays*) can range from 500 to 800 mm depending on climate. The ET for typical alfalfa (*Medicago sativa*) plant can range from 800 to 1600 mm per growing period depending on climate and length of growing period. For a tropical plant such as banana (*Musa* spp.), this value is between 1200 mm in the humid tropics and 2200 mm in the dry tropics. Water requirement of trees can also show wide variations depending on climate, soil type, and root structures. For example, an orange tree (*Citrus aurantium*) can use as much as between 900 and 1200 mm of water per year whereas olive tree (*Olea europea*) can use only between 400 and 600 mm of water per year. The expected water use of natural vegetations can also show significant variation. For example, the seasonal water use of cattail (*Typha*)

☆*Change History*: March 2018. J Pokorný added Sections "Solar Energy Flux Between Sun and Earth," "Main Fluxes of Solar Energy in Landscape," "Cooling and Air-Conditioning Effect of Evapotranspiration," "Effect ET on Local Climate," "Landscape Drying," "Evapotranspiration of Forests (biotic pump)" together with 6 new figures (Figs. 2–4 and 6–8).

This is an update of G. Katul and K. Novick, Evapotranspiration, In Encyclopedia of Inland Waters, edited by Gene E. Likens, Academic Press, Oxford, 2009, pp. 661–667.

 doi:10.1016/B978-0-12-409548-9.11182-0

can range from only 890 mm to as much as 2500 mm. Water use for foxtail (*Lycopodium clavatum*) is about 140 mm and for pine tree (*Pinus*) water use can range from 480 to 1190 mm. Water use of different natural vegetation and agronomical plants are important and necessary for accurate determination of hydrologic balance components.

The Hydrologic Cycle and ET

ET is a major component of the hydrologic cycle. A major proportion of the total precipitation falling on the land surface is returned to the atmosphere by ET. As a global average, 57% of the annual precipitation falling over the land is returned to the atmosphere by ET. ET amounts to about 70% of the annual precipitation of the United States, and more than 90% of the precipitation in the arid and semiarid areas of the western United States. Different components of a typical hydrologic cycle are illustrated in Fig. 1. The hydrologic cycle can be defined as the pathways of water as it moves in its various phases through the atmosphere, to the Earth, over and through the land, to the ocean, and back to the atmosphere. During this cycle, which has no beginning or end, water molecules may assume various states, returning to a hydrologic pathway as new chemical compounds that are mixed with various solid and liquid substances. In the cycle, water evaporates from the oceans, ponds, rivers, and various land surface to become part of the atmosphere; water vapor is transported and lifted in the atmosphere until it condenses and precipitates on the land or oceans. Precipitated water may be intercepted by vegetation, become overland flow over the ground surface, infiltrate into the ground, flow through the soil as subsurface flow, or discharge into streams as surface runoff. In a given watershed, discharge of water is primarily from groundwater withdrawals for irrigation, ET where the water table is near land surface, overland flow (runoff), and seepage to streams and springs where the water table intersects the land surface. Recharge of water is primarily from precipitation; other sources of recharge are irrigation return flow and seepage from streams, canals, and reservoirs. Large amounts of the intercepted water and surface runoff return to the atmosphere through evaporation. Infiltrated water may percolate to deeper soil layers to recharge groundwater, and later emerge in springs, or as seepage into streams, to form surface flow. Finally, this water may flow to the larger rivers and, eventually to the sea and/or evaporate into the atmosphere. Throughout this cycle, water is usually subject to evaporation of one kind. Types of vegetation, management and land use, and climatic conditions significantly affect ET, and therefore determine the amount of water lost through ET from a watershed. In agroecosystems, it is important to have a water balance to protect the sustainability and productivity of the agroecosystems. Water-level declines may result in increased costs for groundwater withdrawals because of increased pumping lift and decreased well yields. Water-level declines also can affect groundwater availability, surface water flow, and near-stream habitat (riparian) areas,

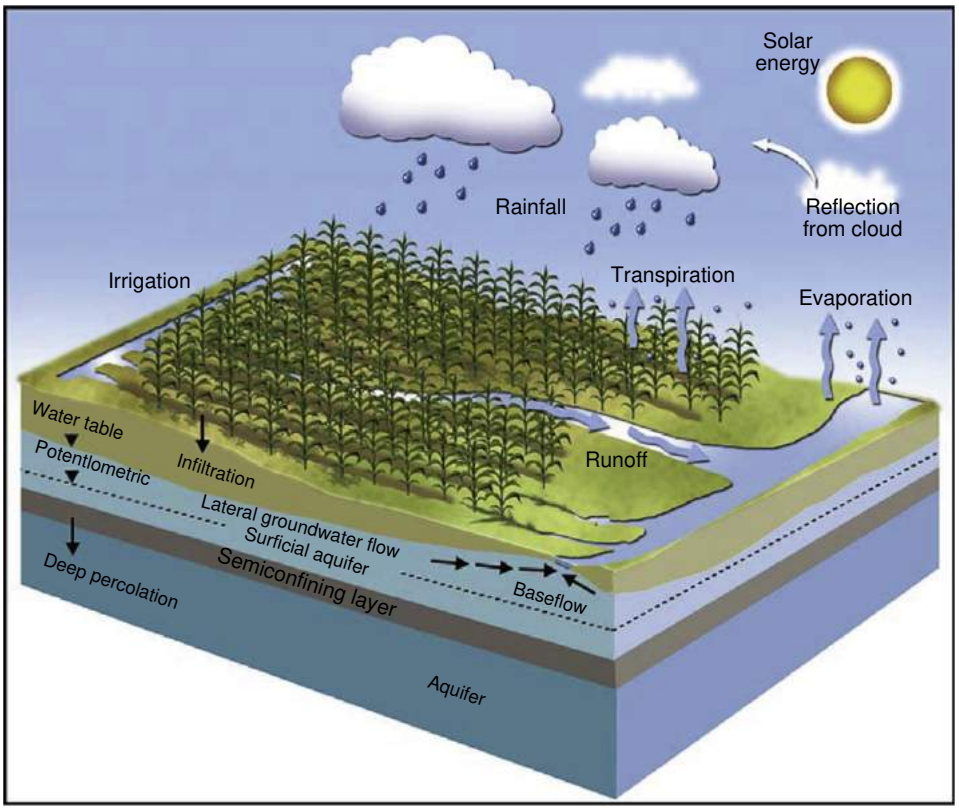

Fig. 1 The hydrologic cycle showing different components of the hydrological process.

and other ecological systems. Therefore developing efficient and effective management strategies is crucial for protecting sustainability of efficient use of water resources, protecting habitat and environment, and preventing ground and surface water degradation.

Solar Energy Flux Between Sun and Earth

For a mean distance between the Sun and the Earth, the intensity of solar radiation incident upon a surface perpendicular to the Sun's rays measured above the atmosphere is approximately 1367 W m^{-2}. This quantity is called the solar constant. The actual direct solar irradiance at the top of the Earth's atmosphere fluctuates during a year from 1412 to 1321 W m^{-2} due to the Earth's varying distance from the Sun. The maximum irradiance on Earth's surface commonly lies between 800 and 1000 W m^{-2} in the tropics and subtropics and during the growing season in temperate zones. This indicates that approximately 25%–40% of energy incident on the upper layer of the atmosphere is reflected, scattered, or absorbed in the atmosphere and does not reach the Earth's surface (Fig. 2).

The amount of incoming energy differs significantly with weather conditions (Fig. 3). The amount of incoming radiation on a clear day (e.g., 8.5 kWh m^{-2} and maximum flux 1000 W m^{-2}) can be an order of magnitude higher than the amount of incoming radiation on an overcast day (e.g., 0.78 kWh m^{-2}, maximum flux 100 W m^{-2}). Part of the energy is reflected straight away after incidence.

The ratio of reflected to incident radiation is called albedo. Dark surfaces such as water, wet soil, and wet vegetation absorb solar radiation whereas light surfaces like snow or sand are more reflective. The sum of incoming radiation minus all outgoing radiation across a unit area of the plane is called net radiation.

Main Fluxes of Solar Energy in Landscape

There is a big difference between the distributions of net radiation in functioning natural ecosystems of high plant biomass well supplied with water versus dry, nonliving physical surfaces (Fig. 4). In ecosystems, net radiation (Rn) is divided in varying proportion into following four parts: latent heat flux (LE), sensible heat flux (H), ground heat flux (G), and storage of energy (S).

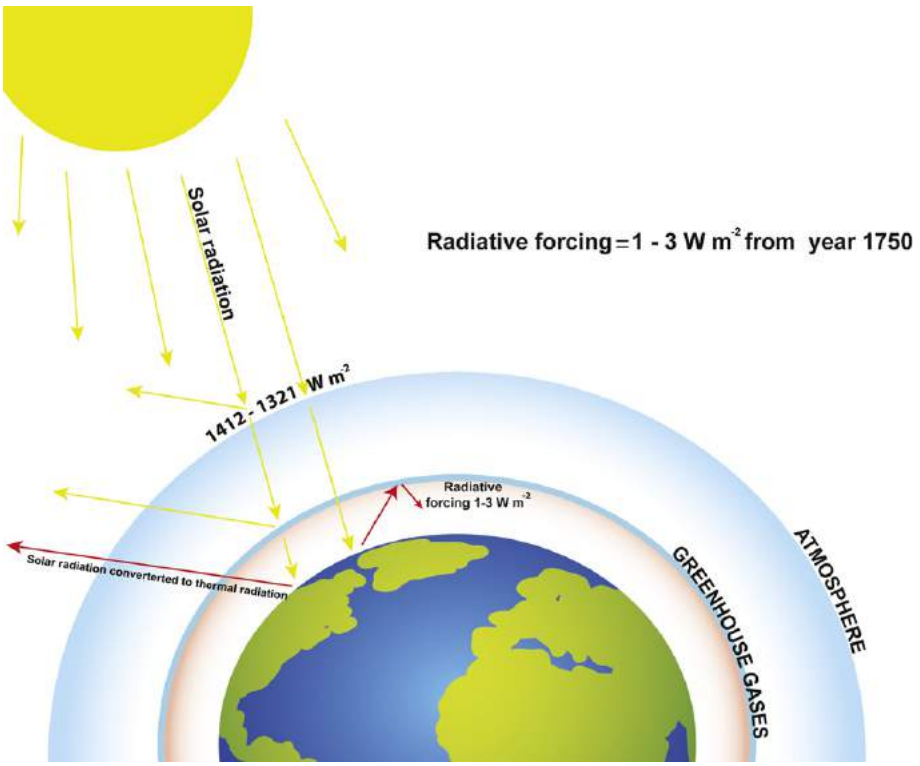

Fig. 2 Energy flux between Sun and Earth. Outer layer of atmosphere gets 1412–1321 W m^{-2} during 1 year. At clear sky up to 1000 W m^{-2} comes to Earth's surface. Radiative forcing due to an increase of concentration of greenhouse gases is 1–3 W m^{-2} from year 1750. ET is most powerful process of distribution of solar energy incoming to Earth's surface.

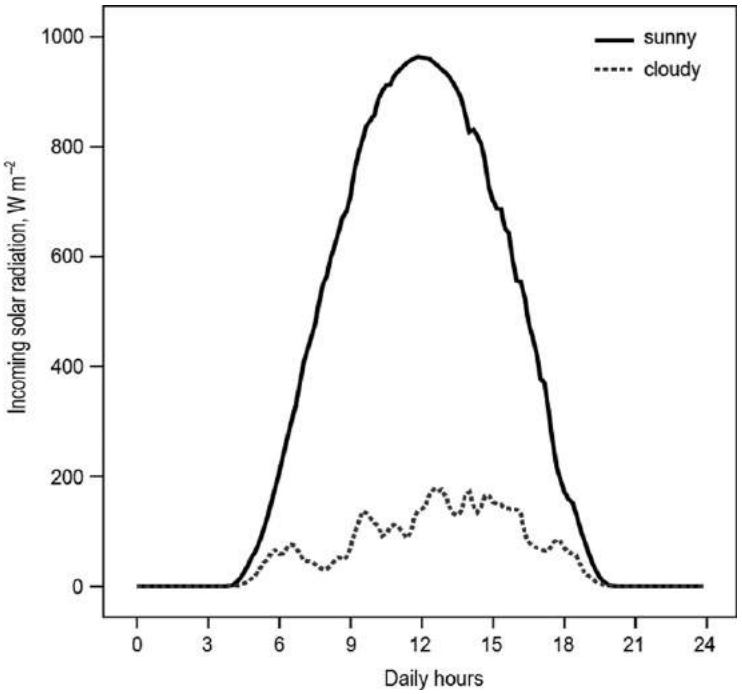

Fig. 3 Daily mean series of incoming solar radiation (W m^{-2}) on five sunny and five cloudy days.

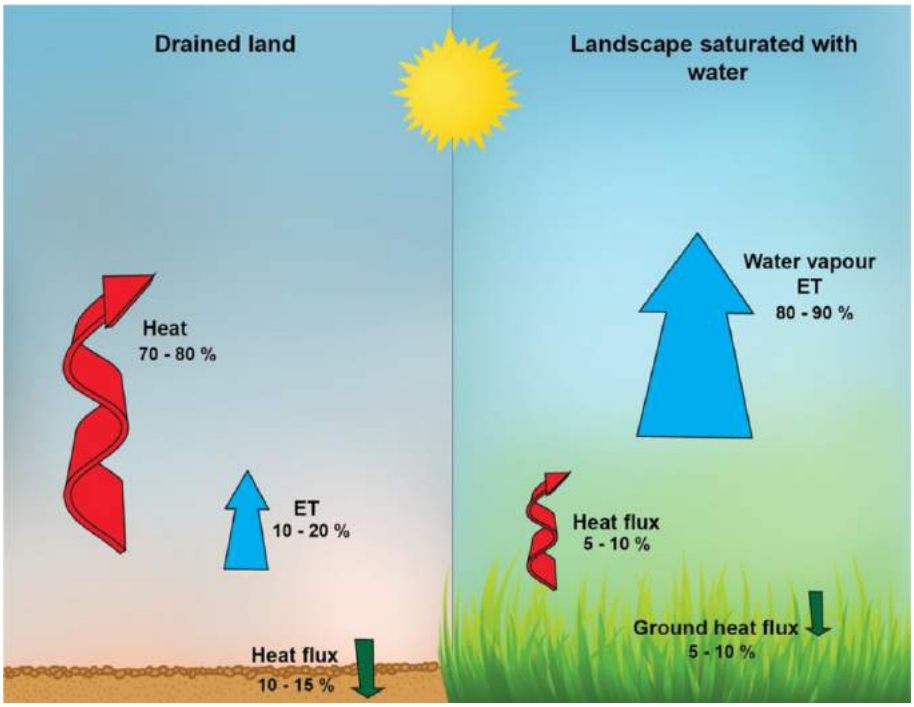

Fig. 4 Evapotranspiration, sensible heat flux, ground heat flux on drained surface, and plant stand well supplied with water.

Latent heat flux (LE) represents the energy that is released or absorbed from the surface during phase transition process. Transition of liquid into a gas phase consumes energy and thus local cooling accompanies it. Latent heat flux is generally referred to as evapotranspiration, which describes the total evaporation from land surface and transpiration by plants. Evapotranspiration from wetlands use several hundred W m^{-2} on a sunny day.

Sensible heat flux (H) represents the sum of all heat exchanges between the surface of landscape and its surroundings by conduction and convection. The proportion of sensible heat in the energy balance of an ecosystem increases when water is not present, since the capacity for evaporative cooling by latent heat is diminished. On dry surfaces, the sensible heat flux may reach values of several hundreds of W m^{-2} at a sunny day.

Ground heat flux (G) is positive when the ground is warming, normally being positive during the day and negative at night. During the plant-growing period in daylight hours, G can reach up to 100 W m^{-2}.

The energy stored in vegetation (S) is the smallest part of Rn. There are two energy sinks within a plant stand: metabolic sink (photosynthesis with consequent biomass production) and a physical sink (heating of the plant material itself). Energy stored flux is a maximum of 30 W m^{-2} on a sunny day, that is, several percent of Rn and usually is neglected in the energy balance calculations.

The transformation of solar energy in landscape is then expressed by the energy balance equation (1):

$$\mathrm{Rn} = \mathrm{LE} + H + G \tag{1}$$

The greatest importance in the transformation of solar energy on the Earth's surface is the latent heat flux of the vapor and the sensible heat flux. The latent heat of vaporization is related to the water vapor, in which, due to the change of phase process, energy is consumed. Phase changes between liquid water and water vapor are linked with the consumption of a large amount of energy. The enthalpy of liquid water is -2.5 kJ g^{-1}. Evapotranspiration (ET) or latent heat flux represents large, invisible fluxes of water and energy in the landscape; the scale of several hundred W m^{-2}. The evaporation of water is not accompanied by temperature increase, because energy is transformed in the change of phase that is acceleration of the kinetic movement of molecules, as a result of which the liquid is converted into water vapor. Evaporation cools the environment. On the contrary, condensation of water vapor (e.g., in the night hours) back to the liquid (e.g., dew formation, frost) releases the stored energy as heat and the surrounding environment is heated.

The sensible heat flux is driven by the temperature differences between the surface and the overlying air. Heat is initially transferred into the atmosphere by conduction. Then, with gradual heating of air, it circulates upwardly through convection. When the surface is warmer than the overlying air, heat will be transferred upwards into the air as positive sensible heat transfer. If the air is warmer than the surface, heat is transferred from the air to the surface creating a negative sensible heat transfer. Sensible heat is therefore part of the energy that warms the environment. We feel increasing surface and air temperature and can measure it with a thermometer.

Ground heat flux is less significant compared to the two previous components of the equation, it accounts for 5%–10% of net radiation. It ranges in summer months from 10 to 100 W m^{-2} for growing crops. The magnitude of this flux depends on the temperature gradient and the thermal conductivity that is affected by the mineral composition of the soil, its texture, and water content.

Bowen ratio is an important variable when evaluating ecosystems in terms of transformation of solar energy. It is defined as the ratio of sensible and latent heat flux. If a great portion of available energy at the surface is transformed into latent heat, the Bowen ratio is less than one. This is usually observed at wet surfaces, vegetation (forests, wetlands) and open water during a day. When major part of available energy becomes sensible heat flux, then Bowen ratio is equal or greater than one. This is typical for sealed, vegetation-free, and dry surfaces.

ET Terminology

Potential ET (ET_p)

Many methods have been developed for direct and indirect measurement of ET. The water loss (evaporative losses) from different surfaces such as turf, bare soil, and water was originally measured in large tanks (lysimeters). The term "lysimeter" was derived from the Greek words "*lysis*" and "*metron*" meaning dissolving and measuring, respectively. The term is applicable to any device utilized that measures the rate, amount, and composition of percolation of water through soil. In a simple term, the lysimeter can be defined as large containers packed with soil located in the field to represent field and environmental conditions, with bare soil or vegetated surfaces (field crops, trees, shrubs, grass, etc.) for measuring the ET of plants or evaporation from bare soil through a mass-balance approach. Lysimeters are expensive and labor-intensive tools to measure evaporation or ET. Thus, other meteorological approaches have been developed over the years to simplify the measurements of ET. One of the commonly used methodologies to determine ET will be discussed later.

The original ET equation was based on evaporation from free water surface as measured with lysimeters. The definition of potential ET that emerged from an earlier work implied a maximum value of ET when there was adequate amount of water to be transpired or evaporated. Formally, potential ET has been defined as "the evaporation from an extended surface of short green crop which fully shade the ground, exerts little or negligible resistance to the flow of water and is always supplied with water." Potential ET cannot exceed free water evaporation under the same weather conditions. However, in the definition of potential ET, the condition of nonlimiting supply of water is never achieved because the resistance of water flow through plants and soil has a finite value greater than zero. Another problem with this definition is the phrase "short green crop." The short green crop has been defined as 8–15 cm tall grass cover, but it has also been defined as a 30–50 cm tall crop of alfalfa. It is important to distinguish

between the short green vegetations because the ET rates from well-watered agricultural crops may be as much as 10%–30% greater than that occurring from short green grass. This dichotomy in the definition of a "short green crop" has led to the use of the term "reference crop ET (ET_{ref})." To eliminate the confusion, in late 1970s and early 1980s, engineers and practitioners introduced and started using the "reference ET" concept rather than "potential ET." The use of the term "potential ET" is diminishing rapidly and the term "reference ET" has been gaining significant acceptance by the water resources community.

Reference Evapotranspiration (ET_{ref})

The reference ET (ET_{ref}) concept was introduced by irrigation engineers and researchers to avoid the confusions that existed in the definition of potential ET. By adopting a reference crop (grass or alfalfa), it became easier and more practical to select consistent crop coefficients and to make reliable actual crop ET estimates in new areas. Introduction of the reference ET concept also helped to enhance the transferability of the crop coefficients from one location to another. Two reference crops have been used to represent the reference ET: grass and alfalfa.

Grass Reference Evapotranspiration (ET_o)

Grass reference ET is defined as "the rate of ET from a hypothetical reference crop with an assumed crop height of 0.08—0.12 m, a fixed surface resistance of 70 s m^{-1}, and an albedo of 0.23, closely resembling the ET from an extensive surface of green grass of uniform height, actively growing, well-watered, and completely shading the ground." In the grass reference ET definition, the grass is specifically defined as the reference crop and this crop is assumed to be free of water stress and diseases.

Alfalfa Reference Evapotranspiration (ET_r)

Alfalfa reference ET is defined as the ET rate from an extensive, uniform surface of dense, actively growing alfalfa, 0.30–0.50 m tall and not short of soil water. In the literature, the terms "reference ET" and "reference crop ET" have been used interchangeably and they both represent the same ET rate from a short, green alfalfa or grass surface. Unlike the potential ET definition, in the alfalfa reference ET definition, an alfalfa crop is specifically noted as the reference crop.

One of the other important differences between potential and reference ET is that the weather data collection site is well defined in the reference ET definition. It is important to note in the reference ET definition that the climate data that are used to estimate reference ET need to be collected in a well-watered and has certain characteristic (reference) environment. Therefore, based on the definition, the weather data for the reference ET estimations should be collected in a well-irrigated and well-maintained grass or alfalfa field. The irrigated grass area of the weather data collection site should be fairly large (e.g., at least 4 ha) to have enough fetch distance between the instrumentation to measure the climatic variables and the edge of the field because the quality of the weather data will ultimately affect the final estimated reference ET value. Enough fetch distance allows the air to travel on the reference crop surface and represent the aerodynamic, humidity, and temperature characteristics of the reference crop before it is sampled at the weather station. In a hot, dry month the average air temperature may be as much as 5°C–6°C higher in a dryland (nonirrigated) area than for a nearby well-irrigated area. The differences in the air temperature will also affect the relative humidity and vapor pressure deficit values, and these differences will ultimately cause differences in the reference ET calculated using the weather data collected from the two sites (dry vs. well-irrigated).

Determination of Crop ET (Plant Water Use) in Agroecosystems Using Climate Variables

In irrigated agroecosystems, a large part of the irrigation water applied to agricultural lands is consumed by evaporation and transpiration. In practice, in field measurements, it is hard to separate evaporation from transpiration, and the two processes are usually considered as one component. Crop ET can be measured directly using precision weighing lysimeters, Eddy correlation system, Bowen ratio energy balance system, atmometers, including evaporation pans, soil water balance by measuring soil water status continuously, etc. However, because direct measurement of crop ET (ET_c) is difficult, time consuming, and costly, the most common procedure is to estimate ET_c using climatic data. Currently, most commonly practiced way of estimating the crop ET rate (or crop water use rate) for a specific crop or vegetation surface requires first calculating reference ET (ET_{ref}) and then applying the crop coefficients (K_c) to estimate actual crop ET (ET_c) as Eq. (2).

$$ET_c = ET_{ref} \times K_c KT_c = ET_{ref} \times K_c \tag{2}$$

where ET_c is the crop ET (crop water use) in units of water depth (inches day^{-1}, cm day^{-1}, or mm day^{-1}), ET_{ref} (ET_o or ET_r) is the reference ET in unit of water depth (inches day^{-1}, cm day^{-1}, or mm day^{-1}) as calculated from the basic weather variables (solar radiation, air temperature, wind speed, and relative humidity) measured with a weather station in reference conditions.

Although the first equation by Penman for potential ET, (ET_p), was introduced almost 60 years ago; it still provides fundamental principles for the calculation and/or modification of ET models today. Numerous methods have been introduced for computing ET_{ref} causing confusion among users, decision- and policymakers as to which method to select for ET_{ref} estimation. Recently, the American Society of Civil Engineers (ASCE) Evapotranspiration in Irrigation and Hydrology Committee established a

Task Committee on "Standardization of Reference Evapotranspiration Calculation." Based on extensive research and data analyses and comparison of lysimeter-measured reference ET across various climates and Task Committee experience, the Task Committee recommended the use of the ASCE-Penman–Monteith (PM) method as the representation for reference ET. A reduced form of the ASCE-PM was used as the basis for "standardized" ET_{ref} computation. Equation parameters differ for hourly and 24-h data. Coefficients and parameters for a taller, rougher crop surface (0.5 m tall, like alfalfa) were also developed. The ASCE standardized ET_{ref} equation based on a surface resistance of 50 s m^{-1} during daytime and 200 s m^{-1} during nighttime provided the best agreement with the full form of the ASCE-PM method applied on a daily basis. The advantages of adapting a specific procedure as a standardized method are (1) it provides commonality to computing ET_{ref}, and (2) the use of a standardized method enhances the transferability of crop coefficients.

The standardized ASCE-PM equation is intended to simplify and clarify the application of the method and associated equations for computing aerodynamic and bulk surface resistance (r_a and r_s, respectively). Equations were combined into a single expression for both grass and alfalfa reference surfaces and for a 24-h or an hourly time step by varying coefficients. Computation of standardized short grass ET_o with a 24-h time step uses a grass height of 0.12 m and an r_s value of 70 s m^{-1}, which is the same as for the FAO56-PM equation. For hourly time steps, r_s is set to 50 s m^{-1} for daytime hours and to 200 s m^{-1} for nighttime hours. The standardized ASCE-PM equation is Eq. (3).

$$ET_{ref} = \frac{0.408\Delta(R_a = G) + \gamma(C_n/(T + 273))\,U_2(e_a = e_a)}{[\Delta + \gamma(1 + C_d\,U_2)]} \tag{3}$$

where ET_{ref} is the standardized reference ET (mm day^{-1} or mm h^{-1}), Δ is the slope of saturation vapor pressure versus air temperature curve (kPa°C^{-1}), R_n is the calculated net radiation at the crop surface (MJ m^{-2} day^{-1} for 24-h time steps or MJ m^{-2} h^{-1} for hourly time steps), G is the heat flux density at the soil surface (zero for 24-h time steps or MJ m^{-2} h^{-1} for hourly time steps), T is the mean daily or hourly air temperature at 1.5–2.5 m height (°C), U_2 is the mean daily or hourly wind speed at 2 m height (m s^{-1}), e_s is the saturation vapor pressure (kPa), e_a is the actual vapor pressure (kPa), $e_s - e_a$ is the vapor pressure deficit (kPa), γ is the psychrometric constant (kPa°C^{-1}), C_n is the numerator constant that changes with reference surface and calculation time step (C_n = 900°C mm s^3 Mg^{-1} day^{-1} for 24-h time steps, and C_n = 37°C mm s^3 Mg^{-1} h^{-1} for hourly time steps for the grass reference surface), C_d is the denominator constant that changes with reference surface and calculation time step (C_d = 0.34 s m^{-1} for 24-h time steps, C_d = 0.24 s m^{-1} for hourly time steps during daytime, and C_d = 0.96 s m^{-1} for hourly nighttime for the grass reference surface), and 0.408 is the coefficient having units of m^2 mm MJ^{-1}. The values of C_n and C_d for the grass and alfalfa reference surfaces for daily and hourly time steps are given in Table 1.

Crop Coefficient Concept

The K_c is the crop coefficient for a given crop and is usually determined experimentally. The K_c values represent the integrated effects of changes in leaf area, plant height, crop characteristics, irrigation method, rate of crop development, crop planting date, degree of canopy cover, canopy resistance, soil and climate conditions, and management practices. Each crop will have a set of specific crop coefficient and will predict different water use for different crops for different growth stages. An example of a K_c curve as a function of days or weeks after planting for a plant for initial, development, mid-season, and end-season stages is given in Fig. 5.

In general, crop growth stages can be divided into four main growth stages: initial, crop development, mid-season, and late season. The length of each of these stages depends on the climate, latitude, elevation, planting date, crop type, and cultural practices. Local field observations are best for determining the growth stage of the crop and adjust the empirical K_c values accordingly. Early in the growing season, during the crop germination and establishment stage, most of the ET occurs as evaporation from the soil surface. As the crop canopy develops and covers the soil surface, evaporation from the soil surface decreases and transpiration component of the ET increases.

Early in the season when plant is small, the water-use rate and K_c value are also small (K_c initial stage) and the crop ET rate increases as the plant develops (Fig. 5). For agronomical plants, the crop ET rate is at the maximum level when plant is fully developed (K_c mid-season). The ET rate decreases again when plant completes development and reaches physiological maturity toward the end of the season (K_c end season).

Table 1 Values for C_n and C_d in Eq. (3)

	Grass reference (ET_o)		*Alfalfa reference (ET_r)*			
Time step	C_n	C_d	C_n	C_d	*Units for ET_o and ET_r*	*Units for R_n and G*
Daily	900	0.34	1600	0.38	mm day^{-1}	MJ m^{-2} day^{-1}
Hourly during daytime	37	0.24	66	0.25	mm h^{-1}	MJ m^{-2} h^{-1}
Hourly during nighttime	37	0.96	66	1.7	mm h^{-1}	MJ m^{-2} h^{-1}

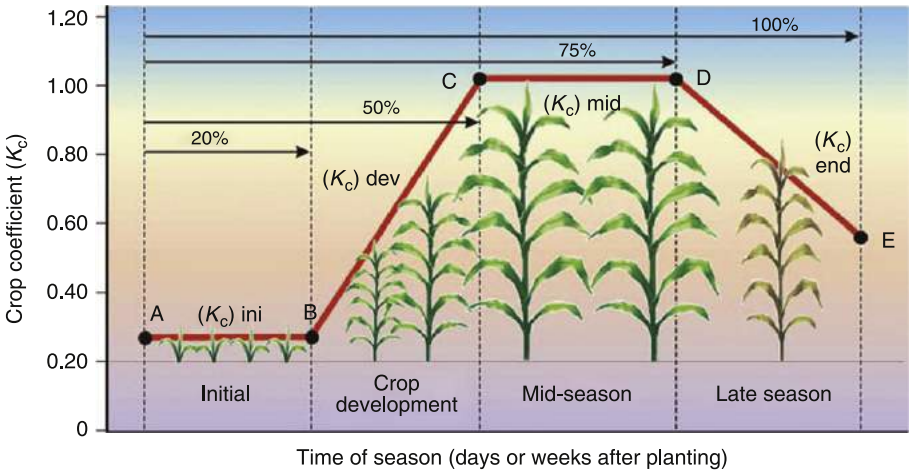

Fig. 5 Schematic representation of increase and decrease in crop coefficient based on different plant development stages.

For perennial crops a similar pattern can occur as the plant starts to develop canopy area, grow new shoots, and develop fruit. The percentage of leaf area, soil water status, and climatic conditions will drive the rate of crop (ET) at a given growth stage. Usually, the maximum canopy cover coincides with the time of year when the solar radiation and temperature are at their peak values (usually mid-season) and the maximum ET therefore occurs during that period. The K_c values for many different crops have been published in numerous literatures.

Cooling and Air-Conditioning Effect of Evapotranspiration

Transpiration by plants can be seen as a water loss in such cases as water scarcity; managers of water reservoirs that supply drinking water would usually see it as a loss. Transpiration is sometimes even called an unavoidable evil, in the sense that water is sacrificed for the sake of enabling intake of CO_2 for photosynthesis. For a plant, however, transpiration is a necessity by which a plant maintains its inner environment within the limit of optimal temperatures. It can be shown on basis of elementary physics that at the level of landscape, evapotranspiration is the most efficient air conditioning system developed by nature. In addition to optimizing temperature, through evapotranspiration plants control the optimum water balance in their root zone. Water, thanks to its high heat carrying capacity, is able to redistribute much of the solar heat energy received by the Earth through the water cycle: by evapotranspiration and condensation. Water evapotranspiration and condensation therefore plays an instrumental role in climate control with regard to temperature distribution in time and space, that is, reducing the peaks and modulating the amplitudes of high and low temperatures on the land surface—making conditions on Earth suitable for life. Just compare daily temperature fluctuation in desert and in forest in the same latitude.

Water has a unique feature. It exists in three aggregate states in our living environment: solid, liquid, and vapor. Phase transition from liquid into vapor is associated with changes of volume (18 mL of liquid forms 22,400 mL of vapor) and consumption or release of energy (0.68 kWh, 2.45 MJ kg^{-1} at 20°C), which is a cooling or heating environment. Water has high heat capacity, so its transformation involves exchange of energy, thus equalizing the temperature differences in time (day and night) and space (between different spaces).

Let us imagine a tree with a crown of 5 m in diameter covers an area of ca. 20 m^2. On a sunny day, at least 150 kWh of solar energy fall on the crown. What happens with this energy? 1% is used for photosynthesis, 10% is reflected in the form of light energy, 5%–10% is released as sensible heat and the same percentages transferred as ground heat flux into soil. The largest percentage enters the process of transpiration whereby water vapor is released from the tree. If a larger tree has a sufficient water supply, it can evaporate more than 100 L of water a day. In order to evaporate 100 L of water, approximately 70 kWh (250 MJ) of solar energy is needed. This energy is hidden in water vapor as latent heat and is released again during the process of condensation to liquid water.

The tree transpired around 100 L of water, thus cooling its environment by c. 70 kWh; during a 10-h period the tree cools its environment with a 7 kWh power output. Energy of 70 kWh did not appear as sensible heat, it stayed in form of water vapor and was released in cool places or during a night. Such a tree has a cooling capacity comparable with several technological air-conditioning system used in households, hotels, offices. Transpiring tree has a double air-conditioning effect: it cools when water evaporates and water vapor passes energy to cool places where latent heat is released when water vapor condensates back to water liquid.

From thermodynamic point of view, trees reduce gradients of energy between the Sun and outer space, they degrade incoming solar radiation through life processes. Sagan, Schneider imagine tree as a giant dissipative structure capturing sunlight and

degrading most of that energy as respiration and "low grade" latent heat via transpiration. Tree is like a giant water fountain spewing water in the form of latent heat. Trees well supplied with water reduce gradients which would realize as strong wind, torrential rain, etc.

Effect of ET on Local Climate

Climate change and global warming are widely believed to be caused only by an increase in CO_2 concentration from 250 to 390 ppm. Novel recent research, however, highlights the dynamic role of water vapor in climate change, with its concentration two orders of magnitude higher than that of other greenhouse gases. The implication of this research is that human landscape management affects the behavior of water vapor and its role in the dissipation of solar energy, in a much more important way than formerly appreciated.

This research has focused on wet meadows in the Czech Republic, which evapotranspirated about 7 mmol m^{-2} s^{-1} (i.e., 126 mg m^{-2} s^{-1}) during a sunny afternoon, converting about 315 W of energy per square meter of its surface into latent heat flux. The wetland, which covered an area of about 4 km^{-2}, evapotranspirated about 500 kg of water per second, which is equivalent to the flow rate of a small river. This invisible stream represents the latent heat flux of approximately 1260 MW. Thus, this ecosystem regulates the temperature through energy and water fluxes with a power equivalent to that of a moderately large power station. In drained or dry landscapes, wetland ecosystems thus act as "wet islands," important both for their conservation value and for their important hydrological function (in addition to their hydrologically dependent nutrient processing).

The drainage of large areas of natural vegetation and the loss of their latent heat function causes surprisingly large amounts of sensible heat to be released into the atmosphere. A drop in evapotranspiration by 1 L m^{-2} (equivalent to about 700 Wh) is capable of increasing the daily flux of sensible heat about 40 times more effectively (by 70 W) than the quoted effect of greenhouse gases [radiative forcing, Intergovernmental Panel on Climate Change (IPCC)]. For example, a drop in evapotranspiration of 1 mm over the territory of the Czech Republic (79,000 km^2) within a single day, releases an amount of sensible heat comparable to the annual production of electric energy from all Czech power plants (about 60,000 GWh).

The Czech study also measured the daily dynamics of radiation surface temperature and air temperature of different land cover types in a temperate, "cultural" landscape and their consequences for the local climate.

Typical rural area with seven localities with different land cover types were chosen in Trebon Biosphere Reserve, Czech Republic, Central Europe. A combined method of airship thermal scanning of Ts (radiation surface temperature) and ground measurement of thermodynamic Ta (air temperature measured in a meteorological screen at 2 m height) was used (**Fig. 6**). The localities differed markedly in both the values and the dynamics of Ts and Ts − Ta. In the early afternoon, the difference in Ts between the different land covers reached almost 20°C. Ecosystems with nonfunctional or no vegetation largely resembled the asphalt surface, whereas ecosystems covered with dense, bushy, or tree vegetation showed relatively well-balanced daily temperature dynamics with low temperature extremes and a slow temperature morning increase or afternoon decrease. Ts − Ta at the peak solar irradiance ranged between −1°C at the forest and 14°C–17°C at the dry harvested meadow and the asphalt surface, respectively (**Fig. 7**). Therefore surface radiation temperature (Ts) can be considered as a measurable indicator of ecosystem and landscape functioning, and the importance of functional vegetation for local climate should also be considered.

Landscape drying: It should be pointed out that air heated by warm surface and ascending into atmosphere contains water vapor. Landscape loses water with the upwards flowing warm air driven by sensible heat. The amount of water in the air transported by sensible heat high into atmosphere can be substantially higher than that released by evapotranspiration. For example, air of 100% relative humidity and temperature 40°C contains 50 g of water vapor in 1 m^3 that is, such air of 20% relative humidity contains still 10 g of water vapor in m^3. Air driven by sensible heat from 1 m^2 at speed 1 m s^{-1} would transport into atmosphere 36 kg water during 1 h. Common value of ET is several millimeters (several liters per m^2 per day). Very high value of ET is about 10 mm. From this point of view, ET can be considered as a process of slowing down evaporation water losses from landscape on regional level. ET binds surplus of solar energy into latent heat of water vapor and reduces release/production of sensible heat, water vapor is not driven up it stays close to the canopy.

Evapotranspiration of forests plays an extensive role in the transport of moisture from ocean in continents. It is evident that annual precipitations are high in continents with large and continuous forest from coast inside of continents (West Africa, Amazonia). The biotic pump theory (Makarieva and Gorshkov) suggests the atmospheric circulation that brings rainfall to continental interiors is driven and maintained by large, continuous areas of forest beginning from coasts. The theory explains that, through transpiration and condensation, forests actively create low pressure regions that draw in moist air from the oceans, thereby generating prevailing winds capable of carrying moisture and sustaining rainfall far within continents. Moreover, considerations of the surface pressure gradients created by the processes of evaporation and condensation, as highlighted in the biotic pump concept, may lead to improved predictions of large-scale climates compared to atmospheric circulation models which only consider temperature effects.

The biotic pump concept explains why moist winds blow readily from ocean to well forested land and how this flow can decline and reverse when forest cover is absent or depleted.

How does the biotic pump work? Natural forests maintain high transpiration fluxes which exceed the evaporation fluxes over the ocean. This moisture condenses as it rises. The resulting low-pressure zone draws in moist air from the ocean. Deforestation reduces evapotranspiration, condensation and hence this pressure difference, thus weakening or removing the coast-to-interior moisture transport (**Fig. 8**).

Eng. **54**, 145–154. https://doi.org/10.1016/j.ecoleng.2013.01.036.

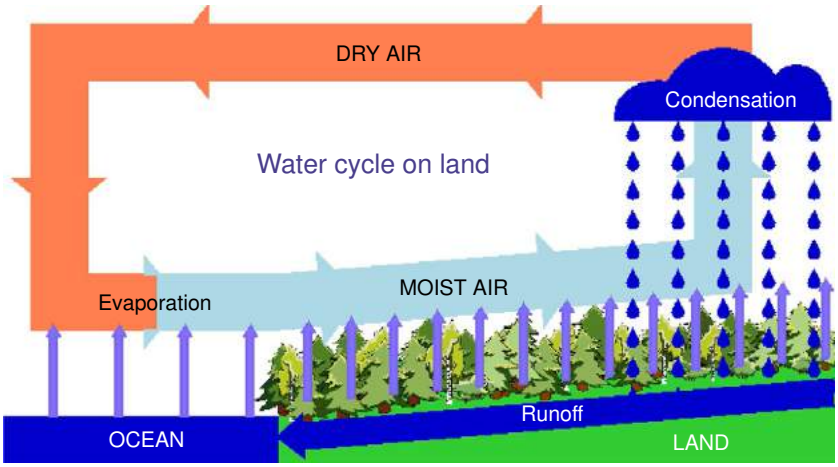

Fig. 8 How biotic pump ecology works.

Reliable rainfall in the continental interiors of Africa, South America, and elsewhere may thus be dependent on maintaining relatively intact and continuous forest cover from the coast.

A corollary of the biotic pump theory has further crucial implications for planetary air circulation patterns: if airflow patterns that move toward continental interiors are dependent upon the presence of forests, then their removal may foretell significant changes or wind pattern reversals. Reforestation and the restoration of degraded forest landscapes on an adequate scale may however reactivate such pumps, returning rainfall to continental interiors.

Evolutionary Ecology: Evolution of Parasitism☆

Gabriele Sorci and Stéphane Garnier, University of Bourgogne Franche-Comté, Dijon, France

Introduction

It is usually believed that all organisms on earth are involved in host–parasite interactions, either as a host or as a parasite. Parasites are not the only organisms that are intimately associated with another individual for their growth, reproduction and survival. The evolution of eukaryotes has been tightly linked with the establishment of permanent and obligate coexistence of genetic entities that were formerly able to live independently from each other. These kind of obligate associations are extremely numerous and can be classified according to the relative net effect that each partner inflicts on the other. The overall spectrum, therefore, goes from associations where both partners benefit from each other presence, to the other extreme where the association comes to the exclusive benefit of one partner at the expense of the other. This latter case is what is commonly called a host–parasite interaction. Here, the parasite entirely depends on the host for its growth, reproduction and survival. The metabolic resources necessary for the vital functions of the parasite are provided by the host, which in turn receives nothing by the parasite. This results in a net negative effect of parasitism on host fitness, as the resources consumed by the parasite are no longer available for the growth, reproduction and survival of the host. In this context, it is easy to understand that parasites are selected to exploit the host in the most effective way and hosts are selected to limit the negative effect of parasites. Therefore, the evolution of parasitism and the exploitation strategies that come along, cannot be easily disentangled from the evolution of host counteradaptations to resist parasitic attacks. This sets the scene for a coevolutionary scenario where hosts and parasites are endlessly selected to respond to the threat provided by the opponent.

Parasitism has evolved from an ancestral nonparasitic form. Although it is difficult (or impossible) to assess the selective pressures that have promoted the shift from a nonparasitic to a parasitic life style, the use of modern phylogenetic tools has provided very interesting insights on the evolutionary history of parasitism. Comparison of closely related extant taxa that differ in their life style (parasitic vs. nonparasitic) also provides an invaluable tool to study the traits (adaptations) that are associated with a parasitic mode of life and to infer the selection pressures that act on these traits.

Parasites are an important factor promoting the evolution of hosts because of their negative effect on them. This negative effect is generally called virulence and as any other traits of parasites, it evolves in response to environmental factors. Understanding how virulence evolves is obviously an important step if we want to fully assess the threat that parasites impose on humans, domestic animals, and wildlife, as well as to guide us to take the proper decisions on how control infectious diseases. In this article, we will go through these different aspects of parasite evolution, starting with a snapshot on the impressive diversity of organisms with a parasitic life style.

Parasite Diversity

Although it is difficult to date precisely the emergence of parasitism in living organisms (and even more difficult within each phylum), paleontological data show that parasitism is a very old life style. Several parasites have been identified in fossils from the Cretaceous period (-135 to -72 MY), and the older traces suggesting parasitism date back to late Cambrian (-497 to -485 MY). The first parasites surely evolved from free-living organisms, simply because no one around means nobody to parasitize. One thing is for sure—there is today a considerable diversity of parasites which can be seen from different angles (taxonomy, life cycles, hosts colonized, transmission modes).

Parasites are widespread among living organisms, as they are thought to represent $>50\%$ of all species on earth. From the simplest viral particle to avian brood parasites, parasitic lifestyle has regularly arisen during evolutionary time. Not all phylogenetic groups have been equally prone to the evolution of parasitism since the proportion of parasitic species is very heterogeneous among taxa. Whereas all viruses are parasites, no parasite is known in echinoderms. Nearly all platyhelminthes are parasites, whereas a unique species of cnidarian is parasitic among the 11,000 species described in this phylum, so far. Finally, some groups contain roughly equal proportion of parasitic and free-living species, such as bacteria, fungi, and nematodes. This heterogeneity raises two main questions. The first one involves the mechanisms responsible for the evolution of this taxonomic diversity, which may result from speciation events (formation of two different parasitic species from a single one) or transitions from free-living stages toward parasitism. Both mechanisms have played a role in parasite history, but they have different implications. Within the context of speciation, parasitic life style is simply inherited from a common ancestor, whereas transition events mean independent acquisitions of parasitism by several species. How many transitions toward parasitism have punctuated the evolution of life? It is impossible to give a precise answer to this question because the number of parasitic lineages which became extinct is unknown.

☆*Change History*: February 2018. Gabriele Sorci & Stéphane Garnier updated section introduction, parasite diversity, competition and further reading.

This is an update of G. Sorci and S. Garnier, Parasitism, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2645–2650.

 doi:10.1016/B978-0-12-409548-9.11094-2

However, phylogenetic analyses have shown no less than 63 independent transitions in the metazoan phylogeny, which contains >100,000 described species (Table 1). Again, the frequency of these events varies among taxonomic groups. For example, only one transition has occurred in cnidarian, whereas parasitism has evolved several independent times in nematodes.

This leads to the second question. Are some taxonomic groups more prone to evolve toward parasitism? Probably yes. A mutation occurring in a free-living organism might enable it to exploit another organism (which needs to be frequently encountered for an intimate interaction to be established). If the mutation provides the individuals with a slight advantage in term of reproductive success, a parasitic lifestyle will be favored by natural selection. However, it is unlikely that a single mutation would allow a free-living species to exploit a host without preadaptations for survival, feeding or reproduction within the host. It is therefore possible that traits currently associated with successful parasitism are exaptations (secondary functions of preexisting traits not directly linked to parasitism). In agreement with this view, the genomic comparison of parasitic trypanosomatids and a free-living relative showed that many of the unique characteristics of trypanosomatids, thought to be tightly linked with their parasitic lifestyle, are already present in the free-living relative *Bodo saltans*. However, once the progression toward a parasitic lifestyle is engaged, the new parasitic lineage is usually subject to morpho-anatomical (such as reduction/loss of sense or digestive organs), functional or physiological changes, leading to a stronger dependence of the parasite upon its host. It seems, however, that this process is not irreversible because the phylogeny of Diplomonadida (a group of protozoa) suggests that reversal to free-living stages has occurred twice.

Parasitism is also characterized by a great diversity of life cycles. In the simplest case, the parasite only needs one host to complete its life cycle. Several fungi, such as mildew, are plant parasites. Once a spore reaches a leaf, the fungus penetrates the plant, matures and starts to produce and release spores in the environment. These spores have to encounter another leaf to begin a new cycle. Complex life cycles involve two or more (up to four) hosts, each host housing a different developmental stage of the parasite (Fig. 1). Adults of the trematode *Halipegus ovocaudatus* live under the tongue of green frogs where they reproduce sexually. Eggs are released in the water and the emerging parasite needs to pass through three intermediate hosts (a mollusk, a copepod and a dragonfly). If a parasitized dragonfly is eaten by a frog, the cycle is eventually completed.

Table 1 Minimum number of evolutionary transitions to parasitism (sensu stricto) and number of living species in the major groups of metazoan parasites of metazoan hosts

Parasite taxon	*Minimum number of transitions*	*Minimum number of living species*
Phylum Mesozoa	1	>80
Phylum Plathelminthes[a]		
Class Cercomeridea (subclasses Trematoda, Monogenea and Cestoidea)	1	>40,000
Phylum Nemertinea[a]	1	>10
Phylum Acanthocephala	1	>1,200
Phylum Nematomorpha	1	>350
Phylum Nematoda[a]	4	>10,500
Phylum Mollusca[a]		
Class Bivalvia[a]	1	>600
Class Gastropoda[a]	8	>5,000
Phylum Annelida[a]		
Class Hirudinea[a]	3	>400
Class Polychaeta[a]	1	>20
Phylum Pentastomida	1	>100
Phylum Arthropoda[a]		
Subphylum Chelicerata[a]		
Class Arachnida[a]		
Subclass Ixodida	1	>800
Subclass Acari[a]	2	>30,000
Subphylum Crustacea[a]		
Class Branchiura	1	>150
Class Copepoda[a]	9	>4,000
Class Cirripedia[a]		
Subclass Ascothoracida	1	>100
Subclass Rhizocephala	1	>260
Class Malacostraca[a]		
Order Isopoda[a]	4	>600
Order Amphipoda[a]	17	>250
Subphylum Uniramia[a]		
Class Insecta[a]		
Order Diptera[a]	2	>2,300
Order Phthiraptera (suborders Ischnocera, Amblycera and Anoplura)	1	>3,000
Order Siphonaptera	1	>2,500

[a]Denotes taxa containing free-living species.

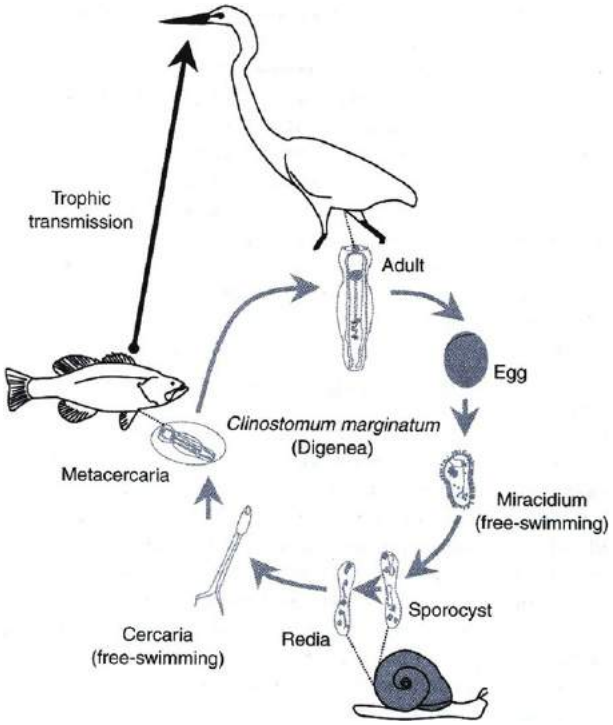

Fig. 1 A complex life cycle. The life cycle of the digenean *Clinostomum marginatum* involves three hosts. Adult worms parasitize the intestine of egrets and other fish-eating birds, where they produce eggs that are dropped into water with the bird's feces. A miracidium hatches out of the egg and swims until it finds a snail and infects it. The miracidium sheds its cilia and develops into a sporocyst, which then produces multiple redia. The redia produce multiple cercaria, which leave the snail and swim until they find a fish to infect, and then develop into metacercaria. Predation of fish by birds facilitates the completion of the parasites life cycle. Reproduced with permission from Thomas, F., Renaud, F. and Guégan, J. F. (2005). *Parasitism and ecosystems*. New York: Oxford University Press.

It seems parsimonious to assume that early evolutionary stages involved simple life cycles, with direct transmission between hosts of the same species. Understanding the evolution of complex, multispecies, life cycles has been more puzzling, as adding intermediate hosts might increase the risk of failing to encounter the right host. Theoretical work has explored the conditions that might have led to the evolution of complex life cycles in helminth parasites with no penetrative infectious stages. Two scenarios, and the benefits associated with each of them, have been put forward. According to the first scenario, transition from a single to a multihost life cycle can be attributed to upward incorporation of a new host which preys upon the original host (**Fig. 2**). In this scenario, benefits for the parasites are avoidance of mortality when the host is eaten by the predator, greater body size at maturity and fecundity. In the second scenario, incorporation comes downwards by adding an host at a lower trophic level (**Fig. 2**). This new host can initially be a paratenic (facultative) host, which later becomes an obligate host, if this enhances transmission rate to the definitive host. Although the addition of a paratenic host in a life cycle is an accidental event, complex life cycles of parasites are probably adaptive responses to the two main hurdles set by their environment, namely the transmission between hosts, and the compatibility between the parasite and the host(s).

Exploitation and Transmission Strategies

The success of a parasitic infection depends on two key steps: the ability of the parasite to establish within the host (to grow and reproduce) and the likelihood of propagules to be transmitted to a novel host. These two steps are associated with a number of adaptations aiming at maximizing parasite fitness. The strategies adopted to exploit the host and to transmit to other hosts can involve different traits. We will briefly discuss some exploitation and transmission strategies encountered in parasitic species.

Compared to most free-living organisms, parasites experience a relatively constant environment: the host. In most cases, the host provides a relatively constant food supply, constant temperature (for endotherms), shelter and protection toward predators. Parasites have adapted to this particular milieu with an array of adaptations ranging from special structures to attach to host structures, to regression of organs no longer needed for a life within a host. The view that the host provides a benign environment for the parasites is, however, too simplistic. Although living in the blood vessels of the host certainly provides shelter and protection, it exposes the parasite to the attack of a particular form of predators: the cells and molecules of the immune system. The immune system is probably the most sophisticated, although not unique, defense mechanism hosts have evolved. Theoretical models have analyzed the impact of host immunity on parasite life histories, using the framework that has been developed to

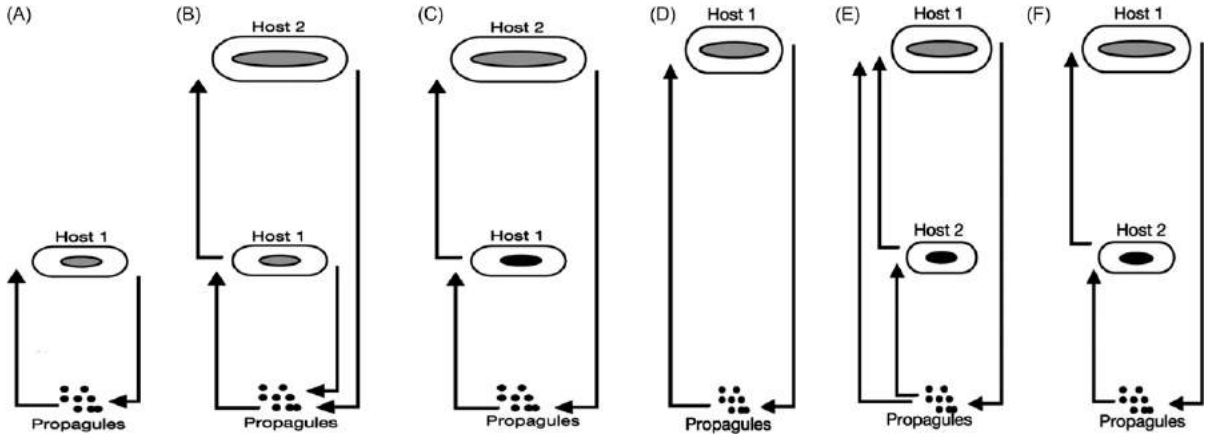

Fig. 2 Transition from a one- to a two-host cycle by upward incorporation of a definitive host (A–C) or by downward incorporation of an intermediate host (D–F). (A and D) The initial life cycle involves one host. (B) Host 1 is frequently ingested by a predator (potential host 2), resulting in a flexible two-host cycle (reproduction of the parasite in both hosts). (C) Reproduction in host 1 is suppressed, leading to a two-host cycle in which host 1 has become an intermediate host. (E) Propagules sometimes enter potential host 2, which can be ingested by host 1 (host 1 can be directly infected or indirectly via host 2). (F) Direct transmission to host 1 may later be lost. The *gray area* indicates adult parasites in definitive hosts; *black areas* indicate immature parasites in intermediate hosts. Reproduced with permission from Parker, G. A., Chubb, J. C., Ball, M. A. and Roberts, G. N. (2003). Evolution of complex life cycles in helminth parasites. *Nature* **425**, 480–484.

model the interactions between prey (here the parasite) and predators (here cytotoxic lymphocytes). These models have shown how pervasive the effect of host immunity can be on the dynamics and the virulence of the infection. Therefore, it is not surprising that parasites have adopted a series of strategies aiming at escaping the host immune response. Viruses, bacteria, protozoa, but also macroparasites such as helminths, can escape the immune response by hiding from or suppressing it. Antigenic variation is one of such strategies, where the same strain of a given microparasite expresses different antigenic epitopes. Antigenic variation allows the parasite to escape the immune response, since epitopes that are first recognized by the immune system are gradually replaced as long as the infection progresses.

As mentioned above, a successful parasite is a parasite that transmits its progeny to other hosts. Thus, transmission is tightly linked to fitness in parasitic species. However, transmission to another host is also associated with high mortality risk. A propagule has to face the hostile external environment during a period that can be quite long, it has to encounter the appropriate host, and finally enter it. Everything else being equal, large fecundities can compensate for the high risk of mortality incurred by propagules during their free-living stage. Several parasite species are well known for their fecundity records with several millions eggs produced during a lifetime. Another way to reduce the hazard of external life and predation is to add an intermediate host and modify its behavior to favor transmission to the final host. This kind of upward incorporation of hosts has been suggested to be at the origin of complex parasite life cycles (see above). Parasites with heteroxenous life cycles, however, face another dilemma. Their cycle is completed only when the intermediate host is eaten by the definitive host. Any mechanisms that make the intermediate host more susceptible to predation directly favor parasite transmission. This process of parasite manipulation (the parasite modifies the morphology and/or behavior of its intermediate host to increase the chance it will be preyed upon) is surprisingly very widespread (it has been reported in several species of protozoa and metazoan parasites) and can take unsuspected forms. Classical examples of parasite manipulation of host behavior include the effect of the digenean *Dicrocoelium dendriticum* on its ant intermediate host. *Dicrocoelium* causes infected ants to climb to the tip of grass blades and stay there waiting for a grazing sheep. As one might expect, sheep are the definitive hosts of *Dicrocoelium*. Other digenean parasites, such as species of the genus *Leucochloridium* are known to alter the shape, size and coloration of the tentacles of the snail they exploit. Modified tentacles strikingly resemble caterpillars which are likely to be detected by birds which are the definitive hosts of the parasite. However, such altered host phenotype facilitates the transmission of the parasite to the definitive host only if predation occurs when the parasite has reached the appropriate transmissible stage. If predation of the intermediate host occurs before the parasite has matured into the transmissible stage, the parasite will die with its intermediate host. It could be expected then that the optimal parasitic strategy to maximize transmission success should be to protect the intermediate host from predation until the parasite reaches the transmissible stage. This early reduced and late increased predation risk has been reported in the tapeworm *Schistocephalus solidus* that exploits copepods as intermediate hosts and fish as final hosts.

Competition

In nature, hosts are frequently infected by multiple parasite species. Depending on environmental conditions and the order of infection, the different species present in the same individual host, at the same time, can interact or not, depending on

whether they have overlapping or nonoverlapping niches (the range of environmental conditions experienced by the species). Two kinds of interactions have received much attention: interspecific competition and host defense mediated interactions.

Opportunities for competition between two species exist when both species exploit the same resource in the host (food, space). The performance (in terms of growth, reproduction, survival) of one species is reduced when the second species is present, either because the amount of available resources has been depleted (competition through exploitation) or because one species prevents the other from exploiting some resources via direct interaction (competition through interference). Asymmetrical competition has been often reported for parasites, when the species A suffers from the presence of species B whereas species A has no effect on species B. This pattern suggests a one-sided interference rather than exploitative competition, but it could also be due to host-mediated effects involving the immune response.

Competition is thought to be one of the main factors driving the assemblage of species within communities. When two parasite species with overlapping realized niche in isolation, co-occur in the same host, the realized niche of at least one of them might be changed (compared to when occurring alone) to minimize competition. This process is called interactive site segregation. There are many examples of site segregation in helminths inhabiting the digestive tract of their hosts, sometimes leading to a more or less regular spreading of species along the digestive tract. If there is some genetic basis for the niche preference, and if the cost of competition (in terms of fitness) outweighs the cost of realized niche change (because of less optimal environmental conditions), then this change may be selected for and become genetically fixed. This can lead to a complete segregation of the fundamental niche, where species have nonoverlapping niches whether alone or together in the same host.

Host immunity can also mediate and affect the outcome of the competition between parasite species. As mentioned above, immunosuppression is a common strategy adopted by parasites to persist within the host. Host immunosuppression can, however, have profound effects on the colonization and the population dynamics of other parasites. The spread of opportunistic diseases following infection with HIV virus is one of the most striking examples of this host immunity mediated interaction. A meta-analysis of published work has shown that resource-based (bottom-up) and predator-based (top-down) mechanisms can actually shape the pattern of coinfection between helminths and microparasites, depending on whether they compete for similar resources or whether they interfere with the host immune system.

Coevolution

It should be clear by now that whatever the parasite trait we consider, its evolution can only be understood in the light of the selection pressures exerted by the environment. A striking and major difference between free-living and parasitic species is that free-living organisms evolve in response to selection pressures exerted by both abiotic and biotic factors, whereas parasites almost uniquely respond to the selection pressure exerted by their hosts (although this does not apply to parasitic species that spend a considerable part of their life outside or not in contact with a host). This means that parasite evolution cannot be envisaged other than in the light of host evolution. In other words, hosts and parasites are involved in a process of coevolution where the emergence and spread of a trait in the parasite (i.e., a trait that confers a better ability to exploit the host) select for a specific response in the host and vice versa the emergence and spread of a trait in the host (i.e., a defense mechanism) select for a specific trait in the parasite.

One particular group of parasites provides, probably, the best illustration of the coevolutionary process. As mentioned above, parasitism in not restricted to microorganisms and invertebrates. Some birds, such as cuckoos and cowbirds, have also adopted a parasitic lifestyle. Of course, cuckoos do not develop inside a host and do not consume host resources as a microorganism would do. Cuckoos and cowbirds exploit a particular resource of the host: parental care. Cuckoos cannot reproduce unless they find an appropriate host (another bird species) that takes care of their eggs and nestlings. To complete its life cycle (producing offspring) a cuckoo needs a host, which fully includes it in the category of parasites. Outside the reproductive season, parasitic cuckoos behave as any other nonparasitic relative. The parasitic behavior is, therefore, clearly restricted to a particular stage of the life cycle of these birds. To be successful, a female cuckoo has to find a suitable host (usually a passerine species) and lay an egg in the nest of the host. If the cuckoo egg is incubated by the female host, a cuckoo nestling will hatch, usually before any other host nestlings. The impact of cuckoo parasitism on host reproductive success is dramatic as the cuckoo nestling ejects all host eggs and nestlings out from the nest, reducing the host brood to a single parasitic nestling. Given the cost for host fitness, it is straightforward to expect that hosts have evolved a set of traits aiming at reducing the risk of brood parasitism and, in turn, brood parasites have evolved a series of strategies to overcome host defense. **Table 2** summarizes the most prominent host adaptations and parasite counteradaptations involved in the coevolutionary process between brood parasites and their hosts. Why is this example particularly relevant to illustrate the coevolutionary process? The specificity (usually brood parasite species or host races exploit a single host species, even though exceptions exist) and the particular nature of the traits involved limit the chances that the presumed adaptation has arisen because of indirect selection exerted by any other source not involved in the interaction.

Even though more diffuse, coevolution is a major and pervasive characteristic of host–parasite interactions. Understanding the evolution of parasitic strategies and lifestyle is, therefore, a particularly tough task as it has and currently still responds to the selection pressures exerted by other living and evolving organisms, the hosts.

Table 2 Adaptations and counteradaptations involved in the coevolutionary process between brood parasites and their hosts

Parasite exploitation strategy	*Host defense*	*Parasite counteradaptation*
Finding a suitable host nest in the appropriate breeding phenology. Laying an egg	Defending the nest against the intruder	Dropping the egg in the nest within few seconds when the host has left the nest unattended
	Spotting any strange egg in the clutch and reject or destroy any egg differing from the other eggs of the clutch	Laying mimetic eggs that match as close as possible host eggs in size and color. Lay thicker eggs that resist dropping in the nest and host puncturing
Monopolize host resources (parental care). Incubation time is shorter in the parasite than the host. As soon as the parasite hatches, it ejects host eggs or kills/outcompetes host nestlings (nestlings of the European cuckoo have evolved a particular structure in the back that, like a spoon, allows them to eject host eggs out of the nest rim). Cuckoo nestlings provide superstimuli (visual and vocal) to the foster parents to obtain sufficient food	Desert the brood[a]	Nestling mimicry[a]

[a]Host defense against parasitic nestlings has been reported for the interaction between the super fairy-wren (*Malurus cyaneus*) and the Horsfield's bronze-cuckoo (*Chrysococcyx basalis*).

Metabolic Biodiversity

In the biological world, the enormous assortment of energy sources can be used in many different ways to support the growth of organisms. The characteristics of the different pathways that can be used to produce the energy that arises from coupled oxidation–reduction reactions and is needed for living processes are listed in Table 1.

The Fermentation Process

When respiration is not possible, due to either a lack of an external electron acceptor or an impairment of the respiratory chain, fermentation is the catabolic pathway that is used for the production of energy from the partial oxidation of glucose or other carbon sources (Figure 1). The oxidation of the substrate, which occurs mainly through the Embden–Meyerhoff and Parnas (EMP) or Entner–Doudoroff (ED) pathways, results in the production of pyruvate, adenosine triphosphate (ATP), and nicotinamide adenine dinucleotide phosphate (NAD(P)H). In the absence of external electron acceptors, the pyruvate or the other organic compounds that derive from the initial substrate reaction undergo reduction, with the regeneration of $NAD^+(P)$. This step is essential for the fermentation process to progress and it leads to the production of waste products (ethanol and organic acids) that are excreted from the cell. ATP is the main product of fermentation, and it is generated by phosphorylation at the substrate level. An exception to this general rule is seen with the fermentation of carboxylic acids. The catabolism of these substrates generates a gradient of H^+ or Na^+ ions across the plasma membrane, and the production of ATP involves the activity of the H^+ or Na^+ membrane ATPases.

While the complete oxidation of 1 mol of glucose to CO_2 through oxidative phosphorylation (respiration) generates up to 38 mol of ATP, fermentation produces only a few moles of ATP (1–3) per mole of glucose. Thus, the recovery of energy from fermentation is rather low compared to that yielded by respiration. Moreover, it varies depending on the initial substrate and the fermentation process itself.

Ecological Distribution of Fermentation Processes

Fermentative metabolism is widespread among living organisms, and the ecology of fermentative processes is particularly complicated due to the ability of different organisms to ferment a plethora of substrates under different environmental conditions. Fermentation is carried out in anoxic environments by strict anaerobic or facultative anaerobic microorganisms, although some microaerophilic or facultative anaerobic microorganisms are also able to carry out fermentation in the presence of oxygen.

☆*Change History:* June 2013. M Ciani introduced small edits in the text of the article, added the sections Controlled Mix Fermentation in Wine, Fermented Vegetables and Fruits through Lactic Acid Bacteria and Fermented Milks: Kefir and Kumis as Matrix of Microbial Interactions, and added Figure 6.

Table 1 Metabolic biodiversity among living organisms

Metabolic diversity	*Characteristics*
Phototrophy	When radiant energy is absorbed by chlorophyll or other similar pigments, resulting in an excitation of the electrons present in the complex and providing oxidation that produces oxygen (oxygenic photosynthesis) or does not produce oxygen (nonoxygenic photosynthesis)
Aerobic respiration	Molecular oxygen is the final acceptor of electrons in a redox reaction and appears in reduced form as water
Anaerobic respiration	Under anaerobic conditions where molecular oxygen is absent or limited, inorganic ions (nitrate, sulphate, carbonate) serve as final acceptors of electrons
Fermentation	An organic compound that is often a metabolic intermediate coming from oxidation of an organic compound serves as terminal oxidant, producing a more reduced organic molecule as the metabolic end product

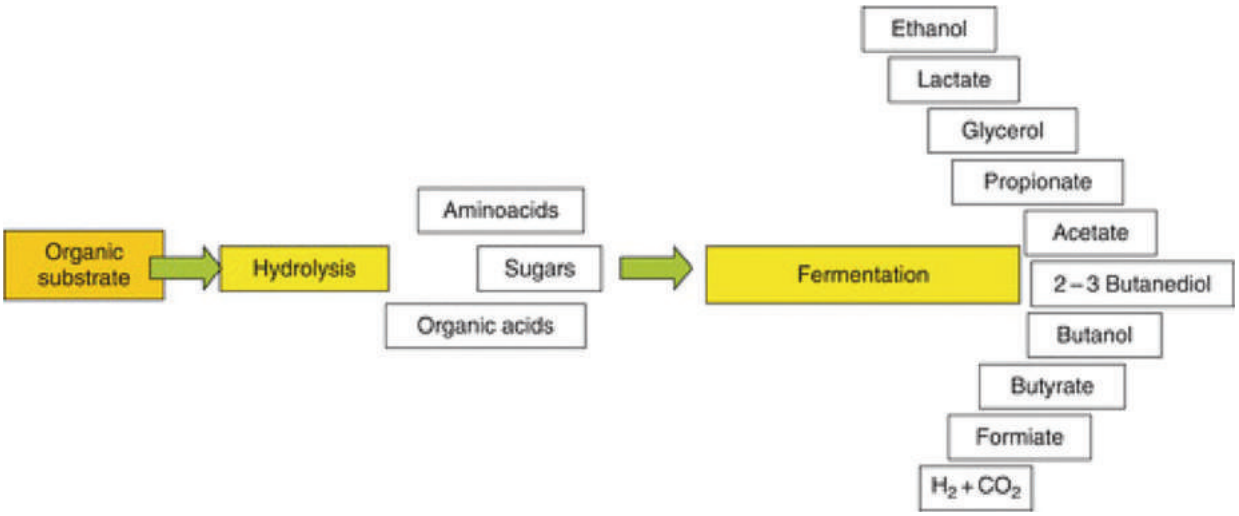

Figure 1 Main end products of the various fermentation processes.

Microaerophilic fermenting microorganisms, such as lactic acid bacteria, colonize habitats that are characterized by low oxygen concentrations or the absence of oxygen (often *c*. 10% of atmospheric levels). These microaerophilic microorganisms show a wide ecological distribution in well-defined habitats, such as the animal and human oral cavity, the gastro-intestinal tract, and feces, as well as in fermented meat, beverages, vegetables (silage, olive brine, sauerkraut), and dairy products. Lactic acid bacteria have limited biosynthetic ability and require pre-formed amino acids, group B vitamins, purines, and pyrimidines. These multiple requirements restrict their growth to habitats where the required compounds are abundant. The fermentation activity of lactic acid bacteria produces large amounts of lactic acid, which can cause a drop in pH to about 4.0, and thus inhibit the growth of most other bacteria and exert an antagonistic effect on spoilage microorganisms and the most common human pathogens. For these reasons, the transformation of food and beverages by fermentation is one of the main modalities for the conservation of food products and the enhancement of their quality.

Besides microaerophilic lactic acid bacteria, anaerobic facultative microorganisms such as yeasts are the main group of microorganisms that are involved in the transformation of fermented food. In contrast to the facultative anaerobic bacteria, which always preferentially carry out respiration as a metabolic pathway in the presence of oxygen, facultative anaerobic yeast can also adopt a fermentative metabolism in the presence of oxygen. This is the case for *Saccharomyces cerevisae*, the most representative yeast used in a wide variety of industrial fermentative processes. *S. cerevisiae* exhibits a specific mechanism of respiro-fermentative regulation that is known as the 'Crabtree effect'. At high sugar concentrations, and even in the presence of oxygen, fermentation overrides respiration. This mechanism results in a high rate of sugar consumption and therefore the colonization of habitats with high sugar content. Consequently, the ecological niche of fermentative yeasts includes sugary fruits, flowers, lymph, and tree exudates.

Anaerobic facultative bacteria represent a group of microorganisms that is broadly diffuse in several habitats. These microorganisms can grow in the presence of oxygen, and they can use fermentative metabolism when oxygen is not available. Anaerobic facultative bacteria such as *Enterobactericeae* colonize the intestinal tract of warmblooded animals, and some species belonging to the genera *Yersinia*, *Salmonella*, and *Shigella* can cause infectious diseases. The habitat of enteric bacteria is very specific. *Escherichia coli*, the most well-known species among the enteric bacteria, is used as indicator of fecal contamination of water and food because of its low survival in other environments. Since enteric bacteria are anaerobic and facultative, they have important roles in the ecology of the gut of warmblooded animals. By consuming the oxygen available in this habitat they maintain the right conditions for the proliferation of other bacteria that constitute the intestinal microflora (lactic acid bacteria, bifidobacteria).

Other facultative or obligate anaerobic bacteria can be found in both soil and water environments, where they have fundamental roles in the transformation of organic substances under anoxygenic conditions. An example is provided by methanogenesis, a bioprocess that occurs in natural environments, such as the rumen, marshes, and the industrial sites of anaerobic wastewater treatment plants. During this process, a first group of fermentative/hydrolytic microorganisms produces low molecular weight organic acids, alcohols, CO_2, and H_2. Another bacterial group, known as the 'syntrophic microorganisms' is very important for the conversion of organic compounds to CH_4 during methanogenesis. In this process, called syntrophy, methanogenic bacteria cooperate with other fermenting microorganisms to produce the substrates that are necessary to realize their specific ecological interactions. The H_2 derived from organic molecules and produced after energetically unfavorable fermentation is consumed by methanogenic bacteria, and the overall reaction produces energy that is used by the syntrophic couple.

Industrial Fermentation

As indicated above, natural fermentation is widely diffuse in several ecological niches where the conditions of anaerobiosis, high concentrations of carbohydrates (the Crabtree effect), or the lack of carbohydrates (fermentation of amino acids) determine the predominant fermenting organisms. All fermentative processes that are today devoted to food and animal feed transformation and preservation have ancient origins and have been traditionally carried out by the microorganisms naturally present in the substrates. The advent of industrialization, the construction of appropriate equipment, and the development of microbiology as an applied science have led the development of the fermentation industry, transforming a great number of the natural fermentation processes into industrial-scale fermentation. These transformations have been applied to wine, beer, distilled beverages and bread industries where alcoholic fermentation is mainly involved, and to the dairy and meat transformation industries, in which lactic fermentation is the main fermentation process. In these fermentation industries, the use of selected starter cultures during different stages of the fermentation processes has become progressively diffuse. The aim of this procedure is to improve the management of the fermentation process through avoidance of the development of spoilage and pathogenic microorganisms, and enhancement of the quality of the final product. Table 2 lists these main fermentation processes that are involved in the food and animal-feed industries.

Alcoholic Fermentation

Alcoholic fermentation is the best known of the fermentation processes, and is involved in several important transformation, stabilization, and conservation processes for sugar-rich substrates, such as fruit, and fruit and vegetable juices. Alcoholic fermentation is carried out by yeasts and some other fungi and bacteria. The first step of the alcoholic fermentation pathway involves pyruvate, which is formed by yeast via the EMP pathway, while it is obtained through the ED pathway in the case of *Zymomonas* (bacteria). In the following step, the pyruvate is decarboxylated to acetaldehyde in a reaction that is catalyzed by the enzyme pyruvate decarboxylase (Figure 2).

The redox balance of alcoholic fermentation is achieved by the regeneration of NAD^+ during the reduction of acetaldehyde to ethanol, which is catalyzed by alcohol deydrogenase. The ATP yield of alcoholic fermentation is 1 or 2 mol of ATP per mole of glucose oxidized via the ED and EMP pathways, respectively. *Zymomonas mobilis* is the most important bacterial species that is able to perform alcoholic fermentation. The habitat of this species is the lymph of tropical trees, such as the palma tree from where it was originally isolated. *Z. mobilis* was proposed and used as a starter for ethanol production at the industrial level, although at present alcoholic fermentation carried out by yeast is better known and has been more thoroughly investigated. Natural alcoholic fermentation of fruit (cacao) and fruit juices (grape must and apple juice) is carried out by different microorganisms that act

Table 2 Examples of industrial fermentation and their producer microorganisms

Fermented food and animal feed	*Microorganisms involved*	*Fermentation*	*Undesired fermentation*
Fermented meat (salami)	Lactic acid bacteria	Lactic	
Fermented milk	Lactic acid bacteria	Lactic	Alcoholic
Fermented milk	Lactic acid bacteria and yeast	Lactic and alcoholic	
Cheese	Lactic acid bacteria; propionic bacteria	Lactic and sometimes propionic	Mixed-acid and butyric acid
Bread and bakery products	Yeast and lactic acid bacteria	Alcoholic and heterolactic	
Beer	Yeast	Alcoholic	Lactic and mixed acid
Wine	Yeast	Alcoholic	Lactic
Olive brines	Lactic acid bacteria	Lactic	Butyric
Silage	Lactic acid bacteria	Lactic	Amino acids Butyric Mixed-acid
Coffee	Lactic acid bacteria and yeast	Alcoholic and lactic	
Cocoa	Yeast and lactic acid bacteria	Alcoholic and lactic

sequentially. The substrate fermentation is first achieved by apiculate yeast (*Hanseniaspora*), which is followed by elliptical yeast (*Saccharomyces*). Other fermenting yeast ascribed to the genera *Candida*, *Kluyveromyces*, *Metschnikowia*, *Pichia*, *Saccharomycodes*, *Torulaspora*, and *Zygosaccharomyces* are also sometimes found during natural alcoholic fermentation.

Controlled Mix Fermentation in Wine

Grape juice fermentation is a complex biochemical process in which wine yeasts play fundamental roles during the transformation of grape sugars into ethanol, carbon dioxide and hundreds of other secondary products. To improve the quality of wine, the inclusion of non-*Saccharomyces* wine yeasts, together with *Saccharomyces cerevisiae* strains as part of mixed and multistarter fermentations, has been proposed as a tool to take advantage of spontaneous fermentation avoiding the risks connected with this last one. Criteria for the selection and development of non-*Saccharomyces* yeasts for wine fermentation have evolved over many years and are largely discussed. On the basis of these criteria yeasts should harbor characters that influence wine quality and affect the performance of the fermentation process, Some characters and properties are associated with the commercial production of these wine yeasts. Within each category, there are properties of varying degrees of significance and importance, some being essential and some being desirable. Possible synergistic and positive interactions between different yeasts might represent a tool for new fermentation technologies. Indeed, a lot of studies demonstrated that in *Saccharomyces*/non-*Saccharomyces* mixed cultures, interactions due to the wide inter-generic metabolic diversity could contribute to improve the final quality of wine.

It is well established that the most important agent of alcoholic fermentation is *S. cerevisiae*, the yeast that is used widely in several fermentation industries (wine, beer, cider, and bread) as a microbial starter. *S. cerevisiae* becomes the dominant species during alcoholic fermentation of fruit and fruit juices because of the strongly selective environment due to the low pH and high sugar and ethanol concentrations, and the anaerobic conditions. The ecological distribution of *S. cerevisiae* and the role of different habitats in the evolution of this species are controversial. Numerous investigations have revealed the low diffusion of this yeast species in natural environments such as soil, fruit surfaces, and tree exudates. On the other hand, *S. cerevisiae* is found widely in wineries and other fermentation plants since it is used to carry out the fermentation processes.

In the winery, several environmental factors, including high ethanol and sugar concentrations, the presence of SO_2, and others, can exert selective pressures on the *S. cerevisiae* population. Following these considerations, *S. cerevisiae* is defined as a domesticated species because of its selection through time in man-made environments.

Glycero-Pyruvic Fermentation

Glycero-pyruvic fermentation is always concomitant to alcoholic fermentation, although it involves a very low percentage of sugar (5–8%). However, under particular fermentation conditions, some osmotolerant yeast species (e.g., *Torulopsis magnoliae*, *Torulopsis bombicola*, and *Candida stellata*) and other fermenting yeast (*S. cerevisiae*) can ferment sugar to produce glycerol and, for example, acetaldehyde, acetic acid, acetoin, 2,3-butanediol and succinic acid, all compounds that can be derived from pyruvate.

The change from alcoholic to glycero-pyruvic fermentation occurs mainly because of the need to regenerate NAD^+ when the reduction of acetaldehyde to ethanol is not possible (Figure 2). This could be due to: (1) the nonavailability of acetaldehyde, if it is

bound by sulfite; (2) the absence or low activity of pyruvate decarboxylase; and (3) the high activity of the aldehyde dehydrogenase enzyme (under alkaline pH) that catalyzes the reaction from acetaldehyde to acetate.

In the past, between the two world wars, glycero-pyruvic fermentation was exploited at an industrial level for the production of glycerol.

Propionic Acid Fermentation

Propionic acid fermentation is carried out by several bacteria that belong to the genus *Propionibacterium* and to the species *Clostridium propionicum*. During propionic acid fermentation, both sugar and lactate can be used as the initial substrate. When sugar is available, these bacteria use the EMP pathway to produce pyruvate; the pyruvate is carboxylated to oxalacetate by methyl malonyl coenzyme-A (CoA) and then reduced to propionate via malate, fumarate, and succinate. The other end products of propionic fermentation are acetic acid and CO_2 (**Figure 3**). In particular, the propionic acid fermentation of 3 mol of glucose produces 4 mol of propionic acid, 2 mol of acetic acid, 2 mol of CO_2, and 12 mol of ATP. When lactate is the initial substrate, propionic fermentation results in the production of 2 mol of propionic acid, 1 mol of acetic acid, and 1 mol of CO_2. In this process, 1 mol of ATP is generated per nine carbons, and because of this, propionic bacteria generally grow very slowly.

The typical natural habitats of *Propionibacterium* are the rumen, the intestinal tract of animals and the skin of mammalians. *Propionibacterium* also colonize cheese during maturation. While the metabolic activity of *Propionibacterium* should be avoided during the maturation of the vast majority of cheese, it is required for the production of some typical products, such as Emmental cheese. In this Swiss-type cheese, two successive fermentations occur. During its manufacture, lactic acid bacteria convert lactose into lactate, and then during ripening, propionic acid bacteria convert the lactate into propionic acid, acetic acid, and CO_2. The CO_2 is responsible for 'eye' formation and the propionic acid promotes the typical nutty flavor of this Swiss-type cheese. The ability to use lactate is particularly relevant for the ecological distribution of propionic acid fermenting bacteria, which can use the final product of lactic acid fermentation.

Amino Acid Fermentation

In the absence of electron acceptors such as oxygen, nitrate, and sulfate, *Clostridium*, *Fusobaterium*, and a few other anaerobes can ferment amino acids. This fermentation occurs during anaerobic and putrefaction processes. The most important mechanism for amino acid degradation is Stickland fermentation; during Stickland fermentation of two amino acids, one serves as the electron donor while the other serves as the acceptor. All amino acids are classified into electron acceptors or donors on the basis of Stickland fermentation, and only tryptophan and tyrosine can behave both as an acceptor and a donor. In addition to decarboxylation of various amino acids by this mechanism, the subsequent reactions yield a variety of products that can have unpleasant odors. In the absence of fermentable carbohydrates and in rich protein substrates, a large number of *Clostridium* species – such as *C. botulinum*, *C. tetani*, and *C. perfringens* – can generate ATP from amino acid fermentation. The ATP yield here is 1 mol per 3 mol of amino acid used, and thus the reaction is highly advantageous for organisms that can grow in rich anaerobic protein environments. The main products of the Stickland reaction are NH_3, CO_2, short-chain fatty acids and H_2, and the minor products are hydrogen sulfide, methyl mercaptane, phenols, and alcohols, which together with fatty acids form a typical putrefying odor. The favorite habitat of *Clostridium* is the soil, in anaerobic scrap previously colonized by aerobic bacteria, and *Clostridium* species can also colonize the mammalian intestine. Moreover, these species can produce infectious diseases, such as botulism caused by

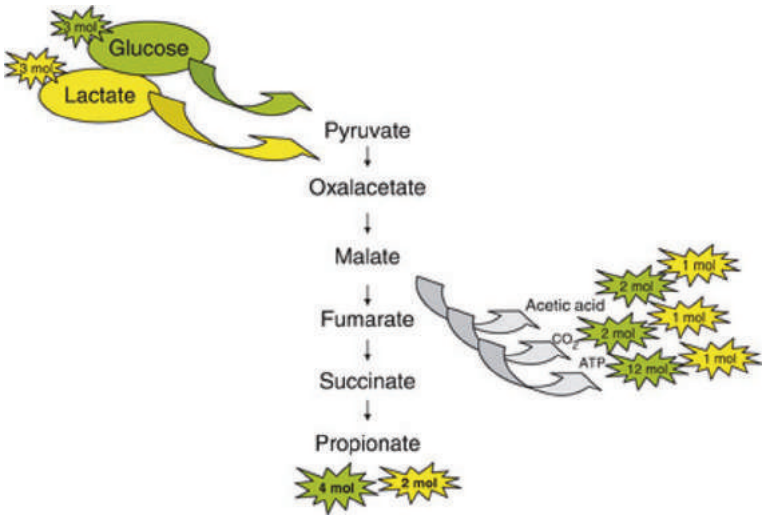

Figure 3 Propionic fermentation and different yields of the final products coming from glucose or lactate as the initial substrate.

C. botulinum, tetanus by *C. tetani*, and gangrene by *C. perfringens*. *Clostridium sporogenes*, a typical soil bacteria, can also participate in peritoneal infection that can occur as a result of the proliferation of food pathogens, intestinal obstruction, or mesenteric thrombosis.

Lactic Acid Fermentation

Depending on the pathway used for glucose oxidation, lactic acid fermentation can result in the production of lactate (homolactic fermentation), lactate, ethanol/acetate, and CO_2 (heterolactic fermentation) or lactate and acetate (the bifid shunt). Lactic acid fermentation is carried out by lactic acid bacteria and bifidobacteria, and also by some species of *Bacillus*, some protozoa and water molds, and the cells of human skeletal muscle when they are subjected to extreme work under oxygen deprivation. Both homolactic and heterolactic fermentation are involved in food and animal feed transformation and preservation. In particular, lactic acid fermentation is mainly responsible for the souring of milk products and is used in the production of yogurt and other fermented milk products (e.g., cheese, buttermilk, and sour cream). However, lactic acid fermentation also occurs during the fermentation of sauerkraut, and in other vegetable and sourdough bread fermentation, and it has important roles in sausage maturation, and silage fermentation and stabilization. The bifid shunt occurs mainly in the human and animal large intestine, where bifidobacteria are among the most abundant of the microbial groups.

Homolactic Fermentation

Homolactic fermentation is carried out by bacteria belonging to the genera *Lactococcus*, *Enterococcus*, *Streptococcus*, and *Pediococcus*, and by some species of the genus *Lactobacillus*. All of these bacteria can convert sugar to mainly lactic acid, via glycolysis. The enzyme lactate dehydrogenase (LDH) catalyzes the last step of this fermentation; in particular, by transferring hydrogen from NADH to pyruvate, LDH leads to pyruvate reduction and NADH reoxidation, with the production of D- or L-lactate. ATP formation is coupled to pyruvate production and the ATP yield of homolactic fermentation is 2 mol per mole of glucose oxidized (Figure 4). The homolactic behavior is not obligatory, but depends on sugar type, rate of the glycolytic flux, and growth conditions. Some homofermentative bacteria can catabolize glucose in a heterofermentative fashion, or carry out mixed-acid fermentation when the glycolytic flux is low, thus decreasing or increasing the ATP yield per mole of glucose, respectively.

Heterolactic Fermentation

Heterolactic fermentation is carried out mainly by bacteria of the genera *Leuconostoc*, *Oenococcus*, and *Weissella*, and by heterofermentative lactobacilli. Obligate heterofermentative bacteria do not perform glycolysis due to the lack of aldolase, the enzyme that breaks down fructose 1,6-bisphosphate into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. Glucose 6-phosphate is oxidized to 6-phosphogluconate and fermentation is carried out through the phosphoketolase pathway (Figure 4). The final products of this fermentation are lactate, ethanol, and CO_2 but acetate may also be produced. The ATP

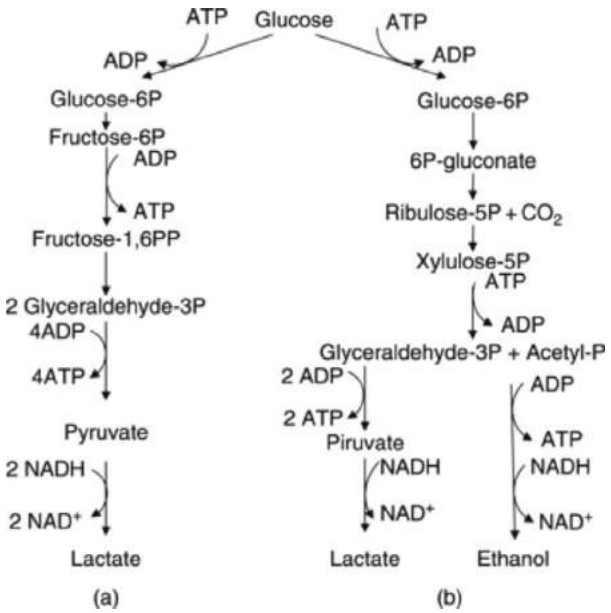

Figure 4 Schematic representation of homolactic (a) and heterolactic (b) fermentations. Pyruvate reduction leads to the regeneration of NAD^+.

yield is 1 mol per mole of glucose; thus, heterolactic metabolism yields less energy than homolactic fermentation. Heterolactic fermentation can also be carried out by facultative homofermentative bacteria.

Bifidobacterium Lactic Acid Fermentation

This type of lactic acid fermentation is exclusive to Gram-positive bacteria belonging to the genus *Bifidobacterium*. These bacteria are found mainly in the intestinal tracts of warmblooded animals and they are recognized as probiotic. In fact, they help in the maintenance of the balanced composition of the intestinal microflora and they exert positive effects on the health and well-being of the host. Bifidobacteria do not have aldolase and glucose-6-phosphate dehydrogenase; they thus ferment hexose via a phosphoketolase pathway that is known as the 'bifid shunt', where the final products are acetic and lactic acids in a molar ratio of 3:2. The key enzyme in the bifid shunt is fructose-6-phosphate phosphoketolase (F6PPK), which converts frutose 6-phosphate into acetyl 1-phosphate and eritrose 4-phosphate (**Figure 5**). The ATP yield is 5 mol per 2 mol of glucose, and it is therefore higher than that of homolactic fermentation.

Fermented Vegetables and Fruits Through Lactic Acid Bacteria

Lactic acid fermentation represents the most suitable approach for increasing the daily consumption of fresh-like vegetables and fruits. Lactic acid bacteria are a small part of the autochthonous microbiota of vegetables and fruits. The diversity of the microbiota markedly depends on the intrinsic parameters such as the pH and aw values of matrix, temperature, and extrinsic parameters of the plant matrix, first of all the interactions between different microorganisms that coexist in the environment.

Besides the above semi-industrial or artisanal products, a large variety of fermented pickles, which represents a culture heritage from the tradition of rural communities, is scarcely documented. Such fermented pickles are very popular in Asian and African countries, where they are fundamental components of the daily diet Under these poor technology conditions, lactic acid fermentation is the simplest, and probably the only, way to preserve fruits and vegetables.

In these natural matrix, spontaneous fermentation was shown to improve some health-promoting features of pickled garlic, especially the concentration of polyphenols and the related antioxidant activity.

Kimchi is the name of various traditional fermented vegetables, which are emblematic of the Korean culture. These beneficial effects are attributed either to functional components (vitamins, minerals, fibre and phytochemicals) or to fermentation by lactic acid bacteria Usually, *Leuconostoc mesenteroides* starts the fermentation but it is suddenly inhibited by the increasing concentration of lactic acid. Acid-tolerant species such as *Lactobacillus brevis* dominate during the middle stage, being replaced by *Lactobacillus plantarum* during late fermentation.

Another example of fermented vegetable regards cucumbers that, fully ripe, is harvested and dipped into brine (with 5–7% of NaCl) inside plastic or glass boxes and subject to spontaneous lactic acid fermentation. During fermentation, lactic acid bacteria synthesize several bacteriocins and liberates antimicrobial peptides, which inhibit spoilage bacteria.

Also fermented capers are typical pickles of Mediterranean countries (e.g., Greece and sud of Italy). Fruits are harvested in June or July, immersed in tap water, and subjected to spontaneous lactic acid fermentation for about 5–7 days at ambient temperature. After that, fermented capers are placed into brine. *Lactobacillus plantarum* is the species more frequently isolated from the brine of capers.

Innovation in food biotechnology plays an important role to improve the nutritional features, possibly also enhancing the hedonistic aspects. Smoothies are an example of this trend to increase the consumption of vegetables and fruits, as an alternative and/or a complement to fresh products. For example, white grape juice and Aloe vera extract are mixed with red (cherries, blackberries prunes and tomatoes) or green (fennels, spinach, papaya and kiwi) fruits and vegetables, and subjected to fermentation with mixed autochthonous starters such as *Lactobacillis plantarum* and *Lactobacillus pentosus* strains.

Functional beverages made with a mixture of rice and barley or emmer and concentrated red grape must are fermented with selected strains of *L. plantarum*, which remain viable throughout storage at 4 °C for 30 days. The use fruit and vegetable matrices as potential non dairy vehicles for delivering probiotic strains is largely assessed. Probiotics have the capacity to grow and to survive, depending on the inherent characteristics of the plant species. Lactobacillus acidophilus, *L. plantarum*, *Lactobacillus casei*, *Lactobacillus rhamnosus*, *Lactobacillus delbrueckii*, *Leuconostoc mesenteroides*, and species of the genus *Bifidobacterium* are mainly used. Compared to cranberry juice, *Lactobacillus* and *Bifidobacterium* strains survive for a longer time in orange and pineapple juices *L. casei*, *L. rhamnosus*, and *Lactobacillus paracasei* remaine viable in orange juice during 12 weeks of storage.

Often lactic acid fermentation occurs spontaneously following protocols of manufacture, which are strongly linked to the culture and traditions of each country. New molecular approaches to study the composition of the microbiota and to select autochthonous starters targeted for different vegetables and fruits have to be encouraged to get new insights and to allow controlled fermentation processes as it was done for other fermented foods (cheeses, sausages, leavened baked goods). Lactic acid bacteria tailored to the various intrinsic and extrinsic environmental conditions completely exploit the potential of vegetables and fruits, which enhances the hygiene, sensory, nutritional and shelf life properties (**Figure 6**).

Mixed-Acid Fermentation

Mixed-acid fermentation is characteristic of the *Enterobacteriaceae* ascribed to the genera *Citrobacter*, *Escherichia*, *Proteus*, *Salmonella*, *Shigella*, *Yersinia*, and *Vibrio*, and to some species of *Aeromonas*; it is also carried out by some anaerobic fungi. This metabolic group includes microorganisms that have a different ecology and impact on human activities. Some of them are members of the normal intestinal microflora of mammals and other vertebrates (*E. coli*) and have a role in the colonization of lignocellulose in the rumen (*Neocallimastix*). Some others are pathogens that are responsible for human and animal diseases, and they can be abundant in

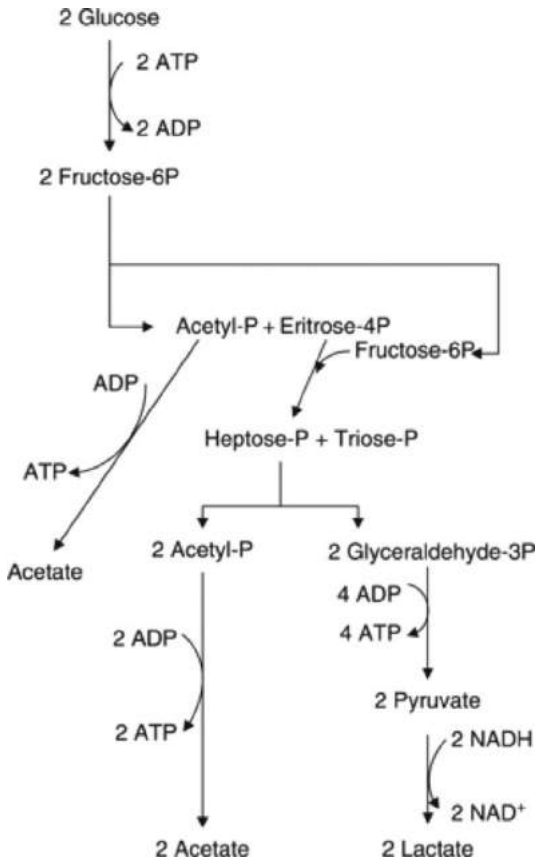

Figure 5 Schematic representation of bifid shunt.

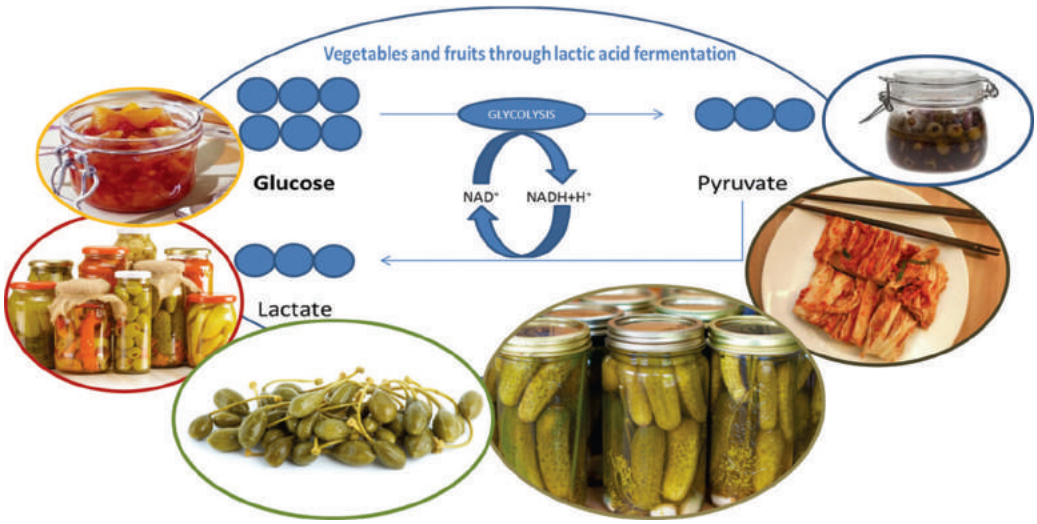

Figure 6 Fermented food through lactic acid fermentation.

aquatic and terrestrial environments. These microorganisms can ferment monosaccharides, disaccharides, polyalcohol, and, less frequently, polysaccharides, via the glycolytic pathway, producing lactic, formic, succinic and acetic acids, and ethanol (Figure 7). The final amounts of each end product vary depending on the microorganism and the growth conditions; however, the ratio of acid to neutral products is 4:1. Mixed-acid fermentation also results in the production of equimolar amounts of CO_2 and H_2 in those bacteria with the formate–hydrogen–lyase complex. Pyruvate formate–lyase and LDH, the enzymes that control entry into mixed-

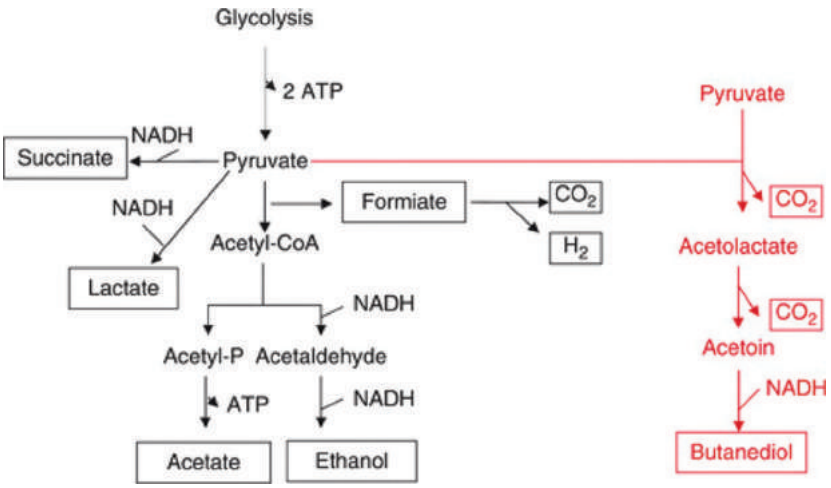

Figure 7 End products of mixed-acid and butanediol fermentation.

acid fermentation, are negatively regulated by oxygen; thus, mixed-acid fermentation requires anaerobic conditions to occur. That is why the natural habitat of microorganism carrying out mixed-acid fermentation is the gastro-enteric apparatus. The ATP yield of mixed-acid fermentation is about 2.5 mol of ATP per mole of glucose.

Butanediol Fermentation

Butanediol fermentation is carried out by members of the genera *Enterobacter*, *Erwinia*, *Hafnia*, *Klebsiella*, and *Serratia*. Most of these bacteria can be found in soil and water (*Enterobacter* and *Serratia*) and they can be plant pathogens (*Erwinia*). Butanediol fermentation produces less acids than mixed-acid fermentation as two molecules of pyruvate are used to produce one molecule of 2,3-butanediol and are therefore not available for the production of acid compounds. Thus, the ratio of acidic to neutral products is 1:6. Moreover, the reactions that lead to the production of 2,3-butanediol involve a double decarboxylation step; thus, butanediol fermentation produces more gas than mixed-acid fermentation, with a ratio of carbon dioxide to hydrogen of 5:1.

Butyric Acid Fermentation

Butyric acid fermentation is characteristic of several obligate anaerobic bacteria that mainly belong to the genus *Clostridium*; by means of glycolysis, these are able to oxidize sugar, and occasionally amylose and pectin, to pyruvate. Pyruvate is in turn oxidized to acetylCoA by the pyruvate–ferredoxin oxidoreductase enzyme system, with the production of CO_2 and H_2. Part of the acetylCoA is converted into acetic acid, with ATP production. The other part generates acetoacetylCoA, which is reduced to butyrylCoA through the production of β-oxybutyrylCoA and crotonylCoA. The transformation of butyrylCoA into butyrate leads to further ATP production. Thus, this fermentation process produces a relatively high yield of energy, with 3 mol of ATP for each mole of glucose. Small amounts of ethanol and isopropanol can also be produced (Figure 8). Butyric fermentation is quite common in silage when the pH is not low enough to ensure the exclusive activity of lactic acid bacteria. The carbon dioxide produced during butyric fermentation also causes an increase in the pH of the silage, thus enhancing further butyric fermentation. Some bacteria, such as *Clostridium acetobutylicum*, produce less acids and more neutral products, thus carrying out acetone butanol fermentation. This fermentation had great importance during World War I due to the need for acetone for the production of munitions.

The main fermentation processes are summarized in Table 3 in terms of energy yield.

Other Fermentation Pathways

The names of some other fermentation pathways derive from the names of the final products. This is the case for caproic, homoacetic, and methanogenic fermentation. For caproic fermentation, *Clostridium kluyveri* is the species that can metabolize acetic acid and ethanol under anaerobic conditions, producing butyric and caproic acids, in a specific controlled mechanism: if acetic acid is present in excess, a considerable amount of butyric acid is formed, while if ethanol is in excess, caproic acid is the main product. These relationships suggest that butyric acid is an intermediate in the synthesis of caproic acid from acetic acid.

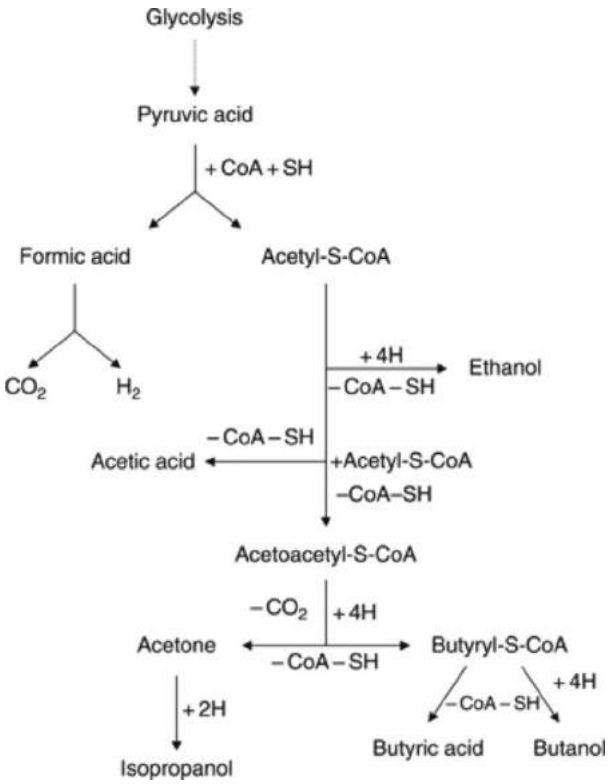

Figure 8 Different metabolic pathways of butyric acid fermentation.

Table 3 Summary of fermentation processes with the corresponding energy yield

Fermentation process	*Energy yield*
Alcoholic fermentation	2 mol ATP/mol glucose
Glycero-pyruvic fermentation	Net ATP production
Propionic acid fermentation (glucose[a])	4 mol ATP/mol glucose
Propionic acid fermentation (lactate[a])	0.3 mol ATP/mol lactate
Amino acid fermentation	0.3 mol ATP/mol amino acid
Lactic acid fermentation (homolactic)	2 mol ATP/mol glucose
Lactic acid fermentation (heterolactic)	1 mol ATP/mol glucose
Bifidobacterium lactic acid fermentation	2.5 mol ATP/mol glucose
Mixed acid fermentation	2.5 mol ATP/mol glucose
Butanediol fermentation	2.5 mol ATP/mol glucose
Butyric fermentation	3 mol ATP/mol glucose

[a]Carbon source.

In homoacetic fermentation, the *Acetobacterium* group converts fructose into acetate, and it appears that the nutritional requirements of this organism are complex. During methanogenesis, methane can be formed via methanogenic fermentation by *Methanosaeta* and *Methanosarcina*, which convert acetate and water into CH_4 and carbonic acid.

In addition, there are some relatively rare fermentation pathways that are carried out by very restricted anaerobic microorganisms. In Table 4, some examples of the fermented substrates, the microorganisms and the biochemistry of the reactions are summarized. Generally, these fermentation pathways are carried out by specialized bacteria that use substrates that cannot be metabolized by other microbiological groups. Nevertheless, during the catabolic process, all of these rare fermentation pathways produce intermediate compounds that have high residual energies and are commonly CoA derived, from which these microorganisms obtain their ATP.

Table 4 Microorganisms and type of substrates metabolized in rare fermentation processes

Substrate	*Microorganism*	*Reaction*
Acetate	*Methanosaeta*	$Acetate + H_2O \rightarrow CH_4 + HCO_3^-$
Ethanol and acetate	*Clostridium kluyveri*	$Ethanol + Acetate + CO_2 \rightarrow Caproate + Butyrate + H_2$
Fructose	*Acetobacterium* spp.	$Fructose \rightarrow Acetate + H_2CO_2 \rightarrow Acetate + H_2O$
Hydroxyhydroquinone	*Pelobacter massiliensis*, *Pelobacter acidigallici*	$C_6H_6O_3 + H_2O \rightarrow Acetate + H^+$
Malonate	*Malonomonas rubra*	$Malonate + H_2O \rightarrow Acetate + HCO_3^-$
Oxalate	*Oxalobacter formingenes*	$Oxalate + H_2O \rightarrow Formaite + HCO_3^-$
Putrescine	Gram + bacteria	$C_4H_{12}N_2 + H_2O \rightarrow Acetate + Butyrate + NH_4^+ + H_2 + H^+$

The first example includes anaerobic microorganisms that can degrade xenobiotic industrial chemical compounds through a combination of co-metabolic steps, which often yield partial degradation, or by serving as growth substrates that are accompanied by mineralization of at least part of the molecule. Indeed, while aerobic microorganisms use oxidative reactions, degradation by anaerobic bacteria takes place by reduction reactions, and they thus degrade aromatic compounds by reductive conversions with the central intermediates that are ready for hydrolytic ring cleavage having a 1,3-dioxo structure. Using an example, including aromatic, chloroaromatic, aliphatic, and chloroaliphatic compounds, one case of anaerobic degradation is presented. The recently isolated fermenting bacterium *Pelobacter massiliensis* is the only strict anaerobe that is known to grow on hydroxyhydroquinone (1,2,4-trihydroxybenzene) as the sole source of carbon and energy, converting it to stoichiometric amounts of acetate. Another example is seen in *Malonomonas rubra*, which is a microaerotolerant fermenting bacterium that can maintain its energy metabolism for growth by decarboxylation of malonate to acetate. *M. rubra* is closely related to the cluster of mesophilic sulfur-reducing bacteria within the delta subclass of *Proteobacteria*, with the fermenting bacterium *Pelobacter acidigallici* and the sulfur reducers *Desulfuromusa kysingii*, *D. bakii*, and *D. succinoxidans* as its closest relatives.

Ecological Niches and Interactions Among Fermenting Microorganisms

Fermentative processes are carried out by different microbial groups that can interact in well-defined habitats for the transformation of the substrate. The balance between the different microbial groups in each specific ecosystem depends on their initial concentrations and on environmental conditions (e.g., temperature, O_2 concentration, pH, and nutrients), and the predominance of one or the other determines the type of fermentation and the characteristics of the final product. Some fermented milks (Kefir, Koumis) and sourdoughs are ecological niches colonized by different fermenting microorganisms, such as lactic acid bacteria and yeasts, which carry out contemporary lactic acid and alcoholic fermentation. Lactic acid and propionic bacteria intervene sequentially during 'eyed' cheese production. Lactic acid bacteria ferment lactose and produce lactic acid during the first stages of cheese making. Lactic acid is then used by propionic bacteria during cheese ripening. Another example of an ecosystem is the intestinal tract of warmblooded animals, where enteric bacteria, lactic acid bacteria, bifidobacteria, and clostridia coexist, all of which are involved in the transformation of the substrate via different fermentation pathways. In this ecological niche, lactic acid and bifidobacteria are involved in the maintenance of the balanced composition of the intestinal microflora. Different fermenting microorganisms, such as lactic acid bacteria and clostridia, are involved in silage fermentation and maturation. Also in this case, lactic acid bacteria should predominate to counteract the development of clostridia and other spoilage microorganisms (**Figure 9**).

Fermented Milks: Kefir and Kumis as Matrix of Microbial Interactions

An example of microbial cooperation is represented by kefir, a typical fermented beverage of Eastern Europe. Kefir is the efficacious consequence of the metabolic activity of several lactic acid bacteria, mainly ascribed to the genus *Lactobacillus*, and of numerous yeast species belonging to the genera *Kluyveromyces*, *Candida*, *Saccharomyces*. This microbial consortium is enclosed in a matrix of proteins and polysaccharides called 'kefiran', which is produced during growth under aerobic conditions. The beverage flavor is due to a mixture of fermentation products such as lactic acid, ethanol, carbon dioxide and acetaldehyde.

Kumis, also spelled kumiss or koumiss is a fermented dairy product traditionally made from mare's milk. The drink is important for the peoples of the Central Asian steppes, of Huno-Bulgar, Turkish and Mongol origin: Bashkirs, Kalmyks, Kazakhs, Kyrgyz, Mongols, Uyghurs, and Yakuts. Kumis is a dairy product similar to kefir, but is produced from a liquid starter culture, characterized by *Lactobacillus leichmannii*, *L. delbrueckii* subsp. bulgaricus and yeasts belonging to *Torulaspora* genera, differently from the solid kefir "grains". Because mare's milk contains more sugars than cow's or goat's milk, when fermented, kumis has a higher alcohol content compared to kefir. Even in the areas of the world where kumis is popular today, mare's milk remains a very limited source. During the fermentation process, lactobacilli acidify the milk, and yeasts turn it into a carbonated and mildly alcoholic drink. In modern controlled production, the initial fermentation takes two- five hours at a temperature of about 27 °C; this may be followed by a cooler aging period. The finished product contains between 0.7 and 2.5% alcohol a very low level of alcohol, comparable to small beer, the common drink of medieval Europe that also avoided the consumption of potentially contaminated water (**Table 5**).

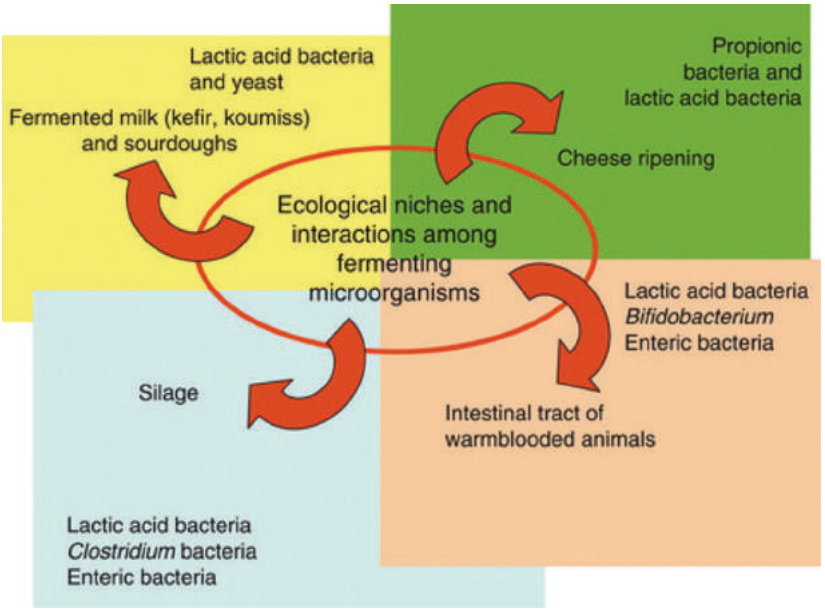

Figure 9 Examples of ecological niches where different fermenting microorganisms coexist.

Table 5 Some of the most popular products obtained by milk fermentation

Food and products	*Raw materials*	*Microorganisms*	*Production site*
Kefir	Cow milk	*Lactococcus lactis*, *L. delbrueckii* subsp. *bulgaricus*, *Kluyveromyces*, *Candida*, *Saccharomyces*	Southeast Asia
Kumis	Crude mare's milk	*Lactococcus leichmannii*, *L. delbrueckii* subsp. *bulgaricus*, *Torulaspora* spp	Russia
Taette	Cow milk	*Staphylococcus lactis* var. *taette*	Scandinavian
Tarhana	Wheat flour and yogurt	Lactic acid bacteria (spontaneous population)	Turkey
Biogurt	Powder milk	*Lactobacillus acidophilus*, *L. lactis*	Worldwide

Grazing☆

Antony J Underwood, University of Sydney, Sydney, NSW, Australia

Grazing in Terrestrial Environments: Why Is the World Green?

Grazing is a widespread and important process, so it has been debated how it comes about that the majority of terrestrial habitats remain dominated by plants. Why have the grazers not removed most of the biomass and cover of their food?

Generally, plants are limited in production by availability of light, which has seasonal patterns in temperate regions and extreme limitation for long periods of the year near the poles. Production of plants is also often reduced or prevented by lack of sufficient water or, in some circumstances, essential nutrients. Plants are not generally limited by their grazers.

To understand why, in general, terrestrial grazers do not keep their food-plants at small abundances therefore requires understanding of what reduces or controls the activities of the grazers. Much discussion of this, as a large-scale, world-wide phenomenon, considers three potential controls. One of these is competition among the grazers. This seems quite unlikely, given that the original phenomenon being explained is the preponderance of plant foods, not their small amounts which would lead to shortages of food. Competition will only occur among herbivorous species when more than one species of grazer requires the same plant foods and the food-resources are in short supply. Competition then occurs among the grazers as they try to gain sufficient resources to breed (adults), to grow (juveniles) or simply to maintain their tissues (all sizes).

Alternatively, abundances or effectiveness of herbivores may be controlled by inclement weather. There is evidence for this for many populations of insects, which do not reach their potential carrying capacity (the size of a population, given a certain availability of resources of food and shelter) because mortality due to bad weather keeps reducing the numbers. Such cases are, however, not considered to be typical. Many types of grazers can deal with bad weather by alterations of activity (e.g., hibernation or estivation) or of reproduction (e.g., by producing offspring during the periods of favorable weather).

The third general mechanism is for populations of grazers to be controlled by their predators (plus pathogens and parasites). This requires that large numbers of herbivores cannot be maintained, even where there is appropriate weather and an abundance of food, because their numbers are culled by their natural enemies.

This led long ago to the conclusion that primary producers-the plants-are largely regulated by availability of and resulting competition for limited resources. Presumably bad weather is also important because many species of plants will not grow outside a specific range of temperature, light-intensity and humidity. Similarly, predators are often limited by availability of their herbivorous prey-suffering from competition when populations of prey are at small abundances. Both are examples of "bottom-up" control. Populations of plants and predators are generally supposed to be regulated by their resources.

In contrast, terrestrial grazing species are thought to be primarily limited by their consumers, which is an example of "top-down" control.

The extent to which such a generality is correct can only be ascertained by examining a large number of experimental studies of the process controlling populations of herbivores, which is beyond the scope of this overview. Nevertheless, it is clear that, in general, plants on land are abundant despite numerous varieties of grazers.

It is evident that when grazers are released from their predators, they can completely destroy their food-plants. Two sorts of examples demonstrate this. Accidental introductions of alien herbivorous species into a new biogeographical region are often followed by outbreaks of the herbivores in extremely large densities, voraciously consuming the plants they use as food. Quite often, the cause of an outbreak is that the natural enemies (predators, pathogens, parasites) of the introduced pest are not introduced with it. The herbivorous species is therefore not held in check and its numbers become excessive.

The other scenario is where human intervention reduces the numbers of insects (or other predators). Spraying forests or farms to remove nuisance herbivores (e.g., larval insects) sometimes also kills other insects which are predatory. Populations of herbivores that are normally killed by these predators then expand and become a new nuisance because they consume trees or agricultural produce. In both cases, the grazers, by being released from their enemies, seriously reduce their food-plants.

There are many exceptions to a general principle that grazers do not control their food-plants. A well-known example is the destruction of plants caused by plague locusts, which break out in massive populations and greatly reduce the amounts of plants in areas where they feed.

The most notable exception is, however, the case of grazing by planktonic animals (see below). In the plankton, grazing generally reduces populations of plants to very small abundances. Given that about 70% of the earth's surface is ocean, the pattern of populations of plants being controlled by grazing is, in fact, more widespread than that described above for terrestrial habitats.

☆*Change History:* March 2018. A.J. Underwood made minor changes to the following sections: Grazing in Terrestrial Environments: Why is the World Green; Modeling Grazing Processes and Defenses Against Herbivores.

This is an update of A.J. Underwood, Grazing, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1765–1773.

The Paradox of the Plankton

In the open oceans, organisms that float about in the open water, either permanently or during their larval development, consist of micro-algae (the phytoplankton) and zooplankton. In many areas of the world, there is essentially a paradox in that there are very large numbers and standing amounts of biomass of zooplankton, but very little in the way of phytoplankton for them to eat. This comes about because, even though the standing stocks of plants are small, their production provides sufficient food for their numerous consumers. Calculations using the amounts of nutrients in the water and the estimated rate of uptake and productivity of the algae demonstrate that algal biomass can be very small, sometimes as small as 0.5% of the amounts expected. The rest is being consumed by grazing as fast as it is produced.

This has important consequences where there are marked seasonal differences in intensity or period of light. During Spring, light intensity and period of daylight increase in the higher latitudes of the northern hemisphere. Phytoplankton then increase in abundance. In most areas, it takes some weeks for the populations of zooplankton to respond, because their reproduction is slower. Therefore, there is an algal bloom, followed by a decline. The decline is due to two processes, the first of which is grazing by increasing numbers of zooplankton. The second process is availability of nutrients. As phytoplankton increase in abundance, they take nutrients out of the water. When grazed and digested by zooplankton, some of the nutrients are released back into the water, but in smaller amounts. Thus, production of phytoplankton is slowed because there are smaller amounts of nutrients.

This situation is made more complex where there are higher-level consumers, such as fish, that eat the zooplankton. It is then possible for the amount of grazing to be reduced and for the algae to become much more numerous and abundant in the waters. In these circumstances, the control of algal productivity is very much a combination of bottom-up (nutrients control productivity) and top-down (grazers are controlled by predators and therefore do not control the algae, but are themselves top-down controlled). Whichever outcome is going to happen in some area is therefore dependent on the seasonality of availability of light and nutrients, the abundances of zooplankton, the availability and intensity of activities of predators, etc.

Modeling Grazing Processes

There have been many different developments of mathematical models to simulate or analyze grazing and its effects. A compelling modeling framework should include what happens to the plants, what happens to the grazers and, where appropriate, the consequences of predators influencing the numbers or activities of grazers. One example from Caughley (1977) is briefly considered here.

The rate of growth of biomass of a population of vegetation, V, can be modeled as a logistic equation:

$$r_v = r_{mv}(1 - V/K)$$

where K is the carrying capacity, that is, the amount of vegetation in some area when it reaches the maximum that can be sustained by available resources. r_v is the rate of increase, V is the amount of vegetation present and r_{mv} is the intrinsic rate of increase, that is, how much the biomass would increase in the absence of any limit or constraint due to shortage of resources. As V gets closer to K (the biomass of plants increases towards its carrying capacity), there is a decrease in r_v, the rate of growth. At the carrying capacity (K), there is no further increase in the plant population.

Meanwhile, if herbivores are eating plants at rate c_1 (how much is eaten by a single herbivore when food is freely available, i.e., V is large), which is reduced when the amount of food is smaller. This consumption by herbivores is at a rate:

$$c_1\left(1 - e^{-d_1 V}\right)/V$$

where c_1 and V are as above and d_1 is a constant describing how consumption changes from 1 to 0 due to decreased amounts of food.

At any moment, the biomass of plants is therefore changing at a rate:

$$r_v = r_{mv}(1 - V/K) - c_1\left(1 - e^{d_1 V}\right)/V$$

The population of herbivores is, however, also changing at a rate:

$$r_H = -a_1 + c_2\left(1 - e^{-d_2 V}\right)/V$$

where a is the rate of decrease per capita when there is no food; c_2 is a constant describing how the decrease is less when food is available.

All other factors being held constant, the grazer-plant interaction will reach an equilibrium (i.e., at populations V' and H') when:

$$V' = \frac{1}{d_2} \qquad \log_e\left(\frac{c_1}{c_1 - d_1}\right)$$

$$H' = \frac{V' r_{mv}\left(1 - V'/K\right)}{c_1\left(1 - e^{-d_1 V'}\right)}$$

This modeling shows, among other things, that the equilibrium population of plants in a grazed habitat is not affected by the intrinsic rate of increase of the plants (r_m is not in the equation for V'). Instead, increases in r_m lead to greater populations of herbivores (c_2 and/or a_1) leading to changes in equilibrial values of populations of plants and herbivores (c_2 and a_1 are in the equation for V'; V' affects H').

Finally, changes of populations of predators feeding on herbivores are modeled by:

$$r_P = -a_2 + c_3\left(1 - e^{-d_3 H}\right)/H$$

where r_p is the rate of change of the population of predators. H is the size of the population of herbivores (the prey); a_2, c_3, d_3 are as explained above for herbivores, that is, a_1, c_2, d_2.

Predators are also reducing the rate of growth of herbivores which is now:

$$r_H = -a_1 + c_2\left(1 - e^{-d_2 V}\right)/V - fP\left(1 - e^{-d_4 H}\right)/H$$

where f is the rate of consumption per capita of herbivores by predators, when there are no shortages of food for predators, P is the size of the population of predators and d_3 is a constant describing how f is altered as the population of herbivores changes.

This type of modeling can produce a steady-state (an equilibrium) or oscillating populations of plants, herbivores and predators, depending on the values of various constants. It is therefore quite a general tool for analyzing various grazer/plant, predator/grazer interactions and to examine "bottom-up" (V matters most) versus "top-down" (P matters most) controls of the populations of herbivores.

This type of modeling makes many assumptions (e.g., that growth of populations fits a logistic trajectory). It also assumes that the ecology of the grazing system is simple and that there are no complex indirect interactions, multi-species influences of competition among species of grazers, etc.

Grazing and Indirect Interactions Among Species

Indirect interactions occur when the presence or activities of one species influence the interactions among other species. There are, in general, two major types of indirect interactions: (i) an interactive chain or (ii) a modifying interaction. Grazing can be involved in either of these. An interactive chain is the situation where one species of plant (A) is a superior competitor for space or light or nutrients compared with a second plant (B). Left to their own devices, A would outcompete B in any shared patch of habitat. If, however, grazers arrive which preferentially consume the superior competitor, there is a resulting indirect, positive effect on B, the inferior competing plant. Thus, grazers have a direct, negative effect on A, their food and an indirect, positive effect on B because of the reduction in competition.

A modifying interaction occurs when one species indirectly influences the direct interaction between two others. An example involving grazing is the situation where a grazer (A) consumes a plant (B). There are, however, other plants (C) which are well-defended from attacks by grazers, because they have spikes, thorns, etc., which discourage the grazers from foraging near them. Where plant species B and C grow together, C causes an indirect, modifying interaction by reducing the effectiveness of grazing on B and, thus, has a positive, indirect effect on B and, usually, a direct negative effect on the grazers (A), which have their foraging reduced.

An example of an interactive chain is grazing of seaweeds on the rocky shores of New England (USA) by littorinid snails. In some areas, the snails consume green algae, such as *Enteromorpha intestinalis*. On the open shore, these green algae can be eliminated by grazing, resulting in a reduction in the number of species present. In contrast, in shallow rock-pools, the green algae can grow over and reduce the cover of encrusting species of seaweed. The encrusting species are tough and difficult for the snails to eat, in contrast to the soft-bodied *E. intestinalis*. As a result, the effect of grazing on *E. intestinalis* is to increase the survival or abundance of the encrusting species.

This is a classically known result for non-selective grazing or lawn-mowing of terrestrial vegetation. This was noted a very long time ago by Darwin, who commented that mowing lawns causes the persistence of more species of plants than is the case where plants are allowed to grow undisturbed. In the absence of mowing, a few species of plants eventually dominate the space, light and resources in the soil. Competition eliminates the others. Lawn-mowers operate in an unselective manner, cutting back all the species of plants and thereby preventing competitive dominance and maintaining a greater diversity of plants.

Most grazers are more selective in their choice of food, but can have important effects on the diversity of plant species. A long-known example (and one of the early sustained experimental ecological analyses of the influences of grazing) concerns rabbits as grazers in British grasslands. Where rabbits have been experimentally excluded from plots of grasses, the experimental areas became dominated by a reduced number of species. Rabbits were generally consuming competitively dominant plants, such as clover.

This situation is, however, made more complex because grazers such as rabbits can exist in very large numbers. Intensive grazing then occurs and selectivity of species of food breaks down, so that less preferred species are also eaten in large quantities. Under these circumstances, large numbers of rabbits cause reduced diversity, as a direct effect of the increased intensity of grazing.

By the 1920s, it was known that the number of species of plants was strongly related to the intensity of grazing by rabbits. When there is no grazing, the direct influences of competition among plants cause there to be few species present. Under intermediate amounts of grazing, competitively dominant species are consumed selectively and inferior competing species persist.

Diversity is greater. At very great intensity of grazing, many species of plants are consumed, some to extinction, thus reducing the diversity of species.

Such influences on diversity of grazing (or predation or physical disturbances) are these days described by the model of "Intermediate Disturbance". Where grazing or disturbance is mild or non-existent, competition results in loss of species. Where grazing or disturbance is frequent or intense, it causes direct elimination of species. Diversity of species is greatest at intermediate levels of grazing or disturbance, where these act selectively to reduce the abundances of competitively dominating species, thus allowing inferior competitors to survive.

Switching and Facilitation by Grazers: Mechanisms Sustaining Biodiversity

Grazers do not only change the diversity of their food-plants by direct action or by indirect interactions as discussed above. By changing their own behavior, grazers can sometimes ensure that food-plants are not eliminated.

The processes used by herbivores to choose what to eat are complex. Some situations conform to "optimal" selection; the composition of the diet reflects how the grazer may be able to maximize the input of energy for the minimal expenditure of energy used to acquire the food. In some cases, the consumption of different species is altered by the risks imposed in feeding. Venturing into open spaces to gain access to some species of plant may make a herbivore vulnerable to attacks by predators.

There are also defensive systems adopted by plants, that is, modifications to morphology to make tissues tougher to eat or to provide protection in the form of thorns and spines. Chemical defenses consist of noxious or bad-tasting chemicals which herbivores learn to avoid.

It is common for herbivores to display choices or preferences among different potential components of diet. Modification of behavior by individual grazers can make very marked differences to the persistence of diversity of the plants they are eating. A well-known example is switching-changing between different species of food as their relative abundances change because of grazing.

Switching occurs when grazers preferentially consume the more abundant of the available food-species, but change to eat different species when these become more abundant. Thus, certain butterflies (e.g., *Battus philenor*) lay eggs on two different species of plants. The caterpillars then hatch and consume the plant on which they have been laid. The adults tent to seek out the more common of the two plants in disproportionately large relative abundances. Thus, if species A to B are in the ratio 60:40, A will be chosen for oviposition at >60% of all the plants on which eggs are laid. In areas or at times when B are more abundant, the butterflies change to lay eggs on an excessively larger proportion of B. Where a grazer actually consumes the more abundant species in disproportionally excessive amounts, it will reduce the relative abundance of that species. Under these circumstances, the grazers then alter the availability of different components of their diet and switch to whichever has now become more available.

Complex interactions among grazers can also have as an outcome the continued persistence of a suite of grazing species. A particularly well-known example is the set of grazing mammals in the Serengeti Plain in East Africa. There are numerous grazers (>20 major species) of which the three most studied are zebra (200 kg weight), wildebeest (160 kg) and Thompson's gazelle (25 kg). These mammals migrate over very large distances, in a cyclic pattern. All three grazers eat the same grasses, but consume different parts of the plants.

Zebra mostly eat stems and the sheaths of grasses, which are the predominant components of older plants. They obtain adequate nutrient by consuming very large amounts of plant material. Removing these coarser and relatively indigestible components of the grasses stimulates growth of new leaves and makes the food-supply more accessible to wildebeest, which eat grass-sheaths and leaves. The wildebeest, in turn, modify the grasses and also expose various understorey herbs, which are then eaten by gazelles. The gazelles' diet is leaves and herbs, the latter containing the most nutrition.

Experimental enclosures demonstrated that wildebeest can reduce the biomass of plants to about 15% of that in ungrazed areas. This does, however, cause an increase in the production of new growth of leaves and, after the wildebeest move to new areas, there is a great amount of food available to gazelles.

Zebra move into areas where there has been no grazing since the previous year. Their feeding reduces the availability of their food, so they move on to new areas. Grazing by zebras facilitates feeding by wildebeest because the zebra have made the plants more suitable for them. The wildebeest, in turn, consume parts of the plants and then, as their food decreases in abundance, move on to the areas recently fed on by zebra. The wildebeest facilitate feeding by gazelles, by making the latter's food accessible. The gazelle then follow the wildebeest. The entire cycle starts again when zebra return to the first areas, where gazelles ceased feeding months before and where grasses have grown up and are now older and with more stems and fewer leaves.

This cyclic pattern of facilitated grazing maintains the suite of grazers which use different parts of the grasses, in turn, maintaining the biodiversity of large grazing mammals.

Defenses Against Herbivores

Plants show numerous responses to being grazed. Morphological and chemical defenses are the two most commonly studied. Some plants produce thickened bark or tough leaves, making them difficult to chew and thus reducing damage done by grazers. Plants can also produce thorns or spikes, preventing some grazers from being able to climb on them to eat their soft tissues.

Many plants respond to grazing by producing bad-tasting or toxic chemicals. These can dissuade actively foraging herbivores from continuing to feed or can cause them to learn to avoid that plant.

The chemicals used in defense seem to be of two general types. First, there are compounds that are produced in the plant's normal metabolism that have noxious or toxic properties when contacted or ingested by animals. The plants respond to herbivory by accumulating these otherwise waste products, so that they are present in their tissues in sufficient quantities to deter grazers.

Second, the chemicals may be produced specifically in response to attacks by grazers, but would otherwise not be part of normal metabolism. Most of such chemicals would be produced at an energetic cost to the plants.

These compounds are called secondary metabolites. They are found in some species or populations of plants, but not others and are not an absolute necessity for metabolism of all plants. The diversity of types of compounds is enormous and the ecology of chemical defense by plants is a vast topic in its own right, so will only briefly be illustrated here.

A well-known example of mechanical defense is that of oak-trees in Europe. This species is attacked by larvae of >200 species of butterflies and moths, but most attack is in spring when the leaves of the trees are young. The leaves change color and toughness during spring. Experimental rearing of larvae showed greater growth on a diet of young leaves (those first produced in the northern spring) than of those fed on older leaves (those collected in the third and subsequent week of the appearance of leaves). Older leaves suffered from reduced grazing, primarily because they are tougher.

A particularly well-studied example of chemical defense is the production of indole glucosinolate compounds by cabbages when they are attacked by herbivores. When grazed, the plants start to produce more of the defensive chemicals and grazing is subsequently reduced or prevented.

Induction of defensive chemicals rather than the plants always containing them is believed to be a response by the plants to the behavior of specialist species of grazers. Thus, experimental evidence demonstrates that production of glucosinolates causes increased attack by larvae of cabbage-white butterflies and some other species. Producing the chemicals only in response to grazing reduces this risk.

There are other influences on production of chemical defenses. For example, insects are quite often found destructively grazing trees which are normally attacked only in minor ways. One explanation for this is that the production of secondary metabolites costs the plant energy. When plants are stressed by environmental factors such as drought or reduced amounts of nutrients, production of energetically expensive chemical compounds is reduced. Attacks by insects are then much more severe. The interaction of excessive grazing on top of other environmental stresses is then a serious problem for the survival of the plants.

Another aspect of chemical defenses is tri- or multi-trophic defense. This occurs when plants subjected to grazing release chemicals to which other organisms respond. Some of the responding animals are predators, which arrive and start to eat the grazers.

An example of indirect defense is plants that are attacked by spider mites (*Tetranychus urticae*). When the mites begin to eat a plant, it releases volatile compounds from the damaged tissues. These are attractive to predatory mites (*Phytoseiulus persimilis*) which arrive at the damaged plant and proceed to eat the plant-eating mites. Adjacent, unattacked plants can also start to emit the signaling chemicals. The chemicals used for such tritrophic (plant–herbivore–carnivore) interactions are of two different types. Some are specific-they are only produced and released from the plant when it is attacked. Others are the same chemicals normally found in undamaged or mechanically damaged plant-tissue. These compounds are, however, released in much greater quantities when the plants are attacked by herbivores.

A final aspect of defense against grazers concerns the biology of plants that cause predators of their grazers to live permanently with them, thus deterring or reducing the activities of grazers.

Some features of plants that encourage predators to live with them are the construction of sheltering galls or special sized "domatia" which are inhabited by predators or fungal-feeding arthropods. These structures are modified veins of leaves or specialized pits or crevices in the cuticle. They provide shelter from wind and weather and can also prevent attacks by enemies of the predators. The presence of permanent populations of their predators clearly reduces the number and effectiveness of grazers.

Other plants maintain populations of defensive predators because they provide food for them. Acacia ants (*Pseudomyrmex* spp.) in tropical regions of America live in hollow thorns on some species of *Acacia*. The ants feed on sugars, proteins and oils produced by the plants. When ants are experimentally removed from plants, the acacias grow much more slowly and more of them die as a result of grazing. While foraging on the plants, the ants also attack any grazing species that they encounter. They also remove seeds and any other new vegetation that appears on the ground around the base of their host-tree. This potentially reduces competition from surrounding plants, resulting in yet more protection for the host acacias.

Grazing Promoting the Growth of Plants: Examples of Gardening

Some grazing animals are territorial, in that they occupy, patrol and defend a patch of habitat in which they live, feed and, often, breed. In some cases, the direct or indirect consequence of this behavior encourages the growth of particular plants, so that the grazing species is farming or gardening its supply of food.

Examples are widespread, but one example of each of a vertebrate and an invertebrate grazer will illustrate some general features. First, pomacentrid or damsel fishes on coral reefs live in areas that are over-grazed by a large diversity of other fish and many invertebrates. Several species in the family Pomacentridae occupy territories in which they threaten and attack intruding fish. In these territories, there can be extensive growth of algae which are absent from adjacent, undefended areas. The territorial

resident grazes on these algae-a supply of resources created by its activities. Some species of fish select what they allow to grow within their territories. They weed out unwanted species of seaweeds by biting them off the substratum and carrying them out of the territory. As a result, territorial fish can have profound influences on local diversity of algal species.

Despite vigilance and rapid responses to intruders, the occupant of a territory can, however, be overwhelmed by the sheer weight of numbers of intruders if large numbers arrive at the same time. This is almost certainly a strong influence on how large a territory an individual can defend. If a school of grazing fish arrive in a territory, no amount of threat, harassment or attack by the occupant will prevent removal of some of the algal food.

The second example concerns grazing by limpets on rocky shores. Most limpets wander around grazing over the surface of the rock using a special feeding organ or toothed "tongue", called a radula. This scrapes over and into the surface of the rock, removing grains of rock and any attached bacteria or microscopic plants, which are then swept into the animal's mouth. In many parts of the world, grazing by these and other gastropods (snails) removes such a large proportion of the algae that the animals generally suffer from a shortage of food and often show evidence of considerable amounts of competition for the food that is present.

In some areas of the world, such competition has resulted in aggressive behavior to defend a territory. On Californian intertidal shores, the owl-limpet (*Lottia gigantea*) reaches a few cm length as its maximal adult size. It patrols an area of rock about 1000 cm^2 extent. When it encounters an intruding limpet or grazing snail, the resident limpet attacks by ramming the front of its shell against the intruder. Sometimes this dislodges the intruder which is then rolled away by waves. Sometimes, the attack, or even the threat of attack as the resident approaches, causes the intruder to leave the territory.

The outcome is a very reduced number of grazers inside the territories. When a resident limpet is experimentally removed, the numbers of other, smaller grazers increases. Often, a resident that has been removed is replaced by a smaller individual of *L. gigantea* from a nearby area. If an owl-limpet is introduced to an area, it will eventually drive away many of the resident grazers.

The result of this activity is the growth inside the territory of a film of visible macro-algae, which are a major source of food for the limpets. When a territorial limpet is removed, smaller grazers enter the territory and remove all the algal film because they scrape much closer to the surface of the rock.

Grazers and Indirect Effects

Some grazing activity can have profound effects on ecological processes, diversity and variety of co-existing species and general structure of assemblages, involving many other species, not just the plants consumed for food. Such interactive consequences of grazing have led to defining some grazers to be ecosystem engineers – species that modify habitats so that they become more or less suitable for occupation by other species. Engineering species must make or modify patches of habitat to create the environmental conditions not found outside the modified patches.

A particularly large-scale engineering species is the beaver, *Castor canadensis*, which grazes on plants on the riparian zones of rivers. Grazing by beavers has profound effects on the composition of species of plants in these areas because of major reductions in the abundances of preferred food-plants.

Importantly, however, beavers also dam a stream creating a pond. In some areas, the dam and pond are maintained for <10 years, during which period the surrounding vegetation is substantially modified by the grazers. The dams trap sediments which store nutrients. The banks of the areas in which beavers forage are generally devoid of woody vegetation, allowing more light than would occur where there were no beavers.

When the beavers abandon a pond to seek new supplies of food elsewhere, the dams eventually break down and large meadows of grasses or swamps dominated by alder (*Alnus incana*) develop. These engineered habitats can persist for at least 50 years before the habitat eventually reverts to the unmodified woodland.

Beavers, as grazers, have clear direct effects on the assemblages of plants where they are actively foraging. Because of their engineering (dam-building), they also create ponds with nutrient-rich sediments and plenty of light. These habitats can continue to exist for decades after the beavers cease their activity.

There are also examples of indirect effects of invertebrate grazers that can cause profound shifts in the species occupying local assemblages. On many rocky shores, intertidal assemblages contain numerous grazers (mostly snails and limpets, but also crabs, chitons, starfish, polychaetes and some fish). Where grazing is sufficiently intense, the grazers remove much, if not all, of the microscopic algal food from the rocks. This food consists of truly microscopic species, such as diatoms. It also contains the spores, gametes and early sporelings of many macroscopic species which would, if not consumed whilst still at unicellular or microscopic sizes, grow up to form erect, upright seaweeds.

Sometimes grazers are absent, as a result of storms or other disturbances, diseases or excessive predation by their own enemies, or simply because of failure to recruit for long enough for the existing adults in a population to die without being replaced. As a result, spores and early reproductive stages of the algae survive in very large numbers compared with the usual grazed condition. The consequence is that these algae then grow up to occupy the space on the shore.

The growth of algae has serious and sometimes long-term consequences for the other species in such an area. Most of the species in the diverse assemblage on intertidal rocky shores require open, relatively bare space to live on or to feed over. For example, barnacles and tubeworms recruit from developing stages in the plankton. These are washed along a coastline by waves, winds and currents, developing to a stage capable of settlement and metamorphosis in a suitable adult habitat. For this to be possible, they need uncluttered space, either bare rock or a surface covered by a biofilm of unicellular and extracellular organic

material. Where the surface is already covered by algae, it is impossible for the sessile species to become established. Even if larvae can settle and metamorphose, they are usually smothered by the algae growing over them, preventing them from growing or feeding.

The grazers themselves are often eliminated by the algae once these grow large enough. Many of the invertebrate grazers are quite unable to consume seaweeds once they are too large. There are some invertebrates, such as sea-urchins, which have no problems, but they are not usually common components of intertidal shores.

Thus, grazing by micro-algal feeders frees space that is then occupied by a range of other sessile space-users and a suite of grazing species. This maintains the diversity of species from many Phyla in the assemblage. Algae grow more quickly in areas lower on the shore, where habitats are subject to greater splash and spray during low tide and longer periods of submersion under water during high tide. As a result, in such areas, grazers are less effective and unable to keep surfaces free from foliose algae. Consequently, there are fewer animals and types of animals in such areas.

In addition to their direct consumption of plants, grazers, through their indirect effects on habitat, contribute a lot to the maintenance of biodiversity in assemblages of other species that are neither the food-plants nor their consumers.

Glossary

Biogeochemical cycles Natural pathways by which the chemical elements that are present in the organic matter are circulated through biological, geological, and chemical cycles in the biotic and abiotic Earth's compartments.
Global warming A rise in the Earth's standard atmospheric temperature that causes related changes in climate and that may result from the greenhouse gases effect.

Introduction

The rising temperature of earth, known as global warming (GW), is mainly the result of the rise of greenhouse gases (GHGs) concentration in the atmosphere since the beginning of the 20th century, mostly due to anthropogenic activities. Global warming, as we know, is one of the major threats to the environment because of the resulting climate change. Oxygen (O_2) and nitrogen (N_2) are the principal atmosphere gases at concentrations of 21% and 78%, respectively, nevertheless it is thought that they do not absorb or emit thermal radiation. Water vapor and less abundant gases, such as carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O), because of their long atmospheric lives and their relatively high thermal absorption capacities, are generally known as greenhouse gases. Besides water vapor that is not considered to be a cause of man-made global warming because it does not persist in the atmosphere for more than few days, the most important greenhouse gas is CO_2, followed by CH_4 and N_2O which are the other most relevant contributors to GW. Hundred year global warming potential of methane, nitrous oxide and other GHGs is compared to CO_2 in terms of CO_2 equivalence (CO_2eq). This last is a simple way to normalize all greenhouse gases in a standard unit based on the radiative forcing of a unit of CO_2 over 100 years. For example 1 g of methane has a global warming potential 28 times higher than 1 g of CO_2 and so it is expressed as 28 g of CO_2eq. Biological and/or non-biological, as natural and anthropogenic processes are involved in GHG cycling (most carbon (C) and nitrogen (N) cycles).

Soils can be a source or a sink of CO_2, CH_4, and N_2O depending on the specific conditions. Natural soils are mainly a sink for natural GHGs and sequester as much C and N they emit, but due to human activities, mainly agriculture, soils can be mainly a source for GHGs. Infact, intensive agriculture, sustained by mineral fertilizer use, has contributed significantly to the elevation of atmospheric GHGs, including CO_2, CH_4, and N_2O. Rising GHG emissions usually lead to a decrease in soil C. Currently, soil organic C is twice that of all standing crop biomass, making it an extremely important player in the C cycle.

Anyhow, agronomic practices have the potential to reduce agricultural GHG emissions. Main management practices that impact GHG emissions and soil C content include various tillage practices, several N fertilization amounts and typologies (mineral, manure, or a combination of both), the use of cover crops, aeration, and water levels. Moreover, other agriculture GHGs sources are intensive livestock such as cattle intensive production systems and rice paddy fields. Furthemore deforestation, expecially in tropical rainforest, adds more C to the atmosphere than cars and trucks trafic; the reason is that when trees are cut down or dead, they release their carbon content in the environment. Employing best agricultural management practices (BMPs), we can promote the sequestration of CO_2 plus N_2O and the preservation of soil C. Measuring soil C storage and GHG emissions and using them as metrics to evaluate BMPs are vital in understanding agriculture's role in this topic.

Carbon Greenhouse Gases

Carbon Dioxide (CO_2)

CO_2 is a colorless gas with a density about 50% higher than that of dry air. In the CO_2 molecule (molecular weight of 44 g mol^{-1}) carbon atom is covalently double bonded with two oxygen atoms, and it is naturally present in the earth's atmosphere. Because the oxygen of CO_2 molecule forms intermolecular hydrogen bounding with the hydrogen of water, CO_2 is soluble in water, and it occurs in groundwater, rivers and lakes, ice caps, glaciers, and seawater (CO_2 solubility in water is about 1.45 g L^{-1} at 15°C) and in deposits of petroleum and natural gas too. CO_2 is odorless at usual concentrations, however its aqueous solution has, at high concentrations, a sharp and acidic odor and taste.

Among the greenhouse gases, CO_2, as presented in the introduction paraghaph is the reference gas with a global warming potential of 1, lower than all other greenhouse gases. However it contributes >60% to GW due to its huge emission amount. The concentration of CO_2 in the atmosphere has increased from approximately 277 parts per million (ppm) in 1750, at the beginning of the Industrial Era, to 402.8 ± 0.1 ppm in 2016. The increase of atmospheric CO_2 above the preindustrial levels was primarily caused by the release from deforestation and other land-use change activities. While emissions from the burning of fossil fuels started before the Industrial Era, they only became the dominant source of anthropogenic emissions to the atmosphere from around 1920 and their relative share has continued to increase until present.

Sources of atmospheric CO_2 include volcanoes activities, the combustion and decay of organic matter, respiration of aerobic (oxygen-using) organisms; extraction and burning of fossil fuels, clearing of lands, and production of cement and steel an so on by human activities.

These sources are at least partially balanced by a set of physical, chemical, or biological processes, called "sinks," that tend to remove CO_2 from the atmosphere. The main C sink are plants that through the photosynthesis process grab CO_2 from atmosphere.

Plant life is a foundamental natural sink. In the oceans, marine life can absorb dissolved CO_2, and some marine organisms even use CO_2 to build skeletons and other structures made of calcium carbonate ($CaCO_3$).

Organic matter respiration, operated by heterotrophic organisms, is the most important path through which the CO_2, photosynthetically fixed as glucose, comes back to the atmosphere:

$$\text{Glucose} + 6\ \text{Oxygen} \rightarrow 6\ \text{Carbon dioxide} + 6\ \text{Water}$$
$$6(CH_2O) + 6O_2 \rightarrow 6CO_2 + 6H_2O$$

This organic matter degradation occurs in both soils (primarily in the rooting zone) and oceans (within the surface mixed layer). Organic matter respiration and CO_2 release in the atmosphere are controlled in part by the composition of the organic matter and the environmental factors (e.g., temperature, soil moisture, and soil porosity, texture/mineralogy).

In total, more than twice as much C is stockpiled in the world's soil than in the vegetation or atmosphere combined. Considering all the C stored in soil, soil organic carbon (SOC) makes up about 50% of all soil organic matter (SOM).

About a third of the soil organic C occurs in forests, another third is in grasslands and savannas, and the rest is in wetlands, croplands, and other biomes. SOM is composed by soil microorganisms communities (mainly bacteria and fungi), plant and animal tissues, fecal material, and products derived from their decomposition. Soil CO_2 flux is primarily the result of a combination of microbial decomposition of SOM and plant root respiration. The main drivers of soil CO_2 flux are soil temperature, soil moisture, and substrate C availability. Temperature affects CO_2 flux by speeding up the rate of microbial decomposition when soils are warm and water is not a limiting factor. Although rising temperatures cause an increase in CO_2 flux rate from soils, in some parts of the world there are no clear trends of decreasing soil carbon with increasing mean annual temperature. This is due, partly, to competing processes within the system, such as SOC rising due to increased primary productivity that principally occurs through the photosintesis process (better water and nutrient availability), and SOC decreasing by increased respiration processes. While in the short-term, warming depletes SOC, in the long-term, C losses by accelerated microbial respiration may be equalized by increases in C inputs to the soil tied to increased net primary production, as well as any acceleration of soil physico-chemical "stabilization" reactions. Additionally, changes in microbial community composition or declines in the temperature sensitivity decomposition processes may reduce the response of microbial respiration to increasing temperature over time (i.e., thermal acclimation cold soil and air temperatures have the opposite effect on CO_2 flux rate, causing it to slow down). Even though slowed, soil microorganisms maintain both catabolic (CO_2 production) and anabolic processes (biomass synthesis) under frozen conditions. Because of this, gaseous exchange between the atmosphere and soil does not stop even under frozen soil, resulting in the accumulation of CO_2 during winter and its release into the atmosphere during spring thaw events. Another dominant factor controlling the net exchange of GHGs is soil moisture, which can vary dramatically over time and space. The production and transport of GHGs in soil is strongly affected by changes in soil moisture through diel 24-h period cycles, wet-up and dry-down events, management practices, seasonal patterns, and interannual variation in climate. Overall, when water is limiting, plant and microbial availability increase with soil moisture, thereby increasing soil CO_2 flux directly by alleviating plant and microbial desiccation stress and indirectly by increasing substrate availability (via higher rates of plant growth, photosynthesis, belowground C allocation by root exudate) and microbial access to substrate for example, increase C diffusion through soil water. Finally, respiration generally increases with C availability. Plant respiration is largely dependent on C from current photosynthetic activity and, under non-limiting soil temperatures and moisture availabilities, microbial respiration increases with labile C availability. Thus, soils with high organic matter inputs and stocks, like those found near the equator, means greater C substrate availability, which is synonymous with greater flux. Depth and

placement of soil carbon is yet another factor to consider when attempting to make precise conclusions about CO_2 flux. For example, in agroecosystems, the bulk of SOM is within the top 10 cm of the soil surface.

Because of this, temporal dynamics of CO_2 flux are more intimately related to air temperature than to soil temperature. Also, it is known that the respiration rates of many soils are strongly linked with the amount of carbon not intimately associated with minerals. Mineral soil occurs below the litter and organic layer, where soil carbon may be closely associated with mineral particles—accounting for over 60% of carbon in most forest soils, proposing that the decomposition/respiration rate of mineral soil carbon is relatively insensitive to temperature. This is because the carbon located here may be protected from microbial mineralization by stabilization mechanisms, such as occlusion in soil aggregates (physical protection) or interactions with mineral surfaces (chemical sorption to mineral surfaces).

Methane (CH_4)

CH_4 is the second most important greenhouse gas in volume after CO_2, contributing to global warming potential with 28 times more infrared radiative heating effect than CO_2 on a mole-per-mole basis at a 100 year time horizon. Its atmospheric concentration, due to human activity, has increased by a factor of 2.5 since preindustrial times, that is, from 722 ppb in 1750 to 1803 ppb in 2011. Furthermore, after almost one decade of stable CH_4 concentrations since the late 1990s, atmospheric measurements have shown a renewed concentration increase since 2006, probably tied to a rise in natural wetland and fossil fuel emissions.

Generally, CH_4 emissions in atmosphere can be due to both human activities or natural processes from biogenic, thermogenic or pyrogenic sources. Anthropogenic emissions account for 50%–65% of total emissions including coal mining, natural gas use, agriculture, wastewater and waste treatment.

Considering CH_4 budget for the decade of 2000–09 (bottom-up estimates) agriculture and waste sectors (rice, animals and waste) are the second contributors to biogenic CH_4 emissions (with values ranging from 187 to 224 Tg (CH_4) year^{-1}) after natural wetlands emissions that ranged from 177 to 284 Tg (CH_4) year^{-1}.

Soils play an important role in the CH_4 cycle because both methanogenesis (CH_4 production) and methanotrophy (CH_4 oxidation) take place in them. In view of this soils CH_4 fluxes are the net result of the CH_4 production by methanogenesis and CH_4 oxidation by methanotrophy processes.

Methane production

Methanogenesis is operated by strictly anaerobic bacteria which requires negative oxydo-reduction potentials ($Eh < -200$ mV). Methanogens belong to the domain Archaea which have a limited trophic spectrum comprised of a small number of simple substrates: $H_2 + CO_2$, acetate, formate, methylated compounds (methanol, methylamines, dimethylsulphur), and primary and secondary alcohols. This allows to distinguish five trophic groups of methanogens: hydrogenotrophs, formatotrophs, acetotrophs, methylotrophs, and alcoholotrophs. The two major pathways of CH_4 production in most environments where organic matter decomposition is significant are acetotrophy and CO_2 reduction by H_2.

The possible pathway for CH_4 emission from soil are: (i) diffusion of dissolved CH_4 along the concentration gradient, (ii) release of CH_4-containing gas bubbles (ebullition), and iii) transport via the aerenchyma of vascular plants (plant-mediated transport).

The first process, diffusion, takes place because of the formation of a CH_4 concentration gradient from deeper soil layers, where the production of CH_4 is large, to the atmosphere, while oxidation of CH_4 occurs in upper layers. Diffusion is a slow process compared to the other two transport mechanisms, that is, ebullition and plant-mediated transport, but it is biogeochemically important because it extends the contact between CH_4 and methanotrophic bacteria in the upper aerobic layer, promoting CH_4 oxidation.

The second process, ebullition, takes place when CH_4 production is large. Gas bubbles are formed and emigrate to the surface. As this process is fast, CH_4 oxidation is absent or negligible.

The third process, plant mediated transport, takes place through an internal system of continuous air spaces named aerenchyma, a structure which is developed by vascular plants to adapt to flooded environments. The basic function of this structure is to transport the O_2 necessary for root respiration and cell division in submerged organs, but it is also used for CH_4 transportation from the rhizosphere to the atmosphere, bypassing the aerobic, CH_4-oxidizing layers. This process involves two major mechanisms: molecular diffusion and bulk flow. The gradient of CH_4 concentration formed inside the aerenchyma conduits is the driving force for CH_4 diffusion from the peat root zone to the aerial parts of the plant. The other plant-mediated transport mechanism, bulk transportation, involves the migration of CH_4 along the plant, also through the aerenchyma structure, from the leaves to the rhizome and back to the atmosphere through old leaves or horizontal rhizomes connected to other shoots. The driving force for this process is a pressure gradient generated by differences in temperature or water vapor pressure between the internal air spaces in plants and the surrounding atmosphere. This is a very efficient and rapid mechanism of CH_4 transportation and, in consequence, it is responsible for most of CH_4 emissions (>95%) to the atmosphere from rice paddies.

The factors controlling CH_4 production in soil are anaerobic conditions and redox potential, electron acceptors, substrate availability, temperature, diffusion, water availability and water table, soil pH and salinity, fertilizer and manure additions and amendments, trace metals, competitive inhibition, vegetation, plant species and cultivars, and elevated CO_2 concentrations.

Methane oxidation

The major fraction of CH_4 emitted in the atmosphere is submitted to oxidation. Oxidation by OH radicals represent the main sink of atmospheric CH_4 (around 90% of the global CH_4 sink) and it takes place mostly in the troposphere according to the reaction:

$$CH_4 + OH\bullet \rightarrow CH_3\bullet + H_2O$$

The remaining sink is thought to be split roughly equally between the stratosphere (removal by OH and O1[D]) and biological consumption in near-surface soils. Uptake of methane occurs via oxidation by specialized aerobic bacteria, methanotrophs, although CH_4 oxidation can be also monitored in anaerobic conditions.

The aerobic methane oxidation, operated by methanotrophs, can be summarized as follow:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

Aerobic methanotrophic bacteria can be classified in three groups (type I, II, and X) considering morphological features, membrane structures, guanine and cytosine content, phospholipid fatty acids composition and various other physiological characteristics.

Several mechanisms have been offered to explain anaerobic CH_4 oxidation. First, sulfate-driven anaerobic methane oxidation:

$$CH_4 + SO_4^{2-} \rightarrow HS^- + HCO_3^- + H_2O$$

Other electron acceptors such as oxides of iron, manganese and chrome, could also oxidize methane anaerobically as below reported:

$$CH_4 + 8Fe(OH)_3 + 16H^+ \rightarrow CO_2 + 8Fe^{2+} + 22H_2O$$
$$CH_4 + 4MnO_2 + 8H^+ \rightarrow CO_2 + 4Mn^{2+} + 6H_2O$$
$$CH_4 + 4/3Cr_2O_7^{2-} + 32/3H^+ \rightarrow 8/3Cr^{3+} + CO_2 + 22/3H_2O$$

Another proposed CH_4 oxidation process is the anaerobic oxidation of methane coupled to denitrification with CO_2 release as below summarized:

$$5CH_4 + 8NO_3^- + 8H^+ \rightarrow 5CO_2 + 4N_2 + 14H_2O$$
$$3CH_4 + 8NO_2^- + 8H^+ \rightarrow 3CO_2 + 4\ N_2 + 10H_2O$$

Biological anaerobic CH_4 oxidation is done by a consortium of anaerobic archaea in association with anaerobic bacteria.

Optimal conditions for most of methanotrophs have been found in environments with near neutral pH, temperature in the mesophilic range (ca. 25°C) and low salinity.

Nitrogen Greenhouse Gases

Nitrous Oxide (N_2O)

The N_2O is one of the most important greenhouse gases with a global warming potential, an index of the total energy added to the climate system by a component in question relative to that added by CO_2, for a time horizon of 100 years of 298 $CO_{2(eq)}$. N_2O is also capable of ozone depletion with negative impact on world life due to the lower capability to shield negative fraction of solar radiation (UV). The concentration of N_2O in the atmosphere increased at a rate of 0.73 ± 0.03 ppb year^{-1} over the last three decades, mostly caused by nitrification and denitrification reactions of reactive nitrogen in soils and in the ocean.

The major source of N_2O in the atmosphere is heterotrophic denitrificatrion, that is, reduction of nitrate to nitrogen gas under anoxic conditions:

$$6(CH_2O) + 4NO_3^- \Rightarrow 6CO_2 + 2\ N_2 + 6H_2O$$
$$4(CH_2O) + 4NO_3^- \Rightarrow 4HCO_3^- + 2\mathbf{N_2O} + 2H_2O$$

It is generally agreed that during heterotrophic denitrification, nitrate is reduced to nitrite, which is followed by a stepwise reduction to nitric oxide, nitrous oxide, and finally nitrogen gas as below schematized:

$$2NO_3^- \Rightarrow 2NO_2^- \Rightarrow 2NO \Rightarrow \mathbf{N_2O} \Rightarrow N_2$$

This reaction is irreversible and occurs in the presence of available organic substrate mainly under anoxic or anaerobic conditions, where NO_3^-'nitrogen is used as an electron acceptor in place of oxygen. Nitrate is the first inorganic compound which used by bacteria as electron acceptor after dissolved oxygen depletion from the water-soil system. Denitrification starts at redox potential values of about +220 mV. Environmental factors known to influence denitrification rates include the absence of O_2, redox potential, soil moisture, temperature, pH value, presence of denitrifiers, soil type, organic matter, nitrate concentration and the presence of overlying water.

Facultative heterotrophic anaerobic bacteria are the main actors of heterotrophic denitrification. Most denitrifying bacteria are chemoheterotrophs. They obtain energy solely through chemical reactions and use organic compounds both as electron donors and

as a source of cellular carbon. Denytrifying bacteria are aerobes that substitute nitrate for oxygen as the terminal electron acceptor when there is little or no O_2 available. The genera *Bacillus*, *Micrococcus*, and Pseudomonas are probably the most important in soils; *Pseudomonas*, *Aeromonas*, and *Vibrio* in the aquatic environment.

The quantity of N_2O evolved during denitrification depends upon the amount of nitrogen denitrified and the ratio of N_2 to N_2O produced. The ratio is also affected by aeration, pH, temperature and nitrate to ammonia ratio in the denitrifying system. If the pH is below 4.5, the denitrification rate is relatively slow and only N_2O is produced. At $pH > 5$, N_2 is the main end product of denitrification. It has also been shown that certain amount of N_2O is formed during nitrification, however, it is difficult to distinguish between nitrification and denitrification as sources of N_2O.

Ozone (O_3)

O_3 is a short-lived trace gas that either originates in the stratosphere or is produced in situ by precursor gases (monoxide (CO), CH_4, and non-CH_4 hydrocarbons in the presence of nitrogen oxides (NO_x)) and sunlight. It is a bluish gas with a pungent smell, dipolar and electrophilic molecule capable of very selective reactions, present in the air at concentrations of 0.01–0.05 ppm. In the atmosphere the presence of the O_3 is crucial for any life because it prevents shortwave solar UV radiation in the UVB (λ 280–315 nm) and UVC (λ 200–280 nm) from penetrating the atmosphere and reaching the Earth's surface. On the other hand O_3 exert a greenhouse effect increasing the global warming. As reported by the Intergovernmental Panel on Climate Change in the fifth assessment report: emissions of carbon monoxide and volatile organic compounds, a not well-defined group of hydrocarbons, lead to production of ozone on short time scales. By affecting OH and thereby the levels of CH_4 they also initiate a positive long-term ozone effect. The effects via ozone and CH_4 cause warming, and the additional effects via interactions with aerosols and via the O_3–CO_2 link further increase the warming effect.

Gross and Net Production in Different Environments

Martin T Dokulil, University of Innsbruck, Mondsee, Austria

Preamble

This pamphlet intends to provide an overview on definitions, methodologies and results of gross and net production measurements as estimates for different ecosystems, and the globe. The content however, might be biased towards freshwater plankton production due to the long-term professional experience of the author.

Introduction

Measurements of photosynthetic rates and the estimation of ecosystem production have a long tradition. The early history has been elegantly summarized by Macfadyen (1948), the history of plankton productivity was described in detail by Barber and Hilting (2002).

Quantification of ecosystem metabolism was introduced by Juday (1940) and Riley (1944) followed by the foundation of ecological energetics through the classic paper by Lindeman (1942). His transfer efficiency concept between trophic levels of ecosystems was the nucleus which inspired the International Biological Program (IBP) for the decade 1964–74. The "biological basis of productivity" to better understand the dynamics of whole ecosystems was one of the essential objectives of the program. IBP boosted methods, their standardization, and measurements of production at the major trophic levels in land, fresh water and marine ecosystems. Studies were based on biomass, gross production, respiration, net production, and many other variables. The focus on production ecology induced by IBP lasted for about the next 50 years or so (see, e.g., Williams *et al.*, 2002).

The world-wide effort by IBP produced a number of mainly methodological "IBP Handbooks" such as, for example, Vollenweider (1969) and finally culminated in a series of "synthesis volumes" (e.g., Cooper, 1975; Le Cren and Lowe-McConnell, 1980; Westlake *et al.*, 1998). Very few scientists might have recognized during IBP that this decade was perhaps innovative in what is now called "Big data" and certainly was part of "Big Science," phrases which were already reflected by Weinberg (1961, 1967) as outlined and discussed by Aronova *et al.* (2010). These authors also emphasized IBP's key role in acceptability of long-term synoptic data collection. As a follow up of IBP, the Long Term Ecological Research Network (LTER) was initiated in1977. Meanwhile the network produced a series of LTER publications including various aspects of production (e.g., Arnott *et al.*, 2006) as well as standards for measuring primary production for a variety of ecosystems assembled by Fahey and Knapp (2007).

Photosynthesis and Respiration

The dominant autotrophic process in most ecosystems on the earth is photosynthesis. The process is separated into light-dependent reactions and light-independent reactions. In the light energy contained within photons oxidizes water to O_2, produces potential cellular energy in the forms of ATP and NADPH, and generates protons. In the dark reactions which are physically separated from the light-dependent reactions, ATP, NADPH, and protons produced in the light are used to reduce CO_2 to carbohydrates (for more details see, e.g., Falkowski and Raven, 2007; Raich *et al.*, 2014). These two net reactions together form the net reaction for plant photosynthesis:

$$CO_2 + H_2O \rightarrow (CH_2O) + O_2$$

Aerobic respiration generates useful cellular products from carbohydrates and oxygen. In short form:

$$(CH_2O) + O_2 + n\mathrm{ADP} + n\mathrm{Pi} \rightarrow CO_2 + H_2O + n\mathrm{ATP}$$

Although both oxygen evolution and carbon uptake are measures of photosynthesis, both variables originate from two physical separated reactions. Therefore clear statements are essential on what has been measured and which conversions were applied if any. As a recommendation measurements based on oxygen evolution estimate *photosynthetic rate* those based on carbon measure *carbon uptake* and shall be named accordingly.

Productivity or Production

The complex process of photosynthesis in photoautotrophic organisms usually creates new organic material from inorganic elements by harvesting light. This time dependent photosynthetic rate often is termed "primary productivity" or "primary production" (e.g., Falkowski and Raven, 2007). Both terms are often confused and used interchangeably (Thornton, 2012).

 doi:10.1016/B978-0-12-409548-9.10891-7

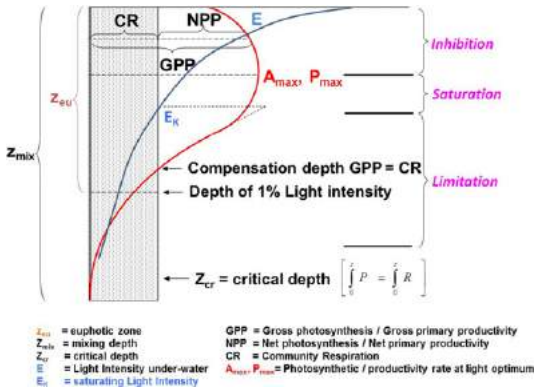

Fig. 1 Conceptual diagram of a schematic vertical depth profile graphically showing definitions of variables and parameters used in production ecology. For abbreviations refer to the legend and the text. Modified from Dokulil, M.T., Kaiblinger, C., (2009). Phytoplankton productivity. In: Likens, G.E. (ed.) Plankton of inland waters, Vol. 1, pp. 210–218. Oxford: Elsevier. https://www.elsevier.com/books/plankton-of-inland-waters/likens/978-0-12-381994-9.

Since there is no generally accepted definition of primary production terms (Underwood and Kromkamp, 1999) various authors have discussed the expressions "productivity" and "production" with the conclusion to abandon one or the other (Williams, 1993a). Until now these concepts are poorly differentiated and often synonymously used. The dilemma can be resolved maybe by adopting a definition from economics where productivity is a *rate* at which something is produced while production is the final product. Accordingly, primary productivity would refer rate per area or depth for a time less than a day, month or year depending on the organism in question. The ultimate end-product of the process is "primary production," the accumulation of organic material leading to growth. Accordingly, primary production will be a derived quantity integrated over area, depth and/or time, usually perhaps a year with units of mass or energy. Productivity can then also be regarded as equivalent to photosynthetic or production rate. Similar differentiation between these terms is not explicitly mentioned but inherent in, for example, Nátr and Lawlor (2005) summarizing photosynthetic plant productivity.

Definition of Major Parameters

The history and development defining production terms was nicely outlined in Williams (1993a). Some of the definitions explained below are graphically presented in **Fig. 1** for a marine/fresh-water vertical depth profile.

Euphotic zone (z_{eu}): Per common definition the zone between the water surface and the 1% light level (LI) where light supports photosynthesis.

Compensation depth (z_c): Determined by the physiology, acclimation or adaptation of the species, population or assemblage where gross photosynthesis is compensated by community respiration. Therefore it might or might not be equivalent or even identical to the euphotic depth as repeatedly assumed. The two terms strictly must be separated due to their different meaning.

Standing crop: All living organisms on a unit area. Equivalent to biomass above-ground.

Biomass (B): Total mass of all living (and dead) material in carbon units (e.g., g C m^{-2}), units of energy (e.g., kJ m^{-2}) or dry organic matter (e.g., tons per hectare) above and below ground.

Gross photosynthesis (GP): The rate of electron equivalents photochemically extracted from the oxidation of water. It resembles gross oxygen evolution rate if no respiration losses can be assumed.

Net photosynthesis (NP): Corresponds to gross photosynthesis minus all losses due to autotrophic respiration.

Photosynthetic efficiency (PE) = 100 × (incident radiation converted to NPP)/(total incident radiation); conversion, for example: 39 kJ per g C.

Photosynthetic quotient (PQ): The volume of oxygen released in photosynthesis as a proportion of the volume of carbon dioxide used in that process.

Primary productivity (PP): Refers to rate at which energy is accumulated by green plant in unit time in the form of organic substance that can be used as food. The rate at which radiant energy is stored by photosynthetic activity of green plants and algae in the form of organic substance is termed primary productivity, because it is the first and most basic form of energy stored in the ecosystem.

Gross primary production (GPP): Is the total amount of CO_2 that is fixed by the plant in photosynthesis or the sun's energy that is assimilated by *total photosynthesis*. It includes the organic matter used up in respiration during the measurement period. It is also called *total assimilation*. Units: g C m^{-2} $year^{-1}$, or kJ m^{-2} $year^{-1}$.

Ecosystem GPP: is then the sum for an entire lake, forest, field, biome, etc. Units: g C $year^{-1}$.

Community respiration (CR): is the amount of CO_2 that is lost from an organism or system from metabolic activity. Respiration can be further divided into components that reflect the source of the CO_2.

R_p = Respiration by plants.

R_h = Respiration by heterotrophs.

R_d = Respiration by decomposers (the microbes).

Net primary production (NPP): Is the net amount of primary production after the costs of plant respiration are included. Therefore, NPP = GPP − R.

Net ecosystem production (NEP): Is the net amount of primary production after the costs of respiration by plants, heterotrophs, and decomposers are all included. NEP = GPP − $(R_p + R_h + R_d)$. Randerson *et al.* (2002) suggested to change the definition of NEP and equate it to the rate of carbon accumulation while Lovett *et al.* (2006) argued to retain the original definition.

Net ecosystem exchange (NEE): Refers to net primary production minus carbon losses due to R_h (Kirschbaum *et al.*, 2001). NEE = NEP = NPP − R_h. Usually used in terrestrial PP.

Net biome exchange/net biome production (NBE, NPB): Refers to the change in carbon stocks after losses due to natural or anthropogenic disturbances. NBE = NEE − L_d or NBP = NEP − L_d with L_d losses by episodic disturbances (Roy and Saugier, 2001).

New production: according to Dugdale and Goering (1967) represents a primary production quantity in the oceans driven by nutrient inputs from outside the euphotic zone, usually nitrate (NO_3). In this sense, nitrogen fixation is new production since the nitrogen source originates from the atmosphere.

Recycled production: Is driven in the oceans by ammonium (NH_3) excreted by grazers within the euphotic zone.

Turnover: Is the ratio of standing crop or biomass to production (Standing Crop/Production) of the system. It is calculated by dividing standing crop or biomass (units of g m^{-2}) by production (units of g/m^{-2} year).

Production to biomass ratio (P:B): Is the amount of biomass replaced per unit time ($year^{-1}$).

Productivity versus irradiance curve and derived parameters are an approach widely used in marine and freshwaters as well as in various terrestrial ecosystems (Dokulil *et al.*, 2005; Dokulil and Kaiblinger, 2009).

Measure Primary Productivity and/or Production

Different techniques will produce slightly different rates of productivity (Bender *et al.*, 1987). As a result of the biases associated with each method no technique can provide "true" rates of primary productivity. Consequently no algorithm or model will estimate "real" production.

The overwhelming quantity of techniques for estimating primary productivity and their manifold modifications are beyond the scope of this article and will therefore not be discussed in detail. Many methodological summaries, reviews and outlines are available such as Newbould (1967), Milner and Hughes (1968), Vollenweider (1969), Cullen (2001), Fahey and Knapp (2007) to name a few. Moreover, instrumentation, methods and techniques for estimation of primary production are constantly evolving.

Three general approaches are possible which will not give the same answer (Marra, 2002):

(a) Measurements of increase in plant biomass—Largely used in terrestrial ecosystems; in marine and freshwater limited by non-discriminatory for algal assemblages; only the changes in chlorophyll-a can be taken as a proxy for autotrophic biomass.
(b) Yield measurements of productivity—The most variable approach to production (see discussion in Marra, 2002).
(c) Rate measurements of photosynthesis/productivity—Extensively used in innumerable alternatives, modifications and refinements.

Primary productivity is typically measured by the following main techniques:

1. *Light and dark bottle method*—Change in oxygen concentration within sealed containers, usually glass bottles (Gaardner and Gran, 1927).
2. *Radioactive tracer LD bottle method*—Incorporation of inorganic carbon as ^{14}C in the form of sodium bicarbonate into organic matter (Steemann-Nielsen, 1951, 1952).
3. Differential measurements of *stable isotopes of oxygen* (^{16}O, ^{18}O and ^{17}O) by, for example, Bender *et al.* (1987) or Luz and Barkan (2000).
4. *Chlorophyll concentration*—Based upon the relationship between chlorophyll concentration and photosynthesis at any given light intensity. If the assimilation ratio and the available light are known gross production can be estimated. Method first used in the sea but later applied to freshwater terrestrial ecosystems (Bot and Colijn, 1996; Gitelson *et al.*, 2006).
5. *Fluorescence kinetics*—Several modifications of measuring modes are in use (Jakob *et al.*, 2005), including passive, in vivo fluorescence and active fluorescence methods (Dokulil and Kaiblinger, 2009).
6. *Stable isotopes of carbon* (^{12}C and ^{13}C)—Measurements of respiration in the light allowing consequently calculation of gross photosynthetic rates (e.g., Carvalho and Eyre, 2012).
7. *Oxygen/argon ratios*—First used by Craig and Hayward (1987) and modified by Reuer *et al.* (2005).
8. *Carbon dioxide flux*—Most useful methods in terrestrial ecosystems for estimating both gross and net primary productivity. Carbon dioxide concentration in incoming and outgoing air is measured in the light and in the dark usually with an infrared gas analyzer (IRGA).
9. *Harvest analysis (standing crop method)*—Several modifications are widely used to estimate PP in terrestrial ecosystems. Vegetation is removed at maximum stand or at periodic intervals. Samples are dried to constant weight or determined as caloric

values. Results obtained are NPP for above ground biomass. Below ground biomass is difficult to estimate particularly in, for example, grass species or trees.

10. *Dimension analysis*—Modified harvest technique estimating standing crop and productivity from the measurement of light, diameter growth and age. Net annual production of wood, bark, leaves, twigs, roots and flower is calculated. All these information are used to calculate production of trees and other vegetation in a sample unit.
11. *Remote sensing*—Continuous monitoring of GPP and NPP possible via satellite imaging spectroradiometer data (Running *et al.*, 2004; Lee *et al.*, 2015). Another possibility is light detection and ranging (LIDAR) with pulsed laser light from aircrafts (Kotchenova *et al.*, 2004; Maselli *et al.*, 2013).

The most important flux of the terrestrial carbon cycle is gross primary production (GPP) of the vegetation. At ecosystem or landscape scales no direct measurement technique for GPP is available (Xiao *et al.*, 2014).

Several basic alternatives exist for marine and freshwater ecosystems (Vernet and Smith, 2007).

1. *Open water* changes in oxygen or carbon dioxide concentration. Diel oxygen techniques to measure lake metabolism are summarized by Staehr *et al.* (2010).
2. In situ enclosures—In containers, commonly glass bottles, which are suspended at in situ depth for a certain time.
3. *Simulated* in situ experiments—Samples from the euphotic zone are filled into containers as above but incubated on the ships deck simulating in situ conditions of light and temperature. A similar technique was adopted for the River Danube (Dokulil and Holst, 1990).
4. *Laboratory incubation* experiments—Productivity is estimated from the response of algae incubated at a range of artificial irradiances and at mean in situ temperature. The resulting photosynthetic versus irradiance behavior (P vs. E curve) is analyzed for certain parameters and finally modeled to represent potential in situ production (e.g., Kabas, 2004). A dilution method was developed by Moigis and Gocke (2003) to estimate primary production of phytoplankton in coastal waters.
5. *Non-invasive, indirect methods*—Besides the open water methods mentioned under point 1 above, these techniques are usually based on fluorescent properties and do not depend on incubation of small samples. Moreover, they have the advantage of being almost instantaneous and closely related to sampling rates of physico-chemical variables (Kaiblinger *et al.*, 2005; Kaiblinger and Dokulil, 2006a,b).

Comparison between different methods measuring marine PP and conversion factors are provided by Regausie-de-Gioux *et al.* (2014) claiming that the ^{18}O technique provides the best estimate of GPP.

Respiration

The "correct" approximation of respiration is of prime importance for the assessment of gross primary production. Respiration in the dark can be unequal to uptake of oxygen in the light due to photorespiration (Peterhansel *et al.*, 2010). Common practice assumed that algal respiration in the oceans was unimportant until a model developed by Langdon (1993) indicated how significant respiration can be and how important is to consider the composition of the algal assemblage. Oceanic respiration has meanwhile identified as a major component of carbon flux in the biosphere or, in other words, whether oceans are net sources or sinks of carbon (Del Giorgio and Duarte, 2002). For a detailed discussion on respiration in aquatic ecosystems refer to Del Giorgio and Williams (2005a,b). Respiration by terrestrial vegetation and net primary production is outlined by Amthor and Baldocchi (2001) and Raich *et al.* (2014). Better separation of autotrophic and heterotrophic respiration is certainly still required (Trumbore, 2006) as has, for example, shown for a tropical forest ecosystem by Chambers *et al.* (2004).

At best respiration can be determined as community respiration (CR) during routine field operations in aquatic ecosystems. Consequently GPP will be overestimated since some of CR will certainly be non-autotrophic. Similarly in situ measurements of respiration in terrestrial vegetation remain largely uncertain which is particularly true for soil respiration affecting the approximation of below-ground GPP. Increasing CO_2 concentrations and warming due to global change may further affect respiration in the near future. These and other aspects of aquatic and terrestrial respiration are detailed in Del Giorgio and Williams (2005a,b). An analysis of ecosystem and background respiration based on free-water high frequency measurements from 25 lakes around the globe revealed GPP and CR positively related to total phosphorus. Respiration was linked to GPP tightly to more weekly depending on trophic level (Salomon *et al.*, 2013).

Although the dark uptake of ^{14}C does not measure respiration, several attempts were made in the past to obtain respiration from carbon uptake experiments (Steemann-Nielsen and Hansen, 1959). More recently, Williams and Lefèvre (2008) critically analyzed assessments of respiration from dark ^{14}C incubations based on the procedure proposed by Marra and Barber (2004). The authors came to the conclusion that the procedure does not exactly measure respiration but might come close when P/R ratios are high. Reviewing net and gross productivity, Marra (2009) concludes that estimates of plankton respiration seem reasonable when compared to the ^{18}O method.

What Does the ^{14}C Method Measure?

The radiocarbon method is one of the most widely used techniques in aquatic systems. Even after more than 50 years of intensive investigations there is still no common consensus as to what the method is measuring (Dring and Jewson, 1982). Measurements

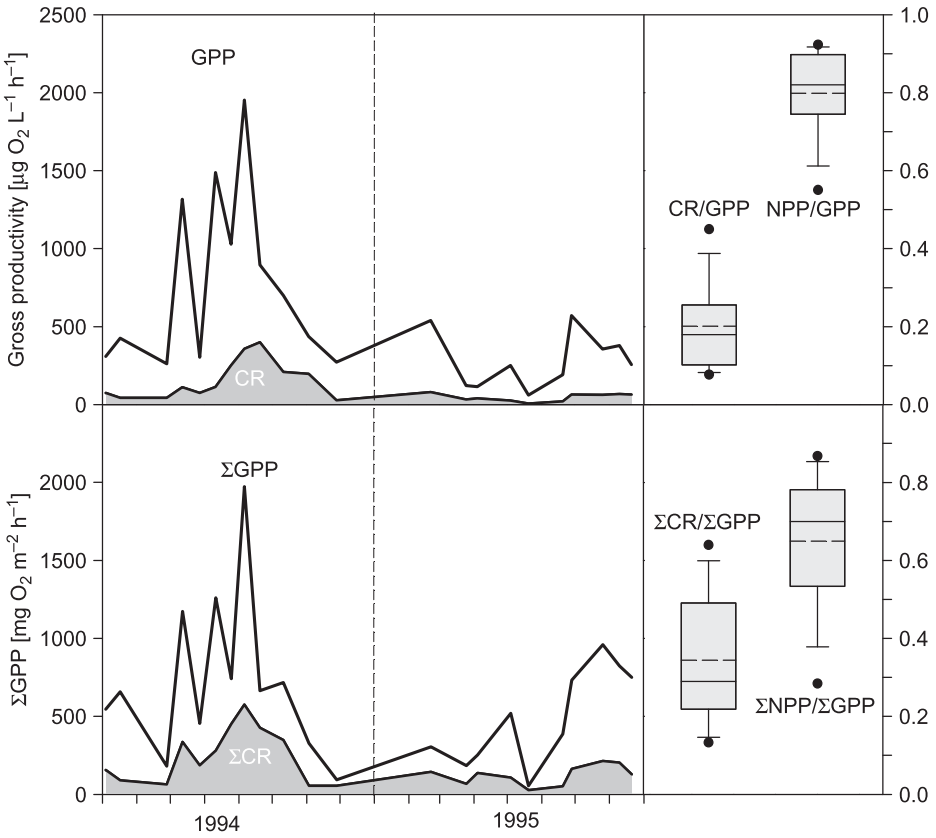

Fig. 2 Seasonal dynamics for the years 1994 and 1995 for gross primary productivity (GPP) and community respiration (CR) at light saturation (upper panel) and as integral (ΣGPP) and (ΣCR) for the water column (lower panel) in the urban lake "Alte Donau" in Vienna, Austria. Box whisker plots for the ratios CR/GPP and NPP/GPP for both panels are added. Continuous line in the box is the median, dashed line is the mean.

and modeled data suggest an imbalance between CO_2 and O_2 dynamics (Williams, 1993b). If internal CO_2 from respiration is taken as a source, then ^{14}C uptake must be smaller than ^{18}O uptake which will then approximate gross photosynthesis while carbon uptake is closer to net productivity. As a consequence, the ^{14}C method approximates gross productivity over very short periods of time when respiration is low and productivity is much higher ($P \gg R$). Whenever production is greater or equal to respiration, ^{14}C uptake approaches net productivity (Marra, 2002; Vernet and Smith, 2007).

Gross and Net Production in Different Environments

A central process regulating the structure and functioning of terrestrial ecosystems is gross primary productivity (GPP). Respiratory processes, supporting plant embolism, loose about half of assimilates derived from GPP back to the atmosphere. What remains is used for new living biomass. Plants also transpire large quantities of water during photosynthesis thus influencing both water and carbon global cycles. Changes in these complex interactions impact local, regional, and global climate. All NPP will finally be released back to the atmosphere as CO_2 because of utilization by heterotrophic organisms.

Aquatic ecosystems and particularly the oceans largely influence the global carbon cycle. The 1–2 Giga tons of autotrophic biomass in the oceans seem small compared to the 600–1000 Giga tons of total terrestrial plant biomass. The importance of the oceans becomes clear when turnover times are compared. Ocean turnover is 0.02–0.06 years while it is 9 to >20 years in terrestrial vegetation (Falkowski and Raven, 2007).

Comparison of different ecosystems can only be achieved if measurements are converted to a common unit. Since terrestrial primary production is usually express per unit area, values from other environments, particularly from aquatic ecosystems need to be converted by integrating vertical profiles over depth.

The time sequence of gross productivity at light optimum and the respective community respiration (CR) are compared to the integral production per square meter (ΣGPP) and ΣCR in an urban lake (**Fig. 2**). Seasonal changes are not very different in their appearance but differ largely in extent and relative importance. Relation of parameters is depicted at the right side of each graph as box-Whisker plots. Contribution of CR to GPP is smaller and varies less than ΣCR/ΣGPP. Accordingly NPP has a much larger share of GPP than does ΣNPP on ΣGPP (**Table 1**).

Table 1 Mean, maximum, minimum, median, 25% and 75% percentiles for the Box plots in Fig. 2

	Mean	*Max*	*Min*	*Median*	P *25%*	P *75%*
CR/GPP	0.20	0.45	0.08	0.18	0.10	0.26
NPP/GPP	0.80	0.92	0.55	0.82	0.75	0.90
ΣCR/ΣGPP	0.34	0.65	0.13	0.29	0.22	0.49
ΣNPP/ΣGPP	0.65	0.87	0.27	0.70	0.53	0.78

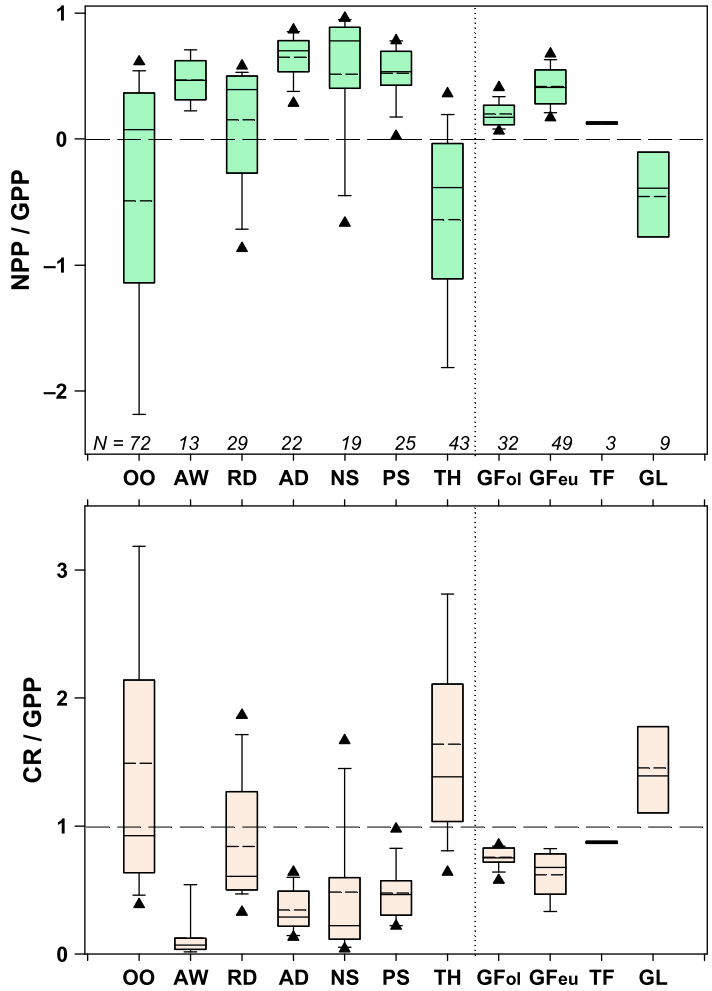

Fig. 3 Relation of NPP to GPP (upper panel) and CR to GPP (lower panel) for different ecosystems as Box–Whisker plots. Continuous line in box is the median, dashed line is the mean. The dashed line in the upper panel at 0 indicates NPP = GPP, the dashed line in the lower panel at 1 indicates CR = GPP. OO—Oligotrophic Ocean from López-Urrutia *et al.* (2006) and Williams (1998), AW—River impoundment "Altenwörth," Austria from Holst and Dokulil (1987), ED—River Danube, data compilation from Dokulil (2014), AD—urban lake "Alte Donau" from Roschitz (1996), NS—Neusiedler See, shallow lake at the Austro-Hungarian border from Dokulil (pers. data compilation), PS—Parakrama Samudra, tropical reservoir in Sri Lanka from Dokulil *et al.* (1983), TH—Tai Hu, sub-tropical shallow lake in east-central China from Liu *et al.* (2011), GF_{ol} and GF_{eu}—Global Forest nutrient poor and nutrient rich, both from Fernández-Martínez *et al.* (2014), TF—temperate forest from Sun *et al.* (2014) and Grassland from Albergel *et al.* (2010). Number of data for each system is indicated in the upper panel. A dotted vertical line separates aquatic from terrestrial ecosystems.

Relations of NPP to GPP and CR to GPP are compared for different ecosystems on a unit area basis in **Fig. 3**. Phytoplankton production data from the open, oligotrophic ocean (OO) indicate high variability in both NPP/GPP and CR/GPP. Negative relations are much more variable than positive ones indicated by the positive median in both cases meaning that over 50% of data are positive (**Table 2**). The debate over the metabolic state of the oligotrophic ocean (if auto- or heterotrophic) is still an open question. Results largely depend on the variability in respiration and certain assumptions over scaling (Serret *et al.*, 2015). The

Abbreviations for ecosystems as in Fig. 3.

authors conclude that oligotrophic oceans are functionally diverse and that variability in respiration needs to be considered before the metabolic state of an ocean area can be defined.

The six specific examples on plankton production from inland waters in Fig. 3 include a river impoundment (AW), the River Danube (RD), a side arm which is now an urban lake (AS), a shallow lake (NS), a tropical reservoir (PS) and a shallow subtropical lake (TH). Five of the examples have largely positive NPP/GPP relations and their medians are all higher than the ocean or the terrestrial examples indicating a high positive net production. Negative ratios are encountered in NS and, to a greater extent, in RD. Interestingly the highly eutrophic shallow system TH is largely heterotrophic possibly due to the shallowness and turbidity. Both mean and median are negative (Table 2). Primary production for freshwater biocenoses other than phytoplankton and in different climatic regions is comparatively assessed in Dokulil (2009).

Terrestrial ecosystem production ratios are provided for four environments, nutrient poor (GF_{ol}) and nutrient rich (GF_{eu}) global forests, temperate forest (TF) and grassland (GL). The forest examples all show les NPP contribution to GPP compared to the inland water examples largely due to a greater share of community respiration. Evident is also that nutrient rich forests have higher NPP/GPP ratios than nutrient poor forests and both are higher than the few ratios available for temperate forests. For more and detailed data refer to, for example, Vogt (1991) and Wehr *et al.* (2016). Grassland vegetation, at least in France, has high CR/GPP ratios and hence all negative NPP/GPP values (Table 2). According to Ma *et al.* (2015) gross primary production was likely overestimated in forest ecosystems because coverage rate has not been taken into account for the past 30 years. Understanding terrestrial carbon fluxes in response to climate change largely depends on understanding and modeling gross primary production (GPP) in forest ecosystems (Chen *et al.*, 2013).

Global Production

Adequate estimation of primary production at global level necessitates an enormous quantity of basic data. The acquisition of information at reasonably high temporal and spatial resolution can be obtained by remote sensing using aircraft or satellite-based technologies. Combined with testing and improving models and algorithms by measurements acquired at ground level, his approach follows ecological principles able to detect even regional disturbances and anthropogenic impacts (Field *et al.*, 1995). Based on these rationales, Field *et al.* (1998) estimated global NPP for terrestrial and marine primary producers at 104.9 Pg (10.5×10^{10} metric tons) C per year. Contributions from land and oceans were roughly equal, 54% and 46% respectively but showed marked heterogeneity.

Turner *et al.* (2005, 2006) report a range of NPP from 80 g C m^{-2} $year^{-1}$ at an arctic tundra site to 550 g C m^{-2} $year^{-1}$ at a temperate deciduous forest site and strong seasonality in GPP. Ground validation and evaluation from satellite agreed closely at temperate deciduous forest, arctic tundra, and boreal forest sites in both NPP and GPP.

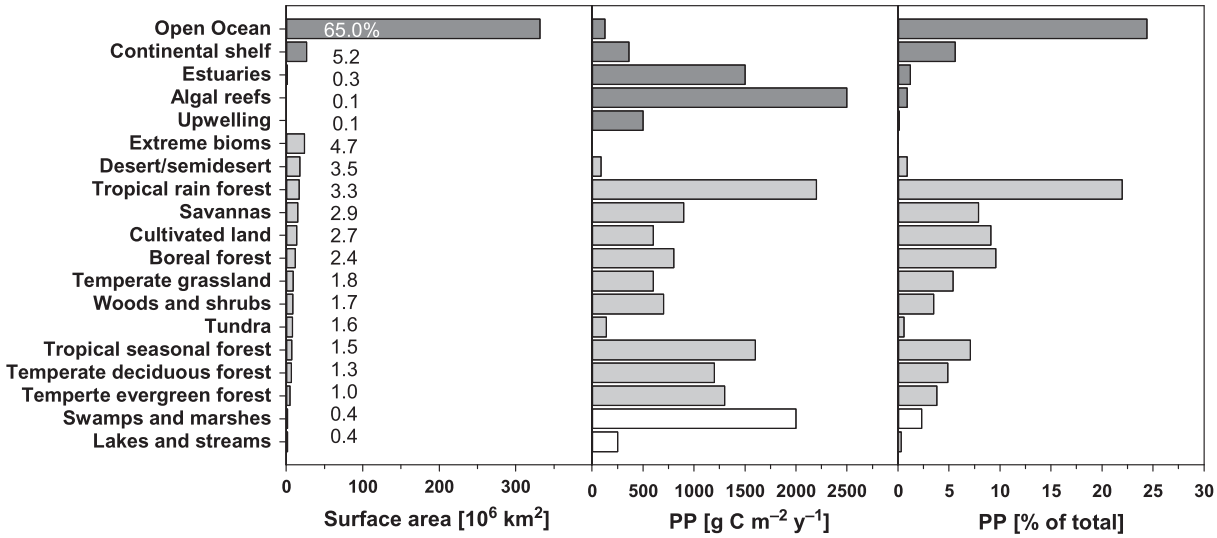

Fig. 4 Surface area for different ecosystems of the earth as 10^6 km^2 with percent contribution added as values (left panel), primary production in g C m^{-2} year^{-1} for these ecosystems (middle panel) and primary production as percent of total world production (right panel). Data modified from Whittaker, R.H., Likens, G.E., 1973. Primary production: The biosphere and man. Human Ecology 1, 357–369.

Table 3 Global NPP, GPP and the NPP/GPP ratio from 2000 to 2003

Year	*GPP*	*NPP*	*NPP/GPP ratio*
2000	108.00	55.92	0.518
2001	110.33	57.57	0.522
2002	107.40	55.36	0.515
2003	107.09	54.63	0.510

Data are in Pg C year^{-1}.

Primary productivity varies widely among different ecosystems of the world. Estuaries, coral reefs, swamps, marshes, tropical and temperate forests are the most productive systems per unit area (**Fig. 4**). The highest productive systems in terms of global NPP are open oceans because of their size. Tropical rain and seasonal forests, and savannas add a high proportion since they are very productive. The contribution of estuaries and coral reefs to global production remains small because of their limited surface area (**Fig. 4**). Similarly, lakes, rivers and streams are of minor importance for global production but are essential for the survival of the world's population.

Improvement and refinements in instrumentation, observational coverage and modeling continuously improved global production estimates over the years. Global assessments are influenced however by the instrumentation and algorithm used but variation between years and within years largely depends on environmental and climatic unpredictability.

Calculations by Zhao *et al.* (2005) using MODIS (moderate resolution imaging spectroradiometer) produced total global GPP and NPP of 109.29 and 56.02 Pg C year^{-1}, respectively for the years 2001–2003. For the same years, global GPP and NPP and their ratio showed minor fluctuations shown in **Table 1** adapted from Zhang *et al.* (2009). Highest global GPP and NPP/GPP ratio occurred in 2001 and the lowest in 2003 (**Table 3**).

Average annual global GPP was calculated as 110.5 $\pm$ 21.3 Pg C for 2000–2003 by to Yuan *et al.* (2010). The humid tropics of Amazonia, Central Africa and South-east Asia had the highest annual production of over 2000 g C m^{-2} since temperature and moisture are optimal for photosynthesis is. Intermediate GPP of 1000–1400 g C m^{-2} occur in temperate regions. Cold and arid regions, where either temperature or precipitation are limiting factors, have lowest GPP of $<$400 g C m^{-2} (Yuan *et al.*, 2010).

Average total global GPP estimated for the decade 2000–2010 using eight biome models was 117 $\pm$ 13 Pg C year^{-1} (Chen *et al.*, 2017). According to the authors Tropical Latin America contributes most to global GPP. The Asian regions are largely linked to the global GPP trend while the Northern Hemisphere dominates seasonal variations in global GPP. The inter-annual variability of global GPP seems likely controlled by the Oceania region.

The global GPP estimates for the period 2000–2016 range from 121.60 to 129.42 Pg C year^{-1} with an increasing rate of approximately 0.39 Pg C year^{-1} (Zhang *et al.*, 2017). Details for each year on continental and global GPP are given in **Table 4** modified from Zhang *et al.* (2017). Inter-annual variation is relatively small on all continents. Maximum and minimum GPP occurs in different years across the globe indicating regional climatic differences. Asia, and Europe had their maxima in 2016 with a clear upward trend on both continents ($r^2 > 0.8$). North America shift upwards with large ups and downs ($r^2 = 0.6$). No trend is

Table 4 Continental and global total GPP for 2000–2016

Units are in Pg C $year^{-1}$.
Bold numbers in the main table indicate maximum values and italics numbers indicate minimum values.

obvious for Africa and Oceania, and production in South America is declining. As a result the global total GPP is on the rise ($r^2 = 0.85$). In this context, Campbell *et al.* (2017) report a 31% ± 5% growth of GPP during the 20th century. Tropical regions have high annual GPP peaking around the equator. Mean maximum daily GPP creates another peak around 50°N (for both see Fig. 4B and D in Zhang *et al.*, 2017).

Analyzing the average global carbon cascade from GPP to net biome production (NBP) for land and ocean, Woodward (2007) concludes that the NBP of 2–3 Pg C produced per year accounts for about 20%–30% of anthropogenic emissions.

Perspective

Climatic signals such as temperature, light availability and humidity are the major factors controlling GPP and consequently NPP. Further important variables are soil fertility, species composition, and age of the vegetation. Since climate is of prime importance for GPP, climate change is expected to seriously impact global patterns of plant production. Enhanced plant growth is expected in colder climates, declining GPP in regions where water losses increase due to evaporation and perhaps dramatic changes in vegetation because of extreme events such as heavy precipitation, fires, storms and hurricanes. Negative feedback to climate change might thus be provided.

Various ways of anthropogenic intervention in global primary production to mitigate climate change are often discussed such as planting trees to reduce terrestrial carbon emissions or iron fertilization of the ocean to stimulate CO_2-uptake by phytoplankton (Woodward, 2007). These and other interventions into global primary production may have short lived positive effects but are unlikely to produce long term solutions to the problem (Woodward *et al.*, 2009).

Light Extinction☆

Alberto Barausse, University of Padova, Padua, Italy

Nomenclature

I	Light intensity (or irradiance), W m^{-2}. In the case of PAR, it can be expressed as PPDF (photosynthetic photon flux density, which is the number of photons in the visible range incident per unit time on a surface unit) (mol m^{-2} s^{-1})
I_{in}	Light intensity before crossing a certain medium of finite length (W m^{-2}). In the case of PAR, it can be expressed as PPDF (photosynthetic photon flux density, which is the number of photons in the visible range incident per unit time on a surface unit) (mol m^{-2} s^{-1})
I_{out}	Light intensity after crossing a certain medium of finite length (W m^{-2}). In the case of PAR, it can be expressed as PPDF (photosynthetic photon flux density, which is the number of photons in the visible range incident per unit time on a surface unit) (mol m^{-2} s^{-1})
k	Extinction (or attenuation) coefficient (m^{-1}) (but dimensionless when applied to canopies)
L	Length of the layer of medium crossed by light (m)
$LAI(z)$	The cumulated "Leaf Area Index" from the top of the canopy to distance z (measured along the vertical direction), dimensionless
z	Distance measured along the direction of light (m)

Glossary

Absorption The capture of the energy of a photon by a medium being crossed by light (e.g., gases and aerosols in the atmosphere, water and the suspended/dissolved substances that it contains, leaves, etc.). It is one of the processes causing light extinction.

Extinction coefficient Also known as "attenuation coefficient," it expresses the capability of a given medium to attenuate the intensity of light when crossed by it.

LAI An acronym for "Leaf Area Index," it is an indicator of canopy structure in plants. It is the ratio of the total one-sided green leaf surface to the surface of the ground underneath the canopy (or the projected needle area per unit of ground surface).

PAR An acronym for "photosynthetically active radiation," it is the light which can be used in photosynthesis, approximately in the wavelength range of visible light (400–700 nm).

Scattering The deviation of photons from their original trajectory, due to interactions with the medium being crossed by light (e.g., gases and aerosols in the air, suspended particles in water, etc.), without loss of energy. It is one of the processes causing light extinction.

Introduction

Light is the main source of energy for most ecosystems and a fundamental driving factor in several ecological processes, such as photosynthesis and evapotranspiration. For this reason, understanding and quantifying the light effectively reaching the Earth, its ecosystems and its living organisms can be of primary importance in ecology. Indeed, not all solar radiation is able to reach the Earth's surface, since gases and aerosols forming the atmosphere partially extinguish it. Light penetration is also impeded in aquatic and terrestrial ecosystems, by diverse factors such as water depth and turbidity or the presence of vegetation. This work describes the process of light extinction in air, water bodies, and terrestrial ecosystems, taking a mainly ecological perspective. Simple relationships for quantifying and modeling light extinction are presented, first order kinetic Lambert–Beer law being the main one.

A General Model: The Lambert–Beer Law

The most common relationship for modeling light extinction across a certain medium is Lambert–Beer law, also known as Bouguer's law. It behaves reasonably well for low-concentration media, like gases or low turbidity water. Its mathematical derivation is simple: z axis being along light direction, let us define a thin (infinitesimal) layer of medium of length dz. The

☆*Change History:* November 2017. A Barausse made several small edits throughout the Abstract and the whole text to clarify concepts, to make text smoother and unambiguous, to make symbols more consistent, to eliminate typos and to mention novel concepts. Two recent books have been added to the "Further Reading" section. The Glossary has been added.

This is an update of A. Barausse, Light Extinction, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2180–2184.

 doi:10.1016/B978-0-12-409548-9.10977-7

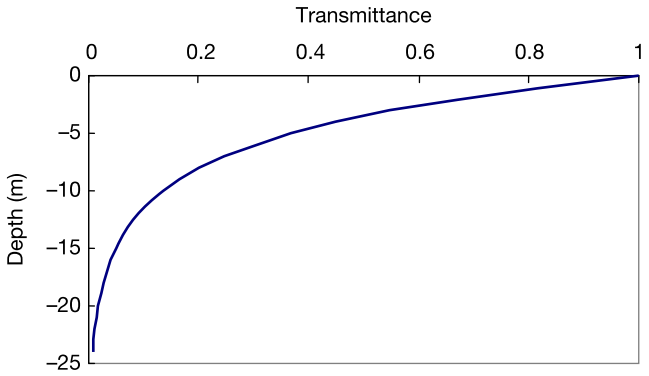

Fig. 1 Light extinction in a certain medium following Lambert–Beer law. The value of the k extinction coefficient used to create the plot is 0.2 m^{-1} (e.g., extinction by water in a coastal sea: for this reason the length of the medium has been plotted as depth).

intensity (or irradiance, W m^{-2}) of light I is diminished passing through the layer by a quantity dI proportional to dz

$$dI = -k \cdot I \cdot dz$$

where k (m^{-1}) is called extinction coefficient and can be determined empirically. It is worth noticing that k is dependent on the type of medium (e.g., clear and turbid waters are characterized by different extinction coefficients), the position in the medium (if heterogeneous), light direction, and (importantly) wavelength.

Rearranging we get,

$$dI/I = -k \cdot dz$$

Integrating over a given layer of finite length L to account for extinction in all the thin layers composing it, and assuming homogeneous extinction properties, it is possible to compute the intensity of the light flux leaving the medium:

$$I_{out} = I_{in} \cdot e^{-k \cdot L}$$

where $I_{in} = I(0)$ and $I_{out} = I(L)$ are the intensities of light fluxes entering and quitting the layer respectively (e.g., if atmospheric extinction is investigated, the flux entering atmosphere and the one finally reaching the ground). The ratio I_{out}/I_{in} is called transmittance (Fig. 1). The quantity $k \bullet L$ is known as "optical depth" and is a measure of the ability of the finite layer to block light.

In stratified systems (e.g., lakes or seas) composed of layers which are heterogeneous with respect to light extinction, in order to obtain more precise results, this relationship can be applied separately to the different layers by using different k values according to layer properties.

Light Extinction in the Atmosphere

Not all the solar radiation approaching the Earth's surface reaches the ground. The atmosphere weakens light intensity in several ways, usually classified as absorption and scattering and summed up as atmospheric light extinction.

Absorption takes place when photons are stopped by atmospheric gases like O_2, N_2, H_2O, CO_2, SO_2, O_3, and N_2O, or by aerosols, which are liquid droplets, solid particles or a mixture of both; they can be due to human activities (e.g., combustion, industrial emissions) or of natural origin (e.g., volcanoes, meteors). In such a case, the photon energy is taken up by gases or particles and can be transformed into heat or radiated.

Photons are scattered when they are deviated without energy loss from their original path by diffusion phenomena due to gases and aerosols, and then no longer reach the ground. Atmospheric scattering is usually divided into Rayleigh scattering, due to particles with diameter smaller than 1/10 of radiation wavelength (mostly oxygen and nitrogen for visible radiation) and Mie scattering, caused by particles with diameter up to 10 times the radiation wavelength. Above this length, a nonselective scattering takes place and geometrical optics laws apply.

Usually, these different extinction phenomena are collectively modeled using Lambert–Beer law. Ignoring Earth curvature effects, light extinction in the atmosphere can be described by the following relationship, which accounts for the fact that solar radiation can hit the atmosphere with a solar zenith angle θ different than zero, and consequently the extinction path can vary in length depending on the hour, day, and latitude:

$$I_{out} = I_{in} \cdot e^{-k \cdot m \cdot L}$$

where I_{out} is the radiation at the ground level, L is the height from the ground at which I_{in} (the incoming radiation) is observed, and m is the optical air mass, defined as the relative length of the path that light has to travel through the atmosphere to reach the ground. Air mass takes the value of one at zenith, and for small zenith angles (up to 60°) it can be computed with good approximation from

$$m = 1/\cos\theta = \sec\theta$$

For larger zenith angles, the effects of refraction, air density, curvature, and nonuniform vertical distribution of substances and temperature are not negligible, so semiempirical formulas derived from field values are used.

The k extinction coefficient can be split into a sum

$$k = (\Sigma)k_i$$

to account for the contributions to extinction of different processes such as absorption and scattering by aerosols, pollution gases, water vapor, and atmospheric gases. As an example, usually, extinction in the visible range due to gases is small compared to the one by suspended particles in inhabited regions.

Light extinction in the atmosphere is strongly wavelength-dependent. For example, greenhouse gases like H_2O, CO_2, N_2O, and CH_4 intensely absorb infrared radiation.

Light Extinction in Water Bodies

Light extinction in aquatic ecosystems can be an important limiting factor for organism growth, particularly for primary producers such as plants and algae, since too strong or too weak light can limit their productivity. Suspended and dissolved substances and water scatter and absorb light; so radiation is attenuated with increasing depth and is often limited only to a superficial layer. Since light used in photosynthesis (PAR or "photosynthetically active radiation") is mainly in the visible range (400–700 nm), henceforth I will refer to PAR when speaking of "light." Anyway, it must be noted that almost all radiation outside that range is extinguished at about 1 m depth. PAR is expressed as W m^{-2} or, more commonly, as PPDF (photosynthetic photon flux density, which is the number of photons in the visible range incident per unit time on a surface unit, μmol m^{-2} s^{-1}).

Light in a water body is attenuated in the so-called euphotic (or photic) zone, often defined as the water layer where photosynthesis can take place or by the depth where 1% of surface irradiance is still to be extinguished, but more precisely limited by the depth where primary producer respiration equals photosynthesis (the so-called compensation depth). The euphotic depth depends on water turbidity and typical values are about a meter or less in very turbid waters like estuaries or some lakes, around 30 m in coastal waters and up to 200 m in clear open ocean waters with low primary productivity.

The attenuation of the intensity of light entering the water surface I_{in} is usually modeled with Lambert–Beer law as a function of depth

$$I(z) = I_{in} \cdot e^{-k \cdot z}$$

where $I(z)$ is light intensity in water at depth z. The extinction coefficient k is associated with a given wavelength and can be determined experimentally by the use of photometers at several depths. It must be noted that most light wavelengths (e.g., red) are filtered after a few meters and then light becomes almost monochromatic (typically blue-green, depending on the presence of suspended and dissolved substances).

Also, k can be computed as the sum of different contributions to extinction, like those of water, suspended solids (e.g., detritus), dissolved material, and living material (e.g., phytoplankton cells). For example, one can consider contributions from water and dissolved matter ($k_{w\text{-}diss}$) and particulate (k_{part}) matter

$$k = k_{w-diss} + k_{part}$$

k_{part} can also be written as a function of particulate matter concentration C:

$$k_{part} = a \cdot C$$

where a is a scalar coefficient to be determined on field. In ecosystems characterized by a shallow euphotic depth or where noticeable algal blooms can be found, phytoplankton concentration usually has dominant effects on light extinction, and it can be useful to express k as a function of such concentration (as measured, e.g., by Chl-a concentration A).

$$k = b + c \cdot A$$

or

$$k = b + c \cdot A + d \cdot A^e$$

where b, c, d, and e are coefficients to be determined experimentally. These equations model the so-called shading and self-shading in phytoplankton, meaning that primary producers attenuate light and can also self-limit their growth because of their increasing biomass blocking PAR. Because of this process, phytoplankton growth as a function of light availability should have a saturation-like behavior (or even a humped, "optimum" behavior, since too high radiation is harmful to algae).

In oligotrophic systems, usually water and dissolved matter have the most significant effects, and b, which is related to background turbidity other than algae and to water effects, is bigger than the other terms.

The extinction coefficient k (m^{-1}) can also be related to Secchi disk depth z_{SD} (m) by the Poole and Atkins equation

$$k \cdot z_{SD} = constant$$

where the proportionality constant must be empirically calculated (it commonly ranges from about 1.7 in clear ocean water to about 1.4 in turbid coastal water). Attention must be paid also to the intrinsic limits of the Secchi disk measure of water

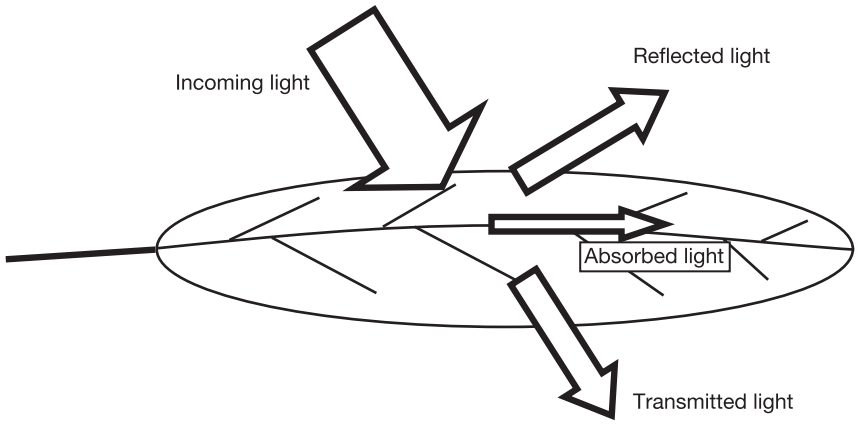

Fig. 2 Conceptual model of the radiation balance for a leaf. The source of incoming radiation can be direct illumination, transmission or reflection.

transparency, defined as the depth at which a standardized white and black disk is no longer visible from the surface: z_{SD} is a simple, cheap, quick and relatively robust measure of water clarity, but it is dependent on observer visual acuity, sun altitude, presence of shadows, and refraction caused by the water surface.

Light Extinction in Terrestrial Vegetation

Light extinction in terrestrial ecosystems is a matter of great interest, as availability of and competition for light can strongly influence plant composition, structure and growth, and consequently shape the productivity and other features of these ecosystems.

In a forest, for example, incoming visible light is mostly attenuated by the upper layer formed by leaves and branches belonging to tall trees (canopy). The underlying, shaded understory and undergrowth vegetation is influenced by this process, and so are the functions it performs, like supporting biodiversity, providing habitat to several animals and nutrient cycling.

The study of light interception and absorption by vegetation is also connected with activities like farming and silviculture, since optimal plant yield depends on whether light can penetrate crops (e.g., those planted in narrow rows to optimize the use of space) and make them grow fast and efficiently. A quantitative knowledge of light extinction can be important to understand and model crop productivity or linked processes like those determining the water balance and the need for irrigation.

Light can penetrate through canopies (this term defines also the upper layer of crops) and reach shaded lower plants and the ground by direct illumination (e.g., through gaps in foliage and canopy), transmission through leaves (with an intensity lower than the incoming one), and reflection by leaves or ground of incoming direct and diffuse radiation. Also, some light is absorbed (e.g., by leaves) or reflected away (Fig. 2).

Given the many, different terrestrial ecosystems influenced by light extinction and their large variability even on short spatial and time scales (e.g., seasonal variability), it is difficult to develop generally applicable models. One of the commonest models used to describe light transmission through a canopy is a modified Lambert–Beer law, obtained assuming a homogeneous (with respect to light attenuation) canopy with small, randomly dispersed leaves:

$$I(z) = I_{in} \cdot e^{-k \cdot LAI(z)}$$

where $I_{in} = I(0)$ is the incoming PPDF (on the top of the canopy, where canopy depth $z = 0$), $I(z)$ is the available PPDF at canopy depth z and $LAI(z)$ is the cumulated "Leaf Area Index" from the top of the canopy to distance z measured long the vertical direction. The Leaf Area Index is the ratio of the total one-sided green leaf surface to the surface of the ground underneath the canopy (or the projected needle area per unit of ground surface). Values are dimensionless and range from 0.2–2.5 (tundra) up to 10 (tropical forest) with higher values for conifers. *LAI* estimates can be achieved by destructive sampling or by using litter traps, allometric relationships (e.g., linking *LAI* to tree diameter or height) and light interception methods (e.g., calculating *LAI* from the inversion of the Lambert–Beer relationship or other models, based on measurements of light transmission through the canopy). Indirect estimates of *LAI* can also be obtained through remote sensing methods such as airborne laser scanning. The extinction coefficient k is species or canopy related and can span from about 0.3 to 2.0. Plants with vertically oriented leaves usually have lower values (e.g., for cereals, $k < 0.5$).

The above relationship linking canopy density and structure to light transmission has showed to be relatively robust with respect to violations of its underlying, often unrealistic assumptions. Anyway, numerous, more complex models describing light attenuation in forest canopies or in single plants can be found in the literature to account for the fact that, for example, many plants do not have a homogeneous spatial structure with respect to light extinction (e.g., leaves are not randomly spatially distributed or their finite size cannot be neglected).

These models can be based on aggregate parameters related to canopy structure, like *LAI*, leaf orientation, and average leaf area density (m^{-1}, total leaf upper surface per unit of volume), can explicitly account for factors like sun position, foliage clumping and distribution, ground and leaf optical properties or diffuse radiation, or can be based on more elaborate approaches, like 3D vegetation models. Also, the importance of the direct evaluation of light extinction by field measurements (e.g., at several canopy depths) is increasing. Data can be collected using different methods, like hemispherical photography, and are also used for obtaining information about canopy structure and for providing inputs to models (e.g., for calibration).

Nitrification☆

BB Ward, Princeton University, Princeton, NJ, USA

Introduction

Nitrification is an essential process in the nitrogen cycle of soils, natural waters, and wastewater treatment systems. It is responsible for the biological conversion of ammonium to nitrate. While both of these compounds are suitable for plant use as nutrients, they behave quite differently in soil systems, and have quite different sources and fates in the marine environment. Ammonium is produced as a waste product from cellular and organismal metabolism, a breakdown product of organic material. It is the preferred nitrogen source for many plants and algae. Nitrate is not only a nutrient, but the substrate for the bacterial process of denitrification, by which nitrate is reduced to dinitrogen gas, N_2. Most plants cannot use dinitrogen gas as a nitrogen source, so denitrification represents a loss term for fixed nitrogen in the ecosystem. Nitrification itself does not directly affect the nitrogen budget, but by linking organic matter decomposition to denitrification, it completes the N cycle.

The significance of nitrification can be summarized in the following list, and the individual items are described in the sections below: (1) transformation of ammonium to nitrate, with implications for the availability of N for plants and algae, (2) production of substrate for denitrification, (3) production of nitrous oxide in aquatic and terrestrial ecosystems, (4) consumption of oxygen in sediments, (5) acidification of the environment.

Nitrifying Microorganisms

Ammonia-Oxidizing Bacteria

Nitrification is performed by two functionally defined groups of microbes, referred to together as nitrifiers. The first group of nitrifiers is the ammonia oxidizers, which oxidize ammonia to nitrite. In most natural waters, ammonium is present predominantly as the positively charged ion, ammonium (NH_4^+), but the enzyme responsible for the first step of the reaction uses the gaseous form, NH_3, which is usually a minor component at equilibrium. We shall use the term ammonium when we are mainly concerned with the form that is important in the environment, and ammonia when referring to the enzymatic oxidation process of the specific substrate. There are two very different groups of ammonia-oxidizing microbes. One is the well-known bacterial group (ammonia-oxidizing bacteria, AOB), which includes a few different kinds of bacteria that all make a living by generating reducing power (ATP) from the oxidation of ammonia and using that energy to fix carbon dioxide (Bock and Wagner, 2006). They are generally considered to be obligate autotrophs, that is, they are unable to utilize or grow on organic carbon to any important extent, and can grow only by fixing their own CO_2 using the Calvin cycle. Ammonia is their only energy source, and their main metabolic product is nitrite. Nitrous oxide is a minor product of ammonia oxidation, and is produced by two different pathways. AOB have been cultivated for over 100 years and their description played an important role in the discovery and early research on chemoautotrophy.

Ammonia-Oxidizing Archaea

A second distinct group of ammonia-oxidizing microbes has only recently been recognized and brought into culture only in 2005 (Konneke *et al.*, 2005). These are not bacteria, but archaea (ammonia-oxidizing archaea, AOA). Like AOB, AOA oxidize ammonia to nitrite and produce nitrous oxide and nitrite from ammonia, but the enzymatic pathways are quite different. AOA are also thought to be predominantly autotrophic, but they fix CO_2 using the 3-hydroxypropionate/4-hydroxybutyrate pathway, rather than the Calvin Cycle (Walker *et al.*, 2010). AOA are abundant in many environments and in the ocean and many terrestrial systems, they far outnumber the AOB. In estuaries, the ratio of AOB to AOB varies widely, with AOB sometimes more abundant.

Although the enzymes and pathways differ for the AOA and AOB, aerobic ammonia oxidation in both groups apparently proceeds by the same stoichiometry:

$$NH_3 + 1.5\,O_2 \rightarrow NO_2^- + H_2O + H^+$$

In addition to the net production of nitrite by the above equation, AOB are also capable of producing nitrous oxide (N_2O) by two distinct pathways. Most AOB investigated to date possess the genes and enzymes necessary for the partial denitrification pathway that reduces nitrite to nitric oxide (NO) and then to N_2O (Casciotti and Ward, 2001, Casciotti and Ward, 2005). The genes involved are homologous to those found in denitrifiers, and the process is often referred to as nitrifier denitrification. The result is the production of N_2O, whereas complete denitrification by the usual denitrifying bacteria produces N_2O only as a

☆*Change History:* March 2013. BB Ward updated the entire article.

transient intermediate. A second pathway produces N_2O from hydroxylamine (NH_2OH), which is an intermediate in the oxidation of ammonia to nitrite by the AOB. The nitrifier denitrification pathway of N_2O production is favored during nitrification at low oxygen concentrations, implying that nitrifiers use this pathway for anaerobic respiration, just as in denitrifiers. AOA also produce N_2O, in approximately the same proportion to NO_2 as in AOB, and with similar isotopic fractionation (Santoro *et al.*, 2011). Nevertheless, the pathways of N_2O production in AOA are unknown, but almost certainly are different from the pathways in AOB. Significantly, AOA do not use NH_2OH as an intermediate, so the production of N_2O from NH_2OH cannot occur in AOA, and AOA do not possess the reductive enzymes used in nitrifier denitrification by AOB.

Anammox Organisms

A third group of bacteria, members of the Planctomycetes phylum, are capable of oxidizing ammonium using nitrite instead of oxygen and producing N_2 instead of nitrite (Kuenen, 2008). This metabolism is strictly anoxic and the process is known as anaerobic ammonia oxidation, or anammox. Anammox organisms are unique in a number of ways; the pathway for oxidation of ammonium is not very similar to that found in AOB or AOA, although the enzymes involved may be evolutionarily related. Hydrazine, more commonly associated with rocket fuel than with biological systems, is an intermediate, while hydroxylamine, an intermediate in AOB, is apparently not involved in anammox. Anammox organisms are strict autotrophs, and apparently use the acetyl-CoA pathway for CO_2 fixation. Their growth is extremely slow, with generation times on the order of 2 weeks. The cells contain an internal membrane-bound 'organelle' called the anammoxosome, in which the anammox reaction is localized. The cell membranes contain unique lipids called ladderanes, after their diagrammatic appearance as a ladder, which form the very dense membrane needed to handle hydrazine as an intermediate, and to prevent its diffusion out of the anammoxosome (van Niftrik and Jetten, 2008). The net reaction for anammox involves a 1:1 combination of ammonium and nitrite in the production of N_2.

$$NO_2^- + NH_4^+ \rightarrow N_2 + 2H_2O$$

Thus, unlike conventional nitrification, anammox results in the loss of fixed nitrogen from the system, and is ecologically equivalent to denitrification, rather than to nitrification. Anammox results in the anaerobic removal of ammonium using nitrite, derived from either aerobic ammonium oxidation or partial denitrification, as the oxidant.

Nitrite-Oxidizing Bacteria

The second functionally defined group of nitrifying microbes is the nitrite-oxidizing bacteria (NOB), which include several genera. The best-known cultivated members, in the genus *Nitrobacter*, are chemolithoautotrophic, like the AOB, using nitrite as an energy source and CO_2 as a carbon source via the Calvin cycle (Bock and Wagner, 2006). However, the lesser know genus, *Nitrospina*, is apparently most abundant in the ocean, and uses the reductive tricarboxylic acid pathway for CO_2 fixation. Many strains are known to possess heterotrophic capabilities and are considered mixotrophic or facultative autotrophs. Although they have limited metabolic capabilities for uptake and degradation of organic molecules, they can supplement their growth with organic carbon and, in some cases, grow slowly in the absence of nitrite when certain organic substrates are present. The oxidation of nitrite is even less energy yielding than ammonia oxidation, so perhaps this ability for heterotrophic growth is not surprising. Aerobic nitrite oxidation proceeds by the following stoichiometry:

$$NO_2^- + 0.5O_2 \rightarrow NO_3^-$$

There are no other pathways, nor any different kinds of bacteria or archaea known to be capable of or involved in nitrite oxidation in the environment. The recent finding of greater diversity among ammonia-oxidizing microbes begs the question, however, of whether additional nitrite oxidation pathways and organisms remain to be discovered.

Heterotrophic Nitrifiers

The ability to nitrify, via pathways involving the inorganic transformations normally associated with the autotrophic nitrifiers described above, or via pathways involving organic intermediates but resulting in the net oxidation of ammonium, has been attributed to some heterotrophic bacteria and fungi. Heterotrophic nitrification does not conserve energy (i.e., is not linked to ATP production) and the rates observed are much slower than rates found in cultivated conventional nitrifiers. Autotrophic nitrifiers are susceptible to inhibition by a number of naturally occurring substances, including secondary metabolites of some trees, for example. AOB are inhibited by acidic conditions, which pertain in some soils. These observations led to the suggestions that heterotrophic nitrification might be particularly important under conditions in some soils that are very unfavorable for known autotrophic nitrifiers. The quantitative importance of heterotrophic nitrification remains uncertain in both aquatic and terrestrial environments.

Ecological Roles of Nitrification

Agricultural and Terrestrial Systems

Nitrogen is the main component of fertilizers applied in many agricultural systems. Addition of N as ammonium is advantageous because it is easily assimilated by plants and, due to its positive charge, it binds to soil particles and is somewhat resistant to loss in runoff. Nitrifying bacteria in the soil can convert the ammonium to nitrate, which is more easily lost in the soil solution, thus reducing the efficiency and increasing the cost of fertilizer application. Nitrification inhibitors are therefore often applied along with fertilizers, to slow down this conversion and increase the amount of N available to the plants.

Not only is the nitrate more susceptible to physical loss from the system, but it is also the substrate for denitrification. If soils become waterlogged to the extent that interstitial spaces become anoxic, denitrifying bacteria present in the soils will switch to anaerobic metabolism, in which they respire oxides of nitrogen, beginning with nitrate, instead of oxygen. Nitrate respiration leads to the removal of nitrate by its conversion to N_2 gas, which is not biologically available to most plants and is lost from the system by evasion. Both ammonia-oxidizing and denitrifying bacteria can carry out the reduction of nitrite to N_2O. For denitrifiers, this is part of the usual pathway from nitrate to N_2 ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$). For AOB, the pathway is analogous but includes only the steps $NO_2^- \rightarrow NO \rightarrow N_2O$ and it is not known what purpose it serves. Most of the N_2O produced by ammonia oxidation is probably produced by AOA via a so far undescribed pathway (Santoro *et al.*, 2011). Especially in low oxygen conditions, substantial nitrogen can be lost as N_2O. Not only is this N lost from the bioavailable pool, but it plays a very important role in the atmosphere as a greenhouse gas. N_2O has a radiative forcing that is on the order of 200 times more potent per molecule than CO_2, the most abundant greenhouse gas. Thus, N_2O fluxes from agricultural systems to the atmosphere are potentially of concern. Management practices that optimize the amount of N added, and the timing and amount of water applied, are important in minimizing N loss both as N_2 and N_2O. Inhibition of nitrification is also widely seen as the main point of control for N loss from agricultural systems, and is practiced by the application of various commercial additives with varying degrees of specificity for nitrification over other microbial processes.

Wastewater Treatment

Waste nitrogen enters the wastewater stream in the form of ammonia, urea, and organic nitrogen. The first steps in wastewater treatment involve oxidative degradation of organic matter, resulting in the conversion of dissolved organic N into ammonium. If released as effluent in this form, the ammonium would fertilize the receiving waters, potentially leading to eutrophication and the growth of undesirable plant life and eventually possibly anoxia. Tertiary wastewater treatment is designed to remove inorganic nitrogen from the stream by nitrification. When carried out by AOB and AOA, this is an obligately aerobic process, and requires aeration to allow the growth and activity of AOB, AOA and NOB to produce nitrate. Water containing the nitrate thus produced is then subjected to an anoxic treatment in which denitrification reduces the nitrate to N_2. In this form, the effluent does not increase the bioavailable N in the receiving waters. Optimization of nitrification in wastewater treatment is the subject of much research, focusing both on the species composition of nitrifying communities in wastewater systems and biofilms, and on the physiology of nitrifiers subjected to the many potentially inhibitory components of wastewater.

Tertiary treatment is an expensive component of wastewater treatment, especially as it involves the cultivation of fastidious microbes and the sequential use of oxic, then anoxic conditions, usually requiring multiple tanks and pumping systems. It is clear, therefore, why the discovery of anammox led to its immediate patenting and a flurry of study on the process. Here is a group of organisms that can oxidize ammonia completely to N_2 in one tank and require nothing but anoxia and a supply of CO_2. In fact, anammox was discovered in an enrichment culture from a wastewater treatment plant, and the real mystery is why it was not found before. This may be due to its slow growth rate; many water treatment plants may have discouraged the development of the anammox process by the timing and conditions of treatment stages. Anammox bacteria have never been grown in pure culture; they apparently require the presence of complex consortia including nitrifiers and or denitrifiers, in order to obtain both ammonium and nitrite in the right proportions. Commercial anammox reactors for wastewater treatment usually involve a mixture of aerobic nitrifiers and anammox bacteria. The nitrifiers produce the nitrite required for anammox, and consume trace oxygen that would inhibit the anammox reaction. Establishment of a stable reactor consortium can require years (Kuenen, 2008).

The Marine Environment

The nitrogen cycle of the ocean is interesting because of the role of N as a limiting nutrient for primary production in the sea, and because the ocean is the ultimate repository for waste from land, in the form of wastewater effluent and natural drainage from rivers. Nitrogen loading in natural waters, from excess fertilizer applications as well as wastewater effluent, has increased in recent decades, such that the impact in coastal waters is now detectable. Nitrification plays a part in both of these processes as described above.

The Ocean Ecosystem

The two primary forms of nitrogen that are available to phytoplankton as nutrients are the same as those used by terrestrial plants, ammonium and nitrate. Ammonium is supplied to surface waters via recycling of organic nitrogen in waste products of grazers and

heterotrophic bacteria. It is rapidly recycled in the euphotic zone (well lit surface layer of the ocean) and usually present in very low concentrations. Nitrate is supplied to the sunlit surface waters by upwelling or wind mixing of deeper waters where nitrate concentrations are generally elevated, or by nitrification of ammonium in near surface waters. Although both ammonium and nitrate are suitable N sources for many phytoplankton, different species of phytoplankton exhibit important differences in their abilities to utilize and grow on them. For example, most clades of the most abundant small phytoplankton, a small cyanobacterium called *Prochlorococcus*, cannot grow on nitrate at all, and some forms cannot utilize nitrite either. Their only inorganic N source is ammonium. *Prochlorococcus* is most important in the oligotrophic central gyres of the oceans, where the mixed layer is so deep that nitrate is rarely mixed into the photic zone; natural selection has evidently led to the loss of genes involved in the assimilation of oxidized nitrogen because they were not useful in this environment.

At the opposite extreme are diatoms, eukaryotic phytoplankton with silicious shells, which are extremely important in upwelling and coastal regimes where nitrate is typically more abundant. Diatoms often show a strong preference for ammonium, presumably because it requires less energy to assimilate than does nitrate. This preference is demonstrated by the observation that in the presence of both ammonium and nitrate, even when the latter is present at much higher concentrations, diatoms will first use up the ammonium before beginning to assimilate nitrate. The irony is, however, that their subsequent growth on nitrate can be much faster than the earlier growth on ammonium. Diatoms can attain very high growth rates on nitrate, and are characteristic bloom formers because they can grow much faster than their grazers can, and thus they avoid predation.

The significance of nitrification in this surface ocean N cycling is the conversion between ammonium and nitrate. The deep ocean has very high nitrate concentrations, while the surface ocean is usually quite depleted in nitrate, and this observation led to the long-held belief that nitrification occurred only in the deep sea. If that were true, then nitrate availability would be controlled by physical processes that somehow mix the deep water up into the sunlit surface zone. In fact, broad patterns of oceanic primary production can be explained at first pass by a consideration of the physical oceanographic constraints on mixing in various regions of the world ocean. It is now known, however, that AOB, AOA and NOB are present in the surface ocean and that the rate of nitrification shows a distinct maximum near the bottom of the euphotic zone. It can be shown in culture, enrichment experiments, and incubations of natural seawater that nitrification, both ammonia and nitrite oxidation, is inhibited by strong light, an observation that likely contributes to the depth distribution of nitrification. Even with maximum nitrification rates near the bottom of the euphotic zone (e.g., at a depth where 5–10% of the surface light intensity penetrates), nitrification can still supply much of the nitrate demand by primary producers. In this situation, nitrate is cycled rapidly too, and contributes to the support of primary production even when present at low levels. The depth distribution of nitrification rates is characterized by a subsurface maximum near the bottom of the euphotic zone, a rapid decrease in rate with increasing depth, and very low rates in the deep ocean (Ward, 2008). The accumulation of nitrate in deep waters is thus explained by its production at very low rates by nitrification and the very slow loss rates; that is, absence of phytoplankton N demand.

The bottom of the euphotic zone is often characterized by a primary nitrite maximum, a small but distinct accumulation of nitrite that usually occurs around the depth of 1% surface light penetration. The origin of this feature has long been debated, and the two main processes thought to be involved are nitrification and nitrate assimilation by phytoplankton. Light plays an important role in both proposed mechanisms. In the case of nitrification, it is proposed that NOB are more sensitive to light inhibition than are the ammonia oxidizers, such that the AOB or AOA are active at slightly more shallow depths than are the NOB (Olson, 1981). Thus, there is a net production of nitrite from ammonium oxidation, but at slightly deeper depths, the NOB are active and remove the nitrite. This is an attractive explanation and is consistent with the widespread occurrence of the primary nitrite maximum at essentially the same relative depth in many parts of the ocean. The alternative explanation is that phytoplankton involved in assimilation of nitrate find themselves severely light, and therefore energy, limited at this depth (Lomas and Lipschultz, 2006). After taking up nitrate, they are unable to obtain the reducing power necessary for its complete reduction to ammonium for incorporation into biomass, and release some of it as nitrite. Both of these mechanisms might result in diel, as well as seasonal, variability in the feature. Both processes probably contribute the primary nitrite maximum, and their relative contributions vary with system and season.

The distributions of AOB, AOA and NOB are now much more well known due to recent advances in enumeration technology. AOA are generally more abundant than AOB and often show a depth distribution that is closely correlated with distribution of ammonium oxidation rate; i.e., low numbers in surface waters, a discrete subsurface maximum and decreasing numbers with depth. The depth distribution of NOB has been investigated very rarely; NOB are generally less abundant that AOA and likely have a similar depth distribution. Isotopic methods for measurement of nitrification rates are not dependent upon the kind of organism responsible for the process, and they generally show that rates decrease rapidly with increasing depth. This is consistent with the general pattern of decreasing biological activity overall with increasing distance from the surface layer.

Oxygen-Depleted Waters and Sediments

In addition to its role in controlling the nitrate distribution in the ocean, nitrification performs the same role in the ocean as it does in agriculture and wastewater treatment, in linking ammonium regeneration to denitrification and thus facilitating the conversion of organic N to N_2 (see Denitrification). In the ocean, denitrification is restricted to sediments and to a few regions of the water column where organic supply and ocean circulation cooperate to limit oxygen concentrations to very low levels. Three such regions account for essentially all of the water column denitrification in the ocean: the eastern tropical North Pacific (the Mexican Margin),

the eastern tropical South Pacific (the Peru upwelling region), and the Arabian Sea (Devol, 2008). These regions are characterized by high surface productivity and limited intermediate water renewal, so that water in the depth interval of about 80–1000 m is very low in oxygen. In this interval, oxygen concentration is low enough that denitrification can occur, and nitrifier denitrification is also enhanced, leading to N_2O production. It is not known how much nitrification and denitrification each contribute to the N_2O flux, but these oceanic regions are responsible for most of the atmospheric N_2O flux from the ocean.

As in other regions of the ocean, nitrification rates are generally highest in the near subsurface region of oxygen minimum zones (OMZs), where there is usually a strong primary nitrite maximum. OMZs are also characterized by the presence of a strong secondary nitrite maximum (**Fig. 1**), usually at the heart of the low-oxygen depth interval where it is assumed that oxygen concentrations are too low to support conventional aerobic nitrification. Nitrite concentration in the secondary nitrite maximum can be much higher than found in the primary nitrite maximum, and is thought to derive from partial denitrification, although an adequate mechanism has never been proved.

Nitrous oxide also has a characteristic distribution in OMZs (**Fig. 1**), typically exhibiting two maxima; one occurs just below the primary nitrite maximum and is often attributed to nitrifier denitrification. The second N_2O maximum occurs below the secondary nitrite maximum and is usually attributed to denitrification. At the depth interval of the secondary nitrite maximum itself, N_2O is at a minimum, and its undersaturation here is attributed to complete denitrification. Although the main processes involved in the maintenance of these characteristic distributions are probably known (i.e., nitrification, denitrification, anammox), the mechanisms by which they are regulated to result in such predictable distributions is unknown.

Anammox does not produce or consume N_2O but can be an important component of the total fixed N loss in OMZ regions, because it contributes to the production of N_2. On a global basis, its contribution to fixed N loss is regulated by the stoichiometry of organic matter that is degraded in the OMZs and averages about 29%, with denitrification responsible for the rest (Dalsgaard *et al.*, 2012).

Coastal regions that receive nitrogen-rich runoff from land are susceptible to nutrient enrichment leading to eutrophication. This can also lead to low-oxygen conditions in the shallow bottom water, and thence to the production of N_2O and fixed N loss via denitrification and anammox, as described for the low-oxygen oceanic regimes. Both coastal and oceanic low-oxygen regions are likely to be sensitive to environmental change brought about by changes in nutrient loading and stratification, both factors that respond to anthropogenic forcing of the atmosphere and land systems. Denitrification, nitrification, and anammox are all sensitive to oxygen concentration, so the extent of oxygen-depleted waters may have a major effect on the overall N budget of the oceans.

Coupled nitrification/denitrification and anammox are also very important in the N cycle of marine sediments. Approximately half the N_2 production via anaerobic organic matter degradation is derived from anoxic sediments, where degradation by aerobic heterotrophs of organic matter settling down from overlying waters leads to consumption of oxygen in the sediments. Ammonium released from both aerobic and anaerobic decomposition of organic matter diffuses into the oxygenated zone of surface sediments and is nitrified to nitrate. Nitrification is often identified as the main sink term for oxygen in oceanic sediments. Conventional nitrification can be coupled to denitrification by the diffusion of intermediates and end products across the oxic/anoxic gradient

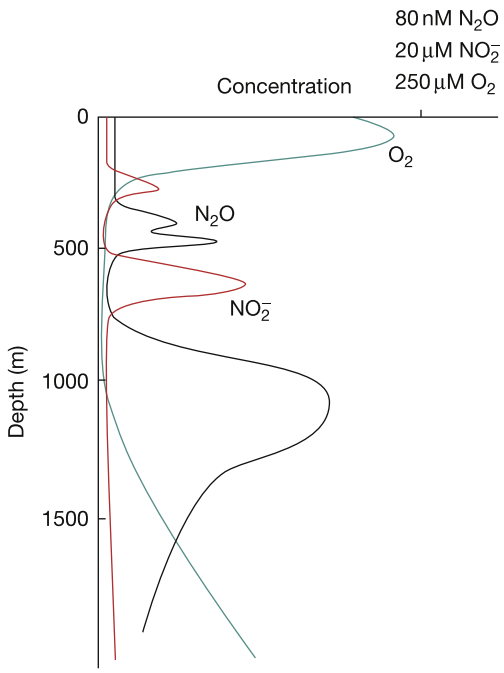

Fig. 1 Characteristic distributions of nitrite (NO_2^-) nitrous oxide (N_2O) and oxygen (O_2) in the water column of an oxygen minimum zone (OMZ) in the ocean. Concentration axis shows the scale for each plotted variable.

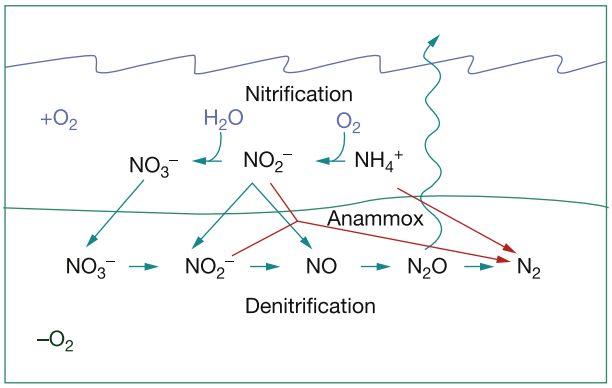

Fig. 2 Interactions between nitrification, denitrification, and anammox across the oxic ($+O_2$)/anoxic ($-O_2$) interface in a marine sediment. In the oxic layer (above the green line) nitrification oxidizes ammonium to nitrate. Nitrate and nitrite diffuse into the anoxic layer where they can be denitrified or used in combination with ammonium for anammox. Both denitrification and anammox are ultimately dependent upon nitrification for the production of oxidized N species, which are reduced to N_2 gas.

near the surface sediment. Similarly, anammox is dependent upon supply of oxidants (nitrate or nitrite) that are ultimately derived from conventional nitrification (Fig. 2). Both conventional nitrification, coupled to denitrification, and anammox are important in sediment systems, and because of the metabolic differences (especially their relationships to oxygen and organic matter) among the organisms responsible, it is likely that their contributions vary greatly among estuarine, shallow, and deep marine systems.

Environmental Factors that Affect Nitrification

Several environmental factors that might control nitrification in various ecosystems have already been mentioned. They include the kinds of things that affect biological processes in general, as well as those particular to the metabolism of nitrifiers: temperature, salinity, light, organic matter concentrations, substrate (ammonium and nitrite) concentrations, pH, and oxygen concentration. A few of the interesting and unique interactions of nitrifiers with their environment are explored below.

Ammonium, the primary substrate for AOB and AOA, is rarely abundant in oxic environments, so the rate of nitrification is likely to be at least partially controlled by substrate limitation. Most cultivated AOB have affinities for ammonium that preclude their being effective competitors for ammonium in the ocean. The one cultivated marine AOA strain, however, has a very high affinity for ammonium (Martens-Habbena *et al.*, 2009), as do natural assemblages (Newell *et al.*, 2013). The absence of ammonium in the deep ocean, where sinking organic material is mineralized to produce ammonium, speaks to the efficiency with which AOA, and to a lesser extent AOB, remove it.

AOB, AOA and NOB require molecular oxygen for their metabolism and thus are restricted to oxic environments. Nonetheless, they seem to prefer and to do quite well under very low oxygen conditions, displaying a microaerophilic lifestyle. Anammox organisms, in contrast, are strictly anaerobic, and while oxygen apparently does not kill them, it does inhibit their activity. Thus, oxygen concentration, in the bulk water of aquatic environments and in the interstices of sediments and soils, is likely a very important variable for regulation of microbial activities and the resulting distribution of nitrogen-cycling processes.

All of the nitrifying microorganisms are predominantly autotrophs, that is, they fix their own carbon from CO_2, and thus do not rely on a supply of organic matter for nutrition. This means that they are not in competition with heterotrophs for the utilization of organic substrates, but rather that they exploit a different niche. This niche involves certain 'sacrifices', in terms of slower growth rates (see Units of Selection). These forms of autotrophic growth are also quite inefficient, due to the low energy yield of the transformations involved. Thus nitrifiers process large amounts of nitrogen in order to obtain the energy required for CO_2 fixation. The molar ratio of N oxidized to C fixed has been estimated at 25–100 for AOB, AOA and NOB, ensuring that their metabolism has a very large effect on the nitrogen cycle, but very little influence on the carbon cycle, where photosynthetic autotrophs are overwhelmingly important.

Light inhibition of nitrifiers is suspected as a mechanism for the formation of the primary nitrite maximum (see above) and it is easily demonstrated in culture that both AOB and NOB are sensitive to light. Cultivated AOA are at least as light sensitive as AOB, perhaps even more so (Merbt *et al.*, 2011). The basis for the light sensitivity of AOB and NOB is assumed to be damage to the many cytochromes that are involved in the energy transduction pathways of nitrification. AOA do contain cytochromes, so light sensitivity must be yet another way in which AOA and AOB exhibit similar physiologies but for different reasons.

Any transformation that involves the production or consumption of hydrogen ions is pH sensitive, and ammonia oxidation is no exception (see Acidification). Oxidation of ammonia by AOB and AOA results in the acidification of the medium. Low pH eventually inhibits both groups in culture, and activity can be restored by pH adjustment. Ammonia oxidation rates in the ocean were reduced by increased acidification, suggesting that nitrification might be affected by ocean acidification due to increased CO_2 concentrations in the atmosphere and ocean (Beman *et al.*, 2011). Short term experiments, however, may overestimate the

response to lowered pH, so the sensitivity of nitrification to long term global change is unknown. It is unlikely that pH is an important controlling variable in the ocean, even in sediments, but pH could be very important in regulation of nitrification in acid soils. While nitrification generally occurs in acid soils, it has proven difficult to obtain acidophilic nitrifiers in culture, leading to speculation about the importance of heterotrophic nitrification in this system. It is now known that many of the kinds of nitrifying bacteria that can be identified by their gene sequences in the natural environment, are not in fact represented in culture collections. Thus it is quite possible that acidophilic autotrophic nitrifiers exist but are resistant to cultivation.

Salinity and temperature do not appear to set any unusual constraints on the range of conditions under which nitrification can occur, and different kinds of nitrifiers appear to have adapted to the wide range of these variables found on Earth. The mechanism by which salinity affects nitrification is not known, but it is clear that salinity is an important determinant of the community composition of nitrifying microbes, if not the net rate of nitrification; that is, different kinds of nitrifiers are adapted to different salinity levels, but nitrification occurs under high as well as low salinity and depends on the presence of different species. Nevertheless, it can be shown that salinity dramatically affects the rate of nitrification, when salinity changes are imposed in an experiment with natural assemblages. Ionic strength effects related to the sorption and availability of ammonium are not sufficient to explain the effects of salinity.

Methods for Measurement of Nitrification Rates

^{15}N Tracer Methods

The best method for quantification of nitrification rates remains the direct ^{15}N tracer approach in which a small amount of either $^{15}NH_4^+$ or $^{15}NO_2^-$ is added to a sample and incubated (Ward, 2010). The labeled product, $^{15}NO_2^-$ or $^{15}NO_3^-$, is then extracted and measured on a mass spectrometer. This approach has suffered in the past from the necessity to enrich the substrate pool by the addition of large concentrations of ^{15}N-ammonia or -nitrite, thus artificially enhancing the observed rate. Improvements in assay techniques and mass spectrometer sensitivity with small N masses have minimized this problem.

The same analytical approaches can be applied in a tracer or isotope dilution format. In the isotope dilution format, label is added to the product pool and its dilution by addition of new product with natural abundance isotopic signature during the incubation provides an estimate of production rate.

The advantages of the direct ^{15}N approaches, compared to inhibitor methods, include shorter, thus less artifactual, incubations, minimal perturbations to *in situ* conditions (ambient light and nutrient conditions can be used), and much greater sensitivity. Inhibitor-based assays have the advantage, however, of requiring simpler less expensive instrumentation, as colorimetric, rather than mass spectrometric, analysis usually suffices.

Inhibitor-Based Nitrification Assays

Inhibitor methods depend on the ability of many compounds to interact specifically with the active site of the ammonia monooxygenase (AMO) or nitrite oxidoreductase (NXR) enzyme. A large number of potential inhibitors has been used for AMO, while chlorate is still the only specific inhibitor reported for nitrite oxidation. Replicate incubations are carried out in the dark with additions of either AMO or NXR inhibitors and the changes in inorganic N concentrations are used to infer nitrification rates. A more sensitive permutation of this approach involves measurement of $^{14}CO_2$ fixation in the presence and absence of inhibitor, where the decrease in the rate of $^{14}CO_2$ assimilation in the presence of nitrifier inhibitor is attributed to nitrification (Rees *et al.*, 2002). A conversion between CO_2 fixation and N oxidation rates is then used to estimate nitrification.

One of the main attractions of the inhibitor approaches is their ease of use and analysis. Scintillation counters are much more common and easier to use than instruments required for stable isotope analysis and inorganic N determinations involve analytical methods that are already standard to most laboratories. Although the inhibitor approaches are usually not appropriate for absolute rate measurements (because of uncertainty in conversion factors and perturbations during incubations) they can be very useful for spatial or temporal comparisons within studies.

Physical Transport Processes in Ecology: Advection, Diffusion, and Dispersion

A Marion, University of Padua, Padua, Italy

Introduction

Most of us experience physical transport of mass and heat in fluids several times in a day. Mass transport is indeed one of the first processes we deal with every day, when we sit in front of our cup of coffee or tea. Our first action is to stir the fluid in the cup, to mix or blend the sugar uniformly in the fluid. We succeed by generating a highly turbulent flow field where mass is displaced very rapidly within the fluid domain. We continually perform countless actions, including breathing, which aim at enhancing or reducing the physical transport of mass in a fluid.

Physical transport of mass and heat in fluids not only occurs in human behavior, but it is also an inherent part of life in all forms, and plays a fundamental role in the fate of organic as well as inorganic matter. In ecological systems, the fate of substances such as nutrients and toxic matter is of fundamental importance and has received increasing attention in the last decades. The aim of these studies is to explain and model how substances move within and across media, typically water or air, and to estimate what concentration the substance may attain in the domain of interest at any given time. The need to understand the complex physical, chemical, and biological interactions in the environment leads to a wide increase of interdisciplinary studies involving physicists, ecologists, biologists, and engineers, to the development of new branches of science, such as biogeochemistry and environmental engineering, and even to the identification of new physical domains of interests, typically at the interface between the elements (water–soil, soil–air, water–air).

The starting point of the discussion on the physical transport of mass is the evidence that, unless temperature vanishes in absolute terms (0 K = − 273 °C), matter moves. Electrons move within atoms, atoms move within molecules, and molecules move within cells and bodies. Even the condition we normally refer to as stillness involves movement, although only at scales that are invisible or imperceptible to our senses. Some examples are trivial: a drop of ink in water is expected to spread in all directions even if the water is motionless! We call this process molecular diffusion – it is the result of small displacements of molecules about their position, a process known as Brownian motion. The displacement of molecules increases with the rise in temperature. While molecules agitate about their local position, we perceive a natural tendency of matter to transfer from regions of high concentration to regions of low concentration. This transfer only stops when the substance is uniformly distributed in the physical domain. However, if Brownian motion is the only cause of mixing, the process is extremely slow and may become negligible when other transport processes are present.

Since ecology is interested in the description of processes at a scale much bigger than the molecular size, a model which describes mass flux as proportional to the gradient of the concentration is sufficient to describe diffusion in still fluids. Such a model, called Fick's law, will be discussed in the section devoted to diffusion. At this point, it is worth noticing that (1) molecular diffusion is active even in the absence of perceivable motion in the fluid, that is, it is the basic process of mass transfer; and (2) diffusion is to be considered an upscaling model rather than a true physical process, as it is a model description of the combined effect of a multitude of individual displacements.

Advection

Advection is defined as the transport of a conserved scalar quantity that is transported in a vector field.

In ecology, the scalar quantity is the mass of transported substance (or its amount per unit volume, called concentration C [ML^{-3}]), while the vector field is the fluid flow field, identified by the three components of a velocity vector $\mathbf{v} = (u, v, w)$ [LT^{-1}] defined at each point as a function of time. In the case of transport of heat, the discussion still holds, as long as the concentration of mass is substituted by the concentration of heat, which is normally expressed proportional to temperature. If the substance behaves like a solute, that is, has the same density as the medium or does not feel significant effect of its buoyant weight, each element of it (molecule or particle) will be displaced along the direction of the local velocity vector following the same path as if it were an element of the medium. This assumption allows the advective transport to be modeled in a relatively simple way. The mass flux Φ[$ML^{-2}T^{-1}$] through a small area normal to direction $\mathbf{n}$ can simply be written as the product of the local concentration times the component of the local velocity vector along $\mathbf{n}$ (Fig. 1):

$$\Phi_n = C\mathrm{v}\cdot\mathrm{n} = Cv_n \qquad [1]$$

In more general terms, the flux vector can be written as

$$\Phi(\mathrm{x}, t) = C(\mathrm{x}, t)\mathrm{v}(\mathrm{x}, t) \qquad [2]$$

where $\mathrm{x} = (x, y, z)$ is the position in Cartesian coordinates and t is time.

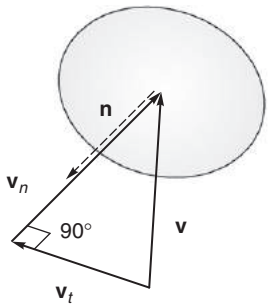

Fig. 1 Schematic of the physical quantities used in eqn [1]. The velocity field generates advective flux through an area only if it has a component in the direction orthogonal to the area, i.e., if $\mathbf{v} \cdot \mathbf{n} \neq 0$.

Deriving a mass balance for a control volume leads to the following differential equation:

$$\frac{\partial C}{\partial t} = -\nabla \cdot \Phi \qquad [3]$$

$$\frac{\partial C}{\partial t} = -\nabla \cdot (C\mathrm{v}) = -\left[\frac{\partial (Cu)}{\partial x} + \frac{\partial (Cv)}{\partial y} + \frac{\partial (Cw)}{\partial z}\right] \qquad [4]$$

where the symbol $(\nabla.)$ indicates the divergence applied to a vector quantity.

The continuity equation shown above can be simplified further if the flow field is solenoidal, that is, the divergence of the velocity is zero $(\nabla.\mathrm{v} = 0)$. This condition applies to incompressible fluids, such as all liquid media found in ecological applications. Under this assumption, the continuity equation simplifies to

$$\frac{\partial C(x,y,z,t)}{\partial t} + u(x,y,z,t)\frac{\partial C(x,y,z,t)}{\partial x} + v(x,y,z,t)\frac{\partial C(x,y,z,t)}{\partial y} + w(x,y,z,t)\frac{\partial C(x,y,z,t)}{\partial z} = 0 \qquad [5]$$

It is simple to show (but omitted here for brevity) that for steady conditions, the solution of eqn [5] is a simple translation of the substance along the paths imposed by the flow field. Although this may not be good representation of the 'diffusive' reality as we experience it, the advective model finds important applications.

Pure advection does not exist alone in nature, as it is always associated at least to molecular diffusion, as discussed above. However, the significance of molecular diffusion in an advective process is negligible in most cases, due to the extremely low value of the diffusive flux. Advection is associated to only molecular diffusion when the flow field is slow, such as in laminar flows. One common application is the flow of water carrying substances in a porous medium, such as an aquifer or the hyporheic zone, as long as the process is modeled at the scale of the pores of the medium. Another useful property of the mass balance equation, valid also when diffusion is significant, is that the center of mass of the substance is subject to advective transport. This is often a sufficient tool to estimate the travel time of a mass of substance between two points of the domain, that is, two locations along a river. The substance disperses in the domain, but its average travel time is always determined by the advective part of the process. Another application is the modeling of the transport of buoyant or heavy substances. These substances are affected by gravity, as their density is either smaller or larger than the density of the medium. Examples are the transport of colloids and suspended solids in water and in air. Particles are subject to the pulsating action of the flow and follow very irregular trajectories. Their behavior is often modeled by the addition of an advective effect, usually defined by a vertical velocity with an intensity dependent on the particle size, shape, and density.

Although the concept of advection and its mathematical description are quite simple, the solution of advective processes of ecological interest in complex flows poses a rather difficult task to modelers. The advection equation is not simple to solve numerically, particularly when strong gradients of concentration (shocks) are treated. Complications arise because numerical methods are indeed curiously affected by a form of diffusion, in this case numerical diffusion rather than the physical one.

Diffusion

One definition of diffusion is the spontaneous spreading of matter, heat, or momentum. Such definition is rather general, and does not differentiate the process based on the cause of the spreading. A key feature of all diffusion processes is the flux of mass from higher to lower concentration.

Diffusion is a spontaneous process that occurs as a result of the second law of thermodynamics, which states that the entropy or disorder of any closed system must always increase with time. The effect of diffusion can only be counteracted by expenditure of external energy. Because substances diffuse from regions of higher concentration to regions of lower concentration, transport occurs only if there is a spatial variation of the concentration. In all cases of diffusion, the net flux of the transported substance is expressed as equal to a physical property (diffusivity, D $[\mathrm{L}^2\mathrm{T}^{-1}]$) multiplied by a concentration gradient:

$$\Phi_n = -D\frac{\partial C}{\partial n} \text{ or } \Phi(\mathrm{x},t) = -D(\mathrm{x},t)\nabla C(\mathrm{x},t) \quad [6]$$

where the symbol (∇) indicates the gradient differential operator.

In molecular diffusion, eqn [6] is written with $D=D_{\mathrm{m}}$ independent of C and is known as Fick's first law.

All diffusion processes are modeled through the diffusion equation, which, in its general form, is a nonlinear partial differential equation obtained combining [3] with [6]:

$$\frac{\partial C}{\partial t} = \nabla\cdot[D\nabla C] = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) + \frac{\partial}{\partial y}\left(D\frac{\partial C}{\partial y}\right) + \frac{\partial}{\partial z}\left(D\frac{\partial C}{\partial z}\right) \quad [7]$$

When D is constant, as in the case of molecular diffusion, eqn [7] reduces to Fick's second law (or heat equation):

$$\frac{\partial C(\mathrm{x},t)}{\partial t} = D_m\nabla^2 C(\mathrm{x},t) = D_m\left[\frac{\partial^2 C(\mathrm{x},t)}{\partial x^2} + \frac{\partial^2 C(\mathrm{x},t)}{\partial y^2} + \frac{\partial^2 C(\mathrm{x},t)}{\partial z^2}\right] \quad [8]$$

The value of the molecular diffusion coefficient varies according to the combination of solute and solvent. As far as water is concerned, molecular diffusion is easier for polar molecules such as salt and sugar due to the interactions with polar water molecules. The molecular diffusion coefficient is of the order of $10^{-9} - 10^{-8}$ m^2 s^{-1}. Conversely, apolar molecules like oils and proteins are subject to hydrophobic effects and diffuse in water at a lesser rate. The molecular diffusion coefficient for these substances is of the order of 10^{-10} m^2 s^{-1}.

Combined Advection–Diffusion Processes

Whenever the fluid is in motion, advective transport and diffusive transport act simultaneously. The complexity arising for the combined effects can be treated mathematically by simply adding the advective and diffusive fluxes indicated in eqns [4] and [7]:

$$\frac{\partial C}{\partial t} = -\nabla\cdot(C\mathrm{v}) + \nabla\cdot[D\nabla C] \quad [9]$$

For incompressible fluids, eqn [9] becomes

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial y} + w\frac{\partial C}{\partial z} = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) + \frac{\partial}{\partial y}\left(D\frac{\partial C}{\partial y}\right) + \frac{\partial}{\partial z}\left(D\frac{\partial C}{\partial z}\right) \quad [10]$$

Finally, if diffusion is only of the molecular type, eqn [10] reduces to

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial y} + w\frac{\partial C}{\partial z} = D_m\left[\frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2} + \frac{\partial^2 C}{\partial z^2}\right] \quad [11]$$

The overall effect of the superposition of advection and diffusion can be visualized as the translation of the center of mass of the substance according to the advective part, while mass diffuses around the center of mass at a rate dictated by the diffusive term, as shown in **Fig. 2**.

Turbulent Diffusion

Molecular diffusion produced by Brownian motion is no longer the dominant diffusion mechanism when the flow velocity becomes fast enough to overcome viscous forces that tend to keep fluid elements aligned along parallel paths. When this threshold is reached, the flow becomes very irregular, and the fluid elements are entrained and transported by eddies which form either from the slowing effect of the bottom and side boundaries or from the disturbances introduced by geometrical irregularities. This type of flow is called turbulent, and it is characterized by an enhanced momentum and mass transfer across the flow field. Diffusion of mass is no longer controlled by Brownian motion, but rather by the continuous displacement of fluid elements in all directions induced by turbulence. While molecular diffusion is isotropic, turbulent diffusion is often different in all directions, as eddies are continuously stretched and deformed by the flow.

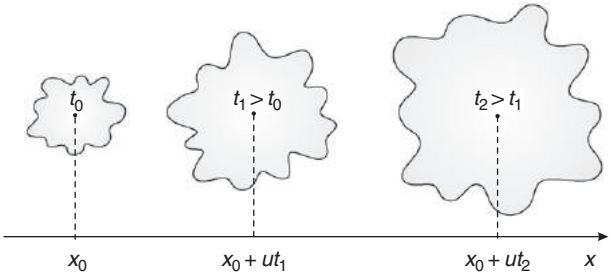

Fig. 2 The combined effect of one-dimensional advection and diffusion on a cloud. The center of mass travels according to the advective process, while the cloud spreads around the center of mass at a rate dictated by diffusion.

Turbulent flows are usually modeled splitting the physical quantities into time-averaged mean values and fluctuations around the mean. After manipulation of the advection–diffusion equation [11], a new mathematical transport term appears, which is the time-averaged product of the fluctuating values of velocity and concentration. If velocity and concentration fluctuations were statistically independent, then these terms would produce no net diffusive mass fluxes. It turns out instead that velocity and concentration irregularities are correlated and that the integral effect over time of turbulent fluxes is always much higher than the fluxes induced by Brownian motion. The mass transport equation can no longer be written as in eqn [11], but it becomes

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial y} + w\frac{\partial C}{\partial z} = \frac{\partial}{\partial x}\left(D_x\frac{\partial C}{\partial x}\right) + \frac{\partial}{\partial y}\left(D_y\frac{\partial C}{\partial y}\right) + \frac{\partial}{\partial z}\left(D_z\frac{\partial C}{\partial z}\right) \quad [12]$$

where D_x, D_y, and D_z are called eddy diffusion coefficients, are direction dependent, and so much larger than the molecular diffusion coefficient D_m to replace it in all terms of the equation. The conceptual difference between eqns [12] and [11] is that the value of the coefficients D_x, D_y, and D_z is now determined by the flow regime, that is, they are flow properties, while D_m was independent of the flow and determined only by the combination of solute and solvent. Another difference resides in the fact that eddy diffusivity is scale dependent, while molecular diffusivity is scale independent. Eddy diffusivity typically scales with a 4/3 power of the length scale of the process. This implies that as diffusion makes the substance spread in the domain, diffusivity increases due to the effect of larger eddies that come into play. This dependence is important in large and deep water bodies such as the sea or lakes, where the diffusion process involves several different scales over time. In rivers, instead, the size of the eddies is controlled by water depth and width, and diffusivity is no longer affected by the scale of the process. Typical values of eddy diffusion coefficients are $10^{-6} - 10^{-4}$ m^2 s^{-1} in slow-moving, deep, and stratified water bodies such as lakes and the sea, $10^{-2} - 10$ m^2 s^{-1} for horizontal surface flows such as rivers and channels.

Dispersion

The word dispersion has several meanings. In physics, it is often used to describe the process of separation of the components of waves with different frequency. In chemistry, a dispersion is a system of fine particles uniformly distributed in a medium. Other definitions apply to biological concepts and a few other technical areas. When dealing with mass transport, dispersion is defined as the combined effect of advection and diffusion acting in a flow field with velocity gradients. This is why it is sometimes referred to as 'shear dispersion'.

The presence of velocity gradients on the fate of the substance becomes apparent when spatial averaging of the physical quantities is carried out along with the temporal averaging described in the section on turbulent diffusion. In surface water bodies, it is often convenient to simplify the description of mass transfer by averaging velocity and concentration over the vertical direction (shallow water approach) or over a cross section (unidirectional approach). If quantities are depth-integrated, they are then described only as a function of the two planimetric Cartesian coordinates, that is, $\overline{C}(x, y, t)$ and $\mathbf{v}(x, y, t)$ (the overbar indicates averaged values). Depth averaging is justified when dealing with large rivers, estuaries, and lagoons, using the the evidence that vertical mixing is usually much faster than lateral and longitudinal mixing, due to the limited extension of the domain in the vertical direction. If the physical quantities are averaged over a cross section, their description is limited to the distribution along the longitudinal direction, that is, $\overline{C}(x, t)$ and $\mathbf{v}$(x,t). The one-dimensional approach is justified when the transverse dimensions of the domain are small compared to the longitudinal dimension. This is the reason why the one-dimensional approach is commonly adopted for dispersion processes in rivers and channels.

The comprehension of the physical mechanism leading to dispersion may be improved by the example presented in **Fig. 3**. Case 1 shows a shear flow in a highly turbulent environment. It is a vertical two-dimensional flow, just for the sake of simplicity, which can easily be generalized to a three-dimensional flow. The horizontal arrows represent the time-averaged velocity field. In these conditions, while solute molecules are transported along the flow by the mean velocity, they are displaced vertically (or laterally) by turbulence. Each molecule rapidly samples regions of the domain characterized by high velocity as well as regions characterized by slow velocity. Due to high turbulent mixing, after a sufficiently long time, all molecules are expected to travel a similar distance downstream, at an average velocity close to the mean flow velocity. The overall result is that mass is advected downstream with relatively small dispersion, that is, without spreading along the longitudinal direction. Case 2 shows instead a similar flow field with a much smaller turbulence intensity. The limited mixing does not allow for the displacement of solutes far from their original location. Elements like A are likely to remain in relatively fast flow regions while elements like B are likely to stay in regions of slow advection. The overall result in this case is a rapid increase of the distance between elements over time, that is, rapid dispersive spreading of mass along the flow direction. It is apparent that, when averaged concentrations are used, dispersion is counteracted by turbulent diffusion. The diagram in **Fig. 3** shows the qualitative response of cases 1 and 2 to a slug injection of mass. In case 1, the depth-averaged concentration remains more concentrated while being advected downstream. In case 2, dispersion is much more efficient due to small vertical mixing.

This result, which may appear surprising at first, finds unambiguous confirmation in all dispersion models. If dispersion is modeled over sufficiently long timescales, it can be proven to be well approximated by a Fickian process. Dispersion models are

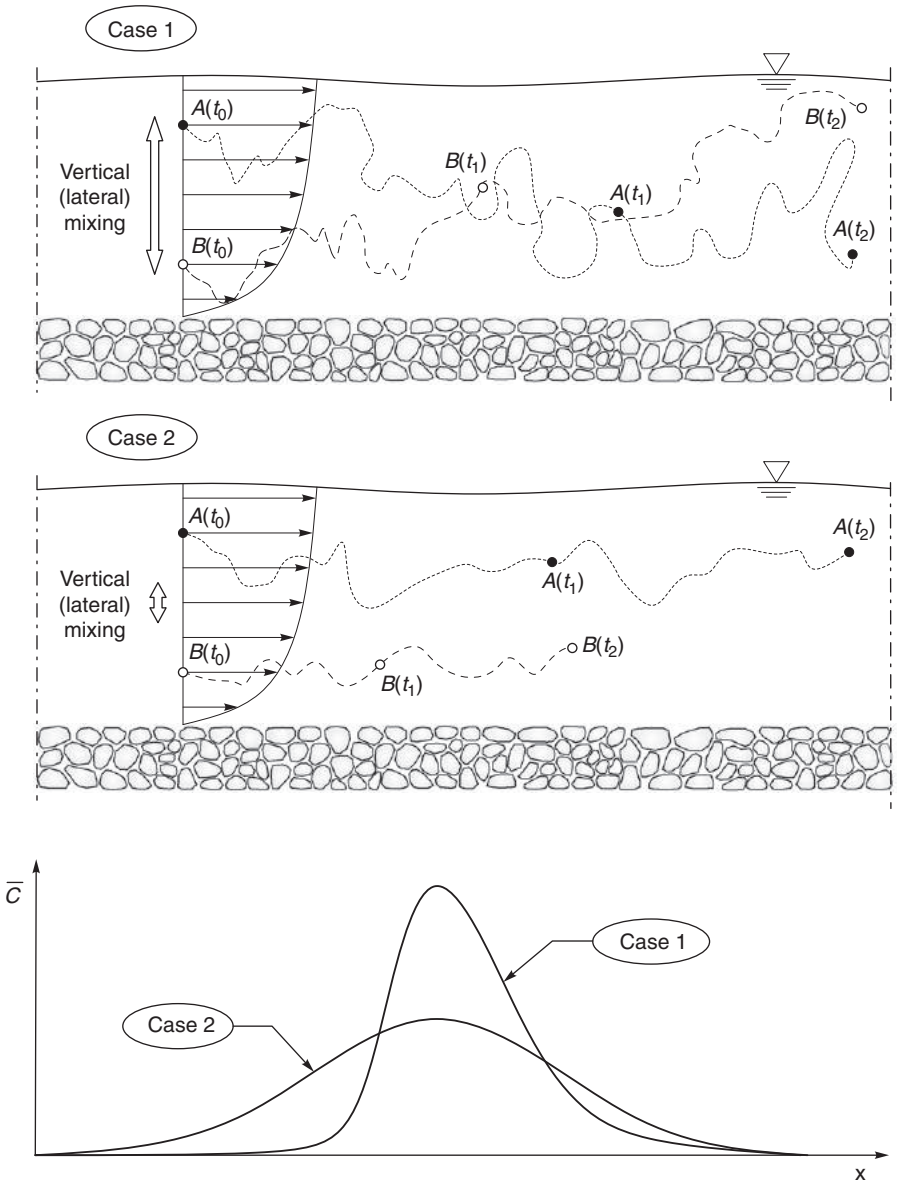

Fig. 3 Schematic of the transport processes affecting shear dispersion. Case 1 shows transport of elements *A* and *B* in a shear flow with high turbulent mixing. Case 2 shows transport of the same elements in a shear flow with low turbulent mixing. The graph shows the response of the two flows to a pulse injection of mass.

therefore mathematically equivalent to advection–diffusion models. For example, in the simplest case of cross-sectional averaging of the physical quantities, the dispersion equation can be reduced to the one-dimensional form:

$$\frac{\partial \overline{C}(x,t)}{\partial t} + \overline{u}(x,t)\frac{\partial \overline{C}(x,t)}{\partial x} = \frac{\partial}{\partial x}\left(D_x^{\mathrm{L}}(x,t)\frac{\partial \overline{C}(x,t)}{\partial x}\right) \quad [13]$$

where D_x^{L} is the longitudinal dispersion coefficient which turns out to be proportional to the spatial variability of the flow field around its mean value and inversely proportional to the turbulent diffusivity. The value of the dispersion coefficient may vary by a few orders of magnitude according to application. The reader is invited to read specialist books and papers to obtain predictions and estimates of the dispersion coefficient.

Predation and Its Effects on Individuals: From Individual to Species

Patricio Lagos, uBiome Inc., Santiago, Chile

Glossary

Aposematism A warning signal present in some species, directed to predators, that informs them about the unpalability or unprofitability of the aposematic individual.

Community Assembly of populations of different species and their interactions, inhabiting the same space and time.

Key species In community ecology, it refers to the species whose effect on the structure of the community is larger than its mere contribution in abundance. The key species is usually a predator that feeds on the dominant competitor (i.e., the individual that dominates in abundance the community in absence of the key species). When a key species is present, the diversity in the community is larger than when it is not present.

Lotka–Volterra equations A set of two models of population dynamics that considers the effect of the predator–prey interaction on the change in abundances of individuals in populations, based on the rates of growth, the effect of predation on prey and how prey consumed contribute to the increase in the number of predators.

Landscape of fear A behavioral trait of an animal, that provides spatially dependent measure of the perceived risk of predation by the individual, and the cost and benefits of foraging or inhabiting the area available.

Population Group of individuals of the same species, occupying the same space and time.

Predation Interaction between two individuals, where one of the individuals benefits from the interaction (i.e., the predator) whereas the other is harmed (i.e., the prey). It includes the carnivory, herbivory, parasitism, parasitoidism, and pathogen–host interaction.

Parasitoidism A particular case of predation, where the adult individual is free-living, but deposits its larvae inside a host. The larvae then feeds on the host and finally kills it.

The study of ecology is, in many aspects, the study of the interactions between individuals. These interactions can differ according to which individuals are positively affected from the interaction and which ones are negatively affected by it. Thus, those cases where both individuals benefit from the interaction are known as mutualism, whereas the case when the interaction is negative for both individuals involved, it is usually known as competition. One important case is positive for one of the individuals, but negative for the other. Some authors refer to these interactions as exploitation, but are more commonly known as predation.

Predation is an interaction between two organisms, where one, the predator, consumes the other the prey, while it is still alive. Predation falls in the category of "exploitation" interactions, where one of the individuals consumes the other. Besides predation, some other examples of exploitation are herbivory (and herbivore that consumes a plant), parasitism (an organism that lives in the tissues of its host, at the expense of it) and parasitoidism (as in parasitism, but the parasite's larvae live in the host's tissues). For some authors, however, predation involves any interaction between species were one consumes partially or totally the other. Here, the focus will be placed in this definition, as it offers a broader spectrum of scenarios to describe the interaction.

Predation, as a consumption interaction, has obvious effects at the individual level, as can reduce the prey's fitness to zero. But does not stop there. In fact, the effects of predation scale up to the population level, determining distinctive patterns in the dynamic of populations. Furthermore, predation plays a role in defining the structure of communities. Lastly, as the predator–prey interactions have strong effects on the fitness of both prey and predators, it is probably the strongest way natural selection has to drive the evolution of the species, determining the frequency of important traits in populations.

Predation at Individual Level

Predator–Prey Interactions: Avoiding Predation

An important part of an animal activities are preventing been consumed by others. Similarly, carnivores spent their day searching for prey to consume. A variety of strategies have evolved for both predator and prey to optimize (i.e., maximizing the benefits and minimizing the costs) either their hunting performance or surviving predation. Looking at the prey's perspective may result very useful in order to understand how important predation is, as we can see how predator push the evolution of species in one or another direction.

Morphological, physiological and behavioral traits are usual targets for natural selection, leading to in many cases, sophisticated mechanisms used by prey to avoid or minimize the risk of predation. The body armor of the armadillo, thorns of the thorny dragon and shells in Mollusca are some examples of how natural selection has favored morphological traits that provide a defense against the attack of predators. Animals that rely on these defense incur in an important energetic cost in order to produce the structures, and energy must be allocated to this rather than growth or reproduction. For example, under risk of predation, tadpoles of the species *Rana dalmatina* develop larger and more muscular tails, enabling them to escape further and faster (Teplitsky *et al.*, 2005). However, tadpoles under risk of predation suffered of reduced rates of growth (Van Buskirk, 2000).

Similarly, different physiological attributes in prey individuals are affected by predation pressure, so much so that the concept of "non-consumptive effects of predation" has been coined. For instance, the resting metabolic rate (i.e., the basal level of metabolism of an organism) has shown to increase in the presence of a predator, or even some predatory cues. This poses a direct cost to prey, which may even cascade up to higher trophic levels (Hawlena and Schmitz, 2010). Similarly, presence of predators triggers a reduction in movement rates and reduction in food consumption in prey individuals (higher giving-up densities), imposing an energetic cost of deploying some anti-predator strategies (Brown, 1988). But this is not only true for animals. In fact, plants' defenses against predators are mostly chemical. Is the well-known case of the wheat Triticum uniaristatum, which produces hydroxamic acid when attacked by Aphids (Abrahamson, 1975). Many plants have trichomes in their leaves, which act as both physical and chemical defense against herbivory (Agrawal and Rutter, 1998).

Furthermore, an important part of the behaviour of most animal species have evolved in order to reduce the risk of predation. Several examples exist of such behavioral traits. Some species will escape when facing a predator, and the cost of escaping is traded-off with the cost of, for example, abandoning a foraging patch. Ydenberg and Dill (1986) proposed the theoretical curves of cost of remaining foraging and cost of escaping for a foraging prey in the presence of a predator. For 30 years the curves of cost remained experimentally unmeasured. Lagos and collaborators (2014) designed and conducted a laboratory experiment where the theoretical curve of cost of remaining foraging was tested for the first time, and matched was predicted by Ydenberg and Dill (1986).

Some species, however, hide in refuges to escape predation. The use of a refuge, is similar to escaping from a predator, as there are cost associated to both remaining hiding (because of the loss of fitness-increasing activities) and leaving the refuge (because of the persistent risk of predation). Martín and López (1999) proposed an economic model, similar to Ydenberg and Dill's (1986) for the optimal time a prey should remain hiding. To the date, however, the curves of cost have not been measured empirically.

Predation at the Population Level

As predators consume prey, they effectively remove individuals from populations. This effect, very important in inter-individual interactions, is also determinant in the abundance of individuals within populations and thus, the dynamics of both predator and prey populations. In the late 1920s, Alfred Lotka and Vito Volterra studied how the rate of population growth in a population changes as function denso-dependent predator and prey factors (Eqs. **(1)** and **(2)**).

$$dN/dt = rN - pNM \tag{1}$$

$$dM/dt = cpNM - dM \tag{2}$$

In Eq. **(1)**, the rate of change in the population of prey over time (dN/dt) is direct function of both the rate of growth of the prey population (rN, where r is the reproductive rate and N is the population size) and inverse function of the effect of the predators (pNM, where p is the rate of predation, N is the prey's population size and M is the predator's population size). Similarly, the rate of change in the predator population over time (dM/dt) is direct function of the number of offspring the predators produce per number of prey consumed ($cpNM$, where c is the rate of prey–predator conversion, p is the rate of predation, N is the prey's population size and M is the predator's population size), and inverse function of the rate of death of predators (dM, where d is the rate of predator's death and M is the predator's population).

The interrelatedness between the dynamics of the populations of both prey and predators can give rise to cyclic dynamics in time, were the growth in the population of prey will be followed by an increase in the population of predators, as prey become more abundant, predators can capture more prey items per unit of time, and the excess of energy available for predators translate into increased reproductive rates. This, however, has a limit, and when the population of predators becomes large enough, their consumption of prey overcomes the rate of growth of prey, leading to a decrease in the size of the prey's population. Having less prey items available for consumption, the number of offsprings produced in the predator population decreases, reducing its size. Under a constant environment and migration rates, this process may lead to a cyclic dynamic that can be sustained in time. This kind of population processes are very well documented, and remarkably examples can be cited. Is the case of the lemming (*Dicrostonyx groenlandicus*), which is preyed on by four different species, the stoat (*Mustela erminea*), the arctic fox (*Alopex lagopus*), the snowy owl (*Nyctea scandiaca*), and the skua (*Stercorarius longicaudus*). In this case, a regular 4-years cycle has been predicted and observed (Gilg *et al.*, 2003). Another noteworthy example of cyclic dynamics the one of the larch budmoth (*Zeiraphera diniana*), which was supposed to be caused by an intra-population feedback. However, Berryman (1996) noted that the regular oscillation of its populations were caused by Diptera and Hymenoptera parasitoid. A parasitoid is a special case of predation, were the free-living adult lays eggs inside another animal. The eggs then hatch, and the larvae feeds on the individual, ultimately killing it.

The effects of predation are not necessarily as strong in the population as they are on individuals though. Two reasons have been proposed to explain this. Firstly, predators usually go after the weakest individuals, as they are easier targets. These individuals are inherently less likely to contribute much to the population, in terms of how many offsprings they leave. Secondly, these targeted prey might well being older individuals, which already reproduced, thus removing these individuals from the populations will not have a deep impact on the overall dynamic of the population. This argument vanishes though if the preferred targets are younglings, and the effect of predation will be stronger in the population when these individuals are consumed, as they have not yet reproduced. But they might not be as likely preyed on, as predators will not profit as much from young individuals, because of their reduced body size.

Predation at Species Level: Evolution of Traits Driven by Predation

Predation acts strongly and negatively on prey's fitness. Therefore, it is only logical that traits that reduce predation (or predation risk) will readily be selected for by natural selection. Many different anti-predator strategies have evolved in order to reduce the risk of predation. And many of these strategies involve using the color or shape to deceive would-be predators. For instance many animals have colors that match their surroundings, reducing the contrast between the animal and their environment. This camouflage makes them virtually invisible in many cases. Such is the case of the Darwin's frog (*Rhinoderma darwinii*), whose brown or green color perfectly matches the colors of the rainforests were this species occurs. Very famous is the example of the peppered moth (*Biston betularia*). This moth has two colors, black and white. Before the industrial revolution, the white ones were more abundant than the black ones, because the trees were they live have light colors, so the black moths contrasted much more than the white ones, making them frequent target of predators. However, with the industrial revolution, the amount of atmospheric CO_2 increased, and the bark of the trees became darker. This change made the dark moth more cryptic now, and the white ones became more frequent target of predation. Nowadays, the black moth is more frequent than the white ones, as the white moth became more conspicuous and is more frequently targeted by predators.

Seemingly paradoxical, it has been proposed that some animals have evolved bright colorations as a response to predators. This is known as aposematism. The idea is that bright colors are used to inform the possible predators about the unpalatability of the prey (Joron, 2009). In fact, aposematic species are usually venomous, or produce some kind of toxin or are somehow distasteful to predators (Mappes *et al.*, 2005). Thus, the bright color in aposematic species actually increase survival, despite the fact that makes them easier to detect.

Over evolutionary time, anti-predator traits might change, as more efficient variant will be naturally selected. However, the same can happen in predators. New variations in hunting strategies will randomly appear in the populations, and those better at foraging or capturing prey will also be naturally selected, leading to further changes in prey anti-predatory traits. And so forth. This reciprocal evolutionary tendency to overcome the enemy's strategies, an arms race of sorts, is known as "coevolution." For instance, there is a group of cacti, the "senita" *Pachycereus schottii* produces a chemical of the alkaloid family, which is toxic, even lethal, for most flies, except for the fruit fly *Drosophila pachea*, which has acquired a resistance to this toxin (Heed, 1978). Another know example of coevolution is the ability of ground squirrels (*Otospermophilus beecheyi*) to resist the venom of rattlesnakes (*Crotalus oreganus*). The squirrels display several anti-predator strategies that seem especially useful against snakes, which suggests a synchronous, joint evolution (Holding *et al.*, 2016).

The relationship between a pathogen and its host is an interaction were one of them, the pathogen, benefits from colonizing the host, whom is negatively affected by the pathogen. Thus, pathogen–host interaction can be considered as a special case of predation. Pathogen–host systems have been very useful to test the hypotheses of coevolution, as the short generational times of most pathogens allow for quick evolutionary changes. For instance, Borghans *et al.* (2004) performed simulations aiming to explain the high polymorphism found in the MHC (major histocompatibility complex), responsible for the immunity in vertebrates. They found that coevolution by itself is capable of generating the variability observed in the MHC. Similarly, *Mycobacterium tuberculosis*, the responsible organism for tuberculosis, has accompanied human ever since they left Africa the first time. In a literature review, Gagneux (2012) showed that *M. tuberculosis* and other closely related pathogens that cause tuberculosis in human have a phylogeographic population structure associated with different human populations. This suggests that coevolution might explain the specificity in the pathogenicity of *M. tuberculosis* with different human populations.

Even though predator and prey change their strategies over time, this does not necessarily mean that their rate of success will increase. This is known as the "Red Queen hypothesis" for coevolution, as a reference to Lewis Carroll novel, where Alice and the Red Queen ran for a long period and did not move from where they stood. In 2011, Morran and collaborators conducted an experiments to test the "Red Queen" hypothesis for coevolution using a bacterial pathogen (*Serratia marcescens*) and its host, *Caenorhabditis elegans*. If the Red Queen hypothesis was correct, it was expected that *C. elegans* would favor outcrossing (i.e., reproducing with another individual) rather than asexual reproduction, and this is exactly what the researchers found, but not just that. In fact, they observed that individuals that selected asexual reproduction were driven to extinction by the pathogen.

Predation at Community Level

A community (i.e., a group of populations inhabiting the same space in the same time) can be described in several ways. One aspect to it is to describe the structure of the community in terms of the interactions between individuals, and ultimately, between populations. Key concepts in community ecology are the transfer of both energy and matter. This transfer occurs mainly by trophic interactions (i.e., interactions were one individual eats the other). The observation of this kind of interactions in a community will quickly reveal a network of interactions were individuals are either producers or consumers. The summary of these trophic interactions is known as a food web. Paine (1969) proposed the idea that one, or a few species can have a disproportionate effect in the structure of their community. Paine called these the "key species." He observed that key predators oppose to the dominant competitors (i.e., those species that dominate the community in terms of abundance). In reducing the abundances of the dominant competitors, new species are now able to colonize the community. This effect of higher trophic levels modifying the structure of the communities is known as top-down regulation.

Paradoxically, the fact that key predators can control the structure of the community by removing the dominant competitor means that a predator's effect on the community can lead to an increase in the community's diversity. This phenomenon has been

observed in several communities. A good example comes from the intertidal communities, were sea stars (*Pisaster* or *Heliaster*) are active predators of many of the inhabitants of the intertidal, mainly bivalves and snails. When sea stars are present in the community, the number of species is high (i.e., high diversity). However, when the sea stars are removed from the community, the structure of the intertidal changes drastically, as the diversity is reduced and the dominant competitor takes over the community (Paine, 1966, 1969). Thus, in this example is easy to see the important effect predation has in determining the structure of the biological communities.

Predators in the communities do not need to actually consume individuals in order to have an effect on the community. In fact, besides the lethal effects, there are also non-consumptive effects of predation on the communities, and individuals will occupy space and time so that the risk of predation is minimized. This idea that predation determines the use of the habitat by individuals in a community is known as the "landscape of fear" (Brown *et al.*, 1999). The concept of the landscape of fear was first empirically observed by Laundré and collaborators (2001), when a population of wolves (*Canis lupus*) was reintroduced in Yellowstone park after 50 years. The researchers studied the anti-predator and foraging behaviors of elks (*Cervus elaphus*) and bisons (*Bison bison*) in areas with and without wolves. They found that in places where wolves were reintroduced, female elk and bisons had higher rates of vigilance and reduced rates of foraging than the same species in areas were wolves had not reached yet. These are results predicted by the idea of changes in the landscape of fear.

Glossary

Deterministic process A process in which the future state is completely determined by present and past states.

Disturbance Any temporary change in average environmental conditions severely disrupting an ecological population or community, such as fire, flood, ice-scouring; such events create open space, available for colonization.

k-selection The type of natural selection experienced by populations that live at carrying capacity or maximal density in a relatively stable environment.

Metapopulation A group of local populations of a species in patches, inter-linked through dispersal.

Niche models Models based on the niche concept, that is, the ecological space occupied by a species, and the occupation of this species in a community.

Patch dynamics An ecological concept according to which communities consist of a mosaic of patches, that is, discrete areas of variable size, shape, composition, history, and disturbance regimes, making up a landscape.

Resilience The ability of a community to return in its former state after disturbance.

r-selection The type of natural selection experienced by populations that are undergoing rapid population increase under high resource availability.

Stochastic process A process where future state is based on probabilities or randomness.

Supply-side ecology An ecological concept according to which population dynamics are driven by immigration from external sources.

Introduction

Communities are assemblages of living organisms in specific areas or habitats; their structure changes in time and the processes of succession and colonization are recognized as the main driving factors. Community change has important implications for management and conservation and great scientific effort has been historically devoted to ascertain relevant patterns and predict future states.

Colonization: A Precondition for Succession

Colonization (L. *colere*, to inhabit) is a very generic term, applied to a wide spectrum of scientific fields, such as archeology, astronomy, biology, cosmology, history, medecin, paleontology, and parasitology. Concerning biology, the term is generally used in community ecology, describing the process by which a species is spreading into a new area. The process gained publicity under the predictions of the Island Biogeography Theory (MacArthur and Wilson, 1967) and the concept of metapopulation (Levins, 1969), which assumes spatially separated populations that interact through successful immigration. Colonization may occur at a broad range of scales, from microcosmic to macrocosmic. Perhaps the lowest scale refers to the biofilm formation, that is, the settlement of microorganisms on bare substrata after molecular fouling, a foundational process for higher-scale colonization, especially in humid or aquatic environments. Although the term usually refers only to the natural spread of species, it could possibly also apply to the field of invasion ecology (Davis and Thompson, 2000). Thus, as previous authors suggested, colonizers of different types can be distinguished under three simple criteria: dispersal distance, uniqueness, and environmental impact. Species that are nor extending their range of occurrence when colonizing an area, are considered as successional colonizers indifferent of whether they originated from a local species pool and their possible impact on the new environment. Regardless of dispersal distance, species that are novel in an area (range extension) may or may not cause severe environmental impacts, and are characterized as novel, invasive or noninvasive colonizers, respectively.

The combined effect of colonization and extinction is the main driver of ecosystem structure and function; the balance between these two opposite processes determines biodiversity levels and keeps ecological systems in a dynamic, self-organizing, and multistable state. The colonization abilities vary between species mainly according to their life-history traits, but are also affected by abiotic environmental factors. Species dispersal is the first step of colonization whereas the second, and maybe the most decisive step, is establishment and persistence (Lohmus *et al.*, 2014). Dispersal skills differ between species depending on the intrinsic reproductive strategies and motility patterns. Furthermore, the original presence of a species in a habitat, that is, local species pool, and landscape connectivity affect species dispersal. Life history traits also determine establishment success, according to the habitat's specific environmental conditions and presence of other species. The outcome of the above processes will determine species persistence over time. Therefore, the colonization success of a species seems to be a function of time.

Whether the environmental factors prevail in the determination of species colonization success, against the biotic ones, remains unclear. Accordingly, two opposed hypotheses, the habitat filtering metaphor or abiotic filtering and the biotic filtering, have been proposed to highlight main drivers and explain species cooccurrence (Purschke *et al.*, 2013). In the former, particular environmental conditions will screen for functionally similar species, while in the latter functionally dissimilar species will cumulate by biotic screening processes such as the competitive exclusion and resource partitioning. Both above hypotheses premise deterministic processes in contrast to the stochastic view of the 'trait-neutral' approach (Hubbell, 2001, in Purschke *et al.*, 2013). Despite the strong ongoing debate on the stochastic or deterministic nature of colonization and succession, the above theoretical approaches have founded the most classical models explaining succession (i.e., inhibition and facilitation/tolerance models, see below).

Succession: Meaning and Relevant Concepts

The term "succession" refers to linear, directional changes in species populations that start from an initial point and continuously modify community pattern. These changes are generally slow and perceptible over long time, resulting from a dynamic balance of species intrusions and exclusions, producing species substitutions over time. As time proceeds, the biotic community tends to a more stable formation or climax state, according to the conventional succession theories. In the climax state, community structure still varies, but within natural variability confines, finally reaching a dynamic equilibrium point outlined by climatic conditions. Despite the simplistic definition, succession is a particularly complex process, operating in various spatiotemporal scales coupled with environmental variability.

There are three possible different types of succession: (i) the degradative or decompositional succession, where scavengers and other microorganisms assiminate dead organic matter, for example, the insect succession on carrion, being widely applied in forensic medicine; (ii) the allogenic succession, where external, abiotic factors, varying from massive disturbance to temporal changes of environmental factors, modify the geophysical conditions of an area driving community succession, for example, volcanic eruptions or seasonal phytoplankton cycles; and (iii) the autogenic succession, where biotic processes, that is, the organisms themselves, modify existing conditions affecting, positively or negatively, other organisms and themselves, for example, the forest succession. Allogenic and autogenic succession, however, may occur simultaneously and are not mutually exclusive; thus, the above terms may apply to the factors involved in succession rather than succession per se (Tansley, 1935).

All succession types, apart from the degradative one, require a vacant space and are typically separated in (i) primary and (ii) secondary succession according to the initial absence or presence, respectively, of living organisms (or biological legacies, see relevant section of succesional theories, below) in the newly available space. Most sucessions are assigned to the latter case involving recovery of sites after disturbance events. However, in disturbances of extreme magnitude, such as glacial retreats and volcanic eruptions, which totally eradicate all organisms and their propagules, primary succession occurs. Typically, primary succession takes places in much slower rates than the secondary one, due to the complete initial absence of life (sterile substrate). The terms "primary succession" and "secondary succession" predominate in recent terminology, due to the problematic application of the terms "allogenic" and "autogenic," as emphasized above.

Another differentiation, mostly applied on terrestrial ecosystems, is the progressive versus retrogressive succession. In the former case, species diversity and biomass increase over time by contrast to the latter, in which the above biocoenotic variables are decreasing. Progressive is the typical form in most directional succession processes. Very few retrogressive successions have been described, such as the case of coastal sand dunes vegetation.

Ecological succession has three intermingling components: mechanisms (species dispersal and establishment), stages (initial, early, mid, and late) and trajectories or pathways (convergent, divergent, and circular). A key concept in succession is seral stage, that is, each distinct community type within succession, from the very beginning to the dynamic equilibrium state. The occurrence of a species within a seral stage is determined by its life history features and natural changes induced by succession. As a general rule, good colonizers are bad competitors and thus nonsurvivors. Early successional species typically follow r-strategy: rapid growth rate and resource uptake, low mature size/biomass, high reproductive output without parental care, and short lifespan.

A particular type of succession is the cyclic one, where the seral stages rotate in circular way; shrub-dominated communities often undergo cyclic succession as the loss of a canopy-forming species opens space to novel colonizers, including their own juveniles, which will in turn become overstory plants.

Finally, relevant to succession is the concept of chronosequence, based on the fact that most ecological communities are not spatiotemporally homogenous; they rather constitute a mosaic of patches in different successional stages (Menge, 1975), under the driving process of disturbance (Sousa, 1984). Such mosaic patterns, representing different recovery stages, and thus having a successional relationship, are called chronosequences, in contrast to toposequences, where the mosaic aspects are due to topographic divergence.

Theories on Ecological Succession and Driving Mechanisms

Succession theories emerged from the two extreme views of community structure; that is, whether the relationships between populations of living organisms in a specific area or habitat are obligatory or not (McCook, 1994; Krebs, 2009). In the first case, community can be viewed as a kind of "superorganism" where species populations are organized in a complex network, a "web of

life," and accordingly, any change to a population will induce seriatim results reflected to the entire community. In the second "individualistic" view, each species functions under its own rules, and they cooccur simply due to their similar physico-chemical niche requirements; accordingly, the community represents a random collection of individual populations with minimal integration. These opposed views triggered a strong debate among ecologists, but, as often happens, reality seems to lie somewhere between the above extremes.

Several attempts have been made towards understanding the processes of succession (McCook, 1994; Raevel *et al.*, 2012), among which we should note the recent work of Pulsford *et al.* (2016) thoroughly revising successional theories. Most theories are strongly related with post-disturbance events as ecologists have long ago realized the importance of predicting how ecosystems will change after disturbance. Alternative theories are based on niche models and patch dynamics.

The first successional theories emerged from the field of plant ecology, based on two opposed ideas: Cowles' dynamic view of vegetation and Clements' static climax state view. Cowles considered succession as "*a variable approaching a variable, not a constant*" (Cowles 1901 in Pulsford *et al.*, 2016) due to the dynamic nature of communities under a variable abiotic environment and biotic interactions. After his pioneer work on sand dunes, he concluded that succession is a complex dynamic process without a certain end point. Sharply contrasting to the above, Clements visualized succession as a strictly linear determinist process leading to a predefined endpoint, the climatic climax state (Clements 1916 in Pulsford *et al.*, 2016). Clements' degraded the importance of abiotic in favor of biotic processes and gained wide acceptance among his confreres; however, his ideas are no longer in use. Although not directly referring to his work, Gleason (1927) supported Cowles' ideas; he regarded succession as being directed by individual plant characteristics and identified migration and environmental selection as the main driving factors. His work has been overlooked at the time but gained support after 1950; Hutchinson (1951) realized the importance of life-history traits and invented the concept of "fugitive species," that is, species that are good dispersers but bad competitors, thus being the first to establish after disturbance and able to resist further invasion by other fugitives, but outcompeted at the end by slower-dispersing and superior–competitor species. Whittaker (1953) also accepted Gleason's ideas and introduced the pattern climax concept, in which the endpoint is a spatially variable pattern of species. Egler (1954) proposed two models: Relay Floristics, fitting with Clements' ideas, and Initial Floristic Composition as an alternative. In his first model, he suggested a deterministic progression of seral stages (alternation of specific species assemblages) ending to the climax state (Clementsian succession). In his second model, he claims that various species invade a barren area and grow according to their life-history traits, with fast-growing/short-lived species (r-selected) dominating during first stages, but outcompeted by slow-growing, long-lived species (k-selected) as succession proceeds, up to an "equilibrium" state; further invasion may occur at any stage altering the above pathway. He proposed both models as ideal cases, actually functioning in conjuction and influenced by biotic interactions (e.g., predation, competition).

Connel and Slatyer (1977) revised the existing successional theories and suggested three possible models according to the effect of the first colonizers to the next ones: Facilitation, Tolerance and Inhibition (**Fig. 1**). In Facilitation model, only pioneer species are able to initially colonize a barren area; these species condition habitat making it more suitable to other species than to themselves. Hence, species replacement is gradual, ordered and predictable, following a directional process towards an equilibrium state. In Tolerance and Inhibition models, any species is assumed able to colonize a barren area, without the prerequesition of conditioning species; after colonization, the occurrence of a species may be indifferent or prohibitive to other species, respectively. Thus, species replacement is not necessarily ordered and predictable, and succession proceeds without converging towards a specific climax state. The Facilitation model is founded on Clements' succession and subsequent Floristic Relay, whereas the Tolerance and Inhibition models paraphrase Egler's Initial Floristic Composition, by accepting that both early and late successional species are able of initial colonization, the former being inferior competitors according to the first model, whereas any early colonizer persists until dead or damaged, in the latter. Thus, life history traits are identified as the prominent driving factors of succession: species longevity in the Inhibition model and species competitiveness in the Tolerance model. Connel and Slatyer's models have been converted by Fox (1982) to fit animal succession under the Habitat Accomodation model, which relates the structure of vegetation to the post-disturbance recovery of associated fauna. Habitat Accomodation model predicts that an animal species will be established in a defaunated area when habitat conditions (i.e., vegetation) fulfill its requirements; it will persists as long as floristic conditions remain favorable, but it will decline or vanish, when floristic compositions turn out to be adverse,

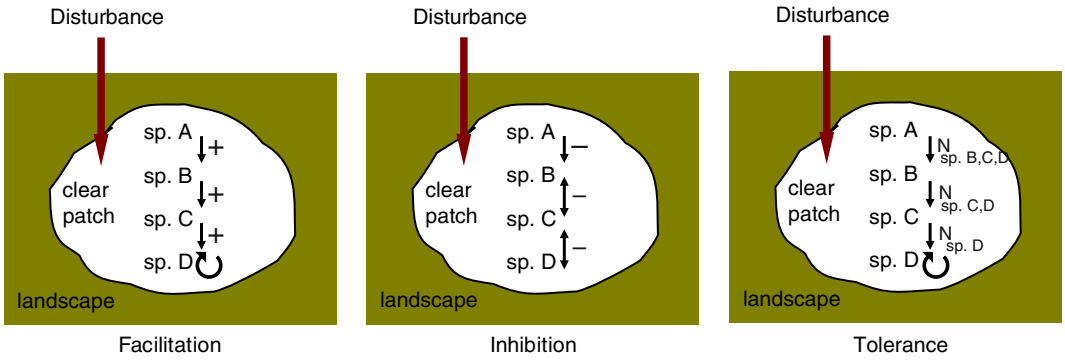

Fig. 1 Schematic representation of Connel and Slatyer's successional model (1977).

getting outcompeted by other better-fitted species. Connel and Slatyer's models are classical in modern ecology (Krebs, 2009). However, they are considered as empirical descriptions of the succession outcome rather than as mechanistic explanations (McCook, 1994).

All successional models presented so far, apart from the Clementsian model, recognize the importance of life history traits. This inspired researchers to explain succession by the individual species response to resource or stress gradients according to life-history traits (McCook, 1994). Among various attempts are the CSR theory (Grime, 1974) and the Logistic Simulation model (Whittaker and Goodman, 1979). The former classifies species in functional types (competitive, stress tolerant and ruderal) and suggests their different contribution under different stress, competition and disturbance levels, as succession proceeds, while the latter substitutes CSR functional types with relevant carrying capacity categories (adversity, exploitation and saturation selection) along environmental gradients (Whittaker and Goodman, 1979).

Succession has been also attributed to limiting resources availability under the predictions of Resource Ratio hypothesis (Tilman, 1985). Synthesizing existing theories, McCook (1994) proposed the "Strategic Resource Allocation" model, in which the specific adaptive strategy of a species is dictated by the particular balance of allocating resources to different physiological functions. Resource and life-trait models have given place to more advanced but similar approaches, grouping species according to shared life-history traits (Raevel *et al.*, 2012). Such examples are the "vital attributes" (Noble and Slatyer, 1980), "functional types" (Gitay and Noble, 1997), and "critical life cycles" (Whelan *et al.*, 2002) concepts. Albeit a promising approach, the definition of these concepts in practice remains challenging, and a general trait-based model is still missing (Pulsford *et al.*, 2016).

Westoby *et al.* (1989) introduced State and Transition models (STMs) to describe ecosystem dynamics, accepting that multiple stable communities can occupy ecological sites. Individual states may be identified by relatively large differences in functional groups and ecological processes and thus, in community structure. Transition between states can be gradual or rushed. STMs have been used to assess ecosystem response to disturbance by predicting the future state of community structure under specific conditions driving the system to one of the possible alternative "equilibrium" states. Thus, it is important to identify thresholds and ecological resilience of individual states to stressors, as well as factors involved in the transitioning of a site between potential alternative states. STMs are advanced succession-retrogression models that accept the existence of multiple equilibria and the return to equilibrium following disturbance (Briske *et al.*, 2005; Bestelmeyer *et al.*, 2017). STMs (**Fig. 2**) can be sequencial, radiated or of maximum connectivity (Phillips, 2011); they provide a promising tool for managers, especially if their predictive power is increased (Pulsford *et al.*, 2016).

A radically different approach to interpret succession is through stochastic models, such as the Markovian chains (Horn, 1975; Van Hulst, 1979). These models predict the transition of community structure from a set of alternative states, where any future state is always dictated by the previous one, to a constant outcome under the same replacement probabilities (following Clementsian successionl view). They may also apply the Neutral metacommunity theory, which considers ecological drift as the main driving factor, to predict transitions (Hubbell, 2001). Appropriate data, however, are generally lacking and these approaches suffer from oversimplifications. Markovian models are non-explanatory, entirely based on empirical estimates of species replacement probabilities, even if proven predictive.

An ultimate interpretation of succession, strongly related to the disturbance theory, is through the concept of biological legacies defined as "*living organisms that survive a catastrophe; organic debris, particularly the large organically-derived structures; and biotically derived patterns in soils and understories*" (Franklin, 1990). Obviously, in most cases, some survivors or residuals remain after disturbance (i.e., biological legacies) and manipulate succession pathways and recovery rate. The impact of biological legacies on subsequent succession by influencing recruitment and accelerating the rehabilitation of ecosystem functioning has been only recently acknowledged (Pulsford *et al.*, 2016), although noted in the early studies.

A carefull reader has already noticed that many of the theories presented above are founded on the same basic ideas. Redundancies in successional theories have been thoroughly revised by Pulsford *et al.* (2016) who synthesized relevant information to propose a framework of a rationalized disturbance theory. Within this framework, a number of mechanisms may account for the transition of a community (represented by a continuum of alternative states) to another state during succession following disturbance. Disturbance activates stabilizing procedures (resilience, biological legacies and inhibitory effects), whereas

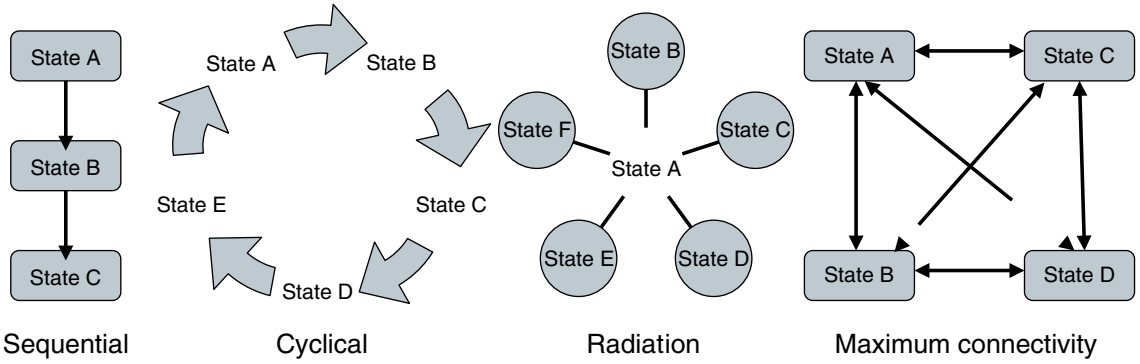

Fig. 2 Graphical representation of State and Transition Models STMs (according to Phillips, 2011).

species traits under varying resource allocation influence possible pathways through pulse events (rapid shift), stochastic drift, facilitation, competition, initial composition and further operation of stabilizing processes. This conceptual framework may assist in the interpretation of successional studies in the future.

General Trends in Ecological Succession

Succession is a central issue in ecology; most relevant studies have addressed various aspects of vegetation dynamics, focusing on major structural components of the communities involved. Through these efforts, and despite the variety of succession types identified and/or the uniqueness of individual successional processes, some common patterns may be observed. When disturbance initiates succession, different pattterns may occur; each possible pattern has its own specific rate and is defined by the outcome of colonization and species interaction processes. Estimation of the successional rate, or otherwise the required time-length for a landscape or seascape to regain its pre-disturbance functions, is critical (Anderson, 2007). Rates are measured through coverage, biomass, species richness, species turnover or by the time required for the community to reach a certain stage. Successional patterns may lead to convergence or divergence towards a "mature," undisturbed community composition in a given area, depending on whether biological processes, such as competition, or biological legacies overcome initial stochasticity of colonization and environmental variability (del Moral, 2007).

Among pioneers, Odum (1969) identified possible ecosystem traits that are expected to vary during succession, according to which alternative community states are conventionally divided into early and late ones. Early successional stages are characterized by the presence of r-selected species (opportunistic, pioneer, fugitive, and early colonizers) having short life cycles, rapid growth rate and small-size, such as grasses. These species are later replaced by larger forms with longer life cycles, that is, k-selected species, such as trees. A shift in energy allocation from reproduction to growth is, therefore, observed during succession. Apart from the very early successional stages, both kinds of species may coexist, depending on resource availability. K- and r-strategies are extreme ends along a continuum and so, many species exhibit intermediate traits. Biomass, coverage, stratification and structural complexity (architectural variation of growth forms) are increasing during succession, overall traping more energy as nutrients are stored as biomass rather than in soil or liquid environment. Foodwebs are becoming more complex with increasing input of litter and organic matter, so that wastes and nutrients are more efficiently recycled. On the other hand, net primary production may decline due to rising respiration and/or nutrient limitation. The effect of macroclimate is gradually reduced in later stages as local conditions are stabilized. In terrestrial succession, the environment becomes more mesic, due to higher soil moisture retention (as soil depth and texture improves), shrinkage of diurnal temperature/humidity fluctuations (as canopy closes) and buffering of seasonal precipitation (Barbour *et al.*, 1999). Species diversity will typically increase during succession from the early to late stages, with the highest values attained in intermediate or more advanced stages and declining towards the "terminal" or dynamic equilibrium state; the same happens with other traits, such as biomass and complexity. Diversity has been traditionally considered as positively related to ecosystem's stability, but such a relationship remains fuzzy. This is partly due to the different definitions of stability, generally falling into two categories, those based on the dynamic stability of the system and those based on its ability to resist change (McCann, 2000). Despite the breadth of definitions, the ecological theory emphasizes equilibrium stability (ability to return to equilibrium after small disturbance) and equilibrium resilience (ability to quickly return to equilibrium after disturbance), which are supposed to increase and decrease, respectively, in late successional stages. However, patterns of community transition and ecosystem development during succession vary (Walker and del Moral, 2011), and there are many exceptions to the above generalized trends, even within a single community type (Barbour *et al.*, 1999). Ecological succession remains a highly complex process challenging the development of generalizable patterns.

Methods to Study Ecological Succession

Succession is an intricate, continuous, physical process extending in long temporal scales, which can be considered as an archetypical evolutionary process (Wurtz and Annila, 2010). This poses a great difficulty for methodological studies that must overcome the serious drawback of the required time-length, usually of eons. Thus, a single ecologist can't follow directly an entire successional process; indeed most studies are restricted to few-year surveys. In general, there are two possible alternatives: (i) aquire field data from permanent plots in a specific site and (ii) aquire field data from plots at different sites of different ages, under the assumption that these sites are ecologically equivalent differing only in age.

Apparently, the first option is the most explicit way to study succession, but very few relevant long-term studies exist. Such attempts require the initiation of a multiannual monitoring survey using a standardized sampling protocol (i.e., repeated measures of permanent plots over decades) strictly adopted by the researchers involved. The outcome is the precise record of change and consequently, a firm documentation of ecological succession. However, this long term commitment is hard to apply in practice and the vast majority of successional studies are either short-term or have followed the second option of using different chronosequences across a landscape. In the latter case, one can use different plots from different patches under different recovery states, across a landscape, and compare community structure to describe succession. The challenge is to establish a series of plots in areas affected by the same disturbance at different but known times. However, this is rarely well-documented and the entire method is much less accurate.

In the past, chronosequence methods were perhaps the only feasible way, but nowadays the advantages of applying direct long-term methods has been widely acknowledged. The use of comparable, standardized, experimental manipulative studies across abiotic and biotic gradients, that is, techniques that allow direct measurements of change and factors, is highly recommened in future efforts for understanding succession (Prach and Walker, 2011).

Ecological Succession on Terrestrial and Inland Water Habitats

Primary Succession Examples

The volcanic eruption of Mount St. Helens (del Moral and Lacher, 2005), the rose of Surtsey island after an underwater volcanic eruption in Iceland (Krebs, 2009), and the glacial retreat at Glacier Bay in Alaska are typical examples of primary terrestrial succession (Barbour *et al.*, 1999). In all such cases, extreme disturbance events cleared extended surfaces from any biological legacies. These catastrophic disturbances have been followed up by ecologists who stressed the importance of soil formation. In Mount St. Helens, the nitrogen-fixing plants (lupines), as controlled by herbivorous insects, proved to be crucial for ecosystem rehabilitation, enriching soil, and allowing establishment of other species. In Surtsey island, sandworts were initially established, followed by lull and a limited number of species, as soil conditions were sterile. Plant colonization accelerated only after the arrival of gulls who transferred seeds but also, and most importantly, due to the enrichment of soil by inputing nutrients from the sea, nitrogen in particular. In Glacier Bay, the constant presence of nitrogen fixing organisms (cyanobacteria substituted then by dwarf-shrub and alder) lead to an exceptionally rapid primary succession; it took only about 200 years after glacial retreat for the development of spruce-hemlock forest, compared to the 1000 years for deciduous forests in Lake Michigan sand dunes, or the 5000 years for moss-birch-tussock grass from glacial debris in Alaska (Barbour *et al.*, 1999). Soil formation, depending on the complex interactions of climate, organisms and time, is the most influencing process driving primary succession (Walker and del Moral, 2011). Nutrients accumulation in soil, nitrogen in particular, determines fertility. Bacterial fixation of nitrogen is especially important; mosses, lichens, fungi, algae, and bacteria (symbiotic bacteria in the roots of vascular plants) are important in soil formation and development after severe disturbances. Animal parts, insect or bird feces (guano) can be also important sources of nitrogen.

Secondary Succession Examples

A well-documented case of secondary succession is the North Carolina Piedmont old-field (Barbour *et al.*, 1999). The Piedmont area supports a patchy landscape of pine and hardwood forests and agricultural fields, and so, abandoned crops, represent ideal systems to study secondary succession (**Fig. 3**). The comparison of community structure through time showed that the cropland was initially colonized by crabgrasses and horseweeds that gave place to white-asters and ragweeds, which in turn gave place to broomsedge and then to pine seedlings. It took about 10 years to reach the stage of young pines canopy combined with broomsedge. Thereafter, seral stages differed according to humidity; in moister sites loblolly pines predominated in contrast to drier sites where shortleaf pines flourished. Gradually, within next 50 years, a hardwood overstory developed in both field types, becoming predominate over pines after about 150 years. However, the effect of disturbances, such as fires periodically occurring every 5–7 years, may maintain old-fields at the pine seral stage, preventing the development of hardwood forests. Old-field succession seems to vary according to the biogeographic area whereas in other cases of secondary succession, a gradual overlapping between seral stages has been observed in contrast to the sharp distinction of seres in Piedmont.

Fig. 3 Generalized patterns of terrestrial succession.

The controlling factor in most secondary succession cases is disturbance; the severity and frequency of disturbances determines available biological legacies initiating community development. Stand-replacing fire promotes succession in boreal forests and several studies documented the replacement of shade-intolerant pioneers by shade-tolerant, late-seral species. However, apart from this simplistic explanatory model, specific-site conditions, initial species composition, structural quality, density dependence, resource levels and intermediate disturbances are also involved leading to converging or diverging successional pathways (Chen and Taylor, 2012).

Successional studies on land ecosystems are typically limited on main structural plants, not taking into account the associated biota; such studies are enclaved in prolonged field observations linked to the generation length of dominant plants, reaching eons for late-successional tree species. On the opposite, in inland aquatic environments, such as lakes, relevant studies are dealing with the annually repeated seasonal succession of plankton communities, which operates in short time intervals, usually of few months. A comprehensive study of planktonic secondary succession, in which population and system level indices were applied, is that of the Lake Constance in Alps (Boit and Gaedke, 2014). This is a large, deep and warm monomictic lake of glacial origin with limited external input, in which a typical shift in community composition along succession was observed passing through predictable stages. The authors observed along the successional stages i) higher energy transfer efficiency across trophic levels, ii) diversification and increasing specialization of consumers on resources exploitation, iii) decrease in total production, iv) increase in functional diversity and complexity of foodwebs. Ongoing grazing pressure, lower prey edibility, lower food quantity and quality, and declining nutrient concentrations were the main successional drivers.

The Special Case of Carrion Succession

Carrion ecology has gained increased attention as ecologists started to realize the importance of carcasses in ecosystem function, nutrient cycling and organic matter input (Michaud and Moreau, 2017). However, many aspects of carrion ecology remain unclear, including the colonization and succession patterns on carcasses. In these processes, arthropods, insects in particular, seem to have the most prominent role. It is generally acceptable that carrion succession is a continuous process with no abrupt changes in faunal composition across sequential stages, representing nonequilibrium systems without a terminal stable state (either monoclimax or polyclimax). Certain flies (families Calliphoridae, Muscidae, and Sarcophagidae) are the pioneer colonizers, thus considered the primary drivers of succession, followed by other arthropod species in a predictable sequence. The patterns of arthropod colonization on carrion is fairly constant at the family level. However, the exact species composition along succession depends on the local colonizers pool, species interactions (trophic interactions in particular, i.e., within or between necrophagous and their predators/parasites, omnivorous or adventine species), and other factors such as habitat, season, climatic conditions and decomposition environment (Sukchit *et al.*, 2015). Despite being a continuous process, carrion succession may be splitted in apparent stages linked both to decay process and succession of specific arthropod groups (**Table 1**); such defined patterns can be used to estimate postmortem interval, which is particularly useful in medico-legal forensic.

Carrion succession patterns often present a typical horseshoe-shaped arch form; faunistic diversity and similarity are low in the early successional stage (fresh stage of decomposition), gain maximum values in midstages (bloating and active decay), decrasing in late seral stages (advanced and postdecay) towards skeletonization (Tabor *et al.*, 2004). Between seral stages, periods of

Table 1 Main arthropod families or faunal groups along succession according to decomposition stage (data from Payne, 1965)

taxonomic stasis, that is, periods with very little change in faunistic composition, may be also observed. In temperate regions, successional patterns varies according to season, but interannual changes are considered negligible. There is a controversy on the application of classical successional theory on carrion succession. The inhibition model seems inappropriate (Krebs, 2009), while Michaud and Moreau (2017) tested experimentaly the facilitation model and rejected it, as the removal of pioneer species did not prevent colonization by secondary colonizers. The latter authors concluded that although facilitation may stand in some cases, succession seems to be driven by the complicated and, not yet fully understood, biotic interactions (within the arthropod community and between the arthropod and the microbial communities), as influenced by abiotic factors.

Ecological Succession in Marine Habitats

In the marine environment, successional studies started in about the middle of the previous century focusing on the dynamics of structural components, that is, sessile animals, algae, and seagrasses, and conducted from the intertidal to shallow subtidal zone. The basic aim was to understand successional patterns per se, to investigate rehabilitation of marine habitats using mimics, for example, artificial reefs or synthetic corals and seagrasses, or to examine fouling development. Instead of chronosequences, direct data acquisition using submerged panels was the most common option (**Fig. 4**). However, the applied protocols were highly variable hindering the extraction of comparable results and general conclusions, and typically suffer from limited replication and immersion-length (<5 years). In spite of the increasing research efforts, the underlying mechanisms of succession in marine environment remain far from understood.

A comprehensive example of secondary succession in the marine environment (to our knowledge there are no examples of primary succession) is the study of Farell (1991) who experimentally examined patterns in a barnacle-*Pelvetia* intertidal community on the coast of Oregon. The author showed that succession followed spatially the same general sequence of species colonization and substitution, though the rate greatly varied among sites according to the timing of successful *Balanus* recruitment. Species interactions, that is, predation, grazing, and competition for space were identified as the most likely driving factors to successional pathways.

Other studies in the rocky sublittoral zone of the eastern Mediterranean (Antoniadou *et al.*, 2010, 2011) and SE Pacific (Pacheco *et al.*, 2011) identified as a general pattern the increase in biodiversity, abundance and biomass as succession proceeds, with maximum values at the intermediate to late stages, under low recovery rates, whereas potential colonizers arrived from surrounding biota. Convergence towards a common structure as succession proceeds has been suggested, despite the strong initial differences attributed either to the effect of seasonal onset of colonization or stochasticity, and explained by supply-side processes and species interactions. A critical issue was the establishment of conspicuous sessile species that provide physical structure, that is, ecosystem engineers, which contribute to the acceleration of succession. However, Brown and Swearingen (1998), studying intertidal fouling assemblages in Northern Mexico Gulf, claimed for the absence of any unidirectional sequence of succession. As Christensen (2014) states "*We now understand that there is no single unique or unifying mechanism for successional change, that successional trajectories are highly varied and rarely deterministic, and that succession has no specific endpoint.*"

Ecological Processes: Volatilization☆

Zhi-Qing Lin, Southern Illinois University Edwardsville, Edwardsville, IL, United States

Significance of Biological Volatilization in Biogeochemical Cycling

Volatilization is the transfer of biogenic volatile elements or compounds from soil or water to the atmosphere. As a natural ecological process, biological volatilization plays an important role in the biogeochemical cycling of elements such as arsenic (As), mercury (Hg), and selenium (Se). For example, on a global scale, biogenic volatile Se emission from the ocean to the atmosphere is on the order of $5–8 \times 10^6$ kg per year and approximately 1.2×10^6 kg per year from the terrestrial surfaces. The flux of volatile Se from agricultural lands varies substantially, ranging from 0.1 to 10 mg Se m^{-2} $year^{-1}$. It was also estimated that as much as 2.1×10^7 kg of As could be lost annually through biological volatilization from land surfaces to the atmosphere. The continental volatile As flux is about eight times that of the continental particulate As flux, suggesting that biological volatilization of As be an important pathway in the global biogeochemical cycling of As.

Biogenic volatilization is a biological metabolism process that varies substantially under different environmental conditions. Thus, the biogeochemical cycling of Se, As, or Hg can be complicated because of those variations. Although several elements can be volatilized biologically from water or soil to the atmosphere, Se and As are the only elements that have extensively been studied to date.

Mechanisms of Biological Volatilization

Different elements involve different mechanisms in biological volatilization. For instance, the production of biogenic volatile Se involves the biological methylation of inorganic Se to dimethyl selenide (DMSe) or dimethyl diselenide (DMDSe), while volatilization of Hg results primarily from biochemical reduction of inorganic Hg to elemental Hg. DMSe, DMDSe and elemental Hg can dissipate from water, soil and plants to the atmosphere.

The pathway of Se assimilation and volatilization in higher plants has previously been constructed. The pathway involves various biochemical reduction and methylation processes catalyzed by different specific enzymes. In brief and for illustration, it contains the following major steps in relation to the formation of volatile Se compounds in most higher plants (but excluding Se hyperaccumulator plants), and needless to say, there are some other intermediate Se-compounds during each step of transformation: *Selenate* (SeO_4^{2-}) → *Selenite* (SeO_3^{2-}) → *Selenocysteine* (*SeCys*) → *Selenomethionine* (*SeMet*) → *Dimethyl Selenide* (*DMSe*)↑. In Se hyperaccumulator plants (such as *Stanleya pinnata*), Se volatilization proccess involves a different approach, including *Selenocysteine* (*SeCys*) → *Methylselenocysteine* (*MeSeCys*) → *Dimethyl Diselenide* (*DMDSe*) ↑. The chemical reduction from selenate to SeCys likely occurs at chloroplasts in plant leaves, while the formation of SeMet and methylation of SeMet likely takes place in the cytosol.

With regard to microbial volatilization, the pathway of Se methylation has not clearly been documented. Experimental evidence indicates that assimilatory selenate and selenite reduction to elemental Se may be an important biological transformation process in anoxic environment. Bio-methylation of inorganic Se compounds (like SeO_4^{2-}, SeO_3^{2-}, or Se^0) might occur under aerobic conditions. Dimethyl selenide is the major metabolite of Se volatilization by microbes and many higher plants except for those Se hyperaccumulator plant species. More DMDSe can be produced by Se-hyperaccumulators (such as *Astragalus bisulcatus* and

☆*Change History*: April 2018. Zhi-Qing Lin prepared the update. Table 1 has been updated with new and additional information and the content has been updated with recent research findings.

Stanleya pinnata) because those Se hyperaccumulator plants metabolize SeCys to methylSeCys, and further DMDSe. Trace amounts of other volatile Se compounds such as dimethyl selenone, methane selenol, and dimethyl selenenyl sulfide, have also been observed.

Selenium volatilization results from the Se mass balance between the production of biogenic DMSe and de-methylation of the biogenic volatile compounds in soil and water systems. Microbial de-methylation removes a methyl group from the methylated compounds, and therefore, reduces the amount of volatile Se to the atmosphere. Laboratory experiments have found that high soil moisture and manganese (Mn) contents could enhance the de-methylation process of Se in the soil.

Major Factors Affecting the Process of Biological Volatilization

Plant Species and Soil Microbe Strains

As a biological process, biogenic volatilization of Se or other elements is significantly affected by the presence of different plant species and soil microbes. Plants and microbes take up selenium and metabolize the element into volatile chemical compounds. Both bacteria and fungi are important in Se volatilization in soil and sediment. Crops, including rice, broccoli, and cabbage, have great capabilities to volatize Se from water under laboratory conditions. Previous field studies identified that pickleweed (*Salicornia bigelovii* Torr.), rabbitfoot grass (*Polypogon monspeliensis* L.), and Prince's plume (*Stanleya pinnata* L.) are among the best plant species for Se volatilization from selenate (Table 1). Unlike Indian mustard (*Brassica juncia* L.) for which selenate reduction appears to be rate-limiting in Se volatilization, pickleweed has an enhanced capacity to reduce selenate to organic Se forms. Such chemical transformation of Se in pickleweed is independent of the presence of microbes.

In addition to Se, some Hg resistant bacterial strains (such as *Klebsiella pneumoniae*) are able to reduce ionic Hg to elemental Hg and effectively volatilize Hg compounds in the substrates. Soil microbes (e.g., *Fusarium* sp. and *Pseudomonas alcaligenes*) can also produce volatile As like dimethylarsenate via the reductive methylation process from inorganic or methylated As compounds. Several fungal species (e.g., *Aspergillus glaucum*, *Candida humicola*, *Gliocladium roseum*, and *Penicillium gladioli*) were found to be capable of transforming inorganic As to volatile trimethylarsine (TMA) compound.

Concentrations and Chemical Forms

The Se bioavailability in soil–plant systems determines the level of Se volatilization. The rate of Se volatilization significantly correlates with the Se concentration in the substrate or plant tissues. The pathway of Se assimilation and volatilization suggests that the production of DMSe from selenate be less favorable energetically than selenite or SeMet. Laboratory experiments have demonstrated that volatilization of Se from different chemical forms (including nanoscale elemental Se or SeNPs) varies substantially, with the following order of magnitude: SeMet $\gg$ selenite $>$ selenate $>$ SeNPs. For example, when broccoli plants were supplied with 20 μM Se as selenate, selenite, or SeMet in hydroponic solution, the rate of Se volatilization from SeMet was about 3 times greater than from selenite, or 13 times greater than from selenate. When in bulk form, elemental Se is not water soluble or not bioavailable; however, nanoscale elemental Se becomes partially bioavailable and can be volatilized at low rates in soil–plant systems.

Under aerobic conditions with a high redox potential, selenate is the dominant chemical form of Se in soil. Different chemical forms of Se or other elements can be transformed in plants or by soil microbes. For instance, most of the Se taken up by India mustard plants supplied with SeO_4^{2-} will remain unchanged, but plants supplied with SeO_3^{2-} or SeMet will contain SeMet-like Se compounds.

Table 1 Maximum rates (μg Se m^{-2} day^{-1}) of Se volatilization observed in different soil/sediment-plant systems under field conditions

Plant species	*Upland system*	*Wetland system*
Baltic rush (*J. balticus*)	–	29 ± 5
Cattail (*T. latifolia*)	–	57 ± 12
Cordgrass (*Spartina* spp.)	46 ± 12	80 ± 10
Elephant grass (*P. purpureum*)	29 ± 1	
Indian mustard (*B. juncea*)	<25	
Pickleweed (*S. bigelovii*)	420 ± 91	–
Prince's plume (*S. pinnata*)	1002 ± 509	
Rabbitfoot grass (*P. monspeliensis*)	–	274 ± 100
Saltbush (*A. lentiformis*)	29 ± 13	–
Saltgrass (*D. spicata*)	28 ± 21	38 ± 27
Saltmarsh bulrush (*S. robustus*)	–	13 ± 9

Values are mean and standard deviation ($n = 3$).

Chemical Interaction of Other Elements

Sulfur and Se are chemical analogs (i.e., having similar chemical properties). High concentrations of sulfate in the substrate inhibit Se volatilization from selenate due to their competition for the uptake transporter or the active sites of enzymes that are responsible for biological transformation of selenate to DMSe. For example, the inhibitory effect of sulfate on Se volatilization by selenate-supplied broccoli increases with increasing the ratio of S/Se in plant tissues. When the sulfate concentration increases from 0.25 to 10 mM in the substrate, the rate of Se volatilization can be decreased by 85%, while effects of sulfate on volatilization of Se from selenite or SeMet are not significant.

Similarly, phosphorus and As are also chemical analogs. Although effects of soil phosphate on the accumulation of arsenate in plant tissues have been documented, there are no experimental evidences indicating that phosphate significantly inhibits As volatilization from arsenate.

Soil Organic Matter and Water Moisture

Soil organic matter content is a critical factor for microbial volatilization of Se and other metalloids. The addition of organic materials to soil can provide soil microbes with essential energy and carbon sources to metabolize inorganic Se to DMSe. Soil amendments with different organic materials (such as casein, manure or plant litter) have been evaluated for the enhancement of Se volatilization in soil and sediment. For example, in a soil-pickleweed system, the addition of shoot biomass/fallen litter to the soil surface at a rate that is equivalent to the annual biomass production of $\sim$1.5 kg m^{-2} increased Se volatilization up to 2.2 times of magnitude. Those research findings have resulted in developing a new concept or remediation strategy for Se-contaminated water and soil through biogenic volatilization process.

The soil water content also significantly affects the process of Se volatilization. For example, sequential changes in soil moisture (such as creating drying and wetting cycles) will enhance Se volatilization because such hydraulic fluctuation will increase the decomposition rate of organic matter, Se bioavailability, and microbial activity in soil. Following up to each wetting event in a soil-pickleweed system, Se volatilization increased up to threefolds repeatedly, and the rate of Se volatilization significantly correlated with soil water potential (kPa). While soil water potential decreased from 0 kPa (water saturation) to -25 kPa in the top 5-cm layer of soil, the rate of Se volatilization was reduced by 78%. For microbial volatilization, the optimum soil water content generally ranges from 20% to 70% of the soil water holding capacity.

Temperature, Redox Potential, pH, and Salinity

Other environmental factors, such as temperature and redox potential, will also affect Se volatilization. Biological volatilization process is temperature-dependent. Therefore, the rate of Se volatilization generally increases with increasing air or soil temperature. Laboratory experiments show that the optimal temperature for Se volatilization is approximately 40°C. In the field studies conducted in Central California, high rates of Se volatilization were oftentimes observed during later spring or early summer months. In addition, more volatile Se can be generated by soil microbes under aerobic conditions than under anaerobic conditions. Changes in soil pH will affect the bioavailability of Se in soil. The optimum pH for Se volatilization is around eight in soil or sediment. Few studies have been conducted to determine the impact of soil salinity on Se volatilization, which is likely depending on the type of salinity (i.e., sulfate salinity or chloride salinity) and the magnitude.

Soil Bacteria and Plant–Soil Microbial Interactions

Soil bacteria and fungi can volatilize Se without the presence of vegetation, although the addition of vegetation generally results in higher levels of Se volatilization. It is difficult to determine the extent to which biogenic volatile Se can be produced directly from plants versus soil microbes (i.e., separating plant roots from the soil microbes). Previous studies showed that rhizosphere bacteria enhanced the uptake and accumulation of selenate in plant roots, and therefore, facilitated volatilization of Se from selenate. Indeed, the presence of soil microbes plays a very important role in the high production of volatile Se in soil–plant systems. For example, in the soil-pickleweed system, the amount of volatile Se dissipated directly from shoots accounts for only 10% of the total volatile Se, and the majority of total volatile Se was produced from the soil–root compartment. Pickleweed has the capacity to reduce selenate to SeMet. Thus, the accumulation of SeMet in plant tissues provides a large pool of bioavailable SeMet that can be easily methylated and volatilized by soil microbes in the field. Therefore, high rates of Se volatilization in the pickleweed field likely resulted from the interaction between pickleweed and the species associated soil microbes. The addition of vegetation will not only increase levels of Se volatilization by directly dissipating Se from plants, but also create special habitats (or rhizosphere) for specific soil microbes. Plant roots may also produce specific root exudates that are essential for certain rhizosphere microbes. In addition, annual biomass production of plants will provide soil microbes with C and energy sources in a sustainable manner.

Specific soil bacteria have been isolated for As methylation and volatilization. For example, paddy-soil abundant *Cytophagaceae* spp. has the ability to convert almost half of 10 μM arsenite in the growth medium to trimethylarsine gas during a 24-h time period. The inoculation of this bacterium had greatly enhanced As methylation and volatilization in the soil contaminated with As.

Genetic Modified Plants for the Enhancement of Biological Volatilization

To substantially increase biological volatilization, techniques of genetic engineering have been applied to overcome biological limitations that are associated with the pathway of Se assimilation and volatilization. For example, the overexpression of ATP

sulfurylase (APS) can facilitate the reduction of selenate to selenite, which is commonly rate-limiting with respect to the production of other organic compounds, such as SeCys and SeMet. Similarly, other downstream rate-limiting steps can also be eliminated by the overexpression of other enzymes. India mustard plants that were overexpressed with cystathionine-γ-synthase (CGS) has shown an enhanced efficiency (about two to three times greater) for Se volatilization under laboratory conditions.

In addition to genetically engineered Indian mustard for Se volatilization, other transgenic plants have also been developed to metabolize ionic- and methyl-mercury and to produce elemental mercury (Hg^0) for volatilization. For example, genetic engineering has added a bacterial mercuric ion reductase to *Arabidopsis thaliana* and therefore, the transgenic plant is able to convert Hg cations to elemental Hg and further releases Hg^0 into the air. Some Hg-resistant bacterial strains like *Klebsiella pneumoniae* are able to reduce ionic Hg to elemental Hg and to effectively volatilize Hg compounds from the substrates.

Transfer of Volatile Compounds From Water to the Air

The environmental transfer process of biogenic volatile compounds of Se or other elements is primarily controlled by a physical dispersion process that is generally governed by Henry's law. Henry's law constant (H) describes the distribution of a volatile compound (e.g., DMSe or DMDSe) between gas and water phases at thermodynamic equilibrium. Therefore, the potential for a volatile compound to partition from water to air increases with increasing Henry's law constant. A larger Henry's law constant value (e.g., >0.1) suggests a higher potential for the organic compound to volatilize from water to the air. For example, using the DMSe water solubility of 0.0244 g g^{-1} and the DMSe vapor pressure of 32.03 kPa, Henry's law constant of DMSe at 25°C is calculated as 0.058, suggesting a moderate tendency to partition between water and air. Henry's law constants generally increase with increasing temperature, primarily due to the significant temperature dependency of chemical vapor pressures. A higher temperature will not only elevate plant and microbial activities but also increase Henry's law constant, which, in turn, will increase the flux of Se volatilization from water to the air.

The stability of DMSe in soil is affected by the soil water content. In water saturated soil, DMSe can be partially dissolved in water before its transfer from soil water to the air. Oxidants (such as manganese oxides) in soil solution may convert DMSe to nonvolatile Se compounds. Therefore, the transport of volatile Se compounds in soil significantly relates with the soil water content. The rate of Se volatilization will be likely low in flooded soil or sediment due to DMSe solubilization in soil solution. For example, the flux of Se volatilization from a natural wetland in Southern Switzerland was generally <0.12 μg m^{-2} day^{-1}, along with As of <0.54 μg m^{-2} day^{-1} and S of <37 μg m^{-2} day^{-1}, during the summer season.

Flux Measurements of Biological Volatilization

Volatile Se compounds in the air can be collected by physical adsorption using activated carbon materials or by chemical oxidation with peroxide (H_2O_2) or acid (HNO_3) trap solutions. The alkaline-peroxide trap solution (30% hydrogen peroxide and 0.05 M HaOH, 4:1, v/v) has commonly been used to directly trap or to extract Se from the surface of the activated carbon material. When nitric acid is used as trapping solution, dimethylselenide (DMSe) can be oxidized to dimethylselenoxide (DMSeO) or dimethyldiselenide (DMDSe) to methaneseleninic acid (MSeA). Thus, speciation analysis of volatile Se compounds can be performed using the nitric acid trapping solution. In addition, solid phase microfiber extraction (SPME) has also been used for sampling airborne organic As compounds from soil–plant systems.

The flux of Se volatilization can be determined using different types of sampling chambers that can be open-bottom cubic compartments made of transparent materials such as *Plexglas*. An open-flow sampling system has been commonly selected because it allows for a minimal heat and humidity buildup inside the chamber as well as for a maximum sampling efficiency. Briefly, with an open-flow chamber sampling system, ambient air is continuously scrubbed of volatile Se before entering the chamber through charcoal filters or the trap solution at the inlet port, and Se-free air mass is then mixed with volatile Se produced inside the chamber. The mixed air is drawn under slight vacuum into the outlet port passing through charcoal filters or the trap solution where volatile Se compounds are collected. To further minimize the effects of rising temperature inside sampling chambers on the volatile Se measurements, the sampling chamber can also be equipped with a cooling radiator connected to an evaporative cooler.

The micrometeorological flux measurement technique is an attractive method for the flux measurement of Se (or other elements) volatilization under filed conditions. The technique provides an average integrated flux of volatile Se over a large area by measuring the difference in Se concentrations in ambient air at two different heights above ground. Indeed, this technique determines the flux of volatilization through eddy correlation under naturally occurring environmental conditions. However, it is difficult to apply this sampling technique in practice because it is costly in instrumentation and often associated with interference such as the footprint effect from other sources of volatilization.

Fate of Biogenic Volatile Se in the Atmosphere

Biogenic volatile Se can be transformed into more oxidized and less volatile chemical species in the atmosphere. Volatile Se compounds (DMSe or DMDSe) can react with airborne oxidants such as O_3, OH, and NO_3 radicals, and be converted into aerosols or particulates during a short period of time, for example, ranging from 5 to 6 h in the atmosphere in Central California. The

dispersion of airborne Se in the mixing boundary layer and its subsequent atmospheric long-range transport are highly controlled by local air stability and regional air mass movement pattern. The forward trajectory analysis showed that volatile Se from the Western San Joaquin Valley can be transported out of the Valley within 24 h toward remote mountain areas. In the atmosphere, aerosol- or particulate-associated Se accounts for 75% of total airborne Se, with the remaining 25% being in the vapor form. Therefore, wet deposition is likely the dominant pathway of Se removal from the atmosphere to the land surfaces.

Significance of Biological Volatilization in Phytoremediation of Se Contamination

Phytoremediation is the use of plants and associated microbes to clean up contaminated water and soil. Phytoremediation of Se contamination mainly involves two processes: (1) biological volatilization that removes Se from contaminated soil–plant systems to the atmosphere and (2) accumulation of Se in plant tissues that will be harvested and removed from the contaminated site (i.e., phytoextraction). Phytoextraction can only be effective during the plant growth season, while biological volatilization can be in action continuously during the whole year. Field studies showed that biological volatilization is a significant pathway of Se removal in phytoremediation. For example, in the pickleweed field in the San Joaquin Valley, the annual total Se removal through volatilization can be 5.5 times more than via phytoextraction. Biological volatilization represents an environmentally sound and sustainable biotechnology for the remediation of Se contaminated soil and water. The volatilization process generates DMSe compound that is ~500 times less toxic than the inorganic forms of Se fed to rats. In addition, Se removal via volatilization likely diminishes the amount of Se available for entry into food chains in the contaminated environment.

There are few long-term studies on Se volatilization conducted under field conditions. In a previous constructed treatment wetland study, different wetland cells were built and vegetated with different plant species for the treatment of Se-laden agricultural drainage water (25 μg Se L^{-1}). The plant species included cattail (*Typha latifolia* L.), baltic rush (*Juncus balticus* Willd.), smooth cordgrass (*Spartina alternifolia* Loisel), saltgrass (*Distichlis spicata* (L.) Greene), saltmarsh bulrush (*Scirpus robustus* Pursh), and rabbitfoot grass. Rates of Se volatilization were determined monthly for 2 years in each wetland cell. Significant variation in Se volatilization was observed among the wetland cells or different plant species. The highest average rate over the 2-year period was 33 ± 12 μg m^{-2} day^{-1} in the rabbitfoot grass cell. Selenium volatilization was highest in late spring and early summer during the year in Central California. About 35% and 48% of the Se entering the rabbitfoot grass cell was volatilized during May and June, respectively, whereas only <5% was volatilized in the winter months. Overall, biological volatilization removed 9.4% of the total Se input to the rabbitfoot grass wetland cell to the atmosphere during the 2-year study period. Clearly, to implement the phytoremediation technology, Se volatilization needs to be substantially enhanced and sustained at high levels during the entire year.

Volatilization of organic pollutants is usually defined as a physical process of compounds transferring from water to air phase without involving metabolism. Although biological degradation of organic compounds may result in different intermediate products that could dissipate to the air, such processes are not included in this paper because they do not involve biological methylation and volatilization as the natural ecological process. Studies have also been conducted on biological volatilization of S, mainly with respect to its geochemical cycling. As mentioned above, because S and Se are chemical analogs, the above discussion on Se volatilization is generally applied to the volatilization process of S in the environment.

Waves as an Ecological Process

CA Blanchette, MJ O'Donnell, and HL Stewart, University of California – Santa Barbara, Santa Barbara, CA, USA

Wave Mechanics

Of the physical process in the ocean, ocean waves are perhaps the most visible to the casual observer. The surface of the ocean is rarely still; slight puffs of wind send small ripples across still water. On exposed coasts, little ripples are usually unnoticed as walls of water rear up from the undulating sea surface and fling themselves against the shore with crashing roars and showers of foam. In shallow habitats, waves can exert an important influence on the distributions of organisms.

Waves on the surface of the ocean get their energy from wind blowing over the top of the water. As air moves over the water, friction causes the water to pull in the same direction, forming small ripples. With time and distance, little ripples become larger ripples and eventually form large waves, which can travel far from the location where they were originally formed. Actually, the idea of a wave traveling needs some explanation: waves are a rhythmic displacement of the surface of the water. The water itself moves in an elliptical pattern, and an individual particle of water returns to almost the same spot at the top of each wave. The waveform itself travels across the surface; what is really moving is the energy of the wave passing through the water. A wave can be described by several parameters: its wavelength, which is the distance between two subsequent peaks; its period, the time it takes for a complete wave cycle; and its amplitude, the vertical distance between the peak and the trough of a wave (**Fig. 1**). Waves travel across the ocean with some speed, known as the celerity. The disturbance of waves does not just occur at the surface; water beneath the surface is also moving in an orbital path, with smaller and smaller orbits until the depth of the water is half of the wavelength.

Once formed, ocean waves can travel long distances with very little dissipation. This means that storms in the middle of the Pacific Ocean send waves to both California and Japan. As they enter shallow water (where the water depth is less than half the wavelength), waves begin to change; the orbital motion of the water interacts with the bottom to become more elliptical. As a result, waves in shallow water undergo a process known as shoaling, becoming taller and steeper. In this region near the shore, waves begin to interact with the communities of organisms living on the bottom, subjecting them to oscillatory water motion. Over soft bottoms, waves will form ripples in the substratum, which help to structure the habitable space.

In very shallow water waves become so steep that they can no longer maintain their shape. The water below the wave is being slowed by drag on the bottom to a greater extent than the water at the top of the wave. At this point, the top portion of the wave will tumble over and begin to break. During breaking, all of the energy of the wave is dissipated in the turbulent motion of water on the shore. Breaking is a violent process, and can result in very high water velocities and high levels of turbulence. Most of the energy of breaking waves is expended in the intertidal zone and the shallow subtidal region. For organisms living in these regions on wave-swept shores, waves are one of the dominant features of their physical environment.

Life in the Wave-Swept Environment

The most direct mechanism by which waves influence populations is by removing or destroying individual organisms that live on wave-swept shores. The velocity of the water beneath shoaling and breaking waves can impose large forces on biological structures in their paths. The primary forces of moving fluid over a stationary object are lift and drag. Both of these forces increase with the velocity of the fluid squared, which means that a small increase in water velocity leads to a large increase in the force that an object experiences. The velocities beneath breaking waves can be very high (investigators have measured velocities in excess of 30 m s^{-1}), as can the forces exerted on organisms living beneath breaking waves. For an organism of the size of a golf ball on a moderately wave-swept shore, this can translate into forces as high as 200 N ($\sim$20 kg) that the organism must resist if it is to remain on the shore.

In coastal ocean regions, waves can impose large hydrodynamic forces on benthic organisms. If the forces imposed by waves are larger than the attachment to the substratum (tenacity) or the mechanical strength of organisms, they may become broken or dislodged (**Fig. 2**). The tenacity of mobile animals is often reduced when they move, raising the possibility that predators and grazers increase their risk of dislodgement when they forage. Breakage and dislodgment does not always lead to death; some organisms can regenerate broken parts or, if dislodged, may be able to re-attach and grow at another location. This may be an effective mechanism of dispersal for organisms that live in extremely wave-swept environments. For a large number of organisms, dislodgment does lead to death and several researchers have been experimenting with predictive models to describe survivorship as a function of wave height. These models are becoming more refined over time as more data become available to strengthen the link between wave height and maximal water velocity.

Strategies for Survival in the Wave-Swept Environment

From coral reefs to temperate intertidal rocky shores to sandy beaches, waves shape near-shore marine communities through interactions with individual organisms. The high energy of water moving in waves has important implications for wave-exposed organisms. There are several ways marine organisms deal with waves.

Behavioral Strategies

Mobile organisms in wavy habitats may time their forays into wave-swept areas to calm periods or high tide when the effect of the waves is less intense. For example, crabs on rocky shores walk around and forage between waves but grab on and assume a low, flattened posture that minimizes drag when waves hit. Seabirds run out of the way of waves as they forage in the swash on sandy beaches (Fig. 3), and burrowing invertebrates dive down into sand to find refuge from waves deep down in between sand grains. Not all organisms avoid waves, however. Seals and dolphins can be found surfing in waves and killer whales have been reported to use the froth of breaking waves as camouflage for hunting seals on the beach.

Strategies of Sessile Organisms

Benthic sessile organisms that cannot move out of the way of wave action use a number of strategies that enable these organisms to withstand the forces imposed on them by waves.

Strength

Strength is a common strategy for persisting in wave-swept habitats. The strength of the attachment (by holdfasts of algae, byssal threads in mussels, and foot size in snails) of organisms exposed to waves is often higher than in calm habitats. Barnacles, snails, and limpets also have strong shells, which protect them against wave action. By retracting into their hard, strong shells, these animals can protect their soft bodies from the high energy of waves breaking directly on them. On coral reefs, the strength of scleractinian (reef building) coral skeletons enables them to thrive under waves breaking on the reef. The strong, stiff structures of corals enable them to resist forces from all directions imposed by waves. Many corals are strong enough to withstand the hydrodynamic forces that they experience in waves, and the substratum to which corals are attached often breaks before the coral itself.

Flexibility and elasticity

Another strategy for surviving waves is to be flexible. Flexible organisms do not require resources for structural support; therefore, this may be a less costly alternative than strength for survival in wavy habitats. Seaweeds provide a good example of this approach. Flexible algae are easily reconfigured into streamlined shapes by water moving around them. This reduces the force exerted on an alga by decreasing the area exposed to hydrodynamic forces. A flexible organism may also be pushed easily down toward the substratum where flow velocities are reduced by interactions with the benthos. A flexible organism can be reconfigured and pushed in alternating directions by the bidirectional flow of waves. The back-and-forth motion of flexible organisms in waves may also rub them against the adjacent substratum. This may damage the organism itself, but can also dislodge potential neighbors and keep the area around it free from competitors. Back-and-forth motions of flexible organisms in waves can also act to dislodge epibionts such as snails or epiphytic algae. These riders may prey upon the organism or may compete with it, as do epiphytic algae competing for light or nutrients with their host alga.

Another approach to survival in waves is used by the alga *Postelsia palmaeformis*. This alga resembles a small palm tree and stands upright, often sticking up in the air (**Fig. 4**). It thrives on the most wave-exposed areas in temperate intertidal zones, where individuals are knocked over by almost every wave. The stipe (equivalent to terrestrial plant stalk) of *Postelsia* is flexible and highly elastic. In combination with the shape of the stipe, this allows this alga to rebound back into an upright posture after it is pushed over by a wave and the wave has passed. In this way *Postelsia* thalli are reconfigured into streamlined shapes and pushed down toward the substratum where water velocities may be reduced, but they then passively spring back to upright postures by energy stored in their resilient stipes, much the same way an elastic band rebounds back into shape after being stretched. Similarly, other algae rely on buoyancy to return them to their upright postures after waves have pushed them over. Such algae are pushed against the bottom by waves, and then passively return to an upright position by the upward force of buoyancy when the flow slows.

Size and numbers

A flexible organism can survive waves by moving along with the flow. This strategy is effective for long organisms, such as kelps. By being longer than the displacement of the water in a wave, such kelps can avoid experiencing high hydrodynamic forces associated with waves. While the kelp moves along at the same velocity as the water in the wave, it experiences no water motion relative to its surfaces, and therefore no force. When the water in the wave reverses direction, the kelp is passively carried along with the water motion in the other direction. If the kelp never becomes completely strung out in one direction before the water velocity of the wave reverses, it can avoid the high forces associated with waves. In this way, large flexible, weak organisms can persist in areas exposed to waves.

Fig. 4 The sea palm, *Postelsia palmaeformis*. Photo by Carol Blanchette.

Small size is also thought to be a characteristic of organisms exposed to waves and, indeed, many of the organisms persisting in wave-swept habitats are small (e.g., many seaweeds, barnacles, snails, and limpets). Organisms capable of altering aspects of their morphology often have a smaller, more compact shape in wave-exposed than wave-protected habitats. However, the long, flexible kelps and large strong corals provide exceptions to this generality.

Some organisms form dense aggregations and this can help buffer then from the velocities and subsequent forces exerted by waves. Mussels, algae, and other organisms can often be limited in rocky substratum for attachment space. As a result, patches of densely aggregated individuals often form on suitable surfaces on wave-swept shores (Fig. 5). Water motion caught inside aggregations can be damped and slowed. As hydrodynamic forces are proportional to water velocity, this can lead to reduced forces inside aggregations, as interior individuals may be buffered from fast water velocities by neighbors.

The Benefits of Life in a Wave-Swept Environment

Because waves can be so destructive, scientists have devoted a great deal of attention to understanding the strategies that organisms have evolved to avoid or cope with damage. However, not all of the ecological consequences of waves are negative. The vast numbers and diversity of organisms living in wave-swept environments indicate that the tradeoffs required for survival there are worthwhile. Many aspects of biological processes are enhanced by wave action.

Reproduction and Fertilization Success

Waves can have significant effects on the numbers of young organisms that produce and release into a population. Beneath breaking waves, the tumultuous water motion is characterized by high turbulence. This turbulence can have important effects on the success of fertilization, and therefore the number of young produced in broadcast-spawning species. Sexual reproduction via the release of sperm into the water column is widespread among marine organisms. Given the limited swimming capabilities of sperm, if adults are separated by more than a few centimeters, some water motion is required to bring sperm and eggs together. Turbulent mixing due to wave energy can be advantageous to bring gametes into contact; however, turbulence will also influence the dilution rate of the gametes and imposes viscous forces on them. If these forces inhibit the attachment of sperm to eggs or damage the gametes or zygote, the advantages of mixing can be negated. Thus, turbulent water motion can either aid or hinder fertilization depending upon the species and the degree of turbulence.

Dispersal of Young

The vast majority of marine benthic animals have a planktonic larval stage, and the dispersal and settlement patterns of these larvae are important determinants of population dynamics. Larval transport is greatly affected by the near-shore flow regime. In this case, a wave phenomenon known as `internal waves' plays a role. Internal waves are similar to surface waves in being periodic undulations of a fluid interface, but internal waves happen within the ocean, at points where there are sharp gradients in the temperature or salinity of water. Such gradients often occur somewhere in the top 30 m of the ocean. Although internal waves cannot be seen by eye, they can be observed with thermometers mounted in the ocean. Though not as obvious as surface swell, internal waves have important ecological consequences. For example, tidally generated internal waves are accompanied by circulating cells of water near the surface, and on many shores these cells are advected shoreward with the internal waves. Larvae that can swim fast enough or are sufficiently buoyant to stay at the water's surface are concentrated in areas of downwelling between cells and are consequently carried inshore. Internal waves thus provide a mechanism for returning dispersed larvae to the shore where they can settle and recruit into the population. The mass transports and long-shore and rip currents accompanying

Fig. 5 *Turbinaria* aggregation. Photo courtesy of Hannah Stewart.

surface gravity waves provide alternative mechanisms by which larvae can be transported, in this case both on- and offshore. For any of these advective mechanisms, behavioral control by the larva over its position in the water column can affect the direction and rate of transport. Aside from advective transport, the process of turbulent mixing, common to wave-swept shores, may also disperse larvae.

Dispersal of Chemical Cues

Waves provide water motion that can spread settlement cues in the water column, but the back-and-forth motion of water in waves slows the rate at which chemical cues are advected away from their area of origin. As the cue moves in the oscillatory flow of waves, it becomes mixed with the surrounding water. Larvae of a coral-eating nudibranch have a settlement mechanism that takes advantage of this situation. When a larva experiences a settlement cue above a certain concentration, it stops swimming and sinks. Due to the oscillatory nature of water under waves, as the larva sinks it is moved back and forth but lands on the bottom roughly below the position in the water column where it sensed the cue. In this way, the simple behavior of the nudibranch and the water motion of waves provide a mechanism that increases the chances of a larva reaching its desired settlement site in a wavy environment.

Feeding and Nutrient Uptake

Turbulence in the benthic boundary layer is generated by the interaction of flow with the roughness of the substratum and can be augmented by mainstream turbulence from breaking waves. The intensity of this turbulence controls the rate at which suspended food and dissolved nutrients can be delivered to benthic organisms. If turbulent mixing is not sufficiently energetic, food or nutrients may become a limiting commodity. This effect has been demonstrated for populations of mussels in estuaries and for kelps in slow-moving flows. Nutrient limitation in kelps due to insufficient mixing appears to be a problem only at very low velocities.

Ecological Consequences

Disturbance and Patch Dynamics

Probably the most important and well-studied ecological effect of wave action is the effect of wave-induced disturbance to the community. Storms and intense wave action can be a leading agent of disturbance in marine communities. Disturbance plays a central role in nonequilibrium theories of community structure, including the concepts of disturbance theory, patch dynamics, and supply-side ecology. These theories attribute high species diversity and species coexistence to the processes of stochastic recruitment in a heterogeneously disturbed, patchy environment. The `intermediate disturbance hypothesis' proposes that species diversity is highest in communities that are subject to moderate levels of disturbance. Disturbances have been shown to be important in many marine systems. For example, the rate at which waves clear gaps in intertidal mussel beds of the northeast Pacific creates opportunities for other, less competitive, species to settle and grow (**Fig. 6**). Species diversity has been shown to be highest in intertidal boulder fields containing boulders of medium size, which are overturned more frequently than large boulders and less frequently than small boulders. Similarly, the rate at which storm waves cause breakage can have a controlling influence on the structure of coral reef communities.

Fig. 6 Patches created in an intertidal mussel bed by wave disturbance. Photo by Carol Blanchette.

Productivity

Intertidal organisms cannot transform wave energy into chemical energy, as photosynthetic plants transform solar energy, nor can intertidal organisms `harness' wave energy. Nonetheless, example after example finds that communities exposed to high wave action are more productive than similar communities in less wave-exposed areas. Despite severe mortality from wave-driven storms, communities at some wave-beaten sites produce an extraordinary quantity of biological structures per unit area of shore per year. Highly productive organisms such as the sea palm, *Postelsia palmaeformis*, are restricted to wave-beaten sites. Water motion is known to enhance the growth of aquatic organisms. In general, productivity of marine and freshwater plants is higher in moving than in still water, and it has long been known that coral reef growth is most vigorous on those margins of the reef where waves pound hardest. Wave-beaten reef platforms produce four times as much calcium carbonate per square meter per year as do those in protected lagoons. Increased exposure to waves does not always increase productivity. Along the southern coast of Chile, the subtidal kelp *Macrocystis* appears to grow best at intermediate levels of water motion: at the most exposed sites, storm waves tear these kelps away. In the northeastern Pacific, however, intertidal kelps do grow better in wave-beaten places, even though waves select stringently for small size, because winter storms shred the fronds of most kelps, and tear away many kelps and mussels. In general, intertidal zones of the northeastern Pacific are more completely covered by plants and animals the more exposed they are to wave action. The mechanisms for this enhanced productivity are complex and different for different systems. However, the phenomenon is well documented as an important component of how waves influence intertidal communities.

Climate Change and Wave Activity

Will the changing climate of the future be accompanied by changes in the wave climate? Recent investigation has shown wave and storm activity to be highly correlated with the intensity of El Niño-Southern Oscillation events. Although it is unclear what mechanism could account for this relationship, the presence of such a correlation suggests that local wave exposure can be strongly affected by the type of large-scale climate phenomena that are currently the subject of intense predictive efforts. Researchers have also noted an increase in wind stress averaged over large areas of the sea surface for the seas adjoining California, Peru, Morocco, and the Iberian Peninsula. Wind stress is a large contributing factor in the formation of waves. These studies suggest that substantial fluctuations in the severity of the wave climate may be a common phenomenon. The ability to predict ecological effects of waves on species distributions will become increasingly important in the face of climate change. For example, many intertidal species present on the central California coast are at or near the limits of their biogeographic ranges. A shift in the rate of disturbance that results in even a slight shift in the ability of a given species to persist may in this case result in a substantial shift in that species distribution. Thus, the ability to make accurate mechanistic predictions regarding wave-induced disturbance may augment our ability to predict future shifts in species distributions.

Wind Effects

W Eugster, ETH, Zürich, Switzerland

Introduction

There are two categories of wind effects in ecology: (1) the effect of the vegetation surface on the wind, how it lowers wind speed near the ground, shelters niches from strong winds where small animals and plants can establish and live; and (2) the effect that wind and turbulence excert on many aspects of animal behavior, plant growth and survival, and the overall metabolisms of organisms.

Studies on forest recovery in North America have pointed to the important role of high winds in temperate forests. Although such catastrophes are rare, they could be instrumental in the creation and maintenance of mosaic patterns and hence the diversity of these woods. Some attempts to reconstruct the history of winds during the past glacial maximum (about 18 000 years ago) indicate that tropical storms generating winds of hurricane force were scarser, less intense, and shorter than those of the present day, with important consequences for forest ecology which include the influence on development, structure, and composition of the migrating and reassembling forests of the mid- and higher latitudes. However, direct evidence of the effects of wind on forests is hard to come by, and also other aspects of wind effects in a wide variety of ecologically relevant topics are rather scarcely covered in the scientific literature. Almost all studies reviewed in this article are based on an ecological question that suggest some partially unknown dependence on environmental variables. Mostly, temperature, precipitation, and humidity are considered important variables in such investigations, and wind effects are rather considered a possible or likely additional side effect of the overall ecological process under investigation. It is therefore not surprising that there are almost no systematic studies in the scientific literature that cover all aspects of wind in all details.

Some specific aspects, where the ecological importance of the wind is rather obvious, are covered in much greater detail in other topics. Thus, here we focus on the very general physical relationship between wind (and thus turbulence) and other environmental factors such as thermal heat loss and metabolic rates of organisms, and the exchange of trace gases such as CO_2 shall be addressed before summarizing the most relevant specific aspects of wind effects in the ecological literature.

Mean Wind Speed and Turbulence

Wind is a vector variable, but in many scientific applications only the scalar wind speed is investigated or of interest. Since wind – that is the term for the atmospheric motion over the solid surface of the Earth with respect to the surface itself – is mainly driven by pressure gradients on relatively large scales over the globe, this term is often used as a short-cut for horizontal mean wind speed. Over sufficiently long observation intervals and over large surface areas, there is no net loss or gain of air due to vertical motion; thus, the vertical component of the wind vector is considered to be zero. Hence, the wind vector is approximated as a two-dimensional entity that can be described by the scalar horizontal wind speed and the wind direction. All standard weather stations use this basic concept for recording wind. This is however not necessarily the best possible simplification for small-scale and short-term investigations, and thus has important implications for ecological processes. As an example, three-dimensional wind gusts in autumn can easily pick up fallen leaves from the ground, despite the fact that the leaves are relatively heavy and the mean vertical and horizontal wind speed over an hour or longer may be rather low. But on the timescale from tenths of a second to several minutes, turbulence – which includes such wind gusts – can be the most relevant wind effect. The turbulent timescale typically extends up to 1 h, whereas longer timescales are associated with mean wind effects. There is not a sharp separation between turbulence and mean wind, although a spectral gap between the two timescales has been postulated by some scientists. In reality, there is a confounding effect with the diurnal course of wind speeds that show different and locality-specific conditions during the day as compared to the night.

Laminar Flow and Turbulent Winds

Turbulence is generated inside a laminar flow when there is mechanical friction or thermal convection that perturbs the flow. **Fig. 1** illustrates this for a laminar flow with a certain wind speed that moves from a smooth onto a rough surface. At a certain distance downwind of the leading edge of this increased roughness, the laminar flow becomes chaotic, that is, turbulent. However, this turbulence does not completely reach the surface, a minute laminar surface layer always exists, over the surface of any object, including plant leaves (**Fig. 2**). Turbulent exchange of heat, moisture, CO_2, and other trace gases is by far more efficient than exchange in laminar flows (see below). Once the air is turbulent the flow does not easily become laminar again since the transition from turbulent to laminar flow is not as clearly defined at it is in the opposite direction. The decay of turbulence in the air is subject

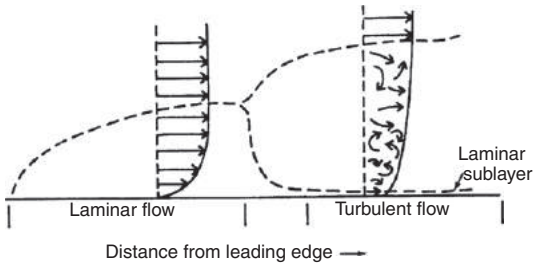

Fig. 1 Transition from laminar to turbulent boundary layer as wind blows over a vegetation surface changing from smooth to rough. Modified from Grace, J., 1977. Plant Responses to Wind. London: Academic Press.

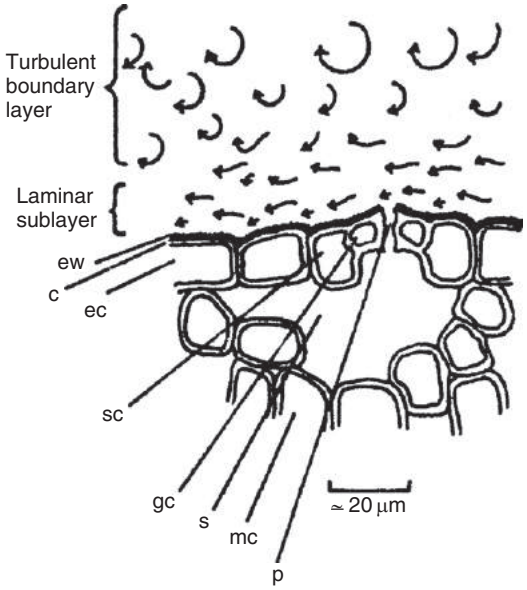

Fig. 2 Diffusion pathways at a leaf surface on a windy day: c, cutin; ec, epidermal cell; ew epicuticular wax; gc, guard cell; mc, mesophyll cell; p, pore; s, substomatal cavity; sc, subsidiary cell. Modified from Grace, J., 1977. Plant Responses to Wind. London: Academic Press.

to the physical rules of turbulent kinetic energy dissipation that ends up in the Brownian motion of single molecules and thus dissipates kinetic to thermal energy.

Wind has a kinetic energy,

$$E_k = \frac{m}{2}V^2 \quad [1]$$

with m the unit mass of the unit air volume, and V the scalar wind speed of the three-dimensional wind vector, that is composed of mean kinetic energy and turbulent kinetic energy. At moderate to high wind speeds the mean kinetic energy is by far greater than the turbulent kinetic energy. In addition, wind carries a momentum,

$$\tau = mV \quad [2]$$

At high wind speeds, especially during storms, a very high kinetic energy (both mean and turbulent components increase with increasing wind speed) may result from the wind, which is responsible for the devastating damages by hurricanes and other storm events, that however are also important for producing gaps (wind throws) in forest ecosystems and thus for these ecosystems' overall life cycle. Turbulent motions that are most relevant at lower wind speeds do not have such a devastating effect when mean wind speed is low. The kinetic energy of the mean wind is what wind mills profit from, and also migratory birds benefit from this component. Near the ground, the vegetation has to absorb both the kinetic energy of the wind and its momentum, but in this case the momentum absorption is by far the more relevant process and as a first approximation only momentum transfer by the vegetation is considered, neglecting the additional effect of energy absorption.

For flying birds it is mostly the kinetic energy of the wind that influences their daily life. It has been shown for Sandwich Terns (*Sterna sandvicensis*) on the isle of Griend, the Netherlands, that their loss of prey to the competing kleptoparasitizing Blackheaded Gulls (*Larus ridbundus*) significantly increases with wind speed. Thus, wind directly reduced the ability of Sandwich Terns to defend

their prey (mostly fish) against attacks of Blackheaded Gulls. This had a negative effect on the amount of food transported to the colony, while kleptoparasitism increased. Therefore, wind speed severely affected energy intake of the chicks and had strong negative effects on chick growth. During the first two weeks posthatching, kleptoparasitism was relatively low and had only small effects on chick growth, even under unfavorable weather conditions. From then on, the negative effects of kleptoparasitism on growth became considerable.

Wind over the Vegetated Surface

Vegetation is the most important interface between the atmosphere and the solid ground in terrestrial ecosystems. On the one hand, vegetation adapts to wind conditions and special plant social community compositions are found in the Arctic and Alpine environments where persistant and strong winds influence exposed locations such as hills, mountains, and crests. On the other hand, vegetation makes the Earth's surface rougher than what would be the case over bare soil (**Table 1**), and thus strongly influences the wind speed (**Fig. 3**) and direction in the atmosphere near the ground. The wind is driven by pressure and temperature differences on large scales, whereas the Earth's surface does not move and becomes stationary under most occasions. Exceptions are very special conditions during hurricane-force winds, and certain exposed locations with corresponding soil conditions, where bluffs are created by the steady wind movement. Under normal conditions, wind speed at some nonzero height above the ground must be zero to fulfill the criterion that the vegetation stays in place. Rough vegetation such as forests excert a much higher roughness ($\sim$1 m) to the atmospheric wind motion than shortcut grass (on the order of millimeters to centimeters; see **Table 1**). Based on this roughness the increase in wind speed with height above the vegetation depends strongly on vegetation type and structure. This vertical wind speed profile tends to increase logarithmically with height above the canopy (**Fig. 3**), and the physical process responsible for this is momentum absorption. Tall vegetation such as forests absorb momentum with their roots, and also in the dynamic motion of the stems. Thus, under strong winds it depends on the rooting type of the tree and the wood quality whether a tree can be uprooted or whether the stem breaks at a certain height above the ground.

Table 1 Relations between canopy heights (m) and aerodynamic roughness length (m) for different vegetation types

Vegetation	*Type*	*Canopy height (m)*	*Roughness length (m)*
Forest	Tropical	32–35	2.2–4.8
	Coniferous	10.4–27.5	0.28–3.9
	Pine	12.4–15.8	0.32–0.92
Woodland	Trees	10–15	0.4
	Savannah	8–9.5	0.4–0.9
Crops	Vines	0.9–1.4	0.023–0.12
	Beans	1.18	0.077
	Corn	0.8	0.064
	Wheat	0.25/0.4/1.0	0.005/0.015/0.05

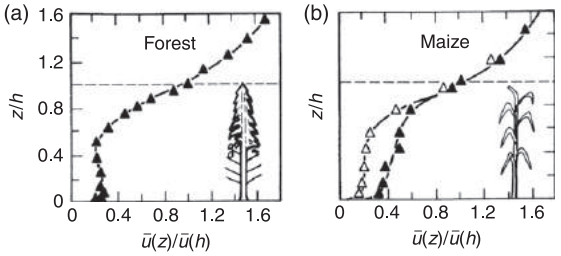

Fig. 3 Wind profiles (a) in a pine forest canopy of 16 m height (h), and (b) in a maize canopy of 2.1 m height. Both profiles show the mean horizontal wind speed, normalized for the wind speed at the top of the canopy ($z = h$). In the case of the forest the specific wind profile inside the trunk space ($z/h < 0.5$) a secondary maximum of the wind speed can be seen. Maize profiles for light winds of 0.88 m s^{-1} (closed triangle) and strong winds of 2.66 m s^{-1} (open triangle) at the top of the canopy are shown. From Raupach, M.R., Thom, A.S., 1981. Turbulence in and above plant canopies. Annual Review of Fluid Mechanics 13, 97–129.

Wind Pruning and Salt Spray

To unroot a tree normally requires strong gusts in heavy mean winds, as for example during storms. If winds are strong and steady, but not very gusty, then the energy may not be sufficient to unroot a tree and thus the wind-pruning effect may shape trees and shrubs (Fig. 4). Along the seacoast of British Guiana, along the subtropical shores of the island and Trinidad and southern California, and the subarctic shores of Hudson Bay and Labrador, the wind is reported to result in pruned trees. It appears that the steady subtropical winds have a similar pruning power as the icy blasts of the subarctic. However, this is not necessarily an effect of the wind alone. It has been argued that the proximity to the sea leads to a high load of salt spray in the wind, and that the toxicity of that salt may be the true ecological factor of wind pruning. Salt spray deposition on young shoots seems to actually kill many of them, thus causing the pruning. This observation is however only weakly based on pH readings along a transect from the shore of the Belcher Islands off the Hudson Bay coast, and it is also noted that the drying effect of the wind, possibly in combination with salt spray and other factors (ice and sand particles), may be as important.

Directional Growth Response

Besides pruning steady winds from a persistent wind direction can lead to directional growth response of trees, it is widely observed in coastal areas, in deep mountain valleys with a well-developed valley wind system (Fig. 5), or on wind exposed crests, rims, and hills. Since wind speeds generally increase with altitude from the lowland to the mountains, it has even been argued that high-altitude plants in wind-swept mountains may be less affected by global warming, and that the spread of lowland plant species into uplands as predicted by some global warming scenarios may be strongly restricted in higher altitudes due to the lack of adaptation of lowland plants to such steady and comparatively strong winds.

Changes in Surface Roughness: The Edge Effect

Sharp edges of vegetation – which are less abundant and less pronounced in natural ecosystems than in anthropogenically disturbed and shaped ecosystems such as agroecosystems and managed forests – are subject to wind effects that depend strongly on the distance to the change in roughness. When the wind first blows over a smooth (e.g., grass) surface and then abruptly has to change to a rough (e.g., agricultural crop or forest) surface, additional turbulence is created within a relatively short distance as wind passes over this roughness change (Fig. 6). This additional turbulence carries extra momentum that has to be absorbed by the vegetation downwind to obtain a new equilibrium with the rougher surface. This leads to the phenomenon that in a wheat field for example there may be a few rows of plants directly at the roughness change that seem quite unaffected even by strong winds, while only 1 m downwind one or several rows may be completely flattend by this additional momentum. In the case of forests, wind throw often excludes the trees at the forest edge, partially due to the same phenomenon. But trees also can adapt to constant wind pressures by building special cells to counteract this pressure. This is best known for trees in mountain valleys and along seashores with persistant and sufficiently strong winds in specific directions. In mountain valleys these are the up-valley (daytime) and down-valley (nighttime) wind directions. Which one is stronger depends on the complex combination of orientation of the valley, length, topographic differences in the surroundings, and more. But by studying trees which are leaning in the direction of the dominant strong winds (Fig. 5), it is easy to determine the locally dominant wind system. Near costs it is the diurnal sea breeze that dominates wind pressure on trees, while the nocturnal land breeze is in most cases much weaker.

On smaller scales, linear landscape elements such as hedgerows, tree lines, and tree lanes are ecologically important surface roughness elements, especially in otherwise rather smooth agricultural landscapes. In the Netherlands, for example, it has been

Fig. 4 Wind-pruning effect on *Metrasideros polymorpha* trees of a cloud forest on the Big Island of Hawaii (left). Under the strong onshore winds, leafs are detached from branches until only clusters of leaves at the outer margin of the tree volume remain (right). Photographs by Werner Eugster.

Fig. 5 Trees growing under conditions with persistently high wind speeds from a specific direction retain their asymmetric shape even when there is no wind. In this example from near Zweisimmen, Switzerland, the daytime up-valley wind (from right to left) shaped the characteristic habitus of these trees. Photograph by Werner Eugster.

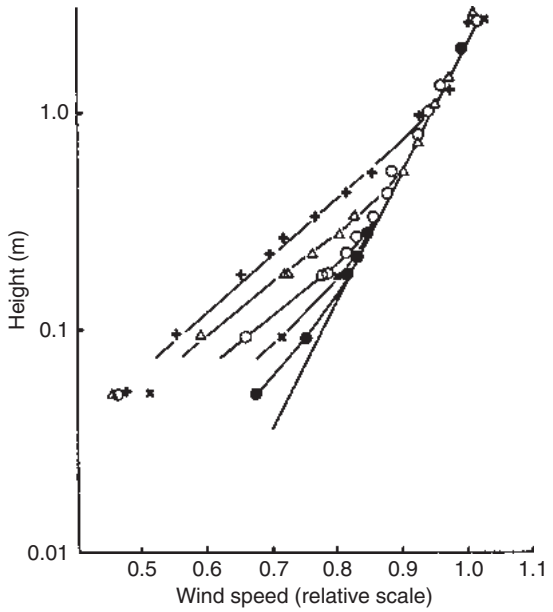

Fig. 6 Effect of a change from smooth to rough terrain. Fetch – that is the distance of uniform surface in the upwind direction – over the rough terrain was: (•), 0.32 m; (×), 1.18 m; (○), 2.32 m; (Δ), 6.42 m; (+), 16.42 m. Modified from Grace (1977) after Bradley (1968), *Quart. J. Roy. Meteorol. Soc.* 94, 361–379.

shown that among other possible functions (orientation clues, foraging habitat) such linear elements provide shelter from wind and/or predators for the two bat species *Pipistrellus pipistrellus* and *Eptesicus serotinus*.

Turbulent Mixing and Trace Gas Exchange

Turbulent exchange is roughly three to four orders of magnitude more efficient than diffusive mixing in a laminar airflow. For trace gas exchange between the atmosphere and the plants, the tiny laminar layer surrounding each leaf (**Fig. 2**) is thus non-negligible. Given this huge difference in effectiveness of turbulent versus diffusive transport a laminar boundary layer of 0.1–1 mm provides a similar resistance against the free exchange of CO_2 between the atmosphere and the plant stomates as does 1 m of turbulent air. In **Fig. 2** it is clearly seen that the laminar layer separates the turbulent atmosphere – where CO_2 is available in vast quantities – from the stomatal opening and the substomatal cavity, the buffer from where CO_2 is used for photosynthesis. Any changes in turbulence, wind speed, and wind direction will also affect the thickness of this laminar boundary layer and thus have an effect on the exchange of trace gases, heat, and momentum between plants and the atmosphere. **Fig. 7** shows that depending on plant leaf shape, the laminar boundary layer and thus the wind speed profile at varying distances from the leaf surface show a relatively large microscale variation.

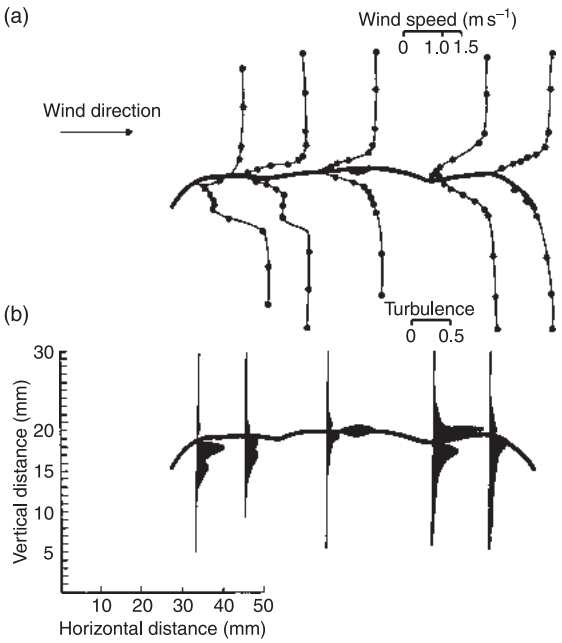

Fig. 7 The boundary layer over a *Populus* leaf. Profiles of (a) mean wind speed and (b) turbulence, shown in transverse sections in a laminar free stream. Modified from Grace, J., 1977. Plant Responses to Wind. London: Academic Press. After Grace, J., Wilson, J., 1976. The boundary layer over a populus leaf. Journal of Experimental Botany 27, 231–241.

On much larger scales, as wind blows over oceans and open water, it induces mixing of the surface layer, thereby enhancing the exchange of gases across the water surface, which is important for the oxygen content in the water and uptake or release of CO_2 and CH_4 to and from water bodies. Similar mixing occurs in the air above the surface which reaerates the plant canopy and essentially is responsible for resupplying photosynthetically active plants with CO_2 from the atmosphere, while at the same time O_2 produced by plants is carried away and mixed into the surface layer of the atmosphere.

Evaporation and Transpiration

A widely investigated topic of wind effects on ecosystems not covered in this article is found in the hydrological and biophysical literature on evaporation of water from ecosystems and transpiration from plants, either as a component of the hydrological cycle (the viewpoint taken by ecohydrologists), or in combination with CO_2 exchange (the ecophysiological viewpoint) for more information.

Dispersal of Pollen, Spores, and Microorganisms

The explosive pollen release from many wind-pollinated plants, particularly tree species with copious pollen production, is triggered by moderately gusty winds. Similarly, spores from the Swiss fern *Asplenium ruta-muraria* are released either by wind-induced shaking of the leaves (ballanemochory) or by the physical energy of impacting raindrops. In some palms (*Chamaedorea pinnatifrons* (Jacq.) Oerst. and *Wendlandiella* sp.) in Peruvian Amazonia the release of the pollen is triggered by movements of insects inside the flowers, and the term `insect-induced wind pollination' has been suggested since these insects do not normally also visit the female flowers of these palms.

On the ground, a wind gust can pick up small dust particles, sedimented pollen and microorganisms such as bacteria and mites from the surface or host organism. Once in the air, moderately turbulent winds are already sufficient to keep such small biotic and abiotic objects aloft. The general concept of updraft of a voluminous body in the atmosphere is described by Stoke's law of sedimentation, where the terminal falling velocity V_t of an object is

$$V_t = \sqrt{\frac{2mg}{c_w \rho A}} \qquad [3]$$

with m the mass (kg m^{-3}), g the gravitational acceleration (≈ 9.81 m s^{-2}), c_w the friction coefficient (≈ 1 for circular bodies, < 1 for aerodynamically formed bodies), ρ the density of the air (≈ 1.2 kg m^{-3} at sea level), and A the projected surface of the body (m^2). Fig. 8 shows the terminal fall velocity for small organisms of 1 μm to 2.5 mm and how typical vertical wind speeds in the air

can counteract the falling of such objects, once they are dispersed in the air. In this respect wind has almost exactly the same effect as the water flow in rivers: under high turbulence and horizontal speeds animals may find sheltered spots where they are not picked up by the motion of water or the air, but once they lose adhesive contact, their body size and weight may be too small to grasp ground again, and they become suspended in the fluid until they happen to end up in a calmer area where their settling velocity is greater than the wind (or water) motion, which allows them to reach the ground surface again. **Fig. 8** shows that bodies with a diameter smaller than ≈ 10 μm are normally too small to return to the ground in the turbulent atmosphere. Thus, for such small bodies, impaction becomes the most relevant process how they can be eliminated from the atmosphere, that is, when they physically hit the surface of a tree or another plant. The sticky stigma of a flower's pistil further helps to capture pollen even when impaction is weak.

Wind pollination is considered inefficient compared with insect pollination. This finding has led to the hypothesis that the rise to dominance of the angiosperms over gymnosperms at evolutionary timescales is due to reproductive innovations, especially those involving coevolution with biotic gene dispersers. This has most likely contributed to the present-day situation that conifers are biogeographically restricted to stressful environments where gymnosperms may suffer a comparative disadvantage if pollinators face persistently high wind speeds.

Influence on Small Animals and Seed Dispersal

Small insects need to adopt to wind speeds. Studies carried out in a wind tunnel indicate that weak winds >0.2 m s^{-1} already have an effect on the flight and landing behavior of the bug *Prostephanus truncatus* (Horn). In the open landscape, mosquitoes (*Anopheles marajoara* in Brazil) can only freely navigate in air with wind speeds below about 0.85 m s^{-1} (3 km h^{-1}). From the aphid parasitoid *Aphidius nigripes*, it is reported that males generally did not reach females at wind speeds of 1.0 m s^{-1}, as the majority of individuals taking flight in the pheromone plume (81.8%) was unable to sustain upwind flight. The general picture is that as wind speed increases these small animals increasingly lose control over their flight trajectory and may no longer target their prey or mate as desired. Swallows, for example, are known to fly close to the ground before thundershowers, where the prefrontal increase in wind speed restricts the activity of small flying insects to the few lowest meters close to the ground. In summer, when mosquitoe abundance is enormous in the Arctic, reindeer and caribou select windy locations for resting and rumination, preferably close to the seashore, on gravel pads in large rivers with a well-developed diurnal valley wind system, or on snow fields with thermotopographic wind resulting from the contrasting surface temperatures between snow and vegetation or rocky surfaces.

Some spider species benefit from this effect by letting themselves drift away – termed ballooning in the scientific literature – to explore new habitats using a short thread that increases their updraft and thus drifting distance at higher wind speeds. Although there are contradictory views between authors about the importance of various environmental factors, it is widely agreed upon the upper wind speed limit of 3 m s^{-1} for ballooning. Most work has been focusing mostly on the meteorological conditions at the time of take-off, whereas literature on the underlying motivation of the spiders and instigation of pre-ballooning behavior (climbing to a prominent point and silk release) is very limited and largely considered supposition by some experts. Since spiders are important polyphagous predators on arable farmland, the high mobility of ballooning species means that they are often the first to arrive in a crop newly infested with pests, and have a role in controlling the outbreak until more specific predators arrive.

In a similar way as ballooning spiders take advantage of the horizontal translocation by wind plants profit from the wind to disperse their seeds. The parachute type seeds of *Asteraceae* and the winged seeds of *Acer*, *Fraxinus*, *Ulmus*, and many coniferous trees are good examples of how plants benefit from available wind to spread out faster than would be possible without the help of the wind. For seeds that do not have wings, hairs, or parachute-type annexes, the Stoke's settling velocity (eqn [3], **Fig. 8**) applies and explains why in general small seeds are wind dispersed because of their long residence

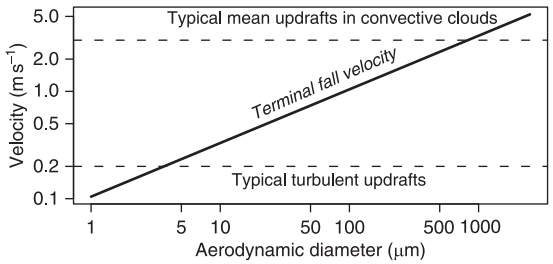

Fig. 8 The terminal fall velocity of ball-shaped objects (pollen, seeds, bacteria, microorganisms) compared to typical updrafts in the turbulent atmosphere (up to ≈ 0.2 m s^{-1}) and typical mean updrafts in convective clouds (thunderstorms). The thick line applies to objects that have a similar density as water. If updrafts are stronger than the terminal fall velocity, then an organism or particle in the atmosphere remains suspended in the atmosphere and will only deposit on obstacles such as trees due to impaction. Larger organisms that are subject to a high terminal fall velocity need active means to keep themselves aloft.

time in the atmosphere (the residence time is inversely proportional to the terminal fall velocity) than large seeds, that lead to small dispersial kernels downwind of the seeder plant unless the seeds are dispersed by animals. A special case exists for vegetation near open water bodies, where large buoyant seeds can float on the water and be dispersed by its currents, such that even large and heavy seeds can be transported over long distance that would not be possible by the wind alone.

Nature has brought about a wealth of shapes and forms of seeds that do not correspond with the simplest version of a spherical with $c_w = 1$. For some plants, specific wind tunnel studies have been carried out to determine the true dispersal capacity of seeds. For six Canadian perennial grassland species with different seed aerodynamic attributes, it was investigated how dispersal distances vary with varying wind speeds and release heights. Dispersal distances of long-range dispersed seeds (99th percentile values) increased exponentially with wind speed. At wind speeds of 14 m s^{-1}, predicted maximum distances were 10–15 m for small and relatively heavy spherical seeds and 20–30 m for large and relatively light cylindrical or disk-like seeds. In the study area, wind gusts >10 m s^{-1} at plant height occur at least annually, and plants of the selected species live up to several decades. This suggests a great potential for long-range dispersal during the lifetime of a plant. It is argued that plants may gain wider dispersal of seeds by increasing the release height (e.g., taller infructescences) and by requiring stronger winds to release seeds (e.g., dispersal in autumn and winter).

Transport distance is one aspect, the other is the release of seeds from the flower heads by wind speed. In a wind tunnel study with flower heads of two thistle species, *Carduus nutans* and *Carduus acanthoides*, with ripe seeds, the effect of laminar versus turbulent flows of increasing velocity was investigated. Seed release increased with wind speeds of both laminar and turbulent flows. However, far more seeds were released, at significantly lower wind speeds, during turbulent flows. In other cases, the seeds are primarily dispersed by the wind, followed by secondary dispersal by rodents living on the ground which collect the seeds and cache them in the soil. Treatment by rodents, primarily yellow pine chipmunks (*Tamias amoenus*), of four species of pine seeds, lodgepole pine (*Pinus contorta*, 8.7 mg seed weight), ponderosa pine (*Pinus ponderosa*, 55 mg), Jeffrey pine (*Pinus jeffreyi*, 157 mg), and sugar pine (*Pinus lambertiana*, 213 mg), that vary in size and weight was studied in the Carson Range of western Nevada. For the species examined, seed size appeared to have had little effect on several other attributes, including mean dispersal distance, substrate choice, and microhabitat choice. It was found that although a larger seed size and weight decreases primary wind dispersibility of pine seeds, the secondary dispersal by scatter-hoarding rodents compensates for poor wind dispersal so that total dispersibility of large-seeded pines is not compromised.

Influence on Bird and Insect Migration

At a much larger scale many long-distance migratory bird species have adopted flight tracks that best profit from large-scale wind fields on the Earth, which saves energy and thus increases the survival rate. On the other hand, migratory birds that are facing strong headwinds, may suffer severe losses if such an occurrence combines with low temperatures, scarce food resources or the like. In general, the nocturnal and diurnal wind directions and speeds are not necessarily the same. Near the ground the so-called low-level jet, a relatively strong wind with its maximum speed at only 100–300 m above the ground surface is active at night, whereas the atmosphere may be calm during the day, and wind speeds are higher aloft.

In a study on the migration patterns and environmental effects on stopover of monarch butterflies at Peninsula Point, Michigan, it was found that wind direction had a significant influence on the number of monarchs recorded on each count over a 7-year period, with higher counts during north winds.

On smaller scales, it has been shown for two dragon fly species, *Pantala hymenaea* and *Pantala flavescens*, in natural flight over a lake at ambient wind speed and direction, that they are able to compensate at least partially for crosswind drift, which shows evidence for use of a ground reference to correct for drift when flying over water, and their ability to cope with much higher wind speeds (5.0 m s^{-1}) than small insects are able to.

No Wind Effect?

Although there are many studies that found ecological effects of wind on animals, plants, and ecosystem processes, it should be remembered that there are other studies that were unable to find such effects. For example, the bat *Pipistrellus pipistrellus* in Oxfordshire did not show an apparent response to wind nor rain in the time spent outside the roost. This is remarkable since it feeds on insects and one might expect a behavior similar to the one known from swallows. Since it is generally difficult to publish negative results in the scientific literature, and moreover wind as a three-dimensional vector variable makes it particularly challenging to derive the relevant information from simple measurements (e.g., if mean wind speed was measured when actually turbulent kinetic energy would have been the variable with higher predictive power), the lack of clear statements on where wind does not have an effect should not come as a surprise.

In forest ecology it has been postulated that there are two main factors why biotic effects of wind have not been well studied: (1) the difficulty of measuring wind in the field and separating its effects from the confounding variables of temperature and humidity; and (2) the expense involved in carrying out wind tunnel experiments in the laboratory.

Wind Chill and Heat Index

The bioclimatic temperature sensed by an organism can differ considerably from the absolute physical temperature that is measured by conventional instruments. For humans, elaborate concepts to compute a wind chill temperature have been established to account especially for the effect of wind. The concept bases on the knowledge that increasing mean wind speeds increase also turbulence, and thus the heat transport away from an organism that has a warmer skin temperature than the atmosphere. Although it is widely known that the ambient moisture or humidity in the air has an additional influence, for the sake of simplicity most approaches only consider wind speed as a specific factor when considering wind chill.

Controlled experiments with humans were carried out to determine the functional relationship between wind chill and preceived temperature. This was not possible with primates, where thermoregulation is known to be an important ecological constraint. Shade temperatures, solar radiation, humidity, and wind speed all serve to alter an animal's `perceived' temperature. In a recent review, three thermal indices currently available were compared. Black bulb temperatures can account for the effect of solar radiation, with wind chill equivalent temperatures and the heat index providing quantifiable estimates of the relative impact of wind speed and humidity, respectively. The authors presented three potential indices of the `perceived environmental temperature' that account for the combined impact of solar radiation, humidity, and wind speed on temperature, and performed a preliminary test of all of the climatic indices against behavioral data from a field study of chacma baboons (*Papio cynocephalus ursinus*) at De Hoop Nature Reserve, South Africa. It was found that the complexity of the interactions among environmental factors that influence thermoregulation in primates will require the development of biophysical models of the thermal characteristics of the species and its environment. Until such models are developed, however, it is concluded that wind chill and heat indices should permit a more detailed examination of the thermal environment, allowing thermoregulation to be given greater precedence in future studies of primate behavior.

Another widely established approach is not to try to compute a bioclimatic temperature or index, but relate the metabolic energy consumption of an animal to environmental factors.

Metabolic Stress by Wind

Small animals can profit from the presence of a laminar sublayer (Fig. 1) even under highly turbulent conditions. Due to the much lower heat exchange in that laminar layer, they may avoid metabolic stress under high winds. This is almost impossible for larger animals, such as breeding arctic shorebirds. It was found that tarsus length in all shorebirds breeding in the Canadian arctic shows an evolutionary response to average metabolic stress encountered across the breeding range, such that birds nesting in metabolically stressful environments have relatively shorter legs. Longer-legged birds living in colder environments will experience greater metabolic costs because their torsos are elevated farther away from the ground's wind-dampening boundary layer. It was suggested that the widely known Allen's rule that relates the metabolic rate of an organism to its volume should be extended: body-supporting appendages of homeotherms may be shorter in colder environments so as to take advantage of a boundary layer effect, thereby reducing metabolic costs.

Another study that investigated the effects of water levels and weather on wintering herons and egrets found that larger and longer-legged species tended to be found in deeper water, although both species frequently were found together in shallow water. Severe weather with high winds caused the birds to suspend foraging and remain sheltered from the wind. Consequently, a higher percentage of smaller heron and egret species did not survive severe storms since searching shelter from wind meant fasting. A 3-day storm period was simulated to lead to $>10\%$ decline in body mass of the smaller herons and egrets.

Wind Throws and Wild Fires

Extreme events with high wind speeds are important in the life cycle of many ecosystems, especially forests. Hurricanes in the tropics, tornadoes, and other windstorms further north and south reshape forest ecosystems via windthrows that eliminate the weakest and thus most often the oldest individuals in the forest canopy. For example, in New England forests, leaning is the most prevalent damage to young stands, whereas breakage and uprooting dominated in older stands. Breaking was slightly more important in older conifer than hardwood stands, comprising 6–14% of the stems and generally occurring 1–5 m from the ground, but numbers vary not only widely between species and stand composition but also among storm events in the same stand.

Since heavy storms are often accompanied with severe lightning strikes, the wind effect can easily be a combination of wind and fire. When a wildfire starts then the wind conditions will strongly determine how quickly the fire advances with the wind, and what damage is done to the ecosystem. In some cases, such as the Bishop pines, the fire even is necessary to free the seeds in the cones and initiate the life cycle of this forest type. In the gaps the new vegetation can resprout, and since more light and precipitation reaches the ground, this provides niches and living space for early successional plants. As a consequence also the fauna may be affected. Organisms with a life size that is much smaller than gaps in forests may only find a suitable ecological niche in the gaps that shift their location over the years. In subalpine forests of the Swiss alps, it was found that the gaps created by windthrows add considerably to the species diversity of macrofungi. Larger animals such as black bears in southeast Alaska were found to react in just an opposite way: 58% of the den sites were found in forests that were most protected from catastrophic storm

effects, and only 6% in forests most exposed to storm damage. These results suggest that the effect of catastrophic windstorm disturbance on overwinter habitat for black bears is the key factor influencing the site selection for black bear dens.

Agriculture Systems

O Andrén, TSBF-CIAT, Nairobi, Kenya
T Kätterer, Department of Soil Sciences, Uppsala, Sweden

Introduction

An agricultural ecosystem is an ecosystem managed with a purpose. This purpose usually is to produce crops or animal products. Agricultural ecosystems are designed by humans, and current agroecosystems are products of a long chain of experimental work. These experiments have been performed by individual farmers as well as research institutions, and when results were positive for the purpose, the methods have been adopted.

The purpose has, however, changed with time. In highly productive regions, for example, Western Europe, the emphasis has changed from maximum productivity to environmental considerations, such as reduction of nutrient losses to groundwater and maintaining an open landscape with high biodiversity, etc. In less-productive regions, where resources such as water or fertilizers are scarce and production is too low to properly feed the farmer, environmental considerations have low priority. This is a major global problem, since this leads to land degradation and even lower production, etc. in a downward spiral.

Agroecosystems are conceptually fairly similar to managed forests and grasslands, and whether extensively cattle-grazed natural grasslands should be included under the category of agroecosystems is a matter of choice in the individual case. Arable land is defined as land that is soil cultivated regularly, but also here the boundaries are not sharp (seminatural grasslands, permanent crops, etc.). At the other end, agroecosystems border horticultural systems, that is, vegetable cropping. Alternatively, horticulture can be viewed as a subset of agriculture. Production of cabbage in a field can be considered as agriculture, but hydroponic (soil-less) production of tomatoes in a greenhouse under artificial light can perhaps not be included. However, in many respects even an artificial ecosystem such as this can be considered as an agricultural ecosystem. It is designed for production of a crop and is just managed to a higher extent than an arable field.

According to FAO statistics for 2002, agricultural ecosystems comprise almost 40% (5 Gha) of the total land area of the Earth. About 11% of the total land area is arable land (cultivated with crops), and approximately 27% of the total land area is under permanent pasture, grazed by cattle, goats, sheep, camels, etc. Clearly, we are actively managing a considerable part of our planet for agricultural purposes, and to this one can add other similar systems, such as intensively managed forest systems (planted and harvested, sometimes fertilized), etc.

Ecological research performed in agricultural systems has many advantages compared with research in most natural ecosystems. For example, there are a number of long-term field experiments running, although originally designed for, for example, crop production response to fertilizer dose, that can give us a 30-year integration of what has happened, for example, to organisms in the soil under different conditions. Further, agricultural fields are `homogenized', that is, trees, larger stones, etc. are removed and regular soil cultivation evens out differences in topsoil properties over time. However, even after many years of cultivation, a fairly high variability in soil properties remain, which is the incentive for `precision farming', where soil and crop properties are measured at high resolution (m^2), and management is based on these measurements. For ecological research, this is an opportunity, since any given hectare will yield numerous observation points, each helping us to answer questions such as: Why does this particular location yield more wheat, or why is more water present at that location?

Another advantage is that agricultural crops often have a short lifespan and a small size, compared with, for example, forest trees. Often, an experiment can be started when the soil is bare, and a single crop can be followed from sowing, through harvest, and finally when the stubble is plowed down at the end of the growing season. This life cycle can take a century for a tree in a northern forest, which, to add insult to injury, also may contain several other plant species. Therefore it is not surprising that a considerable part of modern ecological theory (predator–prey interactions, general soil ecology, above- and belowground plant growth dynamics, organic matter decomposition, nutrient mineralization, etc.) is based on work performed in agricultural land, and that the reluctance of ecologists to work in agricultural systems that was obvious 30 years ago seems to have vanished.

The Agroecosystem

Fig. 1 is an attempt to summarize the characteristics of an agroecosystem as compared to most natural ecosystems. Note that this comparison is between a typical natural ecosystem and a typical, high-production agroecosystem.

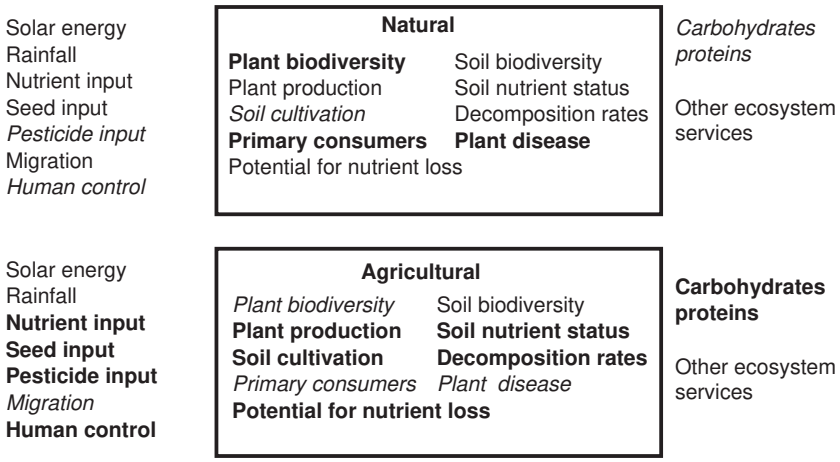

Fig. 1 Similarities and differences between typical natural and high-production agricultural ecosystems. Inputs of energy, mass, and control (left), comparison of selected ecosystem properties (center), outputs (right). Note that cattle, etc. are not included as primary consumers here. (**Bold** = markedly higher value than in the other ecosystem type. *Italic* = very low.)

Abiotic Constraints

Just like natural ecosystems, agroecosystems are constrained by climate and soil properties – maize does not grow in Northern Sweden. However, climate can be modified, that is, in dry climates one can irrigate (with surface- or groundwater), and soil properties can be modified through, for example, liming, organic matter amendments, and fertilization. Too high water tables can be lowered through ditching or tile draining.

Nutrients

Highly productive agroecosystems need high inputs of plant nutrients (nitrogen, phosphorus, potassium, and other elements) to replenish the nutrients removed with the exported products. These inputs can be delivered either as commercial fertilizer, recirculated sewage sludge and ash from garbage burning, or manure from cattle, pigs, poultry, etc. All sources have their advantages and disadvantages. Commercial fertilizers are well defined, low in pollutants such as heavy metals (although exceptions exist), hygienically safe, and are concentrated, easy to transport, and rapidly available to the plant when applied in the field. However, production and long-range transport of fertilizers is energy consuming, and the concentrated product increases the risk for too high doses, leading to environmental pollution. An even greater problem is that a large part of the farmers of the world cannot afford to buy enough fertilizer to maintain soil fertility and obtain good yields. In all, world N fertilizer production in 2001 was slightly less than 90 Mt, very unevenly distributed. In sub-Saharan Africa, only 1.1 kg fertilizer nitrogen is used per person and year, whereas in China the corresponding value is 22 kg.

In theory, recirculation of nutrients from waste of the exported products seems to be ecologically sound. In practice, there are a number of problems. First, sewage sludge mainly consists of water, which either must be removed (requires energy) or transported, which is expensive and impractical. Second, sewage sludge contains harmful bacteria, human parasites, etc. and has to undergo hygienic treatment. Third, and most severe, is the problem with contaminants, such as heavy metals and organic toxins. Therefore recirculation of sewage sludge and garbage incineration ash is strictly regulated in most countries. In this perspective, replacement of nutrients using newly produced fertilizer can be a better solution from an environmental viewpoint.

Naturally, animal manure produced on the farm should be and is recycled to soil as much as possible. Compared with fertilizers, manure has the advantage of containing organic matter, which improves soil structure. On the other hand, manure contains mostly water (expensive storage and transportation, heavy machinery needed for spreading), and it will lose nitrogen through ammonia emission, both at storage and spreading.

Crops, Varieties, and Cropping Systems

The vegetation found in an agroecosystem is usually divided into crop and weeds, where weeds are unwanted trespassers, which traditionally have been regarded only as negatives. More recently, this view has been modified, and weeds, particularly weedy border zones can be accepted to some extent, as biodiversity enhancers and refuges, for example, for beetles.

The crops used today are products of many years (in some cases millennia) of plant breeding, and properties selected for are usually productivity, product quality, pest resistance, etc. This directed selection, in recent years augmented by direct manipulation of DNA, is one of the main differences between agro- and natural ecosystems. Crop species and varieties are being redistributed all over the world; maize, a staple food in Africa, comes from Central America, common West European and North American cereals such as wheat come from the Middle East, etc. This breeding and distribution of improved crops, together with improved

cultivation/fertilization techniques probably is the main reason for the global success of the human species (three billion in 1960, probably nine billion in 2050). For example, world grain production was 631 Mt in 1950, and in 2000 it had increased to 1840 Mt.

Herbicides, Pesticides, and Fungicides

To reach the goal of high production of crops of good quality, weeds (unwanted plants), pests (unwanted animals), as well as fungal, bacterial, and viral diseases must be kept in check. A monoculture crop is vulnerable to attacks, since one (or a pair) of the pests that enter a field will have a high concentration of food with no transport stretches in between. Potential predators may be absent, since they may need a litter layer on the ground for reproduction, which does not exist in the field, etc. Repeated monocultures may build up specialized pests, such as plant parasitic nematodes. Crop rotations (switching crops from year to year according to a predetermined pattern) can successfully deal with many pests and diseases, and careful soil cultivation can reduce weed problems. Intercropping (growing two or more crops together, such as barley/clover) may also help.

However, most fields will benefit from occasional chemical (or biological) pesticide/herbicide treatment. These types of agrochemicals have a somewhat dubious reputation among laymen and perhaps also ecologists (DDT, Agent Orange, mercury, etc.). Three things should be kept in mind, though. First, the substances and formulations used today are thoroughly tested before approval, and their side effects and the fate of their decomposition products are well known. Second, chemical warfare is common in natural systems – all successful plant species present today have at least some chemical defense against microorganisms and pests. Third, which alternatives do we have? A failed crop in a well-fertilized field will lead to high risks for nutrient losses to the environment. A failed crop in poorer conditions may lead to starvation for the farmer and her family.

Alternative methods, such as increased cultivation, hand weeding, or biological pest reduction by introduction of predators all have their advantages and disadvantages, but there is no `silver bullet' available. In summary, an integrated approach with a combination of methods is the solution, and modern agriculture has moved and is moving in this direction. Of course, for commercial reasons it can be profitable to cultivate, for example, `organic' crops (without fertilizer or pesticides) to obtain a higher price, but from an ecological or environmental viewpoint this approach is not necessarily better.

Agriculture can thus be classified according to the use of agrochemicals, for example, biodynamic, organic, integrated, and industrialized farming. Biodynamic farming forbids the use of conventional agrochemicals and replaces them with exotic homemade concoctions, and organic farming *a priori* forbids conventional agrochemicals. None of these farming systems is firmly based on scientific evidence; instead they are based on a green view of nature that leads to the banning of certain chemicals.

Integrated and industrial farming can also be called `conventional', where economic, legal, and environmental constraints limit the end goal, maximum productivity, and profitability. The main difference between the latter two is that integrated is more environmentally concerned (reduced pesticide use, use of biological pest reduction methods, etc.), and industrialized is more leaning to maximum production with whatever means available, with a minimum of environmental concerns. It should be noted that `conventional' and particularly `industrialized' are somewhat derogatory terms, mainly used by those negative to these approaches.

Migration

Natural ecosystems, for example, East African savannas, can be subjected to major migrations of large herbivores that annually move long distances, following the seasonal changes in rainfall and consequential grass growth. Most natural ecosystems are less subjected to migrations, but, for example, in Northern forests at least migratory birds occur seasonally.

In agroecosystems, migration is usually kept to a minimum. Measures are taken to keep large or small grazers out from the cropped field. In some regions, wild grazers are exterminated (or close to extinction – Western European agricultural regions) and in other regions crop fields are guarded or fenced. However, migration is a component in animal husbandry; cattle is often shifted between pastures, which are given time to recover. Nomadic herding of cattle (Sami people, Masai) is similar to the savanna migrations mentioned above; the cattle and herdsmen follow the annual cycles in grazing opportunities.

Biodiversity

In a cereal monoculture, plant biodiversity is extremely low – if weed control is successful there may be only one species present, a highly specialized and genetically homogeneous wheat variety. This is not common in natural ecosystems, although it can occur in extreme environments. As mentioned above, this means that a pest can have a field day if it can reproduce in the field (or migrate into the field at a large scale).

However, agricultural monocultures still are common and continue to produce good yields. There are several reasons for this. First, there is no simple relation between biodiversity, productivity, or ecosystem stability. A plant monoculture that is well adapted, grows under good conditions, and has a reasonable resistance to pests and diseases can survive and produce well. This is exactly what a highly productive agricultural field is – a well-adapted monoculture. The crop variety has been selected for high production under a number of years with different weather (and on different soils) in a region. A variety that would demand intensive treatment with herbicides, pesticides, and fungicides will not be economical and will be rejected.

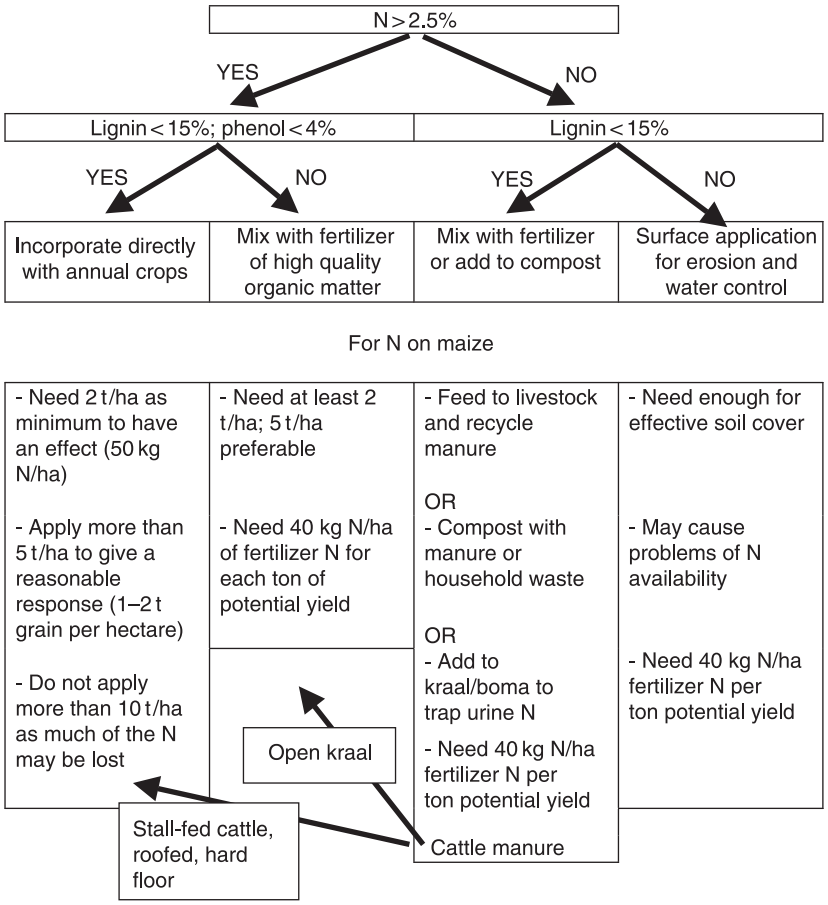

Fig. 2 Example of farmer's decisions regarding N management for a maize crop in sub-Saharan Africa, using a decision support system for organic N management depending on resource quality, expressed as N, lignin, and soluble polyphenol content. General decision matrix (top), more detailed for N economy in a maize cropping system (bottom). Modified from Vanlauwe B, Sanginga N, Giller K, and Merckx R (2004) Management of nitrogen fertilizer in maize-based systems in subhumid areas of sub-Saharan Africa. In: Mosier AR, Syers JK, and Freney JR (eds.) *Agriculture and the Nitrogen Cycle*. 124p. SCOPE 65. Washington Island Press.

Second, the low plant diversity reduces animal diversity in the stand, but perhaps less than one would expect. In a cereal monoculture stand, there can be hundreds of species of insects, mites, springtails, snails, slugs, etc. In the soil under a monoculture the biodiversity is almost always extremely high, though usually lower than in natural systems. Thousands, perhaps millions of bacterial species, tens to hundreds of species of earthworms, enchytraeids, soil insects, springtails, mites, spiders, millipedes, flagellates, amoebae, blue-green algae, etc. can be found. There are no consistent indications that soil functions such as organic matter decomposition is hampered by a low biodiversity under monocultures – a given plant residue will decompose at the same rate under a monoculture as under mixed plants, if soil temperature and moisture are the same.

Third, the last line of defense is the crop protection measures that the farmer takes. For example, in several countries there is a sophisticated monitoring and prediction system for aphid outbreaks. Aphids suck the sap from the crop leaves, but they are also vectors for crop diseases. Therefore their hibernating stages are enumerated, weather is monitored, and if the conditions are `right' the farmers are recommended to spray the fields with an insecticide (or a more specific aphicide) with dose x at date y. In less technically developed regions, experience and skill is a substitute for the model projections, but the principles are the same. It should also be mentioned that in spite of these defenses, pest insects, pathogens, and weeds still reduce worldwide crop yields considerably, and there is a great potential for improvements.

Other Ecosystem Services

The main ecosystem service from agricultural systems is simply to `feed the world'. This simple fact is easily forgotten in the richer parts of the world. However, even in Europe, which for centuries has been thoroughly under agriculture, there are other ecosystem services that are appreciated. In the forest-dominated northern Europe, agriculture actually contributes to biodiversity and landscape diversity. Without agriculture, the forest would cover all land area – the only open areas at lower altitudes would be the lakes and rivers (and the newly clear-cut forest areas, rapidly covered by shrubs). The European rural landscape in general, that is so refreshing for the city-dweller, is an agricultural product.

In other areas of the world, where the agricultural land is not sufficient to properly feed the population, other ecosystem services become relatively less important. However, if agricultural productivity can be increased, some agricultural land can be returned to savanna, forest, or other natural or seminatural states – which would be another type of service from the agroecosystem.

Since the agroecosystem is managed, and more or less sophisticated machinery and management skills are in place, it can easily be converted according to new demands from the society. If the quality requirements are met, agricultural fields can be used for recycling organic waste and ashes, and even for drawing nutrients out of sewage water. Conversion to energy crops is not too difficult (grasses, sugar beet, willow, sugarcane, etc.). Another demand from society, to sequester carbon in the soil to reduce CO_2 in the atmosphere, has recently received much attention. Increasing soil carbon content usually has beneficial effects for soil structure, water-holding capacity and general fertility, and C sequestration, perhaps even with direct payments per ton C sequestered to the farmer, is a new potential service.

The Intelligent Choices

As mentioned in the introduction, an agroecosystem has a purpose. It is designed to obtain certain goals, and the state of the system at any given point in time is a consequence of an array of intelligent choices by the farmer, complementing the border conditions set up by weather and soils, etc. The following decision matrix (**Fig. 2**) illustrates how decisions made by a maize farmer in sub-Saharan Africa can be supported by basic science knowledge. Note that the chemical analyses are not necessary for every farmer and decision. Instead, typical values for the different organic resources are estimated, and the individual farmer uses the rule of the thumb based on these estimates.

In the upper part of the **Fig. 2**, the general decision matrix is shown. Let us assume that we have leaves from a tree, which we know have a low N content and less than 15% of lignin. Then we should mix the leaves with fertilizer or add to compost. Now, in the lower part of **Fig. 2** we can see that if we look in more detail at the N economy of a maize system, we have other options – maybe add the low N material to the cattle corral (kraal/boma) to trap urine N or feed to livestock to produce higher quality organic inputs. Organic resources belonging to the third column from the left could be fed to livestock and the manure thus produced could belong to the first or the second organic resource class, depending on the management of that manure.

All over the world, farmers make these kinds of choices, based not only on biophysical knowledge and constraints, but also on economic and sociopolitical opportunities and constraints. An agroecosystem is not only controlled by farmers, but also by the society the farmer operates in. Subsidies can make growing products that have no market an intelligent choice for the farmer; lack of money can make fertilization impossible, even if it would be profitable in the long run, or real or imaginary environmental concerns from the society can force a farmer to, for example, abandon fertilizer use, cereal cropping, or pig farming.

Summing up, the agroecosystem, although limited by climatic constraints, is a product of decisions made by generations of farmers, supported by advice from agronomists and extension workers – all within a societal context of values, traditions, and legislation. In fact, the present and future agroecosystems are at least equally dependent on the societal context as on the climate and soil. However, the organisms involved are, as in any ecosystem, products of millions of years of evolution, and crop and animal breeding has only contributed with small, although important changes to the germplasm.

Alpine Ecosystems and the High-Elevation Treeline☆

C Körner, Botanisches Institut der Universität Basel, Basel, Switzerland

Definitions and Boundaries

Ecosystems above the upper climatic limit of trees are termed 'alpine.' Scientifically, the alpine life zone is an altitudinal belt defined by climatic boundaries (Figure 1), and the term 'alpine' does not refer to the European Alps but to naturally treeless high-elevation biota worldwide (mostly grassland and shrubland). 'Alpine' supposedly roots in the pre-Indo-European word *alpo* for steep slopes, still used today in the Basque language. By contrast, in common language, 'alpine' is often used for places anywhere in mountainous terrain, irrespective of elevation (e.g., alpine village, even alpine cities). If a city were truly alpine it would have to be above the climatic treeline, but no such city does exist worldwide. Hence, a distinction must be made between the scientific, biogeographic meaning of alpine (the issue of this article) and common (often touristic) jargon.

The upper limit of the alpine life zone or alpine belt is reached where flowering plants have their high elevation limit. This is often close to the snow line (the elevation at which snow can persist year-round), but commonly a few scattered flowering plants also grow above the snow line, in favorable, equator-facing, and sheltered places. The uppermost part of the alpine belt, where closed ground cover by vegetation is missing, is often termed 'nival,' referring to sparse vegetation in rock and scree fields. The highest place on Earth where flowering plants have been found is in the Central Himalayas at 6200–6350 m above sea level. The high elevation record for flowering plants in Europe is 4500 m in the Swiss Alps.

Depending on latitude, the climatic treeline and hence the lower limit of the alpine belt can be anywhere between close to sea level in subpolar regions (>70° N, >55° S) and close to 5000 m in subtropical continental climates (trees >3 m at ~4800 m in Bolivia and Tibet). In the cool temperate zone (45–50° N), the alpine belt may start anywhere between 1200 and 3500 m (in the European Alps at 2000 m, the Colorado Rocky Mountains at 3400 m); that is, it is lower under strong oceanic influence and higher in the inner parts of continents. The common natural treeline elevation near the equator is 3600–4000 m. The altitudinal width of the alpine belt above treeline is roughly 1000 m. It covers ~2.6% of the globe's terrestrial area, if Antarctica is disregarded.

Given this convention on the two boundaries of the alpine belt, it is important to note that these boundaries are not sharp lines but are centered across gradients which change from place to place and depend on topography and region. Usually, these boundaries are obvious from the great distance (an airplane), but hard to depict on the ground, hence depend on scale.

The Alpine Treeline

Since, by definition, the alpine belt is naturally treeless, the mechanisms by which trees are restricted from growing beyond a certain elevation are key to any understanding of alpine ecosystems. The so-called treeline marks the upper limit of the life-form 'tree' irrespective of the tree species involved. Generally, species which form treelines are *Pinus*, *Picea*, *Abies*, *Juniperus*, and *Larix* among conifers, and *Betula*, *Alnus*, *Erica*, *Polylepis*, *Sorbus*, *Eucalyptus*, and others among non-coniferous families. Because tree occurrence does not stop abruptly, and trees gradually get smaller and finally become crippled, any definition of 'a line' is a convention. The forest line or timberline represents the edge of the closed upper montane forest (note, 'montane' is the biogeographic term for the next lower belt, not to be confused with 'mountain'), the zone of gradual forest opening near the treeline is often termed treeline parkland, and the uppermost position where tree species can survive as small saplings or shrubs among other low-stature vegetation is called the tree species line, with the 'treeline' holding a middle ground, used for the line connecting the uppermost patches of trees >3 m. The whole transition zone from montane forest to alpine heathland is termed treeline ecotone, across which alpine vegetation gains space yielded by the thinning forest. The altitudinal range of the treeline ecotone may be 20–200 m, often <50 m.

Where moisture is permitting tree growth at these altitudes (a minimum of 250–300 mm of precipitation per year), the position of the natural climatic treeline matches with a mean growing season temperature of 6.4 ± 0.7 °C worldwide. The duration of the growing season may vary from 10 weeks at high latitude to a full year in the tropics and its onset and end are defined by a weekly mean air temperature of 0 °C (corresponding to ~3 °C in 10 cm soil depth, where most roots occur). This isotherm sets the

☆*Change History*: February 2013. C Körner updated the 'Definitions and Boundaries' section and references.

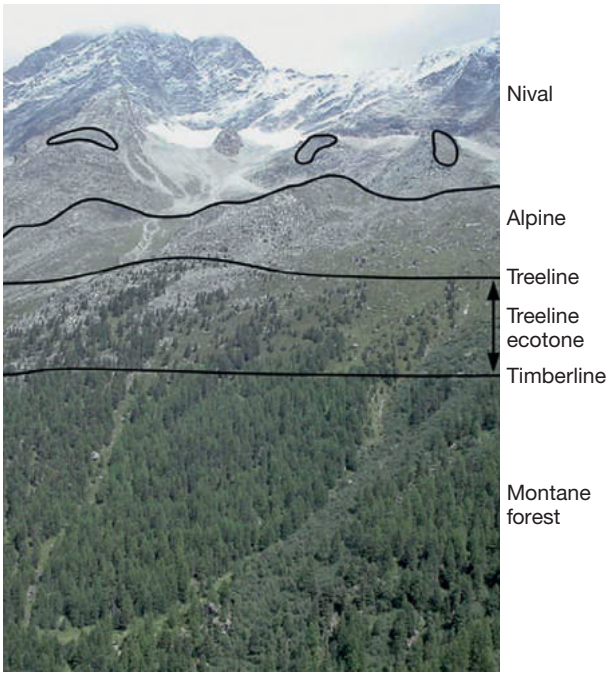

Figure 1 The elevational belts of mountain ecosystems. With increasing altitude, these belts become fragmented and topography (exposure) plays an increasing role. (Example from the Swiss Central Alps with *Pinus cembra* forming the treeline at 2350 m.)

Figure 2 Fire and grazing (both naturally and under human influence) can replace the montane forest, leading to 'alpine-looking' vegetation below the climatic treeline. Here is an example of the Ecuadorian páramos at 3600 m altitude, ~400–500 m below the potential climatic treeline (Páramos El Angel). Giant rosettes of the genus *Espeletia* are the prominent feature of this landscape, with similar vegetation also found in African highlands.

low-elevation climatic threshold for the alpine vegetation, which can be close to 5 °C in dry subtropical mountains and 7.5 °C in cool temperate mountains, a surprisingly narrow range, given the great difference in season length across latitudes.

It is very important not to confuse this climatic (physiological) limit of trees with a multitude of other natural or anthropogenic causes for the local absence of trees such as fire, avalanches, logging and pasturing, loose or missing substrate, waterlogging, or the regional lack of cold-adapted tree species (as is the case, for instance, in Hawaii). In the last case, the treeline observed is a specific tree species line, not representative of the climatic limit of the life-form tree, as can easily be demonstrated by the success of introduced tree species which grow well at much higher elevations in such regions. Open 'alpine-looking' grassland and shrubland may thus occur several hundreds of meters below the climatic treeline; among the most famous of these are the Andean Páramo grasslands with their spectacular giant rosette plants (Figure 2).

Alpine Plants Engineer Their Climatic Environment

Why is there lush alpine vegetation but trees cannot grow? Are alpine plants physiologically superior, able to cope with those low temperatures which otherwise are harming trees? There is good evidence that thermal constraints for growth, that is, building

new tissue, are the same for alpine plants, cold-adapted trees, and winter crops (winter rape and winter wheat), all being halted when tissue temperatures drop below 4–5 °C, and growth is close to zero at 6–7 °C. In contrast, all these species reach 30–50% of maximum rates of photosynthesis at these same temperatures; thus the provision of raw material for growth (sugar) cannot be decisive. Neither are there critical differences in freezing resistance between alpine plants compared to trees. Hence, at tissue level, there is no physiological reason why alpine grasses, herbs, and shrubs should grow at a given low temperature and trees should not.

There are two reasons for success of alpine plant above treeline:

1. By low stature and dense stand structure, alpine plants restrict aerodynamic exchange with the atmosphere, which causes heat to accumulate during periods with solar radiation and permit plants to operate at comparatively warm temperatures, much unlike those experienced by upright, ventilated trees. The life-form 'tree' does not permit any escape from the gradually declining ambient temperatures, whereas alpine plants engineer their microclimate and air-condition their meristems close to the ground so that they can build new tissue at otherwise cold air temperatures above the plant canopy (Figure 3).
2. By developmental flexibility and morphological adaptation, alpine plants are able to make use of short favorable weather conditions, they sprout rapidly, produce only a few, mostly short-lived leaves (~60 days), and have their meristems positioned very close to the ground, in the case of many grasses, sedges, or rosette plants, often 1–2 cm below ground, where the solar-heated soil provides a thermally buffered environment. In contrast, trees operate at longer leaf duration (mostly >120 days; in evergreen treeline conifers, 4–12 years) and leaves take longer to mature, and their aboveground meristems are fully exposed to the cold air temperatures.

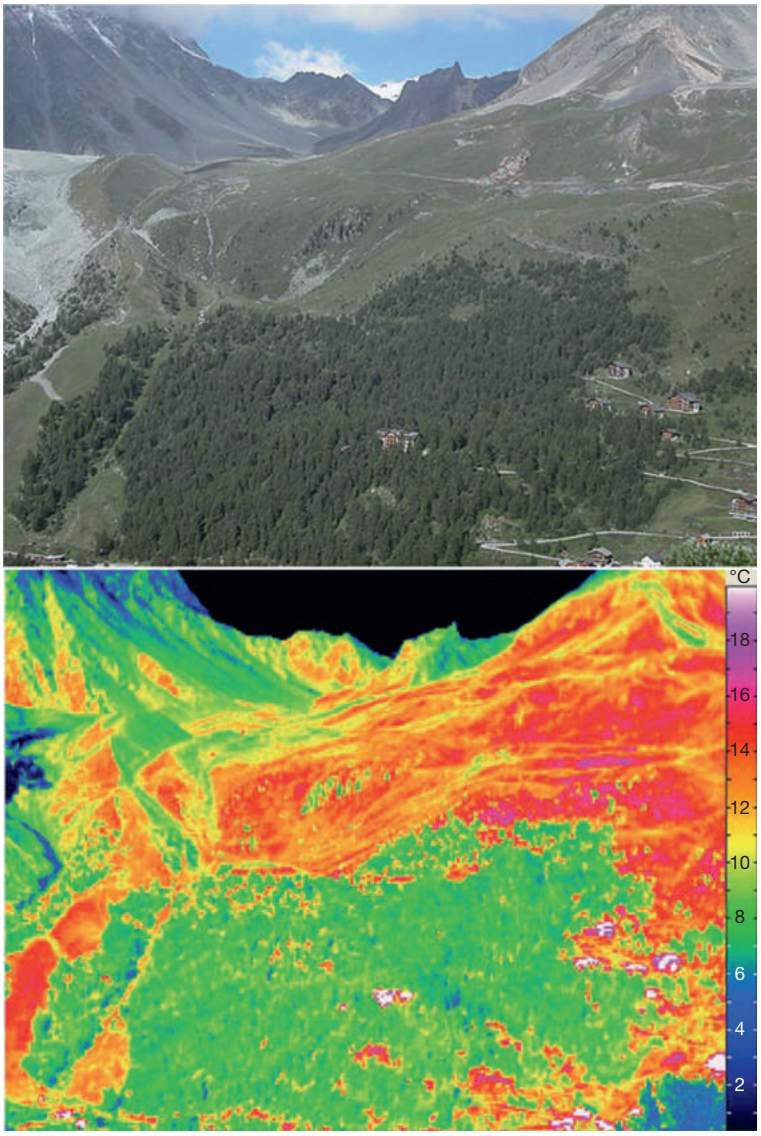

Figure 3 Trees are coupled to air temperature and thus appear 'cool' on this infrared thermograph taken at 10 a.m. on a bright midsummer morning in the Swiss Alps near Arolla. Alpine grassland and shrub heath accumulate heat by decoupling from atmospheric conditions (low stature, dense structures). So the treeline can clearly be depicted as a thermal boundary driven by plant architecture.

The transition from trees to alpine vegetation is thus dictated by plant architecture and not by tissue-specific inferiority of trees compared to alpine plants. This close coupling of trees to atmospheric conditions also explains the surprisingly uniform leveling of treelines across mountain valleys which reminds one of the level of a water reservoir. In contrast, the climate in alpine vegetation varies with compactness and height of the leaf canopy and exposure to the sun. A sun-exposed, sheltered microhabitat at 3000 m of altitude may be warmer than a shaded microhabitat at 1800 m. Altitude per se, or data from a conventional climate station, thus, tells us little about the climate actually experienced by alpine plants. It had long been known that mutual sheltering among alpine plants or leaves/tillers within a plant is very beneficial ('facilitation'), and removing this shelter effect by opening the plant canopy can be disastrous.

Alpine plants are small by 'design' (genetic dwarfs); they are not forced into small stature by the alpine climate directly, though evolution had selected such morphotypes. What seems like a stressful environment is not really stressful for those well adapted. However, there is some additional modulative, direct effect on size by low temperature. Alpine plants that survive in low-altitude rock gardens indeed grow taller than their relatives in the wild. But plants grown in such rock gardens are commonly of montane origin, because most typical alpine plants fade at such high-, low-altitude temperatures, possibly because of overshooting mitochondrial respiration.

Alpine Ecosystem Processes

Almost everything gets slower when it gets cold, but slow production of biomass and slow recycling of dead biomass (litter) go hand in hand, so that the carbon and nutrient cycles remain in balance. Recycling of organic debris is responsible for most of the steady-state nutrient provision and thus controls vigor of growth. When mineral nutrients are added, all alpine vegetation tested had shown immediate growth stimulation, but this holds for most of the world's biota and is not specific to alpine ecosystems. On the other hand, nutrient addition had been shown to make alpine plants more susceptible to stress (softer tissue, reduced winter dormancy) and pathogen impact (e.g., fungal infections) and causes nitrophilous grasses and herbs to overgrow the best-adapted slow-growing alpine specialist species.

It comes as a rather surprising observation that alpine plant productivity – at least in the temperate zone – is only low when expressed as an annual rate of biomass accumulation, but is not low at all when expressed per unit of growing season length. In a 2-month alpine season in the temperate zone alpine belt, the biomass production (above-plus belowground) accumulates to $\sim$400 g dry matter m^{-2} (range 200–600 g m^{-2}). A northern deciduous hardwood forest produces 1200 g m^{-2} in 6 months and a humid tropical forest 2400 g m^{-2} in a 12-month season, all arriving at $\sim$200 g m^{-2} per month. Time constraints of growth are thus the major causes of reduced annual production in closed alpine grass- and shrubland and not physiological limitations in what seems to a human hiker like a rather hostile environment. Acclimation to low temperature, perfect plant architecture, and developmental adjustments can equilibrate these constraints on a unit of time basis. It makes little sense to relate productivity to a 12-month period when 9–10 months show no plant activity because of freezing conditions and/or snow cover.

Similar to carbon and nutrient relations, alpine ecosystem's water relations are largely controlled by seasonality. During the growing season in the humid temperate zone, daily water consumption during bright weather hardly differs across altitude ($\sim$3.5–4 mm evapotranspiration). However, because of the short snow-free season at such latitudes, annual evapotranspiration may be only 250–300 mm compared to 600–700 mm at low altitude; hence, runoff is much higher in alpine altitudes. Given that precipitation often increases with altitude in the temperate zone (a doubling across 2000 m of altitude is not uncommon), annual runoff may be three to five times higher in the alpine belt, with major implications for erosion in steep slopes.

In many tropical and subtropical mountains, moisture availability drops rapidly above the condensation cloud layer at 2000–3000 m altitude, causing the alpine belt to receive very little water, often not more than 200–400 mm per year (e.g., the high Andes, Tenerife, East African volcanoes). The resulting sparse vegetation is often termed alpine semidesert, but because of wide spacing of plants and very little ground cover, those plants which are found in this semiarid alpine landscape were found to be surprisingly well supplied with water even at the end of the dry season (Figure 4). As a rule of thumb, alpine plants are thus better supplied with moisture (even in dry alpine climates) than comparable low-altitude vegetation. True physiologically effective water stress is quite rare in the alpine belt, but moisture shortage in the top soil may restrict nutrient availability periodically, which restricts growth.

Biodiversity in Alpine Ecosystems

For plants and animals to become 'alpine,' they must pass through a selective filter represented by the harsh climatic conditions above treeline. It comes as another surprise that alpine ecosystems are very rich in organismic taxa. It was estimated that the $\sim$2.6% of global land area (outside Antarctica) that can be ascribed to the alpine belt hosts $\sim$4% of all species of flowering plants. In other words, alpine ecosystems are on average similarly rich or even richer in plant species than average low-elevation ecosystems. This is even more surprising if one accounts for the fact that the available land area above treeline shrinks rapidly with elevation (on average, a halving of the area in each successive 170 m belt of altitude). A common explanation for this high species richness is the archipelago nature of high mountains (a fragmentation into climatic 'islands'), the high habitat diversity as it results from gravitational forces (topographic diversity, also termed geodiversity), and the small size of alpine plants, which partly compensates

Figure 4 High-altitude semideserts (near Sajama, Bolivia, 4200 m) are often dominated by sparse tussock grasses, shrubs, and minor herbs in the intertussock space, all together preventing soil erosion, while being used for grazing. The wide spacing mitigates drought stress in an otherwise dry environment.

Figure 5 The four major life-forms of flowering plants in alpine ecosystems: cushion plants (*Azorella compacta*, *Silene exscapa*), herbs (small: *Chrysanthemum alpinum*, tall: *Gentiana punctata*), dwarf shrubs (*Loiseleuria procumbens*, *Salix herbacea*), and tussock-forming graminoids (*Carex curvula*, diverse tall grass tussock).

for the elevational loss of land area. The elevational trends for animal diversity are similar to plants, but some animal taxa decline in diversity with elevation more rapidly (e.g., beetles, earthworms, butterflies) than others (e.g., vertebrates, birds). Often animal diversity peaks at mid-altitudes (close to the treeline ecotone) and then declines.

The four major life-forms of flowering plants in the alpine belt are graminoids (grasses, mostly forming tussocks, sedges, etc.), rosette-forming herbs, dwarf shrubs, and cushion plants (Figure 5). In most parts of the world, bryophytes and lichens (a symbiosis between algae and fungi) contribute an increasing fraction of biodiversity as altitude increases. Each of these life-forms can be subdivided into several subcategories, mostly represented by different forms of clonal growth. Clonal (vegetative) spreading is dominant in all mountains of the world and it secures long-term space occupancy by a 'genet' (a single genetical individual) in a rather unpredictable environment. Because of the topography-driven habitat diversity, rather contrasting morphotypes and physiotypes may be found in close proximity, as for instance succulent (water storing) plants such as alpine cactus or some leaf-succulent Crassulaceae (*Sedum* sp., *Echeveria* sp.) next to wetland or snowbed plants.

Alpine ecosystems are known for their colorful flowers, and it was often thought that this may be a selected-for trait, because it facilitates pollinator visitation. There is also morphological evidence that alpine plants invest relatively more in flowering, given that plant size (and biomass per individual) declines by nearly tenfold from the lowland to the alpine belt, whereas the size of insect-pollinated flowers hardly changes. Furthermore, flower duration increases and so does pollinator visiting duration, and there is no indication that there is a shortage in alpine pollinators. The net outcome is a surprisingly high genetic diversity in what seems like highly fragmented and isolated habitats. Despite the successful reproductive system at the flower-pollinator scale and well-adapted (fast) seed maturation, the real bottleneck is seedling establishment (the risk to survive the first summer and winter), which explains why most alpine plants also propagate clonally.

Overall, mountain biodiversity (the montane belt, the treeline ecotone, and the alpine belt) is a small-scale analog of global biodiversity, because of the compression of large climatic gradients over very short distances. Across a vertical gradient from 1200 to 4200 m in the Tropics one may find a flora and fauna with a preference for climates otherwise only found across several thousand kilometers of latitudinal distance. This is why mountains are ideal places for biodiversity conservation as long as the protected mountain system is large and has migration corridors to prevent biota from becoming trapped in ever-narrowing land area should climatic warming induce altitudinal upward shifts of life zones.

Alpine Ecosystems and Global Change

'Global change' includes changes in atmospheric chemistry (CO_2, CH_4, N_xO_y), the climatic consequences of these changes, and the manifold direct influences of humans on landscapes. All three global change complexes affect alpine biota, either directly or indirectly.

Elevated atmospheric carbon dioxide (CO_2) concentrations affect plant photosynthesis directly, although plants in alpine grassland and glacier fore fields in the Alps were found to be carbon saturated at current ambient CO_2 concentrations (390 ppm). The effect of doubling CO_2 concentrations over four consecutive seasons on net productivity of alpine health was zero. However, not all species responded identically; hence, there is a possibility of gradual shifts in species composition in the long run, with some species getting suppressed and others gaining.

In contrast, even moderate additions of soluble nitrogen fertilizer at rates of those received today by mountain forelands in Central Europe with rains (40–50 kg N $ha^{-1}a^{-1}$) doubled biomass in only 2 years. Even 25 kg $ha^{-1}a^{-1}$ had immediate effects on biomass (+27%), again favoring some species more than others. Atmospheric nitrogen deposition is thus far more important for alpine ecosystems than elevated CO_2. Just for comparison, in agriculture, cereals are fertilized with >100 kg N $ha^{-1}a^{-1}$.

Consequences of climatic change for alpine ecosystems are hard to predict because of the interplay of climatic warming with precipitation. A warmer atmosphere can carry more moisture; hence, increasing precipitation had been predicted for temperate mountain areas. Greater snowpack can shorten the growing season at otherwise higher temperatures. While the temperate zone has seen more late winter snow in recent years, the uppermost reaches of higher plants seem to have profited from climatic warming over the twentieth century. Several authors documented a clear enrichment of summit floras, accelerated in recent decades.

Treeline trees respond to warmer climates by faster growth, but whether and how fast this would cause the treelines of the world to advance upward depends on tree establishment, which is a slow process. Hence, treelines always lagged behind climatic warming during the Holocene by centuries, as evidenced by pollen records. Current trends are largely showing an infilling of gaps in the treeline ecotone, but upward trends await larger-scale confirmation. Eventually any persistent warming will induce upward migration of all biota. By contrast, recent climatic warming has caused the tropical upper montane/alpine climate on Kilimanjaro to become drier, facilitating devastating fires, which depressed the montane forest by several hundred meters with a downslope advance (expansion) of alpine vegetation following.

Land use is still the most important factor for changes in alpine ecosystems. Around the globe, alpine vegetation is used for herding or uncontrolled grazing by lifestock. Much of the treeline ecotone has been converted into pasture land, with both overutilization and erosion (mainly in developing countries) and abandonment of many centuries-old, high-elevation cultural landscapes (mainly industrialized countries) causing problems. The question is not whether there should be pasturing, but how it should be done. Sustainable grazing requires shepherding and observation of traditional practices, which largely prevent soil damage and erosion. Traditional alpine land use has a several thousand years' history and was optimized for maintaining an intact landscape for future generations as opposed to land-hungry newcomers faced with the need of feeding a family today, rather than thinking of sustained livelihood in a given area. All other forms of land use (except mining), as dramatic their negative effects at certain places may look, are less important, because their impact is rather local (e.g., tourism, road projects). Agriculture is by far the most significant factor in terms of affected land area.

Mismanagement of alpine ecosystems has severe consequences (e.g., soil destruction, sediment loading of rivers) not only for the local population but also for people living in large mountain forelands, which depend on the steady supplies of clean water from high-altitude catchments. Almost 50% of mankind consumes mountain resources, largely water and hydroelectric energy; hence, there is an often overlooked teleconnection between alpine ecosystems and highly populated lowlands. Highland poverty is thus affecting the conditions and the economic value of catchments, which goes far beyond the actual agricultural benefits. This insight should lead to better linkages between lowland and highland communities and also include economic benefit sharing with those that perform sustainable land care in alpine ecosystem.

Caves☆

FG Howarth, Bishop Museum, Honolulu, HI, USA

Caves

Caves are defined as natural subterranean voids that are large enough for humans to enter. They occur in many substrata, and cavernous landforms make up a significant portion of the Earth's surface. Limestone caves are the best known. Limestone, calcium carbonate, is mechanically strong yet dissolves in weakly acidic water. Thus over eons great caves can form. Caves form in other soluble rocks, such as dolomite (calcium magnesium carbonate), but they are usually not as extensive as those in limestone. Volcanic eruptions also create caves. The most common are lava tubes that are built by the roofing over and subsequent draining of molten streams of fluid basaltic lava. In addition, cave-like voids form by erosion (e.g., sea caves and talus caves), by earthquakes and by melting water beneath or within glaciers. Depending on their size, shape and interconnectedness, caves develop unique environments that often support distinct ecosystems.

Cave Environments

The physical environment is rigidly constrained by the geological and environmental settings and can be defined with great precision because it is surrounded and buffered by thick layers of rock. Caves can be water-filled or aerial.

Aquatic Environments

Aquatic systems are best developed in limestone caves since water creates these caves. Debris-laden water in voids in insoluble rock will eventually fill caves. A significant exception is found in young basaltic lava that has flowed into the sea. Here, subterranean ecosystems develop in the zone of mixing freshwater and salt water within caves and spaces in the lava. This ecosystem (called anchialine) is fed by food carried by tides and groundwater flow. Frequent volcanism creates new habitat before the older voids fill or erode away. Anchialine systems also occur in limestone and other cavernous substrata in coastal regions. Aquatic cave environments are dark, three-dimensional (3D) mazes, in which food and mates may be difficult to find. In addition, the water can stagnate, locally becoming hypoxic with high concentrations of toxic gases including carbon dioxide and hydrogen sulfide.

Terrestrial Environments

The terrestrial environment in long caves is buffered from climatic events occurring outside. The temperature stays nearly constant, usually near the mean annual surface temperature (MAST); except passages sloping down from an entrance tend to trap cold air and remain a few degrees cooler than MAST. Passages sloping up are often warmer than MAST. The environment is strongly zonal (Fig. 1). Three zones are obvious: an entrance zone where the surface and underground habitats overlap; a twilight zone between the limit of photosynthesis and total darkness; and the dark zone. The dark zone can be further subdivided into three distinct zones: a transition zone where climatic events on the surface still affect the atmosphere, especially relative humidity (RH); a deep zone where the RH remains constant at 100%; and an innermost stagnant air zone where air exchange is too slow to flush the buildup of carbon dioxide and other decomposition gasses. The boundary between each zone is often determined by shape or constrictions in the passage. In many caves, the boundaries are dynamic and change with the seasons.

The subterranean aerial environment is stressful for most organisms. It is a perpetually dark, 3D maze with a water-saturated atmosphere and occasional episodes of toxic gas concentrations. Many of the cues used by surface animals are absent or operate abnormally in caves (e.g., light/dark cycles, wind, scent plumes and sound). Passages can flood during rains, and crevices might drop into pools and water-filled traps. If the habitat is so inhospitable, why and how do surface animals forsake the lighted world and adapt to live there? It is the presence of abundant food resources that provides the impetus for colonization and adaptation.

Food Resources

The main energy source in limestone caves is sinking rivers, which carry-in abundant food not only for aquatic communities but also via flood deposits for terrestrial communities. Rivers are less important in insoluble rock, such as lava, but percolating runoff washes surface debris into caves through crevices. Other major energy sources are brought in by animals that habitually visit or

 doi:10.1016/B978-0-12-409548-9.00725-9

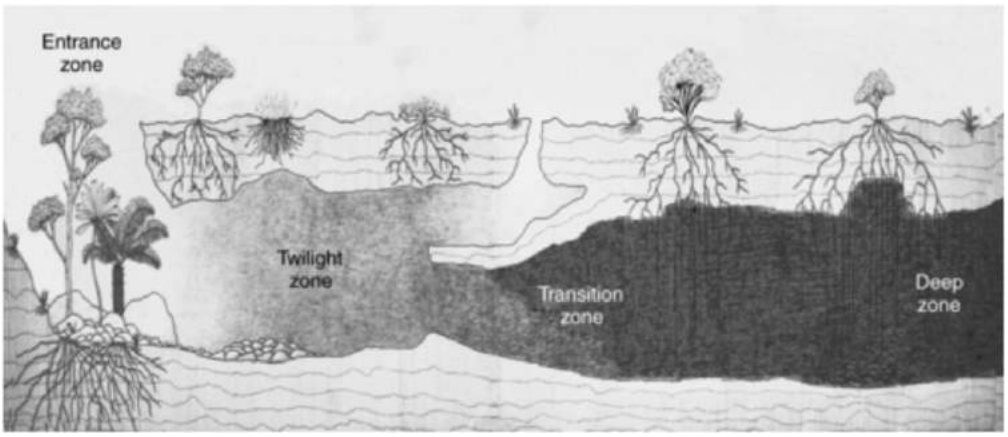

Fig. 1 Schematic profile view of the cave habitat showing the location of principal zones.

roost in caves, plants that are able to send their roots deep underground, chemoautotrophic microorganisms that use minerals (including fossil carbon) and surface animals (i.e., accidentals) that fall or wander into caves and become lost.

Generally in surface habitats, accumulating soil filters water and nutrients and holds these resources near the surface where they are accessible to plant roots and surface-inhabiting organisms. However, in most areas with underlying caves, the soil is thin with areas of exposed bare rock because developing soil is washed or carried into underground voids by water or gravity. Soil formation is limited, and much of the organic matter sinks out of the reach of most surface animals and shallow-rooted plants.

Except for guano deposits, flood deposits, scattered root patches, and other point-source food inputs, the defining feature of cave habitats is the appearance of barren wet rock. Visible food resources in the deep cave are often negligible, and what food deposits there are would be difficult for animals to find in the 3D maze. Food resources in the system of smaller spaces is difficult to sample and quantify, but in theory, some foods may be locally concentrated by water transport, plant roots, or micro point source inputs such as through cracks indirectly or circuitously connecting to the surface. These deposits would be more easily exploited than would widely scattered deposits.

In each biogeographic region, a few members of the surface and soil fauna have invaded cave habitats and adapted to exploit this deep food resource. The colonists usually were pre-adapted; that is, they already possessed useful characteristics resulting from living in damp, dark habitats on the surface.

Cave Communities

Guano Communities

Many animals live in or use caves. Cave-inhabiting vertebrates are relatively well-known. Cave bats, swiftlets (including the edible-nest swiftlet of Southeast Asia) and the oil bird in South America use echolocation to find their way in darkness. Pack rats in North America, along with cave crickets and other arthropods also roost in caves. Large colonies of these cave-nesting animals carry in huge quantities of organic matter with their guano and dead bodies. This rich food resource forms the basis for specialized communities of microorganisms, scavengers, and predators. Arthropods comprise the dominant group of larger animals in this community, and like their vertebrate associates, most species are able to disperse outside caves to establish new colonies.

Deep Cave Communities

In the deeper netherworld, communities of mysterious, obligate cave animals occur. Most are invertebrates, but a few fishes and salamanders have colonized the aquatic realm. Crustaceans (shrimps and their allies) dominate in aquatic ecosystems, and insects, myriapods and spiders and their allies dominate terrestrial systems. Although a few species are specialists on living plant roots or other specific resources, most are generalist predators or scavengers. The relatively high percentage of predators indicates the importance of accidentals as a food resource. However, many presumed predatory species, such as spiders, centipedes, and ground beetles, will also scavenge on dead animals when available. It is not advantageous to have finicky tastes where food is difficult to find. Thus in deep cave communities, the food chain more closely resembles a food web with most species interacting with most of the other species in the community, rather than the energy progressing more or less linearly from plants through plant feeders, scavengers, and omnivores to predators as normally happens in most surface systems.

Adaptations to Cave Life

Animals roosting or living in caves must adapt to cope with the unusual environment. Paramount for the cave-roosting vertebrates is the ability to find their way to and from their roosts at the correct time. Not surprisingly, the birds and bats display uncanny skill in memorizing the complex maze to and from their cave roosts. Pack rats use trails of their urine to navigate in and out of caves. Species using the twilight and transition zones can use the daily meteorological cycle for cues to wake and leave the cave. Those roosting in the deep zone may rely on accurate internal clocks to know when it is beneficial to leave their roost.

Organisms that adapt to live permanently underground must make changes in behavior, physiology, and structure in order to thrive in the stressful environment. They need to find food and mates and successfully reproduce in total darkness. Their hallmark is the loss or reduction of conspicuous structures such as eyes, bodily color, protective armor, and wings. These structures are worthless in total darkness, but they can be lost quickly when selection is relaxed because they are expensive for the body to make and maintain. How such losses could happen quickly is demonstrated by the cave-adapted planthoppers (Cixiidae). The nymphs of surface species feed on plant roots in soil and have reduced eyes and bodily color whereas their adults have big eyes, bold colors, and functional wings. The cave-adapted descendants maintain the nymphal eyes, color, and other structures into adulthood, a phenomenon known as neoteny.

The high relative humidity and occasional episodes of elevated CO_2 concentrations are stressful to most organisms. The blood of insects and other invertebrates will absorb water from saturated atmosphere, and the animals literally will drown unless they have adaptations to excrete the excess water. High levels of CO_2 force animals to breathe more, which increases water absorption. Cave-adapted insects often have modified spiracles to prevent or cope with their air passages filling with water.

Most lava tube arthropods have specialized elongated claws to walk on glassy wet-rock surfaces. Many have elongated legs to step across cracks rather than having to descend and climb the other side. Jumping or falling might land a hapless animal in a pool or water-filled pit or into the clutches of a predator. Small insects are often too heavy or are unable to climb the meniscus at the edge of rock pools and will eventually drown. However, many cave-adapted insects have unique knobs or hairs near the base of each elongated claw and modified behavioral traits that allow them to climb the meniscus and escape. Some of the latter are predators or scavengers, who wait on pools for victims.

Other Cave-Like Habitats

Cavernous rock strata contain abundant additional voids of varying sizes, which may not be passable by humans. These voids are interconnected by a vast system of cracks and solution channels. The smaller capillary-sized spaces are less important biologically because their small size limits the amount of food resources they can hold and transport. Voids larger than about 5 cm can transport large volumes of food as well as serve as habitat for animals. In terms of surface area and extent, these intermediate-size voids are the principal habitat for specialized cave animals. Many aspects of their life history may occur only in these spaces. Some cave species (such as the earwig, *Anisolabis howarthi* (**Fig. 2**), and sheet web spiders, Linyphiidae, in Hawaiian lava tubes) prefer to live in crevices and are only rarely found in caves. In addition, cave-adapted animals have been found living far from caves in cobble deposits beneath rivers, fractured rock strata, talus slopes and buried lava clinker in Japan, Hawai'i, Canary Islands, Australia, North America and Europe. New cave species and ecosystems continue to be discovered in new regions. These discoveries corroborate the view that cave adaptation and the development of cave ecosystems can occur wherever there is suitable underground habitat.

Because these smaller voids are isolated from airflow from the surface, the environment resembles the stagnant air zones of caves. Caves serve as entry points and windows in which humans can observe the fauna living within the voids in the cavernous rock strata. The view is imperfect because so much of the habitat is inaccessible and because the environment is so foreign to human experience.

Case Study: Hawai'i

Food Web

The main energy sources in Hawaiian lava tube ecosystems are tree roots, which penetrate the lava for several decameters; organic matter, which washes in with percolating rainwater; and accidentals, which are surface and soil animals blundering into the cave. Both living and dead roots are utilized, and this source is probably the most important. Furthermore, both rainwater and accidentals often use the same channels as roots to enter caves, so that root patches often provide food for a wide diversity of cave organisms. The importance of roots in the cave ecosystem makes it desirable to identify the major species. This has become possible only recently by using DNA-sequencing technology. The most important source of roots is supplied by the native pioneer tree on young lava flows: *Metrosideros polymorpha*. Additionally, *Cocculus orbiculatus*, *Dodonaea viscosa*, and *Capparis* are locally important in drier habitats. Several different slimes and oozes occur on wet surfaces and are utilized by scavengers in the cave. They are mostly organic colloids deposited by percolating groundwater, but some may be chemoautotrophic bacteria living on minerals in the lava. Cave-roosting vertebrates do not occur in Hawai'i. Several species of native agrotine moths once roosted in caves in large colonies, but the group has become rare in historic times. The composition of the community that their colonies once supported is unknown. Feeding on living roots are cixiid planthoppers (*Oliarus*). Their nymphs suck xylem sap with piercing mouthparts. The blind flightless adults wander through subterranean voids in search of mates and roots. Potential mates locate each other using species-specific substrate borne songs transmitted along their host roots. Caterpillars of noctuid moths (*Schrankia*) prefer to feed on succulent flushing root tips, but they also occasionally scavenge on rotting plant and animal matter. Tree crickets (*Thaumatogryllus*), terrestrial amphipods (*Spelaeorchestia*), and isopods (*Hawaiioscia* and *Littorophiloscia*) are omnivores but feed extensively on roots. Cave rock crickets (*Caconemobius*) are also omnivorous as well as being opportunistic predators. Feeding on rotting organic material and associated microorganisms are millipedes (*Nannolene*), springtails (*Neanura*, *Sinella*, and *Hawinella*), and phorid flies (*Megaselia*). Terrestrial water treaders (*Cavaticovelia aaa*) suck juices from long-dead arthropods. Feeding in the organic oozes growing on wet cave walls are larvae of crane flies (*Dicranomyia*) and biting midges (*Forcipomyia pholeter*). The blind predators include spiders (*Lycosa howarthi*, *Adelocosa anops* (**Fig. 3**), *Erigone*, *Meioneta*, *Oonops*, and *Theridion*), pseudoscorpions (*Tyrannochthonius*), rock centipedes (*Lithobius*), thread-legged bugs (*Nesidiolestes*), and beetles (*Nesomedon*, *Tachys*, and *Blackburnia*). Most of the cave predators will also scavenge on dead animal material.

Succession

Inhabited Hawaiian lava tubes range in age from 1 month on Hawai'i Island to 2.9 million years on O'ahu Island. On Hawai'i Island colonization and succession of cave ecosystems can be observed. Crickets and spiders colonize the surface of new flows within a month of the flow surface cooling. They hide in caves and crevices by day and emerge at night to feed on windborne debris. *Caconemobius* rock crickets are restricted to living only in this aeolian (wind-supported) ecosystem and disappear with the establishment of plants. The obligate cave species begin to arrive within a year after lava stops flowing in the caves. The predatory wolf spider, *Lycosa howarthi*, arrives first and preys on wayward aeolian arthropods. Other predators and scavenging arthropods – including blind, cave-adapted *Caconemobius* crickets – arrive during the next decade. Under rainforest conditions, plants begin to

invade the surface after a decade, allowing the root feeding cave animals to colonize the caves. *Oliarus* planthoppers arrive about 15 years after the eruption and only 5 years after its host tree, *Metrosideros polymorpha*. The cave-adapted moth, *Schrankia howarthi*, and the underground tree cricket, *Thaumatogryllus cavicola*, arrive later. The cave species colonize new lava tubes from neighboring older flows via underground cracks and voids in the lava. Caves between 500 and 1000 years old are most diverse in cave species. By this time the surface rainforest community is well-developed and productive, while the lava is still young and maximal amount of energy is sinking underground. As soil formation progresses, less water and energy reaches the caves, and the communities slowly starve. In highest rainfall areas, caves support none or only a few species after 10 000 years. Under desert conditions, succession is prolonged for 100 000 years or more. Mesic regimes are intermediate between these two extremes. New lava flows may rejuvenate some buried habitat as well as create new cave habitat. Thus in volcanic caves, succession proceeds upwards with the younger inhabitable caves occurring above barren remnant older caves. The opposite occurs in limestone where solution and down-cutting create younger deeper caves while leaving high and dry remnant passages exposed in cliffs.

Conservation

Caves and their resources are vulnerable to the effects of land-use changes on the surface as well as to changes within the caves. Threats include mining, land-clearing, pollution, water impoundments, recreational use, nonindigenous species invasions and climate change. Two emerging global threats are described in more detail below.

Nonindigenous Species

Several invasive nonindigenous species have invaded cave habitats and are impacting the cave communities. In Hawai'i, the predatory guild is the most troublesome, with some species being implicated in the reduction of vulnerable native species. Among these, the nemertine worm (*Argonemertes dendyi*) and spiders (*Dysdera*, *Nesticella*, and *Eidmanella*) have successfully invaded the stagnant air zone within the smaller spaces. The colonies of cave-roosting moths most likely disappeared from the depredations of the roof rat (*Rattus rattus*) on their roosts and in part from parasites purposefully introduced for biological control of their larvae. Many non-native species (such as *Periplaneta* cockroaches, *Loxosceles* spiders, *Porcellio* isopods, and *Oxychilus* snails) survive well in larger accessible cave passages, where they have some impact, but they appear not to be able to survive in the system of smaller crevices. Alien plants have replaced native species and modified the surface environment over caves thereby directly and indirectly impacting the cave ecosystem below. A few alien trees send roots into caves, creating a dilemma for reserve managers trying to protect both cave and surface habitats since their roots support some generalist native species but not the host-specific planthoppers.

In North America, red imported fire ants (*Solenopsis invicta*) have been implicated in the decline of endangered cave species in Texas. The ants prey on foraging cave crickets, thereby causing critical reduction of food inputs into the caves. Similarly, white-nose syndrome (*Pseudogymnoascus destructans*), a fungal disease of bats recently introduced from Europe, is decimating naïve native bat colonies in eastern North American caves, endangering some bat species and disrupting the food supply in affected caves. With expanding globalization of transportation and commerce, problems caused by nonnative species will become more severe.

Climate Change

Deep caves are buffered environments, and except for areas covered by deep ice sheets, the obligate cave species alive today in temperate regions survived the extreme climatic shifts during the Pleistocene, whereas many of their surface relatives perished. This happenstance suggests that these cave species likely will survive the direct effects of climate change. Even with the predicted increase in extreme droughts and storms, and the expansion or contraction of deserts and forests, many cave species will be able to migrate into and out of deeper cave passages and voids in response to climate change as they do now with changing seasons. A few cave regions are vulnerable; for example, submersion of coastal caves in response to sea level rise and desertification, which would result in less food inputs. In addition, climate change will allow the range expansion of invasive species further enhancing their impacts.

However, the main threats to cave ecosystems resulting from climate change likely will be caused by the responses made by humans as we adapt to climate change. These adaptations include increased water impoundments, mineral and fossil fuel extraction, conversion of marginal land for agriculture, urbanization and other changes in land-use. Cave ecosystems, especially in areas that have not been well-studied, will be out of sight-out of mind and possibly destroyed before the fauna can be documented.

Perspective

The fauna of a large percentage of the world's cave habitats remains unknown to science, and new species continue to be discovered even in well-studied caves. Additional biological surveys are needed to fill gaps in knowledge and improve our understanding of cave ecosystems. Improved methods for sampling the inaccessible smaller voids are needed. The cave environment is a rigorous, high-stress one, which is difficult for humans to access and envision because it is so foreign to human experience. Working in caves can be physically challenging. However, recent innovations in equipment and exploration techniques

allow ecologists to visit the deeper, more rigorous environments. Also, the advent of DNA sequencing technology has been a valuable addition to the cave biologists' tool kit.

In spite of the difficulties of working in the stressful environment, several factors make caves ideal natural laboratories for research in evolutionary and physiological ecology. Since cave habitats are buffered by the surrounding rock, the abiotic factors can be determined with great precision. The number of species in a community is usually manageable and can be studied in total. The remarkable suite of characters shared by cave species worldwide and that evolved independently and in parallel among unrelated species demonstrates the universality of natural selection in forcing adaptions to the similar physical environment. Understanding how this convergent evolution occurs promises to improve our understanding of evolution in general. Questions that are being researched are how organisms adapt to the various environmental stressors; how communities assemble under the influence of resource composition and amount; and how abiotic factors affect ecological processes. For example, a potential overlap between cave and surface ecological studies occurs in some large pit entrances in the tropics. The flora and fauna living in these pits frequently experience CO_2 levels 25–50 times ambient for extended periods of time making them natural laboratories for studying the effects of increased CO_2 levels.

Chaparral

JE Keeley, University of California, Los Angeles, CA, USA

Introduction

Chaparral is the name applied to the evergreen sclerophyllous (hard-leaved) shrub vegetation of southwestern North America, largely concentrated in the coastal zone of California and adjacent Baja California. It is a dense vegetation often retaining many dead spiny branches making it nearly impenetrable (**Fig. 1**). It dominates the foothills of central and southern California but is replaced at higher elevations by forests. On the most arid sites at lower elevations evergreen chaparral is replaced with a lower-stature summer deciduous `soft chaparral' or sage scrub.

Chaparral owes much of its character to the Mediterranean climate of winter rain and summer drought. The severe summer drought, often lasting 6 months or more, inhibits tree growth and enforces the shrub growth form. Intense winter rains coincide with moderate temperatures that allow for rapid plant growth, producing dense shrublands. These factors combine to make this one of the most fire-prone ecosystems in the world. This Mediterranean climate is the result of a subtropical high-pressure cell that forms over the Pacific Ocean. During the summer, this air mass moves northward and blocks water-laden air masses from reaching land, and in winter this high-pressure cell moves toward the equator and allows winter storms to pass onto land. On the Pacific Coast it is wettest in the north, where the effect of the Pacific High is least, and becomes progressively drier to the south, and consequently chaparral dominates more of the landscape in the southern part. Interestingly, these synoptic weather conditions form globally at this same latitude (30–38° north or south) and on the western sides of continents. As a result similar Mediterranean-climate shrublands occur in the Mediterranean Basin of Europe, central Chile, South Africa, and southern Australia.

The Ecological Community

Chaparral is a shrub-dominated vegetation with other growth forms playing minor or temporary successional roles after fire. More than 100 evergreen shrub species occur in chaparral, although sites may have as few as one or more than 20 species, depending on available moisture, slope aspect, and elevation. The most widely distributed shrub is chamise (*Adenostoma fasciculatum*), ranging from Baja to northern California, occurring in either pure chamise chaparral or in mixed stands. It often dominates at low elevations and on xeric south-facing slopes. The short needle-like leaves produce a sparse foliage, and soil litter layers are poorly developed and result in weak soil horizons. Chamise often forms mixed stands of vegetation with a number of species. These include the bright smooth red-barked manzanita (*Arctostaphylos* spp.), the sometimes spiny ceanothus, also known as buckbrush or California lilac (*Ceanothus* spp.). On more mesic north-facing slopes chaparral is commonly dominated by broader-leaved shrubs, including the acorn-producing scrub oak (*Quercus* spp.), the cathartic coffeeberry (*Rhamnus californica*), redberry (*R. crocea*), the rather bitter chaparral cherry (*Prunus ilicifolia*), and chaparral holly (*Heteromeles arbutifolia*), from whence the film capital Hollywood derives its name.

The most common shrub species and the majority of herbaceous species have fire-dependent regeneration, meaning that seeds remain dormant in the soil until stimulated to germinate after fire (see the section titled `Fire' below). These include chamise, manzanita, and ceanothus shrubs, which flower and produce seed most years but seldom produce seedlings without fire. Some ceanothus species are relatively short-lived or are easily shaded out by other shrubs and die after several decades. They, however, persist as a living seed pool in the soil. In addition, a large number of annual species live most of their life as dormant seeds in the soil, perhaps as long as a century or more. Also, many perennial herbs with underground bulbs, known as geophytes, may remain dormant for long periods of time between fires.

All of the other shrub species listed above are not fire dependent and produce seeds that germinate soon after dispersal; however, successful reproduction is relatively uncommon. This is because their seedlings are very sensitive to summer drought and because there are a number of herbivores that live in the chaparral understory and prey on seedlings and other herbaceous vegetation. These include deer mice (*Peromyscus maniculatus*), woodrats (*Neotoma fuscipes*), and brush rabbits (*Sylvilagus bachmani*). Both rodents (mice and rats) are nocturnal; however, evidence of woodrats, or packrats as they are sometimes called, is very evident in many older chaparral stands because of the several foot high nests of twigs they make under the shrub canopy. These animals not only affect community structure by consuming most seedlings and herbaceous species, but also are important vectors for disease and other health threats. For example, deer mice are host to the deadly hanta-virus and woodrats are a critical host for kissing bugs (family Reduviidae) that can cause lethal allergic responses in humans. All animals including reptiles act as hosts for Lyme disease-carrying ticks (*Ixodes pacificus*). The browser of mature shrubs is the black-tailed deer (*Odocoileus hemionus*), although many are attacked by specific gall-forming wasps and aphids. Often scrub oak will have large fruit-like structures produced by gall wasp (family Cynipidae). The adult wasp oviposits on a twig, leaf, or flower and the developing larvae hijack the metabolic activities of the plant cells and force it to produce a highly nutritious spongy parenchymous tissue for the developing wasp larva.

 doi:10.1016/B978-0-444-63768-0.00321-8

Fig. 1 Chaparral shrubland in California. Photo by J. E. Keeley.

These shrubs that reproduce in the absence of fire have successful seedling establishment largely restricted to more mesic plant communities such as adjacent woodlands, or to very old chaparral with deep litter layers that enhance the moisture holding capacity of the soil. When seedlings do establish under the shrub canopy, they typically persist for decades as stunted saplings in the understory. These saplings are heavily browsed by rodents and rabbits and often will produce a swollen woody basal burl that survives browsing and continually sprouts new shoots. If these saplings survive until fire, they are capable of resprouting from their basal burl after fire and exhibit a growth release that enhances their chances of recruiting into the mature canopy during early succession. Thus, in some sense these shrubs may be indirectly fire dependent for completion of their life cycle.

Chaparral has a number of herbaceous or woody (lianas) vines, including manroot (*Marah macrocarpus*) and chaparral honeysuckle (*Lonicera* spp.). These vines overtop the canopy of the shrubs and flower on an annual or near-annual frequency. The former produce fleshy spiny fruits with very large seeds that are highly vulnerable to predation and the latter dry capsules with light seeds that may be wind borne. Both have weak seed dormancy and often establish seedlings in the understory.

Yucca (*Yucca whipplei*) is a fibrous-leaved species that persists as an aboveground rosette of evergreen leaves. It often survives fire because it prefers open rocky sites with very little vegetation to fuel intense fires. Because they are monocotyledonous species they have a central meristem that is protected by the outside leaves, which can withstand severe scorching. This species flowers prolifically after fire and exhibits a remarkable mutualism with the tiny yucca moth (*Tegiticula maculata*). Moth pupae survive in the soil and emerge in the growing season as adults that fly to yucca flowers where they collect pollen. They then instinctively fly to another yucca plant and pollinate the flower, ensuring cross-pollination, and then oviposit an egg in the base of the ovary. This egg soon hatches and the larva feeds on the developing seeds. Yucca moths only reproduce on yucca flowers and yuccas apparently require the pollinator services of this moth for successful seed production, a classic example of symbiosis.

Community Succession

Chaparral succession following some form of disturbance such as fire is somewhat different than in many other ecological communities. Generally all of the species present before fire in chaparral will be present in the first growing season after fire, and thus chaparral has been described as being `auto-successional', meaning it replaces itself. In the absence of disturbance chaparral composition appears to remain somewhat static with relatively few changes in species composition or colonization by new species. In part because of the rather static nature of chaparral, old stands have been described with rather pejorative terms such as `senescent', `senile', `decadent', and `trashy', and considered to be very unproductive with little annual growth. This notion derives largely from wildlife studies done in the mid-twentieth century that concluded, due to the height of shrubs in older stands, there was very little browse production for wildlife. However, if total stand productivity is used as a measure, very old stands of chaparral appear to be very productive and are not justly described as senescent. Also, these older communities appear to retain their resilience to fires and other disturbances, as illustrated by the fact that recovery after fire (see below) in ancient stands (150 years old) recover as well as much younger stands.

Allelopathy

The lack of shrub seedlings and herbaceous plants in the understory of chaparral and related shrublands has led to extensive research on the potential role of allelopathy, which is the chemical suppression by the overstory shrubs of germination (known as enforced dormancy) or growth of understory plants. Often this lack of growth extends to the edge where these shrublands meet grasslands, and forms a distinct bare zone (**Fig. 2**). The importance of allelopathy has long been disputed, with some scientists arguing that animals in the shrub understory are the primary mechanism limiting seedlings and herbaceous species from

Fig. 2 Bare zone between chaparral and grassland. Photo by J. E. Keeley.

establishing. While research has not completely ruled out the possibility of chemical inhibition, it is known that for a large portion of the flora, allelopathy has no role in seed dormancy but rather dormancy is due to innate characteristics that require signals such as heat and smoke to cue germination to postfire environments rich in nutrients and light.

Fire

The marked seasonal change in climate is conducive to massive wildfires, which are spawned by the very dry shrub foliage in the summer and fall and spread by the dense contiguous nature of these shrublands. Fires have likely been an important ecosystem process since the origin of this vegetation in the late Tertiary Period, more than 10 Ma, if not earlier. Until relatively recently the primary source of ignitions was lightning from summer thunderstorms. Fires would largely have been ignited in high interior mountains and coastal areas would have burned less frequently and only when these interior fires were driven by high winds with an offshore flow. In many parts of California such winds occur every autumn and are called Santa Ana winds in southern California and Diablo winds or Mono winds in northern California. When Native Americans colonized California at the end of the Pleistocene Epoch around 12 000 years ago, they too became a source of fires, and as their populations greatly increased over the past few thousand years humans likely surpassed lightning as a source of fire, at least in coastal California. Today humans account for over 95% of all fires along the coast and foothills of California.

Chaparral fires are described as crown fires because the fires are spread through the shrub canopies and usually kill all aboveground foliage. Normally, following a wet winter, high fuel moisture in chaparral shrubs makes them relatively resistant to fire. The amount of dead branches is important to determining fire spread because they respond rapidly to dry weather and combust more readily than living foliage. As a consequence, fires spread readily in older vegetation with a greater accumulation of dead biomass. However, there is a complex interaction between live and dead fuels, wind, humidity, temperature, and topography. In particular, wind accelerates fire spread primarily by heating living fuels and often can result in rapid fire spread in young vegetation with relatively little dead biomass. Fires burning up steep terrain also spread faster for similar reasons.

Community Recovery from Wildfires

Rate of shrub recovery varies with elevation, slope aspect, inclination, degree of coastal influence, and patterns of precipitation. Recovery of shrub biomass is from basal resprouts (**Fig. 3**) and seedling recruitment from a dormant soil-stored seed bank. After a spring or early summer burn, sprouts may arise within a few weeks, whereas after a fall burn, sprout production may be delayed until winter. Regardless of the timing of fire, seed germination is delayed until late winter or early spring and is less common after the first year. Resilience of chaparral to fire disturbance is exemplified by the marked tendency for communities to return rapidly to prefire composition.

Shrub species differ in the extent of postfire regeneration from resprouting versus reproduction from dormant seed banks. Most species of manzanita and ceanothus have no ability to resprout from the base of the dead stem and thus are entirely dependent on seed germination. Such shrubs are termed `obligate-seeders'. A few species of manzanita and ceanothus as well as chamise resprout and reproduce from seeds, and these are referred to as `facultative-seeders'. The majority of shrubs listed above, however, regenerate after fire entirely from resprouts and are `obligate-resprouters'.

In the immediate postfire environment the bulk of plant cover is usually made up of herbaceous species present prior to the fire only as a dormant seed bank or as underground bulbs or corms. This postfire community comprises a rich diversity of herbaceous and weakly woody species, the bulk of which form an ephemeral postfire-successional flora. This `temporary' vegetation is relatively short-lived, and by the fifth year shrubs will have regained dominance of the site and most of the herbaceous species will

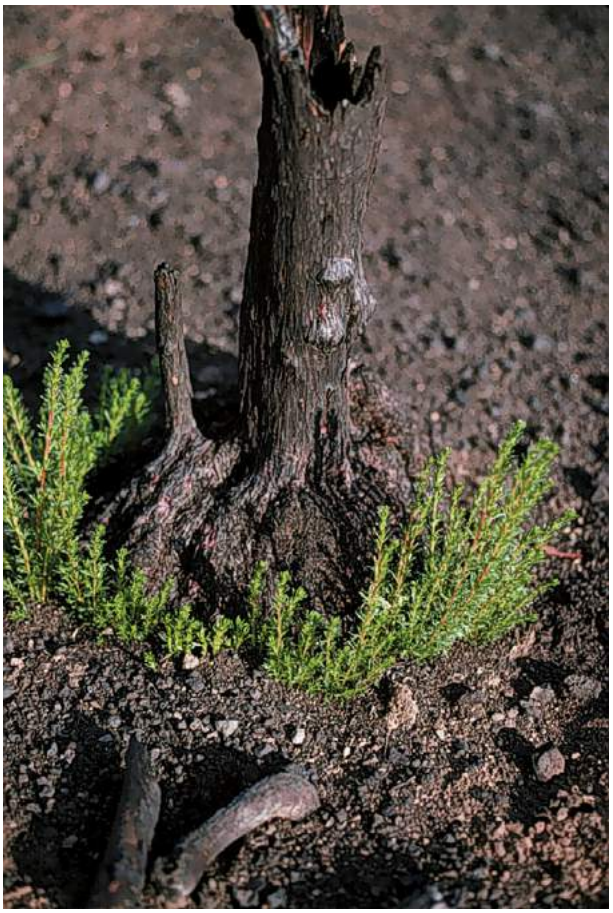

Fig. 3 Postfire resprouts from basal burl of chamise with meter stick. Photo by J. E. Keeley.

return to their dormant state. These postfire endemics arise from dormant seed banks that were generated after the previous fire and typically spend most of their life as dormant seeds. These are termed `postfire endemics' and they retain viable seed banks for more than a century without fire until germination is triggered by heat or smoke of a fire. Postfire endemics are highly restricted to the immediate postfire conditions and if the second year has sufficient precipitation may persist a second year but usually disappear in subsequent years.

Not all of the postfire annuals are so restricted, rather some are quite opportunistic, taking advantage of the open conditions after fire but persisting in other openings in mature chaparral. Such species often produce polymorphic seed pools with both deeply dormant seeds that remain dormant until fire and nondormant seeds capable of establishing in or around mature chaparral. These species fluctuate in relation to annual precipitation patterns, often not appearing at all in dry years.

Herbaceous perennials that live most of their lives as dormant bulbs in the soil commonly comprise a quarter of the postfire species diversity. Nearly all are obligate resprouters, arising from dormant bulbs, corms, or rhizomes and flowering in unison in the first postfire year. Almost none of them produce fire-dependent seeds; however, reproduction is fire dependent because postfire flowering leads to produce nondormant seeds that readily germinate in the second year.

Diversity in chaparral reaches its highest level in the first year or two after fire. It is made up of a large number of relatively minor species and a few very dominant species and is illustrated by dominance–diversity curves (**Fig. 4**). Dominance in chaparral is driven by the fact that a substantial portion of resources are taken by vigorous resprouting shrubs and much less is available for the many annual species regenerating from seed.

Plants are not the only part of the biota that has specialized its life cycle to fire. Smoke beetles (*Melanophila* spp.) are widely distributed in the western US and are attracted by the infrared heat given off by fires. Often while stems are still smoldering they will bore into the scorched wood and lay their eggs.

Seed Germination

Many chaparral species have fire-dependent regeneration, meaning that dormant seeds in the soil require a stimulus from fire for germination. A few species have hard seeds that are cracked by the heat of fire and this stimulates germination. Ceanothus seeds

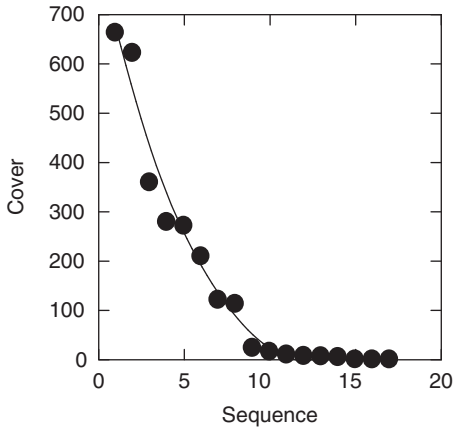

Fig. 4 Dominance–diversity curve based on cover of species in sequence from highest to lowest from postfire chaparral.

are a good example of this germination mode. However, for the majority of species, seeds do not respond to heat but rather to chemicals generated by the burning of plant matter. This can result from exposure to smoke or charred wood. In many of these species seeds will not germinate when placed at room temperature and watered, unless they are first exposed to smoke or charred wood. In natural environments the seeds remain dormant for decades until fire. There is evidence that a variety of chemicals in smoke and charred wood may be responsible for stimulating germination of postfire species, and both inorganic and organic compounds may be involved.

Seeds of many species have a requirement for cold temperatures ($<5\ ^{\circ}$C), which is interpreted as a seasonal cue, but in these chaparral species this requirement is not like the cold stratification requirement of many species from colder climates, where the seeds require a certain duration of cold in order to prevent winter germination. In California species just a short burst of cold often will trigger germination; thus, cold is not a cue that winter is over (as with more northern latitude species) but rather that winter has arrived, which is consistent with the winter germination behavior of these Mediterranean-climate species.

Seed Dispersal

Shrubs can be divided into those with temporal dispersal versus those with strong spatial dispersal. The former are the fire-dependent species that accumulate dormant seed banks, which in essence disperse these shrubs in time, from one fire cycle to the next. Within this group there is limited spatial dispersal. Ceanothus have explosive capsules that shoot seeds a short distance of a meter or two from the parent shrub. Manzanitas drop most of their seeds beneath the parent plant because their small dry fruits are not attractive to birds, although a small number of the seeds are distributed further by coyotes (*Canis latrans*) and bears (*Ursus americans*, historically also included *U. horribilis*). Chamise produces small light fruits that may be carried tens of meters or more by the wind but it appears that most are distributed around the parent shrub.

The postfire endemic annuals also have seeds that are largely dispersed in time rather than in space. Most do not have characteristics suggestive of widespread dispersal. For example, the fire-following whispering bells (*Emmenanthe penduliflora*) derives its name because the flowers and fruits are pendulous and drop seeds directly beneath the parent plant. Postfire endemics in the sunflower family (Asteraceae), a family noted for well-developed dispersal with dandelion-like pappus, commonly have deciduous pappus, which ensures dispersal in time rather than in space.

Shrub species that exhibit fire-free (nonfire-dependent) reproduction have fruits highly attractive to birds and mammals, and the bulk of the seed crop appears to be dispersed by these vectors. Seedling recruitment is sensitive to desiccation and thus it is of some significance that one of the main dispersers of these fruits, the scrub jay (*Aphelocoma californica*), preferentially caches seeds in the shade.

Regional Variation in Fire Regime

California chaparral exhibits regional differences in burning patterns and largely due to regional variation in winds. In much of coastal California autumn winds create severe fire conditions. These occur every year and result in 5–10 days of strong offshore flow with windspeeds of 100 kph or more. These winds result from a high-pressure system in the interior West, and are known as Santa Ana winds in southern California and Diablo or Mono winds in northern California. As these air masses move from the high-pressure cell in the interior to a low-pressure trough off the coast, the air descends and dries adiabatically, resulting in relative humidity below 10%. The fact that these winds occur every year and arrive at the end of an extended drought results in one of the

most severe fire conditions in the world. As a consequence only a small portion of southern California landscape has escaped fire during the last century, and much of the lower-elevation chaparral has burned at an unnaturally high frequency.

In contrast, Santa Ana winds are absent from the southern Sierra Nevada and parts of the central coast, in part to mountain barriers that fail to funnel these winds coastward. This, coupled with lower human population density, has resulted in many fewer fires. As a consequence nearly half of the landscape in the southern Sierra Nevada has not had a fire for well over a century. This condition places these landscapes at the upper end of the historical range of variability. Nonetheless, these older stands of chaparral appear to maintain natural ecosystem processes and exhibit no sign of dying out or replacement by other vegetation types. This is particularly evident, following fires in ancient stands of chaparral from the region, that it exhibits vegetative recovery in cover and diversity indistinguishable from postfire recovery in younger stands.

Future Threats and Management

Degradation and type conversion of native shrublands to alien-dominated grasslands has been noted by numerous investigators, some of whom contend that increased frequency of disturbance is the primary factor that favors non-native annuals over woody native species. In the absence of fire, seeds of non-natives have a low residence time in the soil; thus, the presence of these species on burned sites is more often due to colonization after fire. Typically a repeat fire within the first postfire decade is sufficient to provide an initial foothold for aliens. In addition to outcompeting native plant species, non-native grasses alter the fire regime from a crown-fire regime to a mixture of surface- and crown-fires, where highly combustible grass fuels carry fire between shrub patches. This increases the likelihood of fires and ultimately increases fire frequency. As fire frequency increases there is a threshold beyond which the native shrub cover cannot recover.

Fire management practices potentially conflict with natural resource needs. These landscapes currently experience an unnaturally high frequency of fire; thus, much of it is at risk for alien invasion. When fire managers add to this by using prescription burning and other fuel manipulations, they open up these shrublands and expose them to invasion and potential type conversion to non-native grasslands. In managing these landscapes it might be helpful to consider the fact that the vast majority of alien species in California are opportunistic species that capitalize on disturbance. Adding additional disturbance through prescription burning (or grazing) will only exacerbate the alien problem.

Very little chaparral landscape is protected in parks or wilderness areas. Much of it is in private hands or under federal jurisdiction. Historically, it has largely been managed as rangeland by frequent burning to destroy the chaparral cover, or burned to reduce fuels perceived to be hazardous to more desirable forests or urban environments. Today the expansion of urban development has resulted in large portions of urban communities being juxtaposed with watersheds of potentially dangerous chaparral fuels. Historical studies show that large high-intensity crown fires are a natural part of this ecosystem and there is little reason to believe there will not be more such fires in the future. Fire management has always worked under the philosophy that they can change the vulnerability of communities to wildfires through manipulation of fuels. However, over the past century of such management, every decade has been followed by one of increasing losses to wildfires. Californians need to embrace a different model of how to view fires on these landscapes. Our response needs to be tempered by the realization that these are natural events that cannot be eliminated from the southern California landscape. We can learn much from the science of earthquake or other natural hazard management. No one pretends they can stop earthquakes; rather, they engineer infrastructure to minimize impacts. In the future, living safely with fire is not going to be achieved solely by fire management practices, but will require close integration with urban planning.

Coral Reefs

DE Burkepile and ME Hay, Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Corals are simple, clonal invertebrates that serve as ecosystem engineers, building living structures (reefs) so large that they can be seen from space. These structures, which rival the greatest feats of human engineering, are powered through symbiosis with single-celled algae that are housed within the coral animal. This coral–algal cooperation facilitates a productive ecosystem that can grow in the nutrient-poor `desert' of isolated tropical seas. The rich structural complexity provided by the coral's hard bodies gives shelter to many other species of plants and animals making coral reefs among the Earth's most biologically diverse ecosystems, harboring hundreds of thousands to millions of species worldwide (**Fig. 1**).

Coral reefs also support human societies by providing critical sources of protein, protecting coasts from damaging waves, attracting tourists, and serving as the backbone of the economies for many tropical islands. In addition, coral reefs are crucial in the fight against human diseases, as many of the plants and animals that live on coral reefs produce chemicals that are useful as pharmaceuticals. Reefs have also fascinated naturalists and scientists for centuries. Before publishing his groundbreaking work on natural selection, Charles Darwin published a treatise on reefs in 1842 hypothesizing that coral atolls (rings of reefs in the deep tropical Pacific) were formed around mountain tops as these mountains sank back into the Earth's crust under their own weight. It was more than 100 years before drilling technologies developed to the point where this hypothesis was tested – like with so many other aspects of Darwin's writings, he proved to be correct. For modern ecologists, reefs serve as a model ecosystem for developing basic hypotheses about the ecology and evolution of population structure, of community organization, and about how species diversity evolves and is maintained. In addition, reefs give us a glimpse of the spectacular record of Earth's history because the hard skeletons of corals fossilize to provide a long record of changes in coral distribution and abundance and also record chemical signals of past climatic events, like temperature and sea-level changes. Thus, reefs not only feed and protect humans and other species, but also provide a valuable window into our past, including how our present activities may be changing our environment, and possibly our future.

In this article, we review the major ecological interactions that shape coral reef ecosystems. We pay particular attention to (1) the dynamic relationship between corals and the symbiotic algae living within their tissues, (2) the role of reef herbivores in protecting corals from being overgrown by seaweeds, (3) the numerous ecological processes such as predation, competition, recruitment of juvenile reef organisms, and disturbance that influence the structure of coral reefs, and (4) the dynamic ecological connections between reefs and nearby ecosystems such as seagrass beds and mangrove forests. Finally, we review the current dangers to coral reefs and how these threats undermine the ecological integrity of these diverse ecosystems.

The Coral–Algal Mutualism

Corals are ecosystem engineers in that the growth of their calcium carbonate skeleton creates the biogenic structure on which the entire ecosystem depends. The calcification and growth of reef corals depends on a mutualism between corals and their intracellular, photosynthetic dinoflagellates, *Symbiodinium* spp., also known as zooxanthellae. Both corals and zooxanthellae benefit from this relationship, as corals can receive up to 95% of their carbon from the zooxanthellae's photosynthesis, while the zooxanthellae acquire the nitrogen and other inorganic nutrients in coral excretion products for their growth. Photosynthesis by

 doi:10.1016/B978-0-444-63768-0.00323-1

zooxanthellae enhances calcification in corals and increases coral growth rates, ultimately leading to reef accretion and the massive reef framework found in many tropical seas. Thus, the physical structure of live and dead corals created by the coral–zooxanthellae mutualism provides heterogeneity and habitat complexity, facilitating the coexistence of diverse plant and animal assemblages.

Although zooxanthellae were initially assumed to represent one species, recent molecular evidence shows that there are at least seven distinct types or clades (referred to as clades A–G). Many corals house multiple clades of zooxanthellae, setting the stage for possible competition among symbionts and for symbiont selectivity by the host. Clades of zooxanthellae differ in their photosynthetic capacity and their tolerance of light, temperature, and other stressors, making them differentially useful to their hosts under changing environmental conditions. When corals are stressed by increasing light levels or temperatures, they often expel their zooxanthellae and become pale in color (called coral bleaching). This process of bleaching may allow corals to take up new clades of zooxanthellae that are better adapted to the new environmental conditions. However, corals that fail to re-acquire zooxanthellae or acquire the wrong clades may ultimately die from the stress, suggesting that a failure of corals to acquire appropriate symbionts can be fatal under changing environmental conditions. Such alterations in the coral–zooxanthellae mutualism may allow corals greater flexibility in adapting to global climate change, which is a major threat to the health of coral reefs and the integrity of the coral–zooxanthellae mutualism.

Ecological Interactions on Coral Reefs

Competition

Competition for limiting resources such as nutrients, space, light, or food is often a strong mechanism limiting the distribution and abundance of species in communities. On many coral reefs, the limiting resource for most benthic organisms is space or light, as most of the reef structure is often occupied (Fig. 2). Consequently, corals have evolved a variety of competitive mechanisms including sweeper tentacles, digestive filaments, and rapid growth rates that allow them to fight neighbors for new space or protect the space they already occupy. Slow growing, massive corals often have the most potent direct competitive mechanisms (i.e., sweeper tentacles and digestive filaments that can sting and directly harm neighboring corals) while branching corals such as many

Fig. 2 Competition for space is often an important ecological force structuring coral reefs as corals and other invertebrates cover most of the benthos on healthy coral reefs. Photo credit M.E. Hay.

Acropora spp. rely on their high growth rates to overtop and shade competitors. Other reef invertebrates such as sponges exude chemical compounds that are toxic to their neighbors, essentially using chemical warfare (termed allelopathy) to gain new space.

Although most early studies of competition on reefs focused on coral–coral competition, more recent studies have examined coral–seaweed competition because reefs are now more commonly overgrown by seaweeds that periodically seem to be killing corals. The conventional wisdom is that seaweeds are competitively superior and can overgrow and kill most corals. Although not all seaweeds are harmful to corals, most studies of coral–algal competition show that direct competition from seaweeds reduces the growth, survivorship, fecundity, and recruitment of many corals. Contact with the calcareous green seaweed *Halimeda opuntia* has even been shown to induce black band disease in some corals. Small, filamentous seaweeds, which are not as directly harmful to corals as are larger, foliose seaweeds, often trap sediments next to coral tissue, and this can smother and kill corals. Thus, even competition with typically innocuous filamentous seaweeds can be harmful on reefs that receive high sediment loads. However, corals are not uniformly susceptible to competition from seaweeds, and competitive outcomes may vary with coral morphology. Foliose corals such as *Agaricia* spp. are more susceptible to seaweed overgrowth than massive corals such as *Montastrea* spp. In addition, seaweeds have disproportionately high negative effects on smaller coral colonies, particularly newly recruited corals, and large stands of seaweed can prevent juvenile corals from recruiting to reefs at all.

Competition on coral reefs is not limited to sessile invertebrates; mobile animals also compete. Because herbivores are abundant on undisturbed coral reefs and standing biomass of seaweeds is generally low in these conditions, competition between herbivores would be expected. When the herbivorous sea urchin *Diadema antillarum* was removed from Caribbean reefs by either purposeful experimental manipulations or by disease outbreak, feeding rates of herbivorous fishes increased, as did the densities of some species, suggesting that fishes and urchins competed for food. *Diadema* also competed intensely with each other for food. However, competition for limiting algal resources generally did not result in a decrease in the size of *Diadema* populations but an increase in the size of their mouthparts (called the Aristotle's lantern) relative to the size of their body. Basically, *Diadema* bodies would shrink in size when food was limiting as a tradeoff between growth and survival.

Herbivory

Because seaweeds can overgrow and kill corals, herbivores are critical for coral reef function because they keep reefs free of seaweeds, thus facilitating the recruitment, growth, and resilience of corals. Fishes and urchins are typically the dominant herbivores on coral reefs with fishes in some reef areas biting the bottom at rates of $>100\,000$ times per m^2 every day. When in sufficient numbers, either fishes alone or sea urchins alone can remove greater than 90% of the daily primary production on reefs. By feeding on seaweeds that are competitively superior to corals, herbivorous fishes both clear the substrate for settling coral larvae and prevent seaweed overgrowth of established corals. In return, the biogenic structure and topographic complexity of reef corals benefit herbivorous reef fishes and urchins by providing food, habitat, and refuges from predation. When herbivores are removed by experimentation, overfishing, or disease, seaweeds replace corals and the biogenic structure of the reef degrades. Both reductions in coral structure and increases in seaweeds are associated with losses of herbivorous reef fishes. Interestingly, large-scale manual removals of seaweeds from reefs have resulted in only temporary increases in herbivorous fish abundance with seaweeds becoming the dominant benthic organism once again after several months. Thus, reductions in seaweeds without recovery of corals may inhibit the recovery of many reef fishes, leading to the continued degradation of coral reefs.

The main herbivorous fishes on coral reefs are generally surgeonfishes (Acanthurdiae) and parrotfishes (Scaridae) with rabbitfishes (Siganidae), chubs (Sparidae), and damselfishes (Pomacentridae) also responsible for considerable herbivory in some locations (**Fig. 3**). Surgeonfishes typically feed on turf algae and foliose seaweeds with some species feeding primarily on detrital material. Parrotfishes have robust jaws with teeth fused into a beak-like formation (hence the name parrotfish), which allows them to feed on tough, calcified seaweeds in addition to algal turfs and foliose seaweeds. Although the important role of herbivores in

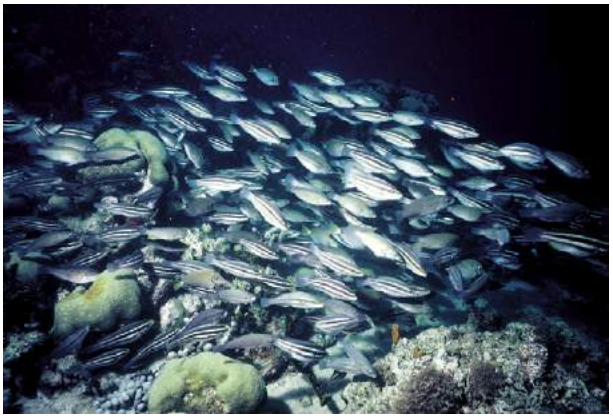

Fig. 3 Herbivores, like this mixed-species school of parrotfishes in the Caribbean, are important to coral reef health because they remove seaweeds that would otherwise overgrow and kill corals. Photo credit M.E. Hay.

influencing reef community is well established, less is known about the importance of individual herbivore species or the role of herbivore diversity in affecting coral reef health. Herbivore diversity should benefit reefs because a more diverse herbivore assemblage should include herbivores with varied attack strategies, which in turn should increase the efficiency of seaweed removal because particular seaweeds are unlikely to be well defended against all types of herbivores. Experimental manipulations of herbivorous fish diversity demonstrate that species-richness is important for reef function because complementary feeding by different herbivorous fishes suppresses upright seaweeds, facilitates crustose corallines and turf algae, reduces coral mortality, and promotes coral growth. Hence not only are herbivores critical for coral reefs, but herbivore species-richness is also essential as a range of feeding strategies and physiologies allows efficient removal of seaweeds and promotes coral health.

Predation

Predation is often a strong top-down force in ecosystems mediating coexistence of lower trophic-level species by preventing competitive exclusion among ecologically similar organisms. In fact, predators often maintain species diversity in ecological communities by preventing expansions of certain prey that would otherwise outcompete competitively inferior organisms and come to dominate the community. If important predators are removed from a food web, the absence of their strong effects can ripple throughout the system, fundamentally altering a variety of predator–prey interactions.

The effects of the largest predators on reefs such as sharks, jacks (Carangidae), and large groupers (Serranidae) are virtually unknown due to the logistical problems of studying such large creatures and the fact that the majority of these species were rare before ecologists began studying reef ecology *in situ* (**Fig. 4**). Although rigorous study of the roles that these fishes play in communities has been limited, a recent model of a Caribbean reef food web suggests that sharks are often the most strongly interacting species in these webs indicating that their removal may have had strong cascading effects on reefs. Further, surveys of lightly fished reefs in the northwestern Hawaiian Islands showed that large apex predators such as sharks and jacks represented $>50\%$ of the total fish biomass as compared to $<3\%$ on heavily fished reefs from the main Hawaiian Islands. These abundant apex predators on lightly fished reefs surely exert a strong top-down force on the community structure of these reefs.

However, the human exploitation of medium-sized predatory fishes has given us the best insight into how predation influences reef communities. On many Pacific coral reefs, outbreaks of the crown-of-thorns starfish, *Acanthaster planci*, cause loss of many square kilometers of coral reefs. These starfish are voracious coral predators that forage in large groups of up to hundreds of

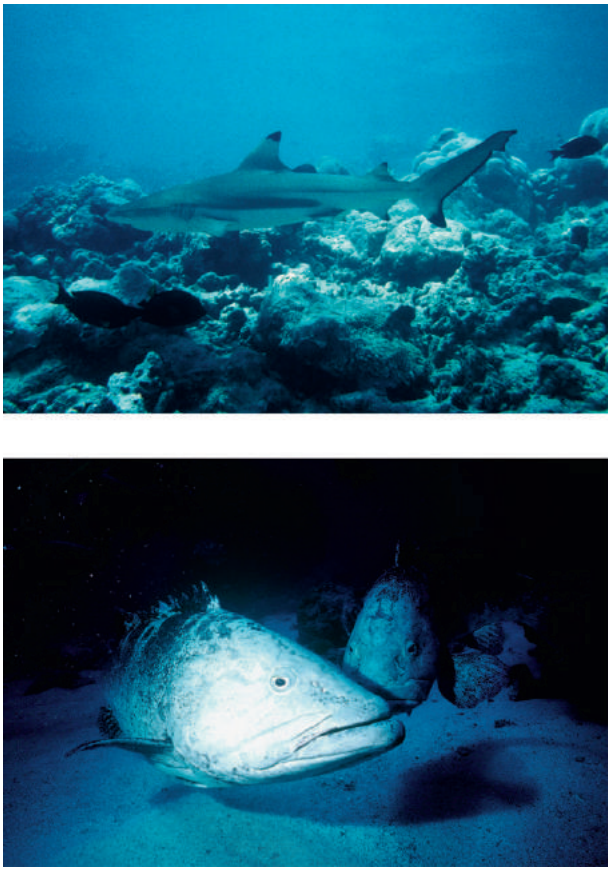

Fig. 4 Apex predators like sharks (top) and groupers (bottom) are now rare on many coral reefs due to overfishing. Photo credit M.E. Hay.

thousands of individuals that can decimate large stands of coral, and their outbreaks have become more frequent since the 1960s when they were first documented. Research in the Fiji islands has shown that outbreaks of *Acanthaster* are correlated to fishing pressure on reefs. *Acanthaster* are 1000 times more dense around islands that have high fishing pressure and low predatory fish abundance than they are on reefs that have light fishing pressure and high predator abundance. High densities of *Acanthaster* decrease cover of reef-building corals and crustose coralline algae while increasing cover of filamentous algae. Thus, the removal of large predators is associated with explosions of *Acanthaster* populations that then have strong cascading effects on the organization of reef communities.

A similar situation exists on many reefs in eastern Africa where intense fishing of triggerfishes and large wrasses allows population explosions of sea urchins such as *Echinometra mathaei*. Reefs unprotected from fishing have six times more urchins than protected reefs, and feeding by these dense urchin populations physically erodes the reef structure once most of the algal biomass has been consumed. This intense grazing decreases coral cover and diversity as well as increases bioerosion rates up to 20-fold compared to reefs that are protected from fishing and have abundant predators. When formerly fished areas were protected from fishing, urchin-eating fishes became more abundant and predation on urchins increased, suggesting that recovery of predatory fish populations should lead to lower urchin populations and a recovery of reef structure over time.

Disturbance

Although biotic interactions (e.g., competition and herbivory) are emphasized as having important consequences for coral reef structure, abiotic disturbances such as hurricanes, temperature fluctuations, sedimentation stress, and sea-level change also produce long-lasting effects on reefs. Coral reefs are one of the hallmark ecosystems strongly influenced by disturbance as the frequency and intensity of hurricanes or disturbance events determines how many species of corals coexist on reefs. If disturbance is very frequent or very intense, then only species that can recolonize disturbed areas quickly or that can withstand intense disturbances will persist. If disturbance is infrequent and mild, then the most competitive species eliminate the less competitive species and come to dominate. However, if disturbance is of an intermediate frequency and intensity, then species with different life-history characteristics (i.e., good colonizers vs. good competitors) can coexist because the disturbance-intolerant species are not displaced frequently and the poor competitors are not outcompeted.

Reefs often recover from acute disturbances such as storms but infrequently recover from chronic disturbances. The coupling of acute natural disturbances with chronic anthropogenic disturbances often leads to precipitous declines in coral reef health. One of the best examples of compounded disturbances driving coral reef decline is from the reefs of Jamaica. Chronic overfishing of herbivorous fishes compounded with two hurricanes and the mass mortality of the herbivorous sea urchin *Diadema antillarum* acted synergistically to force these once coral-dominated reefs into an alternate state of seaweed dominance (**Fig. 5**). In more than two decades, these reefs have shown few signs of recovery. In fact, the episodic effects of natural physical disturbances, coral disease, and coral bleaching along with the constant anthropogenic disturbances of overfishing and pollution have combined to decrease coral cover an average of 80% on reefs throughout the Caribbean over the past few decades. Although disturbance is a natural and integral part of coral reef ecosystems, the compounding of many disturbances over short timescales is often more than reefs can withstand.

Positive Interactions

Ecologists now realize that positive interactions between species can have strong, cascading effects on natural communities and are no less important than negative interactions (i.e., predation or disturbance) in affecting community structure. On reefs, the most obvious positive interaction is the mutualism between corals and their symbiotic algae. Another is the positive feedback between herbivores and corals that maintains a coral-dominated ecosystem. Other crucial positive interactions come from species that are normally thought of as competitors but can mutually benefit each other under the right conditions. Sponges, for example, compete with each other, but can also interact positively. It is more common to find morphologically similar species of sponge growing intermingled in multispecies groups than it is to find a sponge colony growing alone. When growing in these groups, the growth rates of the different species of sponge are often greater than what they would be if these sponges were growing by themselves. This enhancement of growth rates may stem from differences among the species in their susceptibility to predation, pathogens, and physical disturbance. The summed traits of the sponge consortia may enable participants to survive environmental challenges that would be insurmountable for any of them growing alone. Further, sponges are important to the stability and integrity of the reef itself. Sponges actually act as a type of cement that binds the reef together and holds corals in place. When sponges are removed from reefs, storms displace and kill more corals from these reefs than from reefs that have an abundance of sponges.

Net positive interactions may also occur even between consumers and their prey. Herbivorous damselfishes often form mutualisms with some seaweeds on tropical reefs. Through aggressive defense of the algal mats on which they feed, damselfish create patches of species-rich algae on reefs where these algae would normally be grazed to near local extinction by large herbivorous fishes. Although the rapidly growing filamentous algae in the damselfish's territory are its prey, they are also dependent on the territorial behavior of the fish for their persistence at high density. If the territorial fish is removed, its algal lawn is consumed within hours. However, the positive interactions between damselfishes and their algal gardens can be overridden by cooperation among other species of herbivorous fishes that forage in large schools. While schooling would appear to increase the

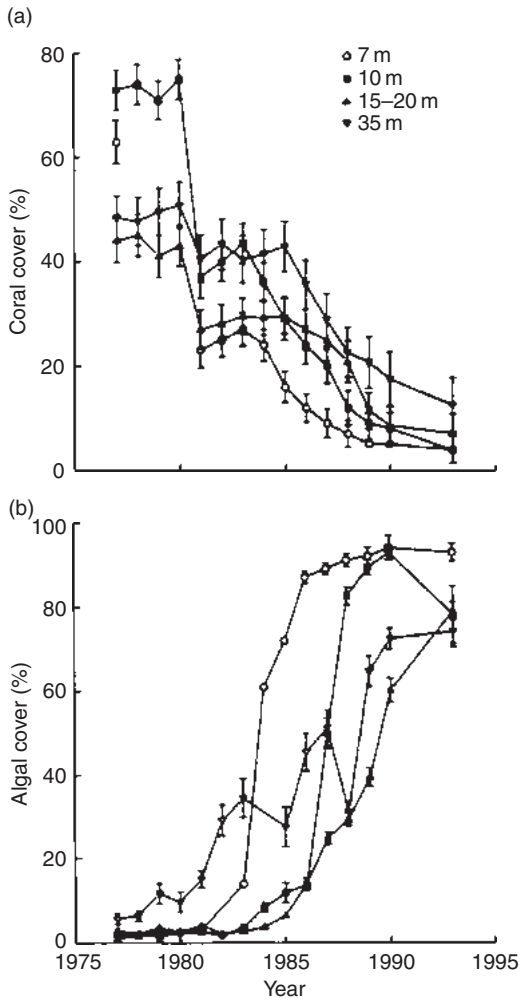

Fig. 5 Degradation of Jamaican coral reefs over two decades. Changes in (a) coral cover and (b) seaweed cover at four depths in Discovery Bay, Jamaica. This decline in corals and increase in seaweeds was the result of synergistic interactions of natural and anthropogenic disturbances including overfishing, hurricanes, disease, and eutrophication. A similar decrease in coral cover occurred throughout Jamaica with coral cover nationwide declining from about 60% to about 4%. From Hughes TP (1994) Catastrophes, phase shifts, and large-scale degradation of a Caribbean coral reef. *Science* 265: 1547–1551.

competition for resources among herbivores, parrotfishes and surgeonfishes often form feeding schools to overrun territories of pugnacious damselfishes. For these large herbivores, increasing school size allows for more bites per individual fish when foraging in and around damselfish territories. The benefits of acting mutually to overwhelm damselfish and gain access to resource-rich habitats must outweigh the potential for competitive interactions between the fishes using these schools. Similarly, piscivorous fishes such as grouper and moray eels often hunt in mixed-species or cooperative foraging groups. For these fishes that forage cooperatively, many mouths may be better than one in terms of overall prey yield to each predator when summed over a lifetime of hunts.

Finally, small wrasses (Labridae) and gobies (Gobiidae) act as cleaner fishes on tropical reefs and remove parasites, mucus, and dead or infected tissue from larger fishes. Reef-based cleaner fish are found at specific cleaning stations, usually situated on prominent portions of the reef. These fish can clean up to 2300 individuals of 132 different species in a day, and some client fish visit cleaners over 100 times a day. If these cleaner fish are removed from reefs, diversity of reef fishes declines, especially for large, transient fishes that may visit reefs specifically to be cleaned. Cleaner fishes can, thus, have a strong effect on parasite loads of their client fishes and on fish-usage patterns across patchy reef environments.

Replenishment of Coral Reefs: The Role of Reproduction and Recruitment in the Ecology of Reefs

Most reef organisms are sessile (corals, sponges, seaweeds) or use only a small portion of a much larger reef habitat (most reef fishes). Thus, colonization of new habitats is achieved through recruitment of juvenile organisms that may drift for long distances

in the plankton before settling onto, and using a small area of reef. Consequently, the production and recruitment of juvenile organisms is a key factor in the ecology of reefs as the replenishment of plant and animal populations is integral to the resilience and recovery of reefs in the face of natural and anthropogenic disturbances.

Coral species differ considerably in their modes of reproduction and in the ability of their larvae to disperse to new reefs. Many corals reproduce both asexually through fragmentation and sexually by the production of gametes. Important reef-building corals such as acroporids are extremely successful at reproducing asexually and are dispersed when storms break apart parent colonies and spread the fragments to new portions of a reef where they can reattach and grow. Sexual reproduction in corals is also variable in that corals are typically either brooders or spawners. Brooders release fertilized larvae into the water column while spawners release sperm and eggs into the water column, where they fertilize and disperse with the ocean currents. These fertilized larvae will eventually exit the plankton and return to reefs as newly recruited juvenile corals. Research from the Great Barrier Reef, Australia has shown that there is large variation in the abundance of coral recruits across both large and small spatial scales. The best predictor of differences in recruitment rates among reefs was the fecundity, not abundance, of adult corals and explained 72% of the variation in recruitment for acroporid corals. Recruitment rates decreased dramatically as the fecundity of adults decreased, but this decrease was not linear; a small decrease in the fecundity of adults resulted in a dramatic decrease in juvenile recruitment (**Fig. 6**). These results suggest that processes such as sedimentation, eutrophication, and competition with seaweeds, all of which reduce the fecundity of adult corals, could dramatically affect the replenishment of coral populations.

Recruitment of juveniles is also important to the replenishment of fish populations and considerable research has gone into determining how recruitment processes affect the assembly of reef fish communities. Most reef fishes, like corals, have planktonic larvae that can disperse wide distances from their point of origin. One of the key questions in the ecology of reef fishes is how the recruitment of juvenile fishes is related to the density of fishes already on the reef (i.e., whether local patterns of recruitment are density dependent or density independent). Despite considerable research on the subject, little consensus has been reached and studies have shown that recruitment rates can be either positively or negatively correlated with adult abundance (positively or negatively density dependent), or show no correlation at all (density independent). These relationships may vary with the species being studied, with location, or with the currents and physical processes prevailing at the time of the test. Continued research is needed to generalize how recruit and adult densities are related and how environmental and biological variables change these relationships.

A key component to the replenishment of populations of coral reef organisms is the extent to which reefs are connected to other reefs (i.e., whether juveniles recruit to reefs from local or distant sources). Coral reefs, and marine ecosystems in general, differ from many terrestrial systems in that juvenile organisms have the potential to ride ocean currents and be dispersed over wide distances potentially connecting geographically distant populations. However, the actual extent that marine populations are connected to each other is still a topic of vigorous debate. This knowledge is crucial to the protection and management of reefs as the connectivity of populations of coral reef organisms will determine whether local populations can be managed with efforts based close to the target population (if the system is fairly closed and recruitment from local populations is frequent) or if management of local populations will necessitate international cooperation (if reefs are fairly open and recruitment is driven by larvae from distant reefs). Thus, solving the question of connectivity among reefs is critical to the preservation of reef health.

Initial models of connectivity for fish populations in the Caribbean suggested that many of the populations were very open and well connected to other populations hundreds of kilometers away. However, these models were based on passive

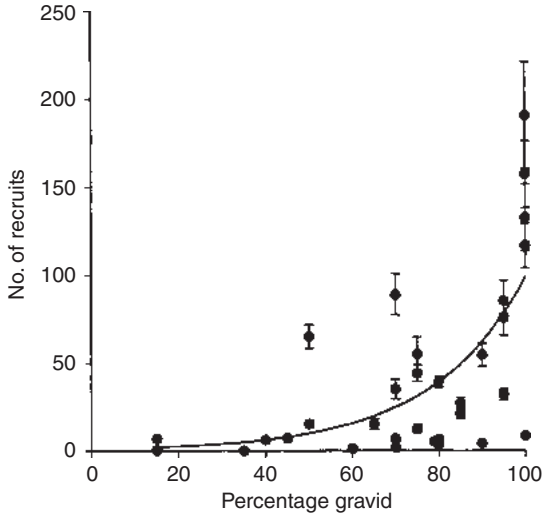

Fig. 6 Relationship between the percentage of coral colonies (*Acropora hyacinthus*) that were gravid and the number of coral recruits. Each point is a separate reef on the Great Barrier Reef, Australia. From Hughes TP, Baird AH, Dinsdale EA, *et al.* (2000) Supply-side ecology works both ways: The link between benthic adults, fecundity, and larval recruits. *Ecology* 81: 2241–2249.

dispersal of fish larvae and simple models of surface currents and did not account for the effect of larval behavior on dispersal or for the effects of fine-scale oceanographic processes. Thus, viewing larvae as passive dispersal agents may overestimate the actual dispersal of larvae and the connections among reefs. Recent models of connectivity in the Caribbean that account for larval behavior suggest that fish populations are less connected than assumed under passive dispersal models and that different regions of the Caribbean are essentially isolated from each other, at least on an ecological timescale. However, there are considerable differences among regions of the Caribbean as to the extent that reefs are connected to distant areas as some regions appear to import a large portion of recruits while other regions are primarily self-seeding. The differences in the relative importance of local and long-distance recruitment of juveniles among regions of the Caribbean underscores the role that careful planning will play in the implementation of marine reserves for protection of coral reefs as understanding how reefs are connected to one another will influence how large reserves should be and where they should be located.

Landscape Ecology of Coral Reefs: Connections of Coral Reefs to Mangrove and Seagrass Systems

Coral reefs are typically found in close proximity to other coastal ecosystems, particularly seagrass beds and mangrove forests. These different ecosystems are often connected to reefs via the movement of animals and nutrients across their boundaries. For example, carnivorous grunts (Haemulidae) forage in seagrass beds at night but school around large coral heads on reefs during the day as a refuge from predation. Coral heads that harbor fish schools receive nutrient supplements from fish excretion, grow up to 23% faster, and have more nitrogen and zooxanthellae per unit area than do corals without resident fishes. Thus, fishes that have no direct trophic link with corals collect nutrients from other ecosystems (seagrass beds) and concentrate these near their host coral. This facilitates coral growth, enhancing the coral's value as a refuge for these fishes and for other reef organisms.

Mangroves and seagrass beds also serve as nursery grounds and provide refuge from predators and an abundance of food for many juvenile fishes that are typically found on coral reefs as adults. Grunts (Haemulidae), snappers (Lutjanidae), barracuda (*Sphyraena barracuda*), and some parrotfishes (Scaridae) are particularly dependent on the presence of nearby mangroves. In Belize, reefs closely associated with mangroves have up to 26 times more biomass of some species of fish than reefs not associated with mangroves. A common species on these reefs, the bluestriped grunt (*Haemulon sciurus*), typically goes through an ontogenetic change in habitat use as it migrates from seagrass beds to mangroves to patch reefs to the forereef as it ages (**Fig. 7**). In areas where mangroves are absent, bluestriped grunts move from seagrass beds directly to patch reefs and are typically smaller than grunts that inhabit patch reefs with nearby mangroves. Thus, mangroves provide important habitat where juvenile grunts feed and increase in size before moving to patch reefs which may subsequently decrease the threat of predation once they move to these reefs. Further, the rainbow parrotfish (*Scarus guacamaia*), the largest herbivorous fish in the Caribbean, is functionally dependent on mangroves for shelter; juveniles of this species live primarily in mangroves, and the species goes locally extinct on reefs when nearby mangroves are removed (**Fig. 7**). Interestingly, density of fishes that have no direct link to mangroves at any stage of their life history can still be influenced by the proximity of mangroves, probably via interactions with mangrove-dependent fishes. Thus, the composition of the fish community on reefs is greatly influenced by the proximity of mangroves, and the rapid removal of mangrove forests from coastlines worldwide will certainly have drastic negative impacts on the ecology coral reefs.

Geographic Distribution of Coral Reefs

Coral reefs exist in tropical areas worldwide (**Fig. 8**). In general, reefs are abundant in areas with shallow coastlines and clear, warm water where riverine discharge of sediments is low. Large coral reefs are rarely found in areas above 29° latitude where ocean temperatures fall below 18 °C for extended periods as this slows coral growth and their capacity to build large reefs; however, zooxanthellate corals can be found in areas with water temperatures as low as 11 °C. In addition, herbivory is often less intense in cooler waters meaning that seaweeds are more abundant in temperate areas and that competition between corals and seaweeds is more intense. The combination of cooler water temperatures and more intense competition with abundant seaweeds likely interact to limit the latitudinal range of large coral reefs. However, when the physical and ecological criteria are met, the results can be phenomenal. For example, the most biologically diverse reefs occur in the tropical Indo-Pacific in the areas around Indonesia and the Philippines and house over 550 species of coral and thousands of species of fish. The Great Barrier Reef off northeastern Australia is the largest reef in the world with more than 2800 individual reefs occupying over 1800 km of the Australian coastline and can be seen from outer space.

Threats to Coral Reefs

Coral reefs are imperiled around the world because of the compounding effects of multiple stressors such as overfishing, pollution, climate change, and change in coastal land use. The decline of reefs is particularly evident in the Caribbean where coral cover has

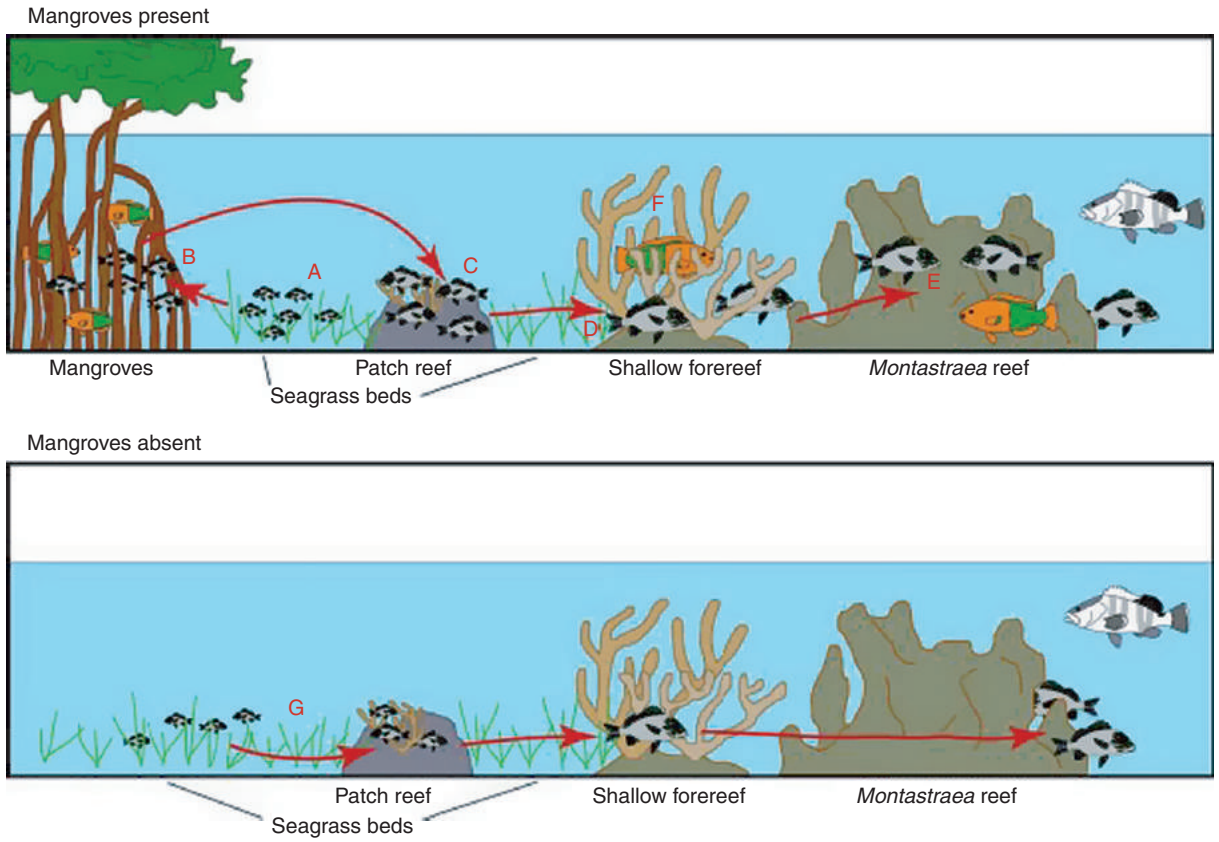

Fig. 7 Schematic illustrating the connection between mangroves and coral reefs. Ecosystem connectivity is stylized for *Haemulon sciurus* (gray and black fish) and *Scarus guacamaia* (orange and green fish) although other parrotfish (scarid), grunt (haemulid), and snapper (lutjanid) species also exhibited similar ontogenetic shifts in habitat use. *H. sciurus* show a substantial shift in size frequency from seagrass (A) to mangroves at approximately 6 cm. On reaching a given size in seagrass beds, juvenile fish then move to mangroves (B) which serve as an intermediate nursery habitat before migrating to patch reefs (C). If mangroves are not present, *H. sciurus* move directly from seagrass to patch reefs, appearing on patch reefs (G) at a smaller size and at lower density (260 ha^{-1} compared to 3925 ha^{-1} in mangrove-rich systems). In the presence of mangroves, the biomass of *H. sciurus* is significantly enhanced on patch reefs, shallow forereefs, and *Montastraea* reefs (C, D, E). *S. guacamaia* (F) has a functional dependency on mangroves and is not seen where mangroves are absent. Illustration describes findings from Mumby PJ, Edwards AJ, Arias-Gonzalez JE, *et al.* (2004) Mangroves enhance the biomass of coral reef fish communities in the Caribbean. *Nature* 427: 533–536. Schematic and description courtesy of Peter J. Mumby.

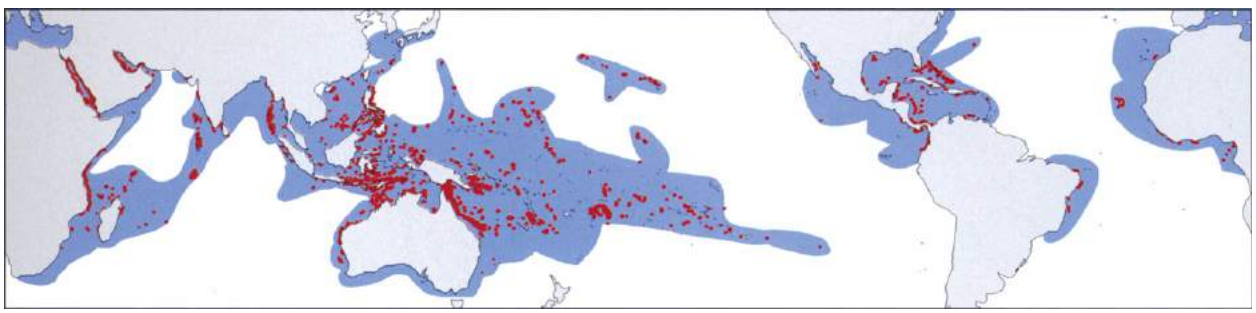

Fig. 8 Worldwide distribution of coral reefs. Coral reefs (red dots) cover roughly 250 000 km^2 of the Earth's surface, but zooxanthellate corals inhabit a far wider range (blue shading). decreased by 80% in recent decades and may drop further as reefs fail to rebound following continued coral bleaching, overfishing, disease outbreaks, and other disturbances. The causes of coral reef decline are many and frequently act synergistically to drive coral reefs to alternate states such as seaweed-dominated reefs or sea urchin barrens (**Fig. 9**). We review the major threats to coral reefs and the role that marine reserves can play in stemming the tide of coral reef decline.

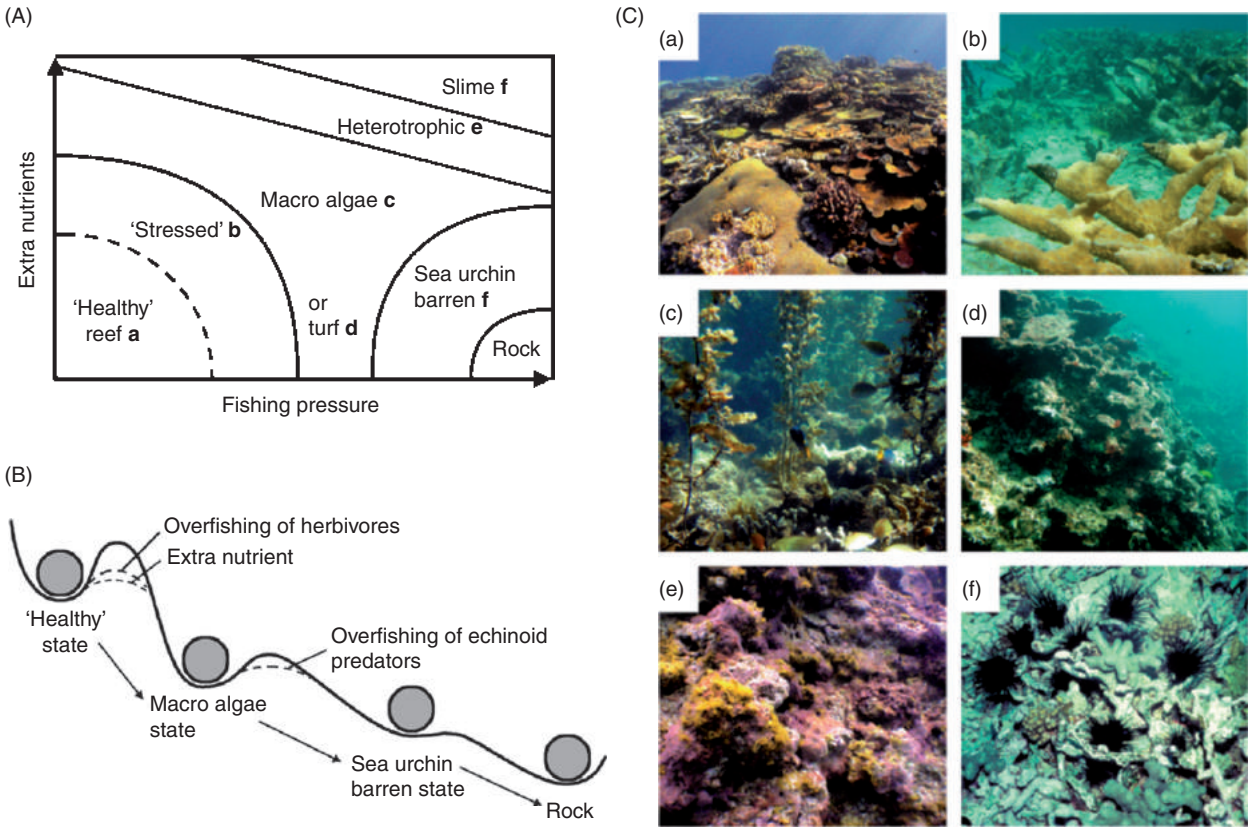

Fig. 9 Alternate states in coral reef ecosystems. (A) A conceptual model showing human-induced transitions between alternate ecosystem states based on empirical evidence of the effects from fishing and excess nutrients. The `stressed' state illustrates loss of resilience and increased vulnerability to phase-shifts. (B) A graphic model depicting transitions between ecosystem states. `Healthy' resilient coral-dominated reefs become progressively more vulnerable owing to fishing pressure, pollution, disease, and coral bleaching. The dotted lines illustrate the loss of resilience that becomes evident when reefs fail to recover from disturbance and slide into less-desirable states. (C) Pictoral representation of the different reef states shown in (A). From Bellwood DR, Hughes TP, Folke C, and Nystrom M (2004) Confronting the coral reef crisis. *Nature* 429: 827–833.

Coral Bleaching

Coral bleaching occurs when corals degrade or expel their dinoflagellate symbionts in response to environmental stressors such as elevated sea surface temperature and increased UV radiation. Although corals can reacquire symbionts and recover in weeks to months, recovered corals may grow slower and have reduced fecundity as compared to previously unbleached corals, giving bleaching-resistant corals an ecological advantage after bleaching events. In severe cases, bleaching may occur on the scale of hundreds to thousands of kilometers and radically alter coral cover and composition with coral mortality from bleaching events approaching 100% in extreme cases. Branching corals such as acroporid and pocilloporid corals are often more susceptible to bleaching and mortality than are massive corals, allowing the slower-growing massive corals to be more persistent on reefs after bouts of strong bleaching. Bleaching events not only decrease live coral cover but also provide large areas for seaweed colonization, and these seaweeds can prevent corals from reestablishing if herbivores are not present in sufficient numbers to suppress seaweed colonization and growth. Additionally, large-scale bleaching and mortality of branching corals can suppress fish populations that are dependent on live coral for shelter and food.

Analyses of coral bleaching on Caribbean reefs over the past two decades suggests that small increases in regional sea surface temperature (0.1 °C) result in large increases in the geographic extent and intensity of coral bleaching events. Given that climate change models suggest an increase in sea surface temperatures of 1–3 °C over the next 50–100 years, coral bleaching events may become an intense, annual stress on coral reefs throughout the Caribbean and even the world. Although corals may adapt and their bleaching thresholds may increase over time as sea surface temperatures rise, the threat of repeated, intense bleaching events over the next several decades is a significant concern. If even the conservative predictions of global climate models are realized, these climate changes could result in the fundamental reorganization of the ecology of coral reefs.

Disease and the Structure of Coral Reef Communities

The impact of diseases on coral reefs has been realized over only the past two decades. Two of the most extensive disease outbreaks have been on reefs in the Caribbean and have fundamentally changed the ecology of Caribbean reefs. In

1983–84 an unknown pathogen swept through the Caribbean and killed approximately 99% of the then abundant sea urchin *Diadema antillarum*. In many areas of the Caribbean, *D. antillarum* had been the dominant herbivore keeping reefs free of most fleshy seaweeds and facilitating recruitment and growth by corals. After the mass mortality, levels of herbivory plummeted and standing crop of seaweeds dramatically increased on many reefs. *D. antillarum* populations are recovering in some areas of the Caribbean, and in these `urchin zones', seaweeds cover 0–20% of the reef as opposed to 30–79% of the reef. Juveniles corals are ten times more abundant in some urchin zones. The potential recovery of this critical herbivore gives hope to Caribbean reefs many of which are still enveloped in a blanket of seaweed.

The other outbreak that altered the structure of Caribbean reefs was the epidemic of white band disease among acroporid corals in the mid to late 1980s. This disease attacked two of the major reef-building corals in the Caribbean *Acorpora palmata* and *A. cervicornis*. These two corals were once so abundant on Caribbean reefs that early coral reef ecologists named characteristic zones on reefs for these dominant corals (i.e., the `palmata zone' and the `cervicornis zone'). These corals that had dominated Caribbean reefs for at least a half million years are now rare to absent on most reefs and have declined so dramatically that they are both being listed as threatened species under the Endangered Species Act in the United States. If the prevalence and severity of coral diseases is linked to pollution and climate change as has been demonstrated for some studies, then a continued increase in the effects of diseases on the ecology of reefs can be expected.

Shifting Baselines, Overfishing, and the Altered Food Webs of Coral Reefs

In many regions of the world, coral reefs are mere remnants of what they were only a few decades ago. These changes to reefs are not adequately appreciated due to the problem of the `shifting baseline syndrome' – reefs that are deemed `normal' today are not what was `normal' only a few decades ago, much less a century or more ago. Each new generation of divers or marine ecologists suffers from reduced expectations of what a healthy coral reef should be. For example, as a graduate student and post-doc, one of us (M.E. Hay) dove on Caribbean reefs dominated by luxuriant stands of elkhorn and staghorn coral (*Acropora palmata* and *A. cerviconis*) the size of football fields and saw reefs abundant with grouper, large herbivorous fishes, and *Diadema* urchins that formed `fields' of gigantic black pincushions on regions of some reefs. In contrast, the younger author here (D.E. Burkepile) has never seen a live stand of elkhorn coral more than a few m^2 and is lucky to see one *Diadema* on most dives. However, both of us dive on reefs that are vastly different from those that the first European colonists would have experienced. Because of this problem of shifting baselines, it is informative for ecologists to explore the history and paleoecology of reefs in order to deduce how reef communities have changed over hundreds, or thousands, of years.

Caribbean reefs were once dominated by sea turtles, crocodiles, manatees, large predatory fishes such as sharks and large groupers, and the now-extinct monk seal. Reefs with such a diversity of charismatic megafauna scarcely exist today anywhere in the world. Centuries of overfishing have made many of these species ecologically extinct and altered the strong trophic interactions that once dominated Caribbean food webs (**Fig. 10**). Including humans into the ecological equation began a process of `fishing down the food web' where large consumers such as sharks and manatees were the primary targets of human harvesting. After the larger animals were depleted, fisheries switched to smaller predators such as groupers and

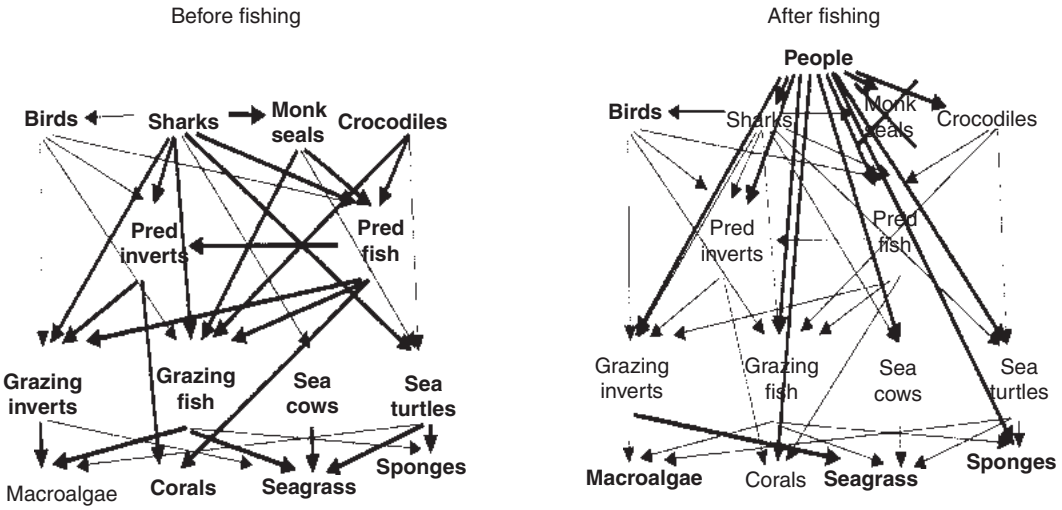

Fig. 10 Simplified coastal food web for coral reefs showing changes in some important top-down interactions due to overfishing; before (left side) and after (right side) fishing. (b) Mean macroalgal cover (gray bars) (±SE) and grazing intensity of parrotfishes (black bars) inside and outside the Exuma Cays Land and Sea Park. Reserve impacts are significant ($P<0.01$) for each variable. From Mumby PJ, Dahlgren CP, Harborne AR, *et al.* (2006) Fishing, trophic cascades, and the process of grazing on coral reefs. *Science* 311: 98–101.

then to herbivores such as parrotfishes. The changes in the connections of these food webs have fundamentally altered the dynamics of these ecosystems and have resulted in cascading effects such as the decline of corals and increase of seaweeds and sponges.

Although the largest megafauna are now largely gone from Caribbean reefs, we have some idea of their historical populations. For example, green turtles were once so abundant that ships' naturalists from the sixteenth to seventeenth centuries remarked that they could navigate to the Cayman Islands via the sounds of turtles swimming and that congregations of turtles seemed so thick as to confound a ship's path. One estimate puts the total pre-Columbian population of green turtles in the Caribbean at greater than 30 million as opposed to the tens of thousands today. Green turtles typically eat seagrasses and seaweeds, but the top-down force that this historical population would have exerted on seagrass production and biomass is unrivaled by any current estimates of herbivory in seagrass beds. Because the biota of coral reefs has changed so dramatically over the past few hundred years, Jeremy Jackson writes that scientists trying to understand the ecological processes that structure coral reefs are ``…trying to understand the ecology of the Serengeti by studying the termites and the locusts while ignoring the elephants and the wildebeest." Basically, the biotic forces that impact coral reefs today are mere shadows of what they once were, and humans have radically changed the ecological and evolutionary trajectories that have influenced coral reef ecosystems for millennia.

Protection and Resurrection of Coral Reefs

One of the saving graces of coral reefs over the next few decades may be the creation and enforcement of marine reserves that protect reefs from overfishing. Overfishing is one of the most devastating threats to reefs, as fishers preferentially remove the large-bodied fishes that are the strongest interactors in these ecosystems, resulting in fundamental changes to the food webs of reefs. The establishment of marine reserves limits or prevents the harvesting of fishes and invertebrates from areas of reef and theoretically allows populations of overharvested species to rebound, reestablishing viable populations of fishes and crucial ecosystem processes on reefs. Recent studies of the efficacy of marine reserves show that reducing fishing pressures on reefs allows increases in the density, biomass, individual size, and diversity of fishes and invertebrates inside the reserves and that these effects occur rapidly and are longlasting. In addition, these reserves not only allow increases in fish density and biomass within the protected areas but also result in the `spillover' of fishes as they migrate from the reserves into unprotected areas. Thus, marine reserves may subsidize fish populations on reefs that are not directly protected from fishing, although the extent to which this spillover effect will actually affect unmanaged reefs is equivocal.

Marine reserves can also restore trophic linkages that enhance the recovery of coral reefs. For some reefs in the Bahamas, long-term protection from fishing (i.e., roughly 50 years of enforcement) has led to increases in the abundance of medium-sized predatory fishes such as the Nassau grouper (*Epinephelus striatus*) (**Fig. 11**). Increases in grouper abundance resulted in increased predation rates on small herbivorous parrotfishes, which would seemingly decrease the rate of herbivory on reefs. However, the protection from fishing also allowed large parrotfishes to recover and actually increased the overall rate of herbivory in the reserve despite increased predation on smaller herbivores (**Fig. 11**). These increased rates of herbivory decreased macroalgal abundance and may increase coral abundance and cover over time if this balance between predation and herbivory can be maintained. Although the benefits of reserves to conservation and fisheries are promising, one of the main challenges to the success of marine reserves is the enforcement of no-harvesting policies once the reserve is established. In many areas, reserves are `paper parks' or parks in name only as there is insufficient money or political will to achieve the enforcement necessary for the reserves to succeed. However, if marine reserves can be implemented and enforced they will be one of the best tools that conservation science currently has to protect, and hopefully resurrect, many coral reefs.

Summary

Fossil evidence shows that corals have dominated many reefs for over 10 000 years. However, the balance between the ecological forces of predation, competition, disturbance, and recruitment that allowed thousands of years of uninterrupted reef growth have now been grossly altered by human activities. Consequently, healthy and dynamic reefs have declined dramatically in the last two decades as a result of overfishing, climate change, pollution, and other anthropogenic insults. Although the ecological future of reefs seems bleak, we hope that creative management of these ecosystems has the potential to protect them for future generations.

Desert Streams

TK Harms, RA Sponseller, and NB Grimm, Arizona State University, Tempe, AZ, USA

Distribution and Physical Template

Desert streams occupy arid and semiarid regions defined by low annual precipitation. Semiarid and arid climate zones are found on all continents and include both hot and cold deserts. Although the range of temperatures varies across desert regions, summer temperatures may exceed 40 °C in hot deserts. Annual precipitation ranges from <100 to 300 mm yr^{-1} and combined with high temperature can result in high rates of evapotranspiration. Higher precipitation in the mountains (up to ~ 1000 mm yr^{-1}) can feed streamflow in the low deserts, often supporting perennial flows in large basins. Arid and semiarid regions are characterized by distinct seasons defined by precipitation and/or snowmelt and the amount of precipitation that falls during these seasons shows high interannual variability. This results in extreme seasonal and interannual variation in stream discharge. Indeed, streams in some desert regions flow in response to rain events that occur only once in several years or even less.

Arid and semiarid lands account for over one-third of global lands, making desert streams prominent among aquatic ecosystems. The large geographic area covered by deserts results in a wide variation in temperature and precipitation regimes as well as in geomorphology. Thus, the hydrogeomorphic templates and resulting ecological characteristics of desert streams exhibit a great diversity of patterns. Despite this extensive distribution of desert streams, the vast majority of ecological studies of desert streams have occurred in the southwestern United States, Australia, and Antarctica. Our discussion thus draws from results of studies in these ecosystems. Future studies of desert stream ecosystems in other regions are likely to add new dimensions to the state of our understanding presented here.

Desert stream hydrographs are punctuated by events when discharge may exceed baseflow by several orders of magnitude. Precipitation falling on the catchment rapidly reaches the stream and stream discharge rapidly dissipates following floods. Infiltration of desert soils is minimal and, at the scale of whole basins, much of the water that is not returned to the atmosphere by evapotranspiration reaches streams via overland flow during storms or via infiltration of permeable low-order channel sediments followed by subsurface flow. Resulting flash floods scour the streambed, resulting in downstream export of sediments and aquatic organisms and creating a wide channel. Large floods also deposit alluvial materials in riparian zones and may remove riparian vegetation. These effects vary depending on the scale of the event (see the section titled `Temporal dynamics').

The boundaries of a stream ecosystem in any climate region extend beyond the wetted channel and comprise a stream–riparian corridor (**Fig. 1**). The aquatic ecosystem encompasses surface water as well as the alluvial sediments beneath the streambed where surface and groundwater mix, termed the hyporheic zone. The parafluvial zone is defined by the region of the active channel over which water flows only during floods and in desert streams this region can be much wider than the stream itself. Finally, the riparian zone is the land area surrounding the stream that is significantly influenced by the stream. The availability of water contrasts starkly among these subsystems in desert streams making each subsystem more distinct than in mesic streams. In deserts, the hyporheic zone often contains water and sustains biological activity in the subsurface even in the absence of surface flow. The parafluvial zone contains surface water only during floods and flow quickly recharges the subsurface through coarse sediments or gravel in this zone, leading to short periods of surface flow but sustained subsurface flow. The riparian zone contrasts starkly with desert uplands owing to the presence of shallow groundwater that is accessible to plants.

Desert streams may contain sections of both gaining and losing hydrologic templates. Gaining sections of streams are those in which the water table is sloped toward the stream channel such that groundwater discharges into the surface stream. Losing reaches are characterized by a water table that slopes away from the stream causing surface flow to recharge groundwater. Along losing reaches, the predominate direction of water flow in desert catchments is from the uplands directly into the stream before recharging riparian groundwater; whereas along gaining reaches, water flowing overland into the riparian zone recharges groundwater there before discharging into the surface stream. These contrasting hydrologic templates can have significant effects on nutrient dynamics, water storage, and biota within stream–riparian corridors. Losing reaches, for example, often have no surface flow during dry seasons, whereas gaining reaches are a more permanent source of surface water. Due to permeable sediments, interactions between surface and subsurface water are dynamic. For example, water moves into the hyporheic zone in regions of downwelling and from the hyporheic zone to the surface in regions of upwelling. Water within the hyporheic zone moves through the interstitial spaces of sediments slowing water velocity compared to the surface stream. Such patterns in hydrologic flows have important implications for nutrient cycling and stream productivity.

Temporal Dynamics

Desert streams are highly variable over time, at a range of temporal scales. In addition to the seasonality that typifies many streams, temporal dynamics of desert streams are strongly influenced by disturbances at two extremes (flash flooding and drying) of a

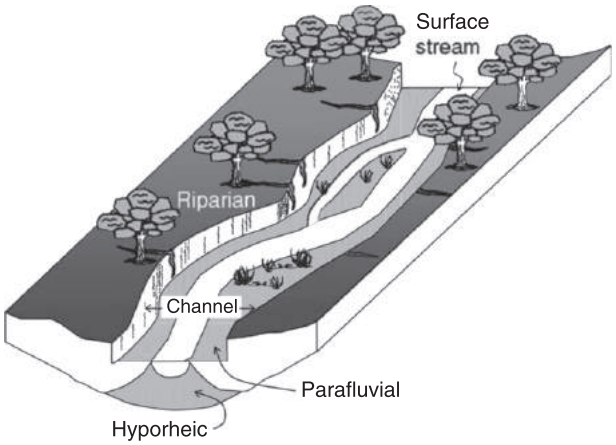

Fig. 1 Schematic drawing of a desert stream–riparian corridor.

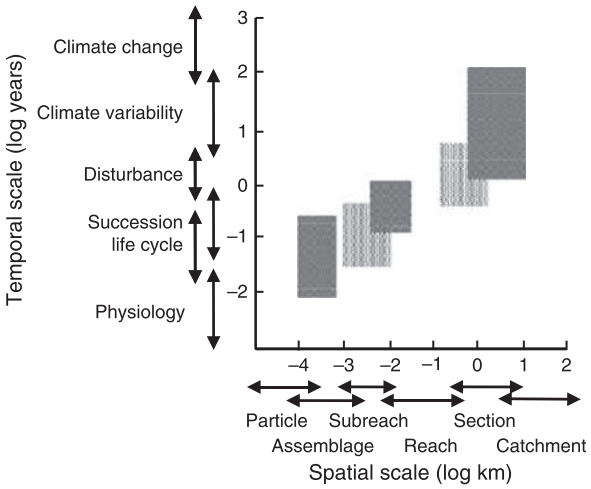

Fig. 2 Temporal scales considered in this section (ordinate) are correlated with spatial scales (abscissa), and each phenomenon discussed is associated with a characteristic range of time and space scales.

hydrologic spectrum. Researchers have largely focused on temporal dynamics at decadal and lower scales; however, decade- to century-scale channel change establishes a geomorphic template upon which these higher-frequency dynamics play out. Our discussion will consider temporal change from low- to high-frequency events (Fig. 2).

The concept of disturbance has various meanings, but in stream ecology disturbance is usually associated with hydrologic extremes that change ecosystem structure and processes. Using terms from disturbance ecology, we can characterize a disturbance regime, which has features such as interannual (or interdecadal) variability, seasonality, and timing, frequency, and magnitude of individual events. Disturbance is intimately connected to succession, which is most simply defined as the change in ecosystem properties on a site following disturbance. Ecosystem components that are affected by a disturbance are those that undergo succession after the disturbance; for example, a flash flood that removes algae and invertebrates but does not affect streamside vegetation initiates succession in the stream but not in the riparian zone.

Successional patterns depict the temporal changes in stream and riparian communities and processes that are superimposed upon a larger temporal scale of variability. For longer-lived riparian vegetation, successional patterns and time frames may be similar to those of terrestrial communities but for stream biota, succession often plays out against a seasonal backdrop. Thus, successional patterns differ between seasons, with faster increases in biomass during warmer months. Successional patterns also vary depending upon the size and nature of the initiating disturbance as well as antecedent conditions (which are themselves influenced by the disturbance regime – timing and clustering of individual events). Whereas disturbances that occur over short timescales may produce predictable recovery sequences, biota recover from longer-term, infrequent disturbances with less regularity. Effects on biota of pronounced interannual variation that characterizes deserts include shifts in community composition of invertebrates and differences in the relative importance of nitrogen-fixing cyanobacteria versus nonfixer algae in the primary producer assemblages.

Flash flooding and drying are the primary disturbances that characterize desert streams. Flood magnitude is usually described by the peak discharge, but other aspects of a flash flood hydrograph – the steepness of its rise and the length of its tail – also determine flood effects. Floods are important geomorphic agents, shaping channel form, as well as disturbances that initiate biotic succession. In deserts, floods connect elements of the landscape, from ridgetops to large rivers to groundwater, which are otherwise isolated and disconnected. Drying is at the opposite hydrologic extreme but is more difficult to treat as a discrete disturbance because it represents a protracted reduction and ultimately loss of stream flow. As drying progresses, there is first a concentration of mobile biota that precedes a concentration of dissolved materials (through evaporation); there may be isolation of sections of a stream and distinctive patterns of surface-water loss; direction of surface–subsurface water exchange may flip; organisms may move into sediments; and, ultimately, surface flow is lost entirely. Drying ends when surface flow resumes, either during a flood or as a gradual increase in discharge.

At the scale of centuries, events that occur only every 50–100 years or so can shape channel form and initiate riparian succession. For example, in the southwestern USA, a period of erosion occurred forming arroyos or gullies and draining the riverine wetlands that were once characteristic of these desert environments. This period left a geomorphic structure that persists today in many southwestern river–riparian ecosystems. Dramatic changes such as these can affect groundwater–surface water interactions and change species composition of the riparian vegetation. Indeed, such large-scale changes have repercussions for many stream characteristics, underscoring the importance of the hydrogeomorphic template in establishing structure and function of stream–riparian ecosystems.

Decadal variability resulting in relatively wet and dry periods in the southwestern USA is related to quasi-cycles of the Pacific Decadal Oscillation and El Niño Southern Oscillation (ENSO). For the southwestern USA, a strong ENSO signal is seen in decadal patterns of winter runoff from the Puerco and Grande Rivers in New Mexico and Sycamore Creek in Arizona. During wetter periods, frequent high-discharge events remove active-channel vegetation, leaving open gravel bars (parafluvial zone). Although these particular characteristics may be unique to desert streams of the southwestern USA, the important point is that larger-scale forcing from global climatic patterns can result in decadal shifts in near-stream riparian vegetation that have profound consequences for stream ecosystem function.

Given the high degree of interannual variability of desert environments, annual averages often carry little information and long-term trends are masked. Years vary not only in the total amount of runoff but also in the temporal distribution and timing of individual events or clusters of events. During the five wettest years of a 30-year period for Sycamore Creek, frequent floods meant the ecosystem was in an early successional state most of the year, whereas stream organisms experienced severe drying conditions over much of the year during the five driest years. Furthermore, years with the same total annual runoff may differ substantially in seasonal distribution of that runoff with consequences for the seasonal patterns of drying. A single, large late-summer flood in 1970 in Sycamore Creek carried the same total volume of water as nine total floods distributed more evenly across the spring season in 1988, with the result that much of the stream was dry during the hottest months in 1970 but was undergoing succession during summer 1988 (**Fig. 3**).

Although seasonality in desert streams may be strongly dependent upon the distribution of disturbance events, other variables in addition to discharge, such as temperature and day length, can influence the biota of desert streams. Deserts are defined only by low precipitation; thus, there is a broad range across the world's deserts in both flow seasonality and annual temperature

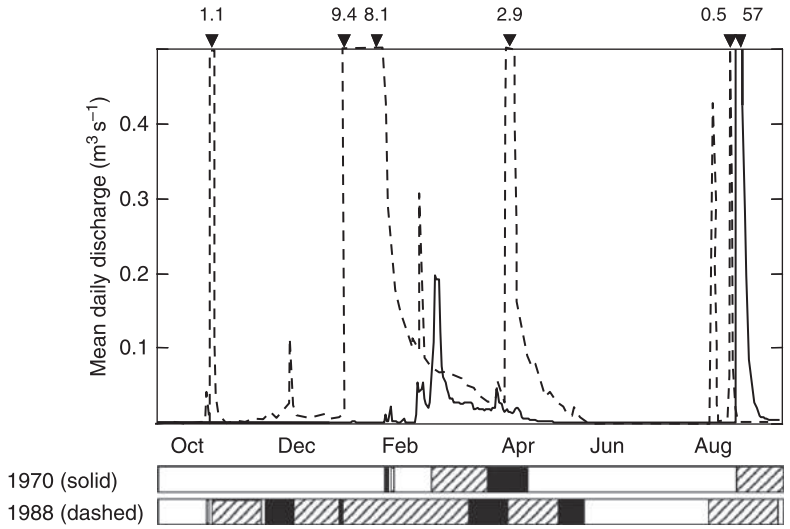

Fig. 3 Contrasting seasonal discharge patterns in 2 years with nearly identical total annual discharge. Bars at bottom show time periods likely to be influenced by postflood succession (hatched), drying (open), or neither (solid). Redrawn from Grimm, N.B., 1993. Implications of climate change for stream communities. In: Kareiva, P., Kingsolver, J., Huey, R. (Eds.), Biotic interactions and Global Change. Sunderland,MA: Sinauer Associates.

distributions. Flow seasonality may vary from highly unpredictable and episodic events to a relatively predictable and sustained increased in discharge associated with a distinct wet season, with consequences for successional patterns. Temperatures of stream water in cool deserts may fluctuate seasonally from near-freezing to 20 °C; in hot deserts, daytime stream temperature can reach >30 °C but may be ameliorated by extensive evaporative cooling.

Temperature variation over the course of a single 24-h period may be nearly as great as seasonal variation. High albedo and low heat capacity of desert land surfaces cause extensive diel fluctuations in air temperatures, leading to wide (though comparatively muted) ranges in stream temperature. Particularly in summer when evapotranspiration rates are very high, streamflow varies measurably over 24 h, causing stranding at stream margins. At points where drying streams sink into the sediments, the end of the stream can migrate up and down the channel by several meters! Desert streams of Antarctica show extreme diel variation in discharge, but by a very different mechanism. Streamflow is generated by solar melting of the vertical walls (ice cliffs) of glaciers. During summer, when the Sun circles around the horizon at a low angle, melting (and streamflow) stops when the cliffs are in shadow.

Biota

Desert stream ecosystems support a diverse assemblage of riparian plants and stream biota. A unifying characteristic of desert stream organisms is the shared evolutionary history in a hydrologically extreme environment. The consequences of this extreme physical template are evident from the variety of adaptations that allow species to thrive in systems prone to flash flooding and prolonged drought. Rather than providing a list of taxonomic names for each group, we place emphasis on life history, behavioral, and morphological adaptations for living in hydrologically variable ecosystems.

Desert stream ecosystems house diverse periphyton communities, which include a variety of filamentous green algae, epilithic, epiphytic, and episammic diatoms (attached to rocks, plants, and sediments, respectively), and nitrogen-fixing cyanobacteria. Both flash flooding and prolonged drought decimate algal biomass in desert streams. Rapid drying is particularly lethal, and algae typically die within hours of exposure to the hot, dry desert environment. Algal species often have physiological adaptations that allow for some resistance to drying, however, and can withstand periods of gradual drying. Such adaptations include the production of extracellular mucilage that increases cellular water retention, and intracellular osmoregulatory solutes that also prevent water loss in drying sediments. In addition to these mechanisms, at the onset of drying, algae may also produce spores, cysts, or zygotes that can reactivate upon rewetting. Benthic algae rapidly recolonize stream sediments following floods, whereas recovery following drought is variable and depends on the degree and modes of drought resistance. In Antarctic desert streams, for example, glacial melt is the primary source of streamflow, and primary producers (cyanobacterial and other microbial assemblages) are activated by higher temperature and renewed flows which may occur seasonally or even on a diel basis. However, these organisms are also able to persist for decades in the absence of liquid water.

A productive and diverse invertebrate fauna characterizes many desert streams, consisting of insect and crustacean taxa residing in both benthic and hyporheic habitats. Life-history characteristics of desert stream invertebrates reflect an evolutionary history in a hydrologically variable ecosystem, and are shaped by both flooding and drying disturbances (**Table 1**). Most stream invertebrate larvae have few mechanisms that confer resistance to either type of hydrologic disturbance. Instead, many species have short developmental times (e.g., 1–3 weeks) that increase the probability of offspring surviving to reproductive maturity in ephemeral environments, and ensure that some aerial adults are available for recolonization following floods or upon rewetting previously dry channels. In addition, organisms with longer life cycles exhibit an array of avoidance behaviors to minimize the effects of flooding and drying disturbance. These include timing reproductive activity to periods of low flood probability, as well as ovipositing eggs in sections of stream that are likely to retain water for longer periods of time (e.g., deep pools, riffles). Finally, air breathing insects (e.g., coleopterans, hemipterans) may exhibit more direct avoidance behaviors, including the use of rainfall as a cue for leaving aquatic habitats before floods.

Relative to mesic counterparts, fish assemblages of arid river systems are species poor, and are composed of taxa that also have specific adaptations to life in hydrologically variable systems. These adaptations include large reproductive efforts, multiple clutches per year, and short developmental times. Such life-history features, along with the ability to migrate long distances during periods of sufficient flow, allow native desert fish to rapidly colonize habitats after disturbances, and result in dramatic temporal fluctuations in population size. In addition, while intense flash floods can decimate fish populations, many desert fish have morphological adaptations that allow for some resistance to high flows. These include depressed skulls, keeled or humped napes, buttressed fins, narrow caudal peduncles, slim bodies, and reduced scales – all of which act to reduce drag and improve swimming ability in turbulent flow.

As desert stream ecosystems contract during drought, fish become isolated in pools where the physical environment can fluctuate dramatically. Although complete water loss is lethal, as streams contract, individuals of many fish species can survive in small pools, as well as beneath logs, stones, and within beds of algae. As a consequence, native desert fish are able to tolerate a broad range of temperatures (7–37 °C); indeed, desert pupfish of western North America can survive in temperatures that exceed 40 °C. Similarly, most desert fish are able to tolerate high salinity and low dissolved oxygen concentration. Others still, like the African lungfish, can burrow into the stream substrate during dry periods and survive for months by breathing atmospheric air with primitive lungs.

Table 1 Invertebrate colonization/recolonization characteristics of desert streams in relation to floods in different physiographic regions

	Mesic	*Hot desert*	*Endorheic cold desert*	*Exorheic cold desert*	*Chapparal*	*Glacial*
Colonization sources[a]	Numerous	Few	Intermediate	Intermediate	Intermediate	Few
Colonization distances[b]	Close	Far	Intermediate	Intermediate	Intermediate/far	Far
Pathways[c]	DD, um, S, O, H	DD, um, S, O	S	dd, um, S, o, h	DD, um, S, O, h	dd, um, d, O, h
Refugia	Abundant	Limited	Limited	Intermediate	Intermediate	Limited
Species diversity	High	Intermediate/high	Low	Intermediate	Intermediate/high	Low
Resilience[d]	High	High	Low	High	High	Unknown
Flood occurrence	Spring/summer	Winter/summer	Winter	Winter/spring/summer	Winter	Spring/summer
Spatial extent of flood	Extensive	Variable	Extensive	Extensive	Extensive	Extensive
Severity of flood	Intermediate	High	High	Intermediate	High	Intermediate

[a]Refers to sources separate from the perturbed stream.

[b]Refers to distance from other unaffected water bodies.

[c]Status at time of spate: DD/dd, downstream drift; um, upstream migration; S/s, survivors; O/o, oviposition; H/h, hyporheic. Upper and lower case indicates major or lesser importance, respectively.

[d]Refers to number of taxa, not individuals, following recovery.

Reproduced from Cushing CE and Gaines WL (1989) Thoughts on recolonization of endorheic cold desert spring-streams. *Journal of the North American Benthological Society* 8: 277–287.

Streamside forests, or riparian zones, stand out as hot spots for aboveground primary productivity in arid landscapes. Arid riparian zones include assemblages of phreatophytic deciduous trees capable of accessing groundwater, as well as shrubs and annual grasses. The overall taxonomic composition of riparian zones is typically in striking contrast to that of the surrounding desert landscape. Deeply rooted riparian trees are well suited to an environment where the water table is temporally variable. Obligate wetland species appear in desert riparian areas with permanent access to shallow groundwater, whereas those found in areas with strong seasonal fluctuations in water table elevation have structures such as tap roots or root architecture that maximizes water capture during precipitation events. Many riparian tree species in arid landscapes actually require over-bank flooding at specific times of the year to induce germination. Riparian vegetation is thought to play an important role in the overall cycling of nutrients in arid landscapes by taking up nutrients present in shallow groundwater and building organic matter pools in riparian soils. Finally, riparian vegetation serves as critical habitat for invertebrate, vertebrate, and avian taxa within arid landscapes.

Energetics

In contrast with streams of temperate and tropical biomes and because of their flood-shaped channel morphology, desert streams generally are not shaded by adjacent riparian vegetation. As a consequence, incidence of photosynthetically active radiation (PAR) reaching desert streams is high, and rates of instream primary production, the process by which energy is captured and organic matter is produced in ecosystems, are among the highest documented for benthic algae. The accrual of algal biomass in turn represents the energetic basis for stream food webs, and is central to the overall ecosystem dynamics of arid streams. For example, the abundance of high-quality benthic algae, together with warm temperatures and selection for rapid growth, result in among the highest rates of secondary production reported for benthic invertebrates. Moreover, owing to high standing stocks and growth rates, invertebrates play an important role in organic matter dynamics and nutrient cycling in desert streams. Indeed, the quantity of organic matter ingested by stream invertebrates can be 2–6 times greater than primary production. Finally, the emergence of desert stream insects represents an important resource for predators in adjacent terrestrial habitats.

At the ecosystem level, high rates of algal productivity in desert streams set them apart from streams of forested regions with respect to the relative rates of production (P) and respiration (R). Specifically, desert streams are often autotrophic ($P > R$). This is in striking contrast to streams of other biomes that receive the bulk of organic matter from outside the stream ecosystem and are often highly heterotrophic ($P << R$). Productivity of desert streams is also influenced by the disturbance regime. Flash floods scour stream channels, decimate existing organisms, and initiate a suite of algal and macroinvertebrate successional processes that correspond to temporal changes in photosynthesis and respiration (**Fig. 4**). Post-flood recovery of heterotrophs is enhanced by availability of organic matter that was stranded or deposited on the stream margins and in the riparian zone during dry periods.

In addition to metabolic changes associated with flash floods, spatial patterns of photosynthesis and respiration and post-flood successional dynamics are further influenced by hydrologic exchange between hyporheic and parafluvial subsystems and the surface stream. Specifically, rates of photosynthesis and the speed of post-flood recovery are greatest where nutrient-rich water from hyporheic and parafluvial sediments enters the surface stream. Conversely, rates of respiration are greatest where oxygen and organic matter from the surface stream enters subsurface and lateral sediments (**Fig. 5**). When both surface and hyporheic processes are taken into account, desert streams may more closely approximate a balanced metabolism ($P = R$), which highlights the connection between the two subsystems.

Nutrient Dynamics

Various factors can limit the rate of primary production if demand (requirements of autotrophs) exceeds availability. Limiting factors in streams are typically light and nutrients. Because desert streams often have open canopies and receive abundant light, nutrients are the primary constraint on algal growth. Lack of precipitation in arid and semiarid regions leads to very slow rates of weathering of parent materials, which can lead to phosphorus (P) limitation as rocks are the ultimate source of P in ecosystems. However, in many well-studied arid and semiarid watersheds of the US southwest, volcanic-derived parent materials yield highly dissolved P. Primary production in these desert streams is thus limited by nitrogen (N).

Nutrients enter streams via inputs from upstream, from groundwater and overland flow, in plant materials deposited from the riparian zone, and in the case of N, via fixation of atmospheric N_2 by cyanobacteria. Unidirectional flow of water results in continual input and output of nutrients in dissolved and particulate forms, although inputs of limiting nutrients may be low due to processing that occurred upstream. Nutrient spiraling theory, a set of hypotheses that describe how nutrients move between water column, subsurface, and biotic compartments while being transported downstream, predicts that nutrient uptake should be more efficient under conditions of nutrient limitation. In streams limited by N, for example, inorganic N is rapidly removed from the water column by biota. For hot desert streams, rates of nutrient uptake can be particularly rapid due to high temperatures and light availability, which increase rates of biological reactions. Concurrent with rapid uptake by algae, excretion of inorganic N by invertebrate consumers can represent nearly 30% of the total N delivered to the ecosystem. Over successional time, export of rafting algal mats or stranding of algae on the stream banks during dry periods results in loss of organic N from the stream ecosystem. Budgets of organic N for desert streams thus conform with the successional trajectory of terrestrial ecosystems wherein ecosystems at late successional stages tend to lose nutrients. In contrast to terrestrial ecosystems, however, net primary productivity may continue to be positive during late successional stages of desert streams, resulting in continued uptake of inorganic nutrients by primary producers.

In surface water, nutrient cycling is dominated by uptake of nutrients by algae and benthic biofilms. The dominant pathway of nutrients in the surface is therefore from inorganic to organic forms. Regeneration (mineralization) of inorganic nutrients in the subsurface may in turn resupply dissolved inorganic nutrients. Processes occurring in the hyporheic and parafluvial zones thus contribute strongly to patterns of nutrient availability in desert streams. Water flowing through sediments slows in velocity

allowing for greater interactions between sediment surfaces and materials delivered in water. Microbes inhabiting the interstitial areas of sediments transform nutrients present in these downwelling zones, influencing the spatial distribution of nutrients in the stream channel.

In coarse sediments where dissolved oxygen remains relatively high as water moves through the hyporheic zone, mineralization often dominates N transformations, resulting in a localized increase in streamwater dissolved inorganic N concentrations at locations of upwelling. Increased nutrient availability in zones of upwelling is often associated with hot spots of algal biomass. These patterns are typical of alluvium-dominated reaches where algae are the predominant primary producers. In patches where macrophytes colonize gravel bars and parafluvial zones or in patches of fine sediment deposition, dissolved oxygen concentration in the subsurface is decreased due to root respiration and decomposition of plant-derived organic matter, and hyporheic flows are slowed, all of which lead to hypoxic or anoxic conditions. Hot spots of denitrification are associated with anoxic conditions in the hyporheic zone and water upwelling downstream of such patches is therefore depleted of inorganic N (**Fig. 6**).

Because of these differences in nutrient processing between surface and subsurface flowpaths, streams that undergo drying may exhibit marked spatial variability in nutrient availability. Sections of the stream that dry may continue to harbor subsurface flows and rapid transformation of nutrients for some time after surface flows are depleted. Nutrient inputs and outputs from dry reaches may show strong contrasts in forms or concentration of nutrients. In contrast, reaches characterized by perennial flow tend to show dampened upstream–downstream contrasts due to the homogenizing effects of processes occurring in surface flows.

As with nearly all aquatic ecosystems, the surrounding terrestrial landscape influences nutrient dynamics in desert streams. In deserts, however, hydrologic connectivity between the stream and terrestrial portions of the catchment, including the riparian zone, are variable in time. Deposited nutrients and those stored by plants and microbes may accumulate in the riparian zone and uplands during dry periods. When precipitation or snowmelt events occur, water carries these particulate and dissolved nutrients overland from the uplands to the stream, and between the riparian subsurface and the surface stream. This creates pulses of nutrient transport between desert streams and their watersheds. Pulsed inputs of nutrients result in hot moments of nutrient processing, short time periods with rapid rates of nutrient transformations. Hot moments may account for a significant fraction of annual nutrient processing within riparian zones of desert streams.

Connectivity between terrestrial and aquatic portions of desert stream–riparian corridors may also occur from the stream to the riparian zone. Riparian plants can access water and nutrients from the hyporheic zone as well as from shallow groundwater. Access to these more permanent sources of water and nutrients leads to high productivity in riparian zones relative to desert uplands. Stream biota may transfer nutrients between streams and riparian zones of desert streams. Owing to high rates of primary

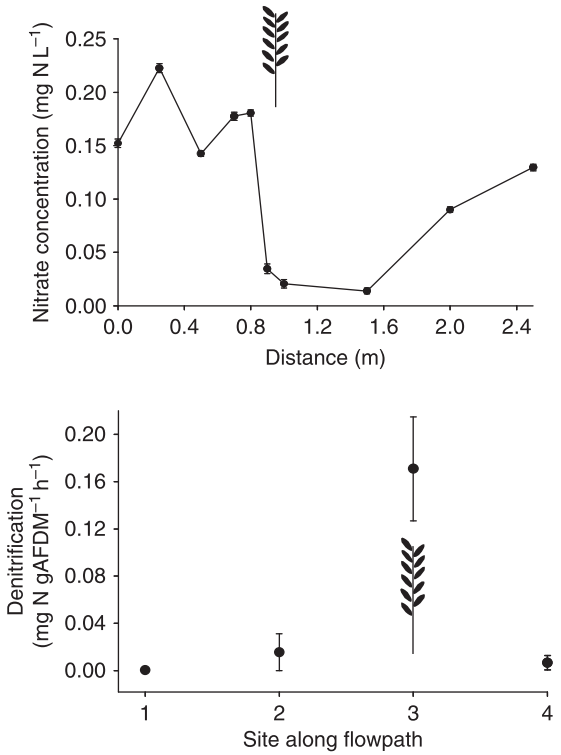

Fig. 6 Changes in concentration of nitrate in water flowing through plant-colonized gravel bars (top). Note precipitous drop in concentration when water encounters a plant patch (denoted by branch figure). Denitrification is a likely mechanism accounting for the drop in concentration of nitrate; *in situ* rates of denitrification increase in plant patches (bottom). Redrawn from Schade, J.D., Fisher, S.G., Grimm, N.B., Seddon, J.A., 2001. The influence of a riparian shrub on nitrogen cycling in a Sonoran desert stream. Ecology 82, 3363–3376.

productivity, insect emergence from desert streams can result in significant exports of nutrients out of the wetted stream. Emerging aquatic insects may thus provide a significant source of nutrients to riparian food webs.

Human Modifications

Desert streams present important challenges to understanding and management of water resources. They exemplify the resource that is most precious to humans inhabiting arid and semiarid regions, yet they are threatened by increasing pressures of human exploitation, agricultural expansion, and urbanization. Direct appropriation of streamflow to support human activities is the most serious threat to desert streams. This takes the form of diversion, interbasin water transfer, and groundwater withdrawal (which reduces baseflow); for example, groundwater withdrawals over the past century have converted the Santa Cruz River in Tucson, Arizona from a perennial to an ephemeral stream. In the Salt River of central Arizona, river diversion into a system of canals that feed agricultural and domestic/industrial demand in Phoenix has left a dry riverbed throughout the metropolitan region. Water extraction, primarily for irrigation, has also resulted in salinization of streams in much of the world and has triggered shifts in the composition of biotic communities.

In their appropriation of water for a variety of uses, people also modify the form and hence the function of desert streams. For example, the creation of canals that are straightened and lined with concrete replaces structurally complex streams with ecosystems that are unlikely to support the ecosystem functions characteristic of unmodified desert streams. Furthermore, impoundment and flow regulation can have profound effects on riparian ecosystems, for example, through the colonization and persistence of exotic plant species that outcompete native species under conditions of lowered water tables and reduced flow variability.

Deserts

C Holzapfel, Rutgers University, Newark, NJ, USA

What makes the desert beautiful is that somewhere it hides a well. Antoine de Saint Exupéry

Geography

Definition of Deserts

It is common belief that all deserts are hot and sandy places. While this is generally not true, a common factor of deserts is aridity, the temporal and/or spatial scarceness of water. True deserts can be delineated from other biomes based on their aridity. Of the following groups, only the first two are considered as true deserts here.

Aridity can be divided into four groups:

- extreme arid: less than 60–100 mm mean annual precipitation;
- arid: from 60–100 to 150–250 mm;
- semiarid: from 150–250 to 250–500 mm; and
- nonarid (= mesic): above 500 mm.

Since evaporation depends largely on temperature, bioclimatic aridity cannot be defined solely by the amount of precipitation. Therefore, the higher limits given above refer to areas with high evaporativity in the growing season (e.g., in subtropical areas with rainfall in warm seasons). This is taken into consideration in UNESCO's `World Map of Arid Regions' that defines bioclimatic aridity by P/ET ratios (annual precipitation/mean annual evapotranspiration). P/ET ratios smaller than 0.03 qualify for hyperarid zones (roughly corresponding to the extreme arid zone above) and a ratio of 0.03–0.20 as arid zone (thereby corresponding to the arid zone mentioned above).

Another common way of delineating deserts is based on their vegetation pattern and optional land use. Extreme arid zones typically show contracted vegetation restricted to favorable sites or lack vegetation altogether. Arid zones are characterized by diffuse vegetation. Semiarid zones mostly are characterized by continuous vegetation cover (if edaphic conditions allow for it) and only very locally dry-land farming (without irrigation) is possible. Farming without irrigation becomes a reliable option at larger scale in nonarid zones only.

Based on geographic location and a combination of temperature and geographical causes of aridity, deserts can be separated into five classes:

- *Subtropical deserts*. They are found in the hot dry latitudes between 20° and 30°, both north and south. These deserts lie within the subtropical high pressure belt where the descending part of the Hadley's cell air circulation causes general aridity.
- *Rain shadow deserts*. They are found on the landward side of coastal mountain ranges.
- *Coastal deserts*. Found along coasts bordering very cold ocean currents that typically wring moisture as precipitation from the air before it reaches the land, these deserts are often characterized by fog.
- *Continental interior deserts*. They are found deep within continents and far from major water sources.
- *Polar deserts*. They are found both in the northern and southern cold dry polar regions.

This article focuses on extreme/hyperarid and arid zones and on the first four of geographic desert classes listed above.

Where are Deserts Found?

True deserts are found on all continents except the European subcontinent (see **Fig. 1**). Altogether about 20% of landmass can be classified as desert, making it the largest biome on Earth. **Table 1** gives an overview of the largest deserts. In addition to these major deserts, many smaller, separately named deserts exist; many of these can be classified as local rain shadow deserts. All desert areas of the world border on land semiarid zones. These are either Mediterranean-type climate and vegetation, or dry temperate or tropical grasslands/savannas. The vicinity to these areas is important as many desert organisms are either shared with these transitional biomes or evolved from similar more mesic organisms.

Desert Landforms

According to relief type, two general groups of desert landforms can be distinguished: (1) shield-platform deserts and (2) mountain and basin deserts. The shield-platform deserts are most common in Africa, the Middle East, India, and Australia and are characterized by tablelands and basin lowlands. Mountain and hill slopes in this type of deserts are restricted to ancient mountains or areas with

Fig. 1 Map of world distribution of deserts. Shown are the arid and hyperarid desert region. Borders are somewhat tentative as a clear separation from semidesert scrublands is often not readily possible. Polar deserts are excluded.

Table 1 List of the major desert areas of the world (larger than 50 000 km^2)[a]

Name	*Size (km^2)*	*Type*	*Temperature*	*Countries*
Sahara Desert	8 600 000	Subtropical	Hot	Egypt, Libya, Chad, Mauritania, Morocco, Algeria Tunisia.
Kalahari Desert	260 000	Subtropical	Hot	Botswana, Namibia, South Africa
Namib Desert	135 000	Coastal	Hot	Namibia
Arabian Desert	2 330 000	Subtropical	Hot	Saudi Arabia, Jordan, Iraq, Kuwait, Qatar, United Arab Emirates, Oman, Yemen, Israel
Syrian Desert	260 000	Subtropical	Hot	Syria, Jordan, Iraq
Kavir Desert	260 000	Subtropical	Hot	Iran
Thar Desert	200 000	Subtropical	Hot	India, Pakistan
Gobi Desert	1 300 000	Continental	Cold	Mongolia, China
Taklamakan	270 000	Continental	Cold	China
Karakum Desert	350 000	Continental	Cold	Turkmenistan
Kyzyl Kum	300 000	Continental	Cold	Kazakhstan, Uzbekistan
Great Victoria Desert	647 000	Subtropical	Hot	Australia
Great Sandy Desert	400 000	Subtropical	Hot	Australia
Gibson Desert	155 000	Subtropical	Hot	Australia
Simpson Desert	145 000	Subtropical	Hot	Australia
Great Basin Desert	492 000	Continental	Cold	United States
Chihuahuan Desert	450 000	Subtropical	Hot	Mexico, United States
Sonoran Desert	310 000	Subtropical	Hot	United States, Mexico
Mojave Desert	65 000	Subtropical/rain shadow	Hot (cold)	United States
Atacama Desert	140 000	Coastal	Hot	Chile, Peru
Patagonian and Monte Deserts	673 000	Rain shadow	Cold	Argentina
Antarctic Desert	1 400 000	Polar	Very cold	Antarctica

[a]Various sources.

more recent volcanic activity. The geologically younger mountain and basin deserts (also called mountain and range) are predominant in the Americas and Asia and consist typically of mountain ranges separated by broad alluvially filled valleys. Within the two groups of desert landforms, there are several dominant geomorphological landscape types that are described here briefly.

Desert mountains consist chiefly of sheer rock outcrops and tend to rise abruptly from desert plains. The slopes of these mountains differ according to geological origin of the parent material. Igneous rock mountains tend to be characterized by large debris (boulder fields), while softer sedimentary rocks tend to lack these. Desert mountains (**Fig. 2**) dominate the desert of the USA (38% of desert area), the Sahara (43%), and Arabia (45%).

Piedmont bajada formations (**Fig. 3**) cover roughly a third of the arid Southwest USA but do less so in other desert areas of the world. These formations are built up from alluvial material that tends to accumulate in fans at the mouth of mountain canyons. Individual alluvial fans often coalesce and form large-scale graded slopes called piedmont bajadas (often only `bajadas'). Depending on deposition age and location along the bajada, the fill material is very diverse and differs strongly in alluvial particle size and soil structure, thus creating complex gradients and mosaics of distinct geological landforms. These gradients have been studied extensively in the Sonoran and Mojave Deserts and it had been shown that predominantly, the age and consequent erosion of the alluvial material within these mosaics determine the biological communities that can establish on it.

Desert flats (basins) are another common landscape type (about 20% in the USA and 10–20% in other regions). Often these flats have rather fine-textured soils and with sufficient rainfall vegetation is diffuse and rather evenly spaced across the landscape (**Fig. 4**). In

Fig. 2 Desert mountains: the Cambrian sandstone formations rise almost vertically from the valley floor filled deeply by sands that locally eroded from the mountain fronts. Wadi Ram, Jordan, October 2003. Photograph by C. Holzapfel.

Fig. 3 A piedmont bajada in the Mojave Desert: alluvial fan deposits stemming from a nearby mountain range vary in age and structure (here a mixture of Pleistocene and Holocene deposits). The position along the fan and the composition and structure of the deposits determine hydrology and plant growth (here the common desert shrubs *Larrea tridentata* and *Ambrosia dumosa*). Fremont Valley, California, USA, March 2006. Photograph by C. Holzapfel.

Fig. 4 Desert flats: this large desert basin in the Atacama Desert has very little surface dynamics and fine-textured soil materials are overlain by rocks forming a partial pavement. Among the harshest deserts on Earth, the Atacama receives very little to no rainfall and plant growth is lacking in most years. South of Antofagasta, Chile, October 1994. Photograph by C. Holzapfel.

more arid regions and when rainfall redistribution is patchy due to minor relief differences, distinct banded vegetation patterns can arise. These bands exist mostly in Africa and Australia but are also present in restricted areas in the Middle East and North America. The open areas produce the runoff of rainfall that accumulates in the bands, supporting the growth of vegetation. Another type of flat desert region can be differentiated as hammadas (bedrock fields). These bedrock fields develop *in situ* and depending on the size of rock fragments, can build dense pavements (regs) consisting of densely packed surface stones resting on finer-textured subsoil. This desert landscape type is common in the Sahara and the Middle East and accounts for 40% of the area.

Sand dunes (**Fig. 5**), known as `ergs' in Arabic-speaking countries, are dominant desert landscapes only in extreme arid desert areas (25% of Sahara and Arabian Deserts, less than 1% in arid Southwest USA). Characterized by moving sands, they depend on sources of sand, sufficient wind energy, and favorable accumulation areas. Depending on these factors and prevailing wind direction, different dune types arise. Crescent-shaped dunes (barkhan dunes) form perpendicular to the prevailing wind direction and tend to be highly mobile. Linear dunes form in the direction of the wind and therefore do not move over the desert landscape. This distinction is of biotic importance as the edges of dunes are favorable to plant growth, while the dune crest and upper slopes, due to sand drift and fast erosion, are usually devoid of vegetation. In sandy flats, individual shrubs tend to accumulate sand deposits and eventually form phytogenic hummocks (so-called nebkhas).

Playas (**Fig. 6**) are depressions with very fine-textured, often saline soils. Playas are the beds of former lakes that can be flooded in years of abundant rainfalls. These depressions are known under various names (North Africa and Middle East: chotts, sebkas). Even though individual playas can be large, worldwide they cover only 1% of desert.

Badlands form in areas with clay-rich soils and are typically located at the margins of arid lands, although they are found locally in arid regions as well. Depending on the strength of water forced erosion, badlands are areas with extremely high surface relief, typically forming fantastic `lunar landscapes.'

Dry river beds of ephemeral streams (**Fig. 7**) are of little importance with respect to land cover in deserts (only 1–5% worldwide), but are of immense biological importance. In extreme arid regions, these are the only places with vascular plant growth, and almost all

Fig. 5 Sand dunes: ergs are seas of sands that are constantly on the move. Vast sand deserts are typical for the Sahara (shown here) and Arabian Desert. Douz, Southern Tunisia, March 1986. Photograph by C. Holzapfel.

Fig. 6 Desert playas are often prehistoric lake beds with fine-textured, alkaline soils. Depending on current rainfall and temperature, playas can be flooded and then resemble the former lakes, as this playa on the altiplano of the Andes at an elevation of 4400 m. Plant life on playas is typically sparse but when microorganisms and invertebrates are active, birds such as these Andean flamingos (*Phoenicopterus andinus*) assemble in large numbers. East of San Pedro de Atacama, Chile, November 1994. Photograph by C. Holzapfel.

Fig. 7 Ephemeral stream: in arid areas vegetation concentrates along and in the bed of temporal stream beds. Due to available water in the subsoil that is plant extractable even long after temporal surface flow ceased, most of the primary production and species diversity in extreme deserts is restricted to these habitats. Nahal Zin, Negev Desert, Israel, April 1987. Photograph by C. Holzapfel.

Fig. 8 A flash flood obstructs traffic on a desert road. Depressions and stream beds quickly flood after strong rainfall events due to the high surface runoff in deserts. As in the case here, the precipitation source of the water can be remote and floodwater travels far distances. Due to high stream velocity and carried erosion material, such sudden floods can be disruptive to biotic communities and dangerous to humans. Sedom, Israel, March 1991. Photograph by C. Holzapfel.

animals depend at least at times during their life on the primary production here. This biological importance of ephemeral streams is therefore a foremost feature in deserts, and even though small in size, these landmarks were always distinctly named by human desert dwellers (washes in North America, wadi/*oued* in Arabic-speaking regions, *arroyo seco* in Spanish-speaking regions).

What is Special about Desert Climates?

Life in desert is limited by the scarceness of water. Secondary limiting factors are correlated to the main factor: the dearth of nutrients for producers and food energy for consumers and for both – at least temporally – high heat stress. Precipitation typically is so low that water becomes the controlling factor for biological processes. Precipitation is also highly variable throughout the year and typically occurs in infrequently defined events (discontinuous input). To make things even worse, precipitation varies randomly between years and is therefore not predictable. The coefficient of variation between years in arid areas is typically larger than 30% of the long-term average (and ranges in some extreme deserts to 70%). For comparison, temperate zones and tropical areas typically have coefficient of variation of less than 20%. Individual precipitation events in deserts can be tremendously large (for instance, 394 mm in a single rainstorm in the Peruvian desert that receives a long-term annual precipitation average of 4 mm) and due to surface runoff, large-scale flash flooding can occur (**Fig. 8**). Even though such sudden floods will replenish needed water to desert systems, erosion and direct damage to desert plants are the consequence. Because of the small and temporally highly variable rainfall amounts, deserts have been described by Noy-Meir as ``water-controlled ecosystems with infrequent, discrete, and largely unpredictable water inputs."

Adding to and interacting with the pronounced temporal variation is the high spatial variation of rainfall in deserts. This variation is caused by: (1) oreographic features (e.g., increase with altitude), (2) differences in degree and direction of slopes, and (3) the typically small size of precipitation fronts (often less than1 km in diameter).

Depending on the latitudinal geographical location and the origin of rain fronts, deserts receive either precipitation in the cooler season (cyclonic/frontal rainstorms) or in the warmer season (tropical, convective rainstorms). Some transitional desert regions receive both. The seasonality of rainfall is of great bioclimatological importance as evapotranspiration is larger during the warmer season and rainfall therefore tends to have a smaller biological effect. On the other hand, cold deserts receive precipitation during the cold season mostly in the form of snow and biological activity is then limited both by low temperatures and aridity. Snowmelts in spring create deep-reaching wetting fronts that will hold water available for plant uptake during the warmer growing season. Locally important other water inputs are condensations of atmospheric moisture as dew. These are crucial for plant production in the coastal fog deserts that otherwise do not receive direct precipitations. It is less common inland but can be noticeable in high desert areas as well (for instance in the Negev Desert of Israel). Fog water inputs are directly usable for cryptogamic organisms (e.g., lichens) and many arthropods. Foliar uptake of fog by vascular plants has been demonstrated but its relative importance in the water balance remains controversial. Water vapor tends to move along temperature gradients and can be important in dry soils with strong diurnal radiation. An upward movement of water vapor at night causes formation of dew close to the surface. Such water might sustain germinated plants until they produce roots long enough to reach deeper and wetter soil depths.

Deserts usually experience an extreme diurnal temperature range, with high daylight temperatures (up to 50 °C, the highest temperature recorded in Death Valley was 56.7 °C), and extremely low nighttime temperatures (often dropping below 0 °C). This is caused by very dry air that is transparent to infrared (heat) radiation from both the sun and the ground. Thus during daylight all of the sun's heat reaches the ground. As soon as the sun sets, the desert cools quickly by radiating its heat into space. Clouds reflect ground radiation and desert skies are usually cloudless, thereby increasing the release of heat at night. With intense sun radiation, surface temperatures can be extreme and depending on the color and type of surface can exceed 80 °C.

Desert Soils

The main features of desert soil that affect water and nutrient availability include texture, content of organic matter, pH, and orientation within the landscape. Desert soils show typically little development from parent material and some authors even state that typical developed soils do not exist in deserts. Most desert soils are classified as Aridisols and are differentiated into soils with a clay (argilic) horizon (Argids) and soils without such horizons (Orthids). Other soils, less common in deserts, are mollisols, soils with dark A horizons, and Vertisols, cracking clay soils. Accumulated subsurface horizons with either clays or calcium carbonate (calcic horizons) have clear implication as impediments to water infiltration.

Most desert soils tend to be slightly to highly basic. Such reactivity can negatively affect phosphorous and micronutrient availability as these are generally not in solution at pH $>$ 7.0. Organic matter helps to increase infiltration and via decomposition adds to nutrient availability. It is often distributed unevenly in desert soils (see below).

Soils in deserts have important effects on water inputs as they act as short-term water stores and modify water availability by a number of regulation processes. These regulation processes include direct infiltration and often more importantly runoff and horizontal redistribution of water. Redistribution by runoff tends to be of crucial importance in deserts and contributes to spatially very patchy distribution of water. Relatively impermeable surfaces (e.g., biotic or physical crust in clay-rich soils) create runoff areas that result in catchments that are water rich. Such water redistribution enables patchy plant production even in extreme arid zones, where plant growth would not be possible since evenly distributed sparse rainfalls would not exceed the threshold needed for plant life. Because of sparse plant growth, soil-created redistribution of water is more important than precipitation interception through plant surfaces. However, locally such interception combined with stem flow can create water-rich spots under shrub or tree canopies. In contrast, smaller precipitation events can be locally intercepted and lost by evaporation. This is the reason that soils in the understory of desert shrubs or trees can be either wetter or dryer than the surrounding soil.

Soil texture is of large importance as it affects both infiltration and the movement of wetting fronts. Fine-textured soils that are high in clay and silt fraction tend to impede infiltration, in which wetting fronts move only very slowly, and surface evaporation after rainfalls can be very high. More-coarse-textured soil rich in sand fractions, as for instance sandy loams, is characterized by high infiltration rates and rapid percolation. For this reason, coarse-textured soils are often better for plant growth. As this is in contrast to soils in mesic areas where fine-textured soils are commonly considered to be superior for plant production, this is called the `inverse texture effect'.

Clearly, the orientation and dynamics of soil surfaces within the landscape plays a large role in arid ecosystems. Exposed southern (or northern, depending on the hemisphere) slopes receive high solar radiation and therefore due to higher evapotranspiration, tend to be drier than opposite slopes (Fig. 9). These inclination differences are observable on large-scale landscape level or small-scale microtopography level. An example is the sun-exposed sides of shrub hummocks that are often only raised by a few centimeters, but can be bioclimatically and ecologically very different from the less-exposed side. Slope exposition also plays a role when rainfall directions due to prevailing winds are constant. Rain-exposed slopes can receive up to 80% more water than other slopes.

Biogeography and Biodiversity

General Diversity

The casual observer often assumes that deserts support only low species richness and diversity because of the harsh environmental conditions prevalent in arid areas, but among plants and animals almost all taxa are represented (even aquatic groups like fishes

Fig. 9 Marked phenological and plant composition differences due to slope exposition (southeast facing slope on the left and northwest facing slope on the right). The southeast-facing slope is subject to higher evaporational water losses and receives less direct rainfall compared to the northwest-facing slope. Such abiotic differences result in clear biotic contrast in arid environments, making these systems ecological model cases. Judean Desert, Palestine, December 1989. Photograph by C. Holzapfel.

and amphibians) here, and their species richness may be comparable to that of more mesic environments. Even though detailed comparative data are lacking, it has been argued that the diversity in North American deserts is comparable to some grasslands and even temperate forests. In general, however, evidence based on correlations along climate gradients indicates a decrease of species richness in plants and animals with increasing aridity. Regardless of this, specific taxa can be more species rich in deserts than in bordering less arid systems and regionally show negative relationship of richness with increasing precipitation. Examples for these are reptiles and birds in North America, and ants in Australia. Taxonomic groups that are generally species rich in deserts are rodents, reptiles, some insect groups (e.g., ants and termites), solpugids (camel spiders), and scorpions. In the following, an overview of typical desert taxa is given, and some emphasis is given on the ecological role of these groups in deserts. More specific treatment of ecophysiological adaptations follows in the next section.

Ecological Role and Diversity of Microorganisms

Even though obviously not readily observable, microorganisms inhabit all desert areas and in the extreme arid zones are often the only life forms present. Relatively little is known about the diversity within the lower three kingdoms (Fungi, Protista, Monera) in general and even less is known about the species richness of these groups in deserts. A recent survey that uses `DNA fingerprinting', aiming at resolving bacterial ribosomal DNA, indicated that soils of semiarid sites can harbor higher bacterial richness then mesic sites. Since factors other than water availability are more important (chiefly soil pH) in determining microbial diversity, it can be assumed that true desert can be quite rich as well.

Mycorrhizal fungi seem to be quite important in desert ecosystems, as in more mesic ecosystems. It appears that mycorrhizae of desert plants not only supply the plants with nutrients but also supply moisture during the dry season, at times taking the place of root hairs. Studies conducted in the Chihuahuan Desert indicated that most dominant, perennial species have high arbuscular (AM) fungal infection rates in their coarse roots system, while fine-rooted annual species in comparison show much lower infection rates and are also much less dependent on mycorrhizal associations in general. Worth mentioning are mycorrhizal desert truffles (*Terfezia* and *Tirmania*: *Ascomycetes*), that are host specific to *Helianthemum* species in the arid region of the Middle East and the Mediterranean zones of the Old World. The desert of the American West supports an elusive community of aboveground observable fungi in which the *Gasteromycetes* (puffballs and allies) figure predominately. Another common example is *Podaxis psitillaris* (desert shaggy mane), a species most common in sandy deserts.

Except for their crucial part in mycorrhizal associations, desert microorganisms are noteworthy for their role in three typical desert phenomena: desert crusts, desert varnish, and interstitial communities. Desert crusts are microbiotic communities composed of drought and heat-tolerant algae, cyanobacteria, fungi, lichen, and mosses. These often species-rich communities are held together by sticky polysaccharide secretions and thus form surface crusts. Desiccated crusts are often indiscernible until rainfall or dew moistens the surface and microbial communities become active and green. Under extreme conditions, such crusts can form below the surface. This is possible especially under the protection of semitransparent calcareous or siliceous stones (quartz is a good example) that enables transmission of light up to a depth of 5 cm. The most common life form in crusts (and in some areas also in hot deserts in general) is cyanobacteria. Among their roles in the desert ecosystem are atmospheric fixation of nitrogen and the binding of soil particles. Together with mineral-reducing bacteria, the cyanobacteria are important in soil fertilization and soil formation and thereby have clearly important effects on vascular plants and dependent animal consumers. In hot deserts, cyanobacterial crusts often form smooth surfaces, while in cold deserts, where crust forming interacts with frost heaving, a very rough surface is typical. These different surface types clearly affect vascular plants differently.

Even exposed desert rocks can support life. Clearly the most visible organisms are crustose lichens. However, when conditions become too extreme for growth of lichens, bacteria can still survive on the surface of rocks. Desert varnish, the dark and shiny surface found on sun-exposed, porous stones in hot deserts, is the result of bacterial activity. These bacterial colonies obtain energy from inorganic and organic substances and trap submicroscopic, wind-borne clay particles. These particles accumulate in a thin layer and act as sun protection. Over very long time periods, estimated at thousands of years, these bacterial communities oxidize wind-blown manganese and iron particles and when baked together with clay particles form the dark desert varnish. The color of desert varnish varies depending on the relative proportion of oxidized manganese (dark black) to iron (reddish).

Environmental conditions even more extreme than those that support surface bacterial growth can still allow the formation of interstitial communities. These communities consist mostly of algal species that inhabit the matrix of sedimentary rocks in depth up to 4 mm. These communities can stay dormant for long periods of time and inhabit hot and cold deserts alike (they are known to exist on exposed rocks in Antarctica).

Desert Flora

Even though the geological record indicates that arid conditions existed for a long time (since the Devonian), the current modern desert flora might have originated in the Miocene, expanded in the Pliocene (after restrictions during moist periods in the Cretaceous and Tertiary), and reached its current distribution only during the Pleistocene. Specifically, the deserts in the North American Southwest are relatively young. Overall richness and uniqueness of desert floras reflect size, age, and isolation of desert areas, with larger deserts typically hosting larger numbers of endemic species. Smaller desert regions and edges of larger regions are often characterized by species that evolved in adjacent more mesic areas and partially adapted to arid conditions. A good illustration is the high incidence of Mediterranean plants in desert areas bordering regions with semiarid Mediterranean climates in all parts of the world. In general, desert floras tend to have high affinity to bordering semiarid climate zones, such as Mediterranean climate-type regions and semiarid grassland. Taxonomical studies of many species groups revealed that desert species have evolved (recently) from nondesert species. Biogeographically, strong floristic links exist between old deserts in North Africa, Middle East, and Asia. Floristic similarities among desert regions stretching from North Africa to Central Asia are particularly obvious since no wide barriers of ocean or humid vegetation exist to restrict plant migration; these floristic similarities are present despite strong climatic contrasts ranging from hot environments in North Africa to the much colder, arid Central Asia deserts. Apparent links between the North American Great Basin and Central Asian deserts might be explained by plant migration across the Beringian land bridge. Clear affinities between the deserts in both Americas can be explained by the Panamanian land bridge. In this respect, the distribution of Larrea shrubs is remarkable. The two recognized species – *Larrea divaricata* in South America and *L. tridentata* in North America – are taxonomically and phenotypically very close. It appears that the genus *Larrea* evolved in South America and migrated only tens of thousands of years ago (bird assisted?) to North America where it quickly became the dominant shrub in all warmer desert areas. Corresponding to the isolation of the Australian continent, the flora of the Australian desert is very different from all other deserts of the world.

Dominant plant life forms in deserts reflect water stress conditions typical for deserts (for a treatment of drought adaptations see the following section). While trees are relatively rare and restricted to more-mesic microsites, a wide range of plant life forms can be found that include many short-lived and seasonal active plants (e.g., annual or ephemeral plants and bulbous plants/geophytes). The dominant life forms that visually shape the plant formations are perennial woody plants (mostly shrubs) and fleshy succulent plants (cacti and others). Large succulent species can be dominant in some of the hot desert regions (e.g., the saguaro cactus in the Sonoran Desert). A few plant families are predominant in desert areas. The aster family (Asteraceae) is the most diverse plant family in deserts overall; it is especially numerous in Australia, southern Africa, the Middle East, and North America. Some deserts can be dominated by grass species (Poaceae). Some plant families have their global center of diversity in deserts and most likely evolved here. Notable examples are the chenopods (Chenopodiaceae) that are diverse in arid and semiarid regions of Australia, North America, and from the Sahara to Central Asia. The New World cacti (Cactaceae) are another example of a group of species rich in deserts but relatively sparse in other biomes.

Deserts are home to some of physiognomically extremely unusual plant types. Worth mentioning in this respect are plant characters as the Joshua trees of the Mojave Desert (*Yucca brevifolia*), the famous Welwitchia of the Namib (*Welwitchia mirabilis*), and the boojum tree (**Fig. 10**) of the Sonoran Desert in Baja California (*Fouquieria columnaris*). Exactly why and how deserts host these exceptional plant types is not clearly understood and such `Dr. Seussification' of the desert flora deserves systematic study.

Desert Fauna

The faunas of deserts are often biogeographically more distinct between regions than the desert floras are. Despite this, many similarities exist between the different desert regions. Such phylogenetic similarities typical for the African–Asian deserts are explained by the lack of dispersal barriers, and similarities between North American and Asian regions on one hand and North American and South American regions on the other are likely the result of existing land bridges. The Australia desert fauna, as its desert flora, is very distinct. As mentioned earlier on, almost all animal taxa are present in deserts, but some groups are more diverse than others, with the major deciding factor for this being the general aridity.

Relative to other insect groups, ants and termites are very diverse in deserts. However, their species richness is lower than it is in the Wet Tropics, where these groups originated. These groups reach high population densities and ecological importance is high. With up to 150 species per hectare, the highest species richness for ants is found in Australian deserts. Most desert arthropods are either detrivores (termites, beetles, etc.) or granivores (mostly ants), or are predators feeding on these (scorpions, spiders, etc.). Due to the lack of constant

Fig. 10 Boojum trees (*Fouquieria columnaris*) with associated shrubs, agave, and cacti on a bajada in the Sonoran Desert of Baja California. Cataviña region, Mexico, October 1997. Photograph by C. Holzapfel.

plant production, herbivores are relatively sparse or show pronounced, often dramatic temporal–spatial fluctuations (e.g., mass flights of desert locusts). Species rich substone communities consisting of protozoa, nematodes, mites, and other microarthropods are typical for deserts, creating a microcosm where grazers and predators feed on bacteria, algae, fungi, and detritus.

Fishes live in almost every aquatic habitat on the globe and small, permanent desert water sources are no exceptions. Obviously richness is extremely low, but species often live in very restricted areas and often under extreme conditions. The desert pupfishes (*Cyprinodon* sp.) in the deserts of North America are among the most species-rich groups in deserts. Some species live at temperatures of 45 °C and salt regimes 4 times that of seawater, while some species are restricted to an area as small as 20 m^2 (e.g., the Devil's Hole pupfish in Nevada). These fishes are opportunistic omnivores.

Likewise, desert amphibian communities are depauperate since at least the juvenile stages depend on water. Only a small fraction of the world's amphibians, mainly anurans, are able to occupy deserts.

Reptiles are common and widespread in all deserts and, with the exception of crocodilians and amphisbaenians (worm lizards), all orders are represented in deserts. Relatively few tortoises occur in deserts since they are restricted due to their plant diet. Snakes and lizards are well represented (especially in Australia). The extreme high diversity of reptiles in Australian deserts has been explained by low diversity of mammal and birds which resulted in lower competition for food and lesser predation pressure than in other desert regions. It appears that reptiles as endothermic consumers enjoy an advantage over other ectothermic consumers in the deserts of Australia that are characterized by low-quality plant production.

Even though birds have basic adaptation to cope with dry climates, diversity in deserts worldwide is relatively low and a clear positive relationship between rainfall and bird diversity is typical. Despite this, few desert specialist species developed among the avifauna: sand grouse, lark, parrots, etc.

Likewise, mammals are not very diverse in comparison to other biomes, but some taxa evolved to be true desert groups. Among smaller mammals are the heteromyds in North America, the jirds and gerbils in the African–Asian deserts, and the dayurid marsupials in Australia. Some of the desert mammals are rather large and therefore have advantageous low surface-to-volume ratios (see next section). The `flagships' for this are clearly the camel species (Camelidae) that originated in the Americas in the Miocene and are now naturally found in desert regions of the Old and New Worlds; they are clearly the largest animals in all desert regions. It is of significance that most large herbivorous mammals, including camels, donkeys, goats, sheep, and horses, have been domesticated historically in deserts and semiarid regions and are common as domesticated livestock today. Other large, non-domesticated ungulates such as gazelles, ibexes, and oryxes are generally extinct or at least rare and endangered.

Convergence of Desert Life Forms

Most desert plants and animals initially evolved from ancestors in moister habitats, an evolution that occurred mostly independently on each continent. Despite this phylogenetic divergence, a high degree of similarity of body shape and life form exists among the floras and faunas of different desert regions. Since desert environments are defined by their water limitation and have similar landscapes worldwide, it is not surprising that many organisms show convergent evolution and are morphologically and functionally alike. Similar pressures of natural selection have resulted in similar life forms. In fact, many of these analogous species groups became textbook examples of evolutionary convergence:

- Stem and leaf succulence is found in nonrelated plant taxa: cacti in New World, milkweeds and *Euphorbia* species in the Old World (however, this form is lacking in Australia).
- Bipedal locomotion is found in unrelated small rodent groups: jerboa (family Dipodidae) in the Old World, kangaroo rats (family Heteromyidae) in the New World.

- Bipedal locomotion is shared in a few larger mammals: African springhare (genus *Pedetes*), desert-living kangaroos (Macropodidae) in Australia.
- North American horned lizards (genus *Phrynosoma*) and the Australian thorny devil, the unrelated agamid lizard *Moloch horridus*, share similar grotesque spiny body armors. This has been explained as an adaptive suit that facilitates their need of having a large body due to their specialization on ants. Ants as eusocial insects present a clumped however low digestible source of food (formic acid, chitin). Both lizard groups are in need of a larger digestive system and therefore large bodies that in turn makes them slow moving and in need of protection.

Many adaptations that are discussed in the following sections are typical for all desert regions of the world. A combination of these traits creates the `typical' desert life form that to some extent is similar worldwide.

Ecophysiology and Life Strategies

Strategies for Coping with Drought

All life originated in the sea and all organisms that have left their ancestral home depend on an `inner sea', high internal water content. This phylogenetic inheritage restricts life in many habitats, and obviously deserts are among the harshest in this respect. Even though deserts are not only water limited (they are also low in nutrients and energy resources), adaptations to cope with the spatiotemporal scarcity of water are predominant of most (if not all) true desert organisms.

All desert life forms, animals, plants, and microorganisms alike, employ one or more of three basic strategies to cope with the dearth of water: (1) drought evasion, a strategy of avoiding water stress temporarily in inactive states; (2) drought endurance, a suit of adaptations that reduce actual stress and enable being active during drought; and (3) drought resistance, a suit of adaptations evolved to avoid water stress altogether. Note that water and heat stresses are coupled, thus many of the adaptations mentioned below can be understood as strategies to cope with both.

1. Drought-evading organisms `choose' to pass exceedingly dry periods in dormant stages. Predominant examples are short-lived (ephemeral) plants that survive the dry season or longer periods of drought in the dormant seed stage. Such annual plants are indeed very common in many deserts of the world and compose a large portion of the plant diversity in many areas (up to 80% of species richness). An equivalent for animals can be found in cryptobiosis of invertebrate eggs and larvae. Such aridopassivity can be found in fully developed organisms as well; examples are bulbous geophytes and desert animals that pass dry season belowground inactive (estivation). Choosing of less arid microsites is another way of avoiding drought. In animals, these are typically behavioral space choices (e.g., permanent habitation or temporary use of stress-protected microsites: below shrubs or stones, rock fissures, litter, below tree and shrub canopies, or even soaring in high air). Likewise, many plants are restricted to favorable microsites (e.g., under tree and shrub canopies, runon microsites, algae growing under stones). Some organisms, mostly plants, are able to lose water almost completely and `resurrect' once water becomes available again (poikilohydry: *Selaginella* species, algae, lichens, and moss species).
2. Drought endurance is a main strategy common among the dominant desert organisms worldwide. A suit of ecophysiological, morphological, and behavioral adaptations work together to reduce the most detrimental impacts of water stress.
   Reducing water expenditure. Evergreen desert shrubs are capable of fine-tuned regulation of stomatal movement. Specialized photosynthetic pathways evolved in desert plants that minimize water loss and maximize carboxylation. C_4 and crassulacean acid metabolism (CAM) pathways are adaptations to hot temperatures, compared to the C_3 pathway adapted to colder conditions. Animals of arid regions are able to regulate and restrict water loss by concentrating urine. Birds and reptiles excrete urinary waste as uric acid that can be concentrated and allow reabsorption of water in the urinary tract, a trait not available to mammals. Desert mammals and most other taxa excrete dry feces and reduce the urine flow rate. Water loss through surfaces is reduced in plants through an increase in thick lipid cuticulae, epidermal hair cover, sunken stomata, small surface/volume ratio (leafless plants with photosynthesizing stems – xenomorphic). Animals employ a variety of adaptations that reduce water loss: impermeable integuments (e.g., in arthropods), changes of lipid structure in the epidermis that create diffusion barriers to water vapor (some desert birds), denser hair or feather cover, and small surface-to-volume ratios (common in large mammals).
   Prevention of overheating. High-temperature stress is closely connected to water stress as many of the ways of coping with higher temperatures involve expenditure of water, thereby exacerbating water stress. Examples are transpiration cooling in plants and evaporative cooling in animals (including humans; see below). Desert organisms typically have high heat tolerance and capability to function at high temperatures. The comparatively high-temperature optima and temperature compensation points of photosynthesis in plants and high body temperatures and high lethal temperatures in animals attest that. Among the most thermotolerant species are desert-dwelling ants that forage on extremely hot surfaces. A Saharan desert ant species (*Cataglyphis bicolor*) is noted to hold the record with a critical thermal maximum of $55 \pm 1\ ^{\circ}C$.

Apart from tolerating high temperatures, an array of mechanisms evolved to decrease or dissipate heat loads both in plant and animals. The formation of sheltering boundary layers, employment of insulating structures, and increase of reflection (white color, glossiness) are among these mechanisms. Behavioral space and temporal choices are a contribution to the prevention of overheating. Seeking of sheltered microhabitats and nocturnal activity of many (if not most) desert animals are obvious examples. The nocturnal CO_2 uptake in CAM plants is an interesting analog to this.

3. Drought-resisting organisms employ adaptations that allow them to pass dry periods in an active state without experiencing physiological water stress. The succulence of many typical desert plants worldwide is a form of water storage that enables these plants to use water during dry periods. Examples for taxa that are rich in succulent species are the cacti (Cactaceae) and yuccas (Agavaeae) in the New World and some members of Euphorbiacea and Crassulaceae in the Old World. Succulent plants typically cannot become dormant and therefore require at least periodically predictable precipitation, a requirement that explains the general lack of succulent plants in extreme arid environments where prolonged droughts are common. Most succulent plants have fairly shallow root systems that react very quickly following larger rainfall events. An analog to plant succulence in animals can be found in desert snails that can store large amount of water. The ability of desert mammals (notably the camel) to store large amount of water in the blood is another analogous trait. The accumulation of fat tissue that can be metabolically transformed into water (see below) as a water storage mechanism is somewhat controversial and is more universally understood as being merely an energy source (e.g., fat reserves in desert reptile tails, body of rodents, and the famous camel's hump).

Water Uptake in Deserts

Animals

Vertebrates are able to obtain water from three sources: (1) free water, (2) moisture contained in food, and (3) metabolic water formed during the process of cellular respiration. Some are able to receive water from all three sources, while others are able to exploit only one or two methods. Highly mobile animals tend to be restricted to the use of open water sources that are often sparse and far between. Typical examples are desert birds that fly in regular intervals to the few bodies of water available. To mention are the desert-adapted orders of sand grouse (Pteroclidiformes) and some doves (Columbiformes) that tend to visit standing water in large flocks at dawn and/or dusk. The former are even known to transport water soaked in their specialized belly feathers to their flightless chicks. Many desert animals are able to use available water opportunistically by drinking large quantities in short time. This ability is proverbial in the camel that can take up to 30% of its body weight in a few minutes. Camels and other desert mammals have resistant blood cells that can withstand osmotic imbalance. Animals living in more mesic environments (including humans) would destroy their red blood cell at such high water content in their blood. Much of the free available water has high salinity, and so it is not a surprise that many desert animals show high salt tolerance, for instance by employing salt-excreting glands. Other animals, mostly the ones that are restricted in their mobility (e.g., mammals, reptiles, and insects), rely on water obtained from their food. Carnivorous and insectivorous animals typically receive enough water from their prey. Herbivores do so as well, as long as the moisture content of the consumed plant material is relatively high ($>$ 15% of fresh weight: fresh shoots and leaves, fruits, and berries). The ultimate desert-adapted method however is the extraction of metabolic water. Especially seed-eating (granivorous) animals are able to metabolically oxidize fat, carbohydrate, or protein. Rodents and some groups of desert birds (e.g., larks, Old World and New World sparrows) are able to convert these energy sources into water: 1 g of fat produces 1.1 g of water, 1 g of protein produces 0.4 g of water, and 1 g of carbohydrates produces 0.6 g of water. Schmidt-Nielson has shown that kangaroo rats (genus *Dipodomys*) are able to obtain 90% of their water balance from metabolic water derived from consumed seeds. The remaining 10% is obtained from moisture stored in seeds. The use of already stored body fat as source of water is controversial. It has been argued that metabolizing fat and other storage sources into water requires increased ventilation and therefore increases water loss by transpiration from lung tissue. At the most, no net gain of water will be the result. According to this, the camel's hump might function simply as a fat energy storage facility, one that is situated in one place in order to reduce isolation and allow dissipation of heat.

In areas with high humidity, animals are able to receive water from dew. Such direct uptake as the main source of water is probably restricted to arthropods and some mollusks (snails). There is some evidence that rodents can utilize condensation by water enrichment of stored food (**Fig. 11**).

Fig. 11 Desert sand rat (*Psammomys obesus*). As the scientific name implies, this day-active desert rodent can store large amounts of body fat as reserves during unproductive seasons. Like other desert rodents, it obtains all of its needed water through its plant diet. Negev Desert, Mitzpe Ramon, Israel, May 2003. Photograph by C. Holzapfel.

Plants (and microorganisms)

Plants, with few exceptions, depend on water uptake by their roots from the soil. Due to low soil matrix water potentials and high salinity in arid regions, such soil water is often not readily available. One way for desert plants to overcome this restriction physiologically is to osmoregulate the plant cell water potentials to overcome the low potentials of desert soils, a mechanism that also aids them in extracting water from saline solutions. Indeed, some of the lowest water potentials have been measured in desert shrubs (-8 to -16 MPa (mesic plants rarely go below -2 to -3 MPa)) and salt-tolerant (halophytes) desert perennials (as low as -9 MPa). In general, many desert plants tend be deep rooted and are therefore able to exploit water reserves that tend to be available in the deeper soil layers. Due to the need of desert plants to forage extensively for water, root-to-shoot ratio of desert plants is typically high and rooting depths are larger than in other ecosystems. In extreme cases, as in phreatopytes, rooting depth can exceed 50 m. This was found for mesquite trees (genus *Prosopis*) that are practically independent from local precipitation and are able to maintain very high transpiration rates for prolonged periods. In contrast and as mentioned before, many succulent plants that store water in their tissues tend to be shallowly rooted and are able to intercept even light summer rains that do not cause a deeper recharge of soils and would otherwise be lost to evaporation. Annual plants and most grasses also benefit from being shallowly rooted. In general, many desert plants can react quickly to available water by deploying fast-growing `water roots' from special dormant root meristems. Shallow rooting plants show temporally intensive water exploitation patterns while plants with deeper root systems are characterized by spatially extensive water exploitation patterns.

Some deep-rooted perennial plants exhibit hydraulic redistribution from deeper soils to shallow soils. Water is absorbed from the soil at greater depth during the day and moves via the transpiration stream upward into shallower roots and the aboveground parts of the plant. At night when the air is more humid and plant stomata are closed, plants become often fully hydrated and water may be exuded from the root into the dry shallow soil. This pattern, described as hydraulic lift, may have nutritional benefits for the perennial plant itself, as it enables it to utilize the nutrients from what would have otherwise been dry soil. Released water – on the other hand – might become available for competing plants. Hydraulic lift has been described in almost all of the dominant shrubs of the arid Western US (e.g., *Artemisia tridentata*, *Larrea tridentata*, *Ambrosia dumosa*) and might be prevalent all over the world's arid zones.

Plants of saline habitats, halophytes, must be able to acquire water with high salt concentrations. They need to overcome the high osmotic pressure of saline solutions and need to avoid the potential toxicity of some ions (Na^+, Cl^-). In order to achieve such a high salt tolerance, halophytes employ strategies as osmoregulation, dilution of inner cell salt concentration by succulence, and use specialized salt-excreting glands.

Special water-rich habitats within deserts, for instance, permanent stream sides and springs, attract extrazonal plants that often possess only few aridity adaptations. Found in these oases are wetland plants and some salt-tolerant tree species that can be characterized as `water spenders'. Good examples are palm trees (the date palm *Phoenix dactylifera* and the Californian palm *Washingtonia filifera*) and salt cedars (*Tamarix* species).

Direct uptake of condensed atmospheric water (dew and fog) and water vapor is generally possible only for some specialized poikilohydrous vascular plants, but is of much greater importance for microbiotic organisms such as lichens and cyanobacteria.

Strategies to Cope with Unpredictable Water Resources

A wealth of adaptations arose in desert organisms that allows them to utilize the pronounced spatiotemporal stochasticity of water availability typical to deserts. As detailed before, mobile organisms are able to use spatially patchy water sources that are not available to less-mobile organisms. These sessile organisms often have dormant dispersal units that can reach good microsites where they can establish, reproduce, and eventually send their own diaspores onto other favorable microsites. Such life cycles are typical for short-lived plants (annuals, ephemerals) and some invertebrates. These diaspores typically remain viable for long periods and can `sit and wait' for years with sufficient precipitation. Most annual desert plants form such extensive seed banks. Seeds within such seed banks tend not to germinate equally and even after strong precipitation events, a fraction of the seed will remain dormant. Such fractional dormancy might serve as avoidance of sibling competition as it will reduce densities, but more importantly has been explained as a bet-hedging adaptation in order to cope with rainfall stochasticity. When no supplemental rainfall follows an initial germination triggered by a rainfall event, at least a fraction of the seeds will be available in the following years, thereby ensuring the long-term survival of the population. In addition to dormancy, many desert plants develop some water-sensing adaptation (so called `water clocks') that controls both dispersal and germination. Dry inflorescences of the famous rose of Jericho (*Anastatica hierochuntica*) and other annual plants (e.g., the New World *Chorizanthe rigida*) open up only after abundant rainfall and release only some of their seeds (**Fig. 12**). Many desert plants have morphologically different seeds that differ in dispersal ability and have different germination requirements (amphicarpic plants). In general, a high proportion of desert plants suppress seed dispersal altogether (atelechory). This has been interpreted as an adaptation to remain on the mother site, as it has already been proved to be a favorable location.

Most perennial plants suppress flowering (aridopassive shrubs) or sprouting altogether (e.g., geophytes) in drought years. This is analogous to many desert animals that shift sexual maturity and mating to synchronize with favorable conditions. Similar to plants, sterility is typical for extreme drought years and dispersal and migration (nomadism) are triggered by precipitation regimes. There is some indication that insects and desert shrubs can shift their sex expression with changing rainfall regimes. Especially, monoecious shrubs, plants that have male and female reproductive units on the same individual, can shift their sex ratio with water availability. The male function requires fewer resources from the plant (`cheaper sex'), and is typically the predominant sex in dry years.

Fig. 12 Dry dead plant of the rose of Jericho (*Anastatica hierochuntica* – mustard family Brassicaceae). Seed pods of this annual plant are contained within curled branches forming a ball that opens when moistened and seeds are released only after rainfall events. Dead Sea region, Israel, March 1987. Photograph by C. Holzapfel.

Many desert shrubs tend to break apart into separate shoot sections over time (axial disintegration). This so-called `clonal splitting' is very common for desert shrubs worldwide and has been explained as a risk-spreading adaptation. In time of severe drought, instead of the death of the whole original individual, some segments of the original shrub may survive. The consequence of this growth strategy is often the formation of shrub rings that grow outward and have a dieback zone in the center. Age estimations have been made based on this growth form. Large creosote bush (*Larrea tridentata*) rings in the Mojave Desert, for instance, have been determined to be of an age exceeding 11 000 years (e.g., the famous `King Clone' located by Vasek in 1980).

System Ecology (Ecosystem and Communities)

The leading question in desert ecology is whether aridity alone can explain all aspects of biological systems. If so, desert environments could be understood simply by characterizing the harsh, abiotic environmental factors that prevail in desert systems. Thus, desert systems do not follow the typical ecosystem view and can be described as simplified systems that react to discrete rain events (triggers) by short-term growth production (pulse), interspersed by long-term storage of organic material (seeds, roots, and stems – reserves). This pulse–reserve conceptual desert model is clearly too simplistic; however, it provides an important framework for the description of major ecological components of deserts.

In contrast to this basic view of deserts, two major alternative hypotheses have been developed in regard to the driving factors defining communities and populations in deserts. One hypothesis states that only the primary producers are water limited and all other trophic levels (consumers) are determined by the magnitude of this water-dependent primary production. Another hypothesis postulates that water shortage affects organisms only individually and has no direct effect on higher-order species interactions. According to this view, aridity effects on ecosystems and communities are rather the indirect outcomes of direct physiological and behavioral responses of individual organisms (and their populations) to scarcity of water. Despite the fact that the temporal and spatial lack of water is clearly the driving force behind the individual ecologies of desert species, current research makes it clear that species interactions, including both negative and positive ones, can be strong in deserts. The following sections strive to provide a brief summary of the types of interactions typical to deserts.

Production

Net annual primary production (NPP) is lower in deserts than in most major biomes. However, when taking into account that deserts typically are also characterized by low amounts of permanent plant mass (standing phytomass), relative primary production (the ratio of NPP/standing phytomass) is among the highest worldwide (see **Table 2**). As rainfall fluctuates strongly within and between years, it is no wonder that there is a tremendous spatiotemporal variation in the amount of primary production. However, due to the lack of responsive vegetation structure and typically low levels of soil fertility, deserts are somewhat limited in their biological potential to react to extremely wet years. Semiarid grasslands, rich in very plastic perennial plant structures and therefore exhibiting high potential growth rates, show much larger fluctuations in response to changing water availability (**Fig. 13**). Also water-use efficiency (NPP divided by annual water loss) in deserts is lower than it is in dry grasslands (0.1–0.3 g per 1000 g water in deserts compared to up to 0.7 g in dry grasslands and 1.8 g in forests).

During brief periods when water is available in excess, the typically short supply of nitrogen (and other plant macronutrients) is limiting. Even though nitrogen is limiting in almost all terrestrial ecosystems, deserts are typically more limited due to four reasons: (1) plant growth is triggered by available water faster than nutrients can be replenished by decomposition; (2) desert soils

Table 2 Phytomass and primary production of deserts in comparison to some other major biomes of the world[a]

Plant formation	*Phytomass of mature stands (t ha^{-1})*	*Net annual primary production (t ha^{-1} yr^{-1})*	*Relative primary production*
Tropical forests	60–800	10–50	0.004–0.05
Deciduous forest	370–450	12–20	0.03–0.06
Boreal forest	60–400	2–20	0.03–0.05
Savanna	20–150	2–20	0.1–0.14
Temperate grassland	20–50	1.5–15	0.08–0.3
Tundra	1–30	0.7–4	0.09–0.1
Deserts	1–4.5	0.5–1.5	0.33–0.5

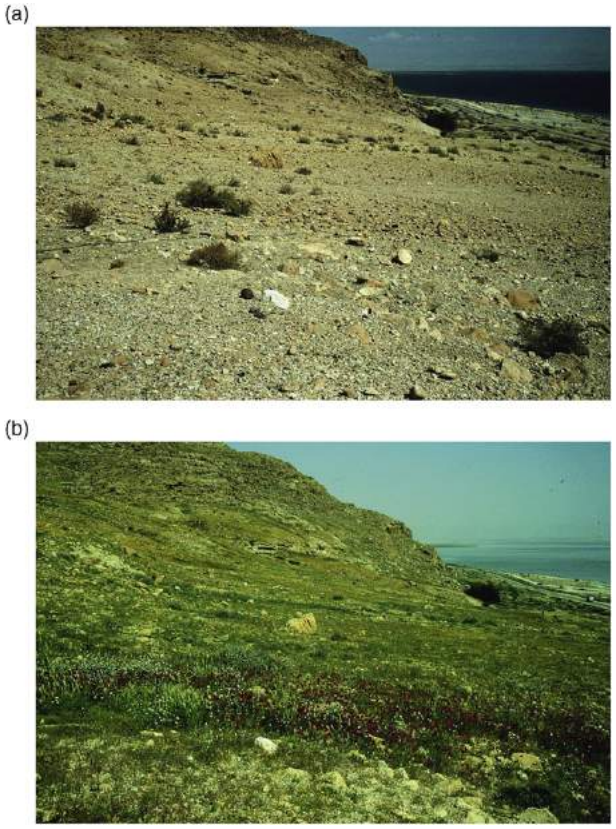

Fig. 13 Extreme, 30-fold differences of plant growth on a rocky desert slope during (a) a dry (precipitation 40 mm, NPP 0.03 t ha^{-1} yr^{-1}) and (b) an extremely wet year (193 mm, 0.87 t ha^{-1} yr^{-1}). Northern Dead Sea, Palestine, March 1991 and March 1992. Photographs by C. Holzapfel.

typically have little nutrient-holding capacities; (3) the nutrient-rich organic matter is located in the upper layers of soils, a layer that is typically too dry for root growth to occur, rendering the nutrients inaccessible; and (4) detritus and other organic material is deposited and accumulated unevenly across the desert surface. Plant debris typically accumulates passively under the canopy of shrubs or is concentrated in nests of animals such as harvester ants and termites. Thus the desert is an `infertile sea' with interspersed islands of fertility.

Resource–Consumer Relationships (Trophic Interactions)

In contrast to some ecosystems, food chains in deserts can be characterized by the importance of the link between producers and consumers via decomposition. Less than in most mesic environments, plant material is typically not directly consumed alive; some estimation puts the amount of energy that moves via decomposition into the food web as above 90% of total primary production. Since food resources are unpredictable, many animals can opportunistically switch from one mode of consumption to another (e.g., many arthropods are either herbivores or decomposers).

Decomposition

Microbial decomposition is often limited by low water availability, resulting in the accumulation of dry plant material and seeds. For that reason, animal detrivores are more important in deserts than in more mesic environments. Examples are darkling beetles, termites, and isopods. Termites are abundant in most of the warmer deserts and are often the dominant decomposers of dead plant material (above- and belowground) that play an extraordinarily important role in nutrient cycling. Since most termites live belowground, they are also important in the formation of soils. A similar phenomenon is displayed by scavenging animals, which are comparatively abundant among the desert fauna. Examples are large mammals (hyenas, coyotes, and jackals) and many birds (Old World and New World vultures, ravens, etc.). Like smaller detrivores in the desert fauna, many of these scavengers can switch to a predatory diet when needed.

Herbivory

Similar to other ecosystems, deserts host a large variety of herbivorous animals that potentially utilize every part of the plants. Some of the drought adaptations of plants, discussed before, also function to deter herbivores. Tough outer layers, spines, and elevated leaf chemicals, all typical for desert plants, can therefore also be understood as mechanisms to protect low and therefore costly primary production. Some plants appear to employ growth forms that make them less conspicuous for herbivores. Remarkable examples are the living stones (*Lithops* species, Aizoaceae) of South Africa that blend with the surrounding rocky desert pavement.

Predation

Abundant detrivorous arthropods are the most important prey source in the desert and provide the base for a relatively large assembly of smaller (e.g., spiders, scorpions) and larger predatory animals (e.g., reptiles, birds). The abundance of long-term stored seeds and fruits in desert systems supports an assembly of a diverse guild of granivores (seed predators). These granivores are recruited from taxonomically much differentiated groups (e.g., ants, birds, rodents), all of them potentially competing for similar food sources. Carnivorous predators can be abundant as well. These predators are mammals, birds, and reptiles (mostly snakes). Because of the relative openness of the desert terrain, prey organisms rely on a number of predator avoidance strategies. Examples are general crypsis (camouflage), `freezing behaviors', and nocturnal activity pattern. Active deterrents are spines (desert hedgehogs, horned lizards), hard shells (desert tortoise), and poisons that can be employed in active predation as well. Strong predator pressure combined with the need for efficient predation in a desert environment poor in prey might be the reason that some of the most poisonous animals we know (e.g., snakes, scorpions, Gila monster) are true desert animals.

Parasitism

Parasitic interactions are often very conspicuous in desert environments. Many desert shrubs show abundant signs of an attack by gall-forming insects. For instance, *Larrea tridentata*, the dominant shrub in all the hot deserts of North America, is attacked by 16 specialized species of gall-forming insects. Parasitic plants, stem and root parasites alike, are common in deserts worldwide. Though detailed studies are lacking, these parasites seem to have the potential of reducing host plant production and performance (Fig. 14).

Nontrophic Species Interactions

Competition among and within species has been recognized as an important force that shaped the communities in all mesic environments and the question whether this is also true for deserts is a natural one, however one that has not been answered univocally. Some researchers conclude that biomass production and densities in desert are typically below a threshold that would

Fig. 14 Heavy infestation of a desert shrub (*Ambrosia dumosa*) by an epiphytic parasite (*Cuscuta* sp.). Parasitic plants can be common in deserts and their effects can add to the abiotic stresses of aridity. Panamint Valley, California, USA, April 1995. Photograph by C. Holzapfel.

necessitate competition for resources. Observing the same density pattern, other researchers state that because such low densities indicate strong resource limitation in desert, strong competition should ensue.

Based on studies of spatial plant community structure, it appears that current competition in deserts is rare; most studies show clumped or neutral patterns – itself a sign of the lack of competition – while only few studies show a clear regular pattern (a sign of past competition). Experimental removal of individual plants in the Mojave Desert, on the other hand, demonstrated interspecific competition among dominant desert shrubs. Spatial studies that assess the size distributions in dependence of distance between desert shrubs typically detect signs of negative association; larger shrubs tend to be spaced farther from each other than smaller ones. Removal experiments with granivorous rodents commonly result in density increase of the remaining species, thereby indicating current competition. The fact that character displacement, the evolution of divergent body features in coexisting species, has been demonstrated for desert rodents is another sign that competition has been of importance at least at one time.

Ecological theory predicts that negative interactions (such as resource competition) decrease in importance with increasing abiotic stress, and positive interactions (such as facilitation) increase. Following this, it should be possible to observe along a mesic to arid gradient a waning of competitive interaction and an increase of facilitative interactions. Indeed, a clear indication of this has been observed in a survey of positive effects among plants that resulted in a proportionally large number of cases from arid regions. In many deserts of the world, one can easily observe the positive association of either young perennials with adult perennials or herbaceous plants with larger perennial plants. Experimentally, it had been shown that the perennials had net positive effect on the smaller sheltered plants. Examples for these so-called `nurse plant effects' are the associations of young succulent plants (often cacti), trees, and shrubs and the prevalent, close association of annual plants with desert shrubs. Typically the larger nurse plant provides canopy shading and increased soil fertility (see above discussion on islands of fertility), and sometimes protection from herbivorous animals to the sheltered plants. In accordance with this prediction, shrub–annual associations tend to be strongly positive in arid sites and less so (or even negative) in less arid sites (**Fig. 15**). As nothing ever in nature is one-sided, these unidirectional facilitative effects are countered by negative effects as the nursed plants can have negative, competitive effects on their benefactor. Competition for water has been shown between annuals and sheltering shrubs and such negative effects are typical once sheltered young succulents outgrow the nurse plant.

Tradeoffs in competitive/facilitative interactions are also found between taxonomically very distant groups. One example is the complex nature of interaction between microbial crusts and vascular plants. For one, these crusts can have very contrasting effects on seed placement. Cold deserts tend to have very rough crust surfaces that facilitate seed deposition and establishment, while the smooth crusts typical to hot deserts decrease such seed entrapment. Because of these differences, no general effect of desert crusts on the performance of vascular plants has been recognized. Nitrogen fixation by cyanobacteria increases nitrogen availability, thereby favoring plant growth; however, the creation of crusts can result in runoff and water redistribution that in turn locally reduces plant performance.

Human Ecology

Origin and History

Humans have lived at the edge of desert and in the desert proper for ever and there are some indications that modern *Homo sapiens* evolved when the world climate turned to be more arid at the end of the Pleistocene. Though lacking many of the physical adaptations of true desert dwellers, we humans might be a desert species after all. One of the adaptations humans bring to live in the desert is a rather high heat tolerance. The combination of upright position that minimizes direct sun exposition during hottest times of the day, the profusion of sweat glands all over the body, and the lack of body hair, together with an energetically

Fig. 15 Clear associations of annual plants with shrubs (here *Ambrosia dumosa*) are common in deserts. Annual plants benefit from nutrient enrichment and shade provided by the shrub canopy and since they usually only provide little benefit to the shrub (e.g., thatch-induced increase in water infiltration and lower soil surface evaporation), they can compete with the shrub for resources. Owens Valley, California, USA, March 1997. Photograph by C. Holzapfel.

conservative way of movements, contributes to our ability to cope with hot deserts. As long as water and salt balances are maintained, humans can perform relatively well under heat stress. This is evidenced by the success of persistence-hunting practices in desert and semideserts, which involves tracking large ungulate prey on foot during midday heat. Such persistence hunting, today only employed by hunter-gatherers in the Kalahari Desert, has been the most successful mode of hunting prior to the domestication of dogs, and uses the relative heat balance advance that a well-hydrated and trained human can have over animal quadrupeds. Recent data show that contemporary hunters run for 2–5 h over distances of 15–35 km at temperatures of 39–42 °C until prey items (mostly antelopes) overheat and can be overcome.

Deserts have been important throughout human history and the first civilizations arose in or close to deserts (Mesopotamia and Egypt). Agriculture practices, often involving irrigation, are sometimes interpreted as cultural ways to deal with the stochasticity of the desert climate. It is interesting to note that the first written law, the codex written by the Babylonian King Hammurabi dating back to 1750 BC, was designed to manage such crucial irrigation systems. It is basically the same set of laws that gave rise to our modern laws. Since ancient history, deserts have been the cradle of great civilizations on one hand and the theater of fierce armed conflict on the other (Fig. 16). One wonders whether the nuclear weapons tests that have been conducted in the deserts of New Mexico and Nevada (among other desert sites worldwide) symbolize that deserts can foster both the beginning and the end of civilization.

Desert Economy

For humans, there are traditionally only three basic ways to sustain themselves in deserts: hunting-gathering, pastoralism, and to some extent agriculture.

Ever since the rise of agriculture in the Neolithic era, foraging as the exclusive mode of production (hunter-gatherers) became limited to areas that were marginal to agriculture or animal husbandry. Naturally deserts are among these zones. Examples of peoples who foraged as hunter-gatherers are the aborigines in Australian deserts (this practice receded since the European discovery of the continent), and the !Kung (bushmen) of the Kalahari, who remain foragers in our times. Recent research on the !Kung people showed that hunting-gathering is a suitable lifestyle that can sustain healthy populations that are even able to spend sufficient leisure time, all this as long as population densities are low. Some Amerindian people employed hunting-gathering in deserts as well. There are some evidences that a later immigration wave of people, the Nadene, linguistically distinct from the first Clovis people, were culturally better adapted to harsh environments and settled first in semiarid grasslands and eventually in deserts (the Navajo and Apache might be the descendents of the Nadene).

Pastoralism is a true desert activity that is also typical for semiarid grasslands. It is obvious that many of the livestock animals that were and are herded by pastoralists originated from arid and semiarid areas and therefore are well adapted to such environments. The ancestors of horses, sheep, and goats evolved in semiarid environments and donkeys and camels in arid environments. People who live as pastoralists in deserts often combine animal husbandry with some scale of horticulture; this combination is called transhumance. In order to use the stochastic desert environment optimally, many pastoralists have to follow rainfall events and are partly or truly nomadic, as is exemplified by the traditional lifestyle of the Bedouin of the Arabian Peninsula (Fig. 17).

The use of agriculture most likely did not evolve in the desert proper, but it has to be mentioned that the first cultured plants, annual grasses, and legumes were domesticated near the edge of the desert in the Middle East (10 000–8000 BC Natufian culture). Independently, in likewise semiarid areas in Mexico (Tehuacan Valley, before 7200 BC), the domestication of Teosinte into corn (*Zea mays*) took place. Deserts harbored in historical times small-scale horticulture near springs and elaborately designed irrigation systems that utilized the effects of runoff and water redistribution. Water-harvesting systems in runoff farms have been found and

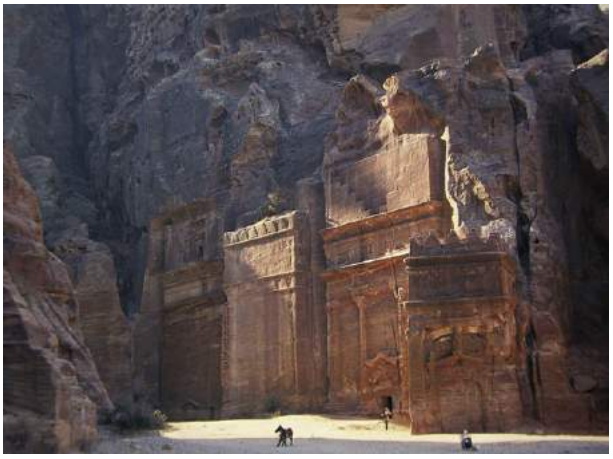

Fig. 16 Many ancient sites thrived near or in deserts. The former Nabatean capital Petra is located in a desert valley surrounded by steep mountains. From here the Nabateans, an Arabic tribe, controlled the trade through the deserts of the Middle East. Petra, Jordan, October 2003. Photograph by C. Holzapfel.

Fig. 17 The nomadic lifestyle is a cultural adaptation of desert-dwelling people to the unpredictability of the desert environment. As still seen here in the Sahara Desert, traditionally camels were essential for transport between grazing areas and arable oases. Douz, Southern Tunisia, March 1986. Photograph by C. Holzapfel.

partly recreated in the Negev Desert (e.g., the Nabatean system in Avdat and Shifta) and in the arid southwest of North America. Large-scale agricultural enterprises depend on permanent water courses. As along the Nile in Egypt and along the Tigris and Euphrates in Mesopotamia, these water sources originated from areas far beyond the desert region. Modern, often large-scale irrigation projects are mostly independent from surface water and use deeper aquifers.

In history, many large cities were established in desert areas (Egypt, Middle East, South America) and there are many cites in deserts in our times (Phoenix, Tucson, Las Vegas). Incidentally, the climate and ecology of urban areas even in the temperate, nonarid zones has many similarities to true deserts (e.g., water limitation due to surface sealing and runoff, high temperatures, etc.).

Human Impact on Deserts

As all ecosystems with low productivity, deserts are fragile to disturbance. Some ecologists go as far as to state that no direct succession occurs at all after disturbance but it is at least obvious that regeneration times after perturbations can be very long. The few long-term studies following disturbance, as for instance the vegetation recovery of ghost towns in the American West, demonstrate these long recovery times that often exceed many decades. It can be generalized that any human impact that changes the soil structure will last very long. Unlike in mesic environments, abandoned agricultural fields in deserts will recover only very slowly (if at all) to natural desert vegetation. Additionally, formerly irrigated fields will have elevated salt concentrations for long periods of time. Soil surface disturbance caused by off-road vehicles inflict severe changes in hydrological characteristics of soils, which might remain permanently. The increase in off-road vehicles in the North American deserts, and increasingly also in the Middle East, is a serious threat to deserts and desert biotas.

Desertification, largely the human-caused extension of the desert, is one the most serious problems facing the globe. Causes of the growth of the desert regions are multifaceted and are a combination of natural long-term variation in the weather, climate destabilization, and human mismanagement due to overpopulation and land-use change. Under the UN Convention to Combat Desertification, desertification is defined as land degradation in arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities. The effects of desertification promote poverty among rural people, and by placing stronger pressure on natural resources, such poverty tends to reinforce existing trends toward desertification. It is now clear that in several regions, desert environments are expanding. This process includes general land degradation in arid, semiarid, and also in dry and subhumid areas. Clearly in areas where the vegetation is already under stress from natural or anthropogenic factors, periods of drier-than-average weather may cause degradation of the vegetation. If such pressures are maintained, soil loss and irreversible change in the ecosystem may ensue, so that areas that were formerly savanna or scrubland vegetation are reduced to human-made desert. To counter this process that will increasingly endanger lives and livelihood of millions of people (not to speak of drastic effects on the biodiversity of the planet), synoptic management approaches are needed that combine understanding of the process and investigation into the regional causes of the process, in order to comprehend the effects on the Earth's overall system. It is important to emphasize that desert border areas that undergo desertification will not simply convert into natural deserts. Disturbed and overused semiarid zones are characterized by lower biodiversity than original, natural deserts. Therefore desertification will not simply increase the global area of deserts; it will create large tracts of devastated lands.

Human activity and human-caused climate change will facilitate the migration of ruderal (disturbance-adapted) plant species into locally favorable microsites within the desert. This has been shown for the vegetation along roadsides in the Middle East and in the North American southwest. Even though this might enhance local, small-scale species richness, an overall reduction in regional diversity and a loss of desert-adapted species might follow. Such a strong mixing of former distinct biotic zones has been observed along the edges of deserts in the context of human-caused disturbances and climate change. A wide variety of `extrazonal'

Fig. 18 Many larger desert animals became extinct in the wild due to hunting pressure. These captive Arabian oryx (*Oryx leucoryx*) are part of a breeding effort that led to release operations into formerly occupied desert ranges (Oman, Bahrain, Jordan, Saudi Arabia). Wadi Araba, Israel, May 2003. Photograph by C. Holzapfel.

plants are crossing zonal borderlines, a process that will potentially lead to a marked decrease in large-scale species diversity. This migration by species that are native to the general geographic area but are now spreading into new climatic or biogeographic zones is an overlooked aspect of species invasion.

Due to typically strong abiotic stress, desert areas have been in the past remarkably resistant to invasions by non-native organisms. Notable exceptions have been biological invasions by deliberately introduced organisms in Australian deserts (e.g., rabbits and *Opuntia* species). However, invasion seems to increase rapidly worldwide and many desert areas today show a dramatic increase in the arrival and spread of non-native species. At present, the deserts of the American South West seem to be affected most. Plants originated from the Old World, mostly grasses (e.g., annual *Bromus* species, some perennial grasses), but increasingly members of other plant families also have invaded many desert communities and can have strong impacts on native desert communities. Among the detrimental effects are dramatic changes in fire regimes and direct competition with recruiting shrub seedlings and native annual plants, and even negative effects on adult desert perennials have been demonstrated. The main reason for these trends is due to general land-use changes in desert and desert margins. In the Southwestern US, disturbances due to increasing suburbanization of deserts, besides increases in nutrient depositions, seem to be central agents of these changes.

Endangered Species

Many of the larger vertebrate desert species are threatened and a number of species have been lost to global extinction. The openness of the desert habitat and naturally small population size makes large mammals and birds conspicuous and thus very vulnerable to overhunting. Threatened species include the central Asian wild Bactrian camel (*Camelus bactrianus*), the onager (*Equus hemionus*; a wild ass of southwestern and central Asia), and large antelope species as the addax (*Addax nasomaculatus*) of North Africa and the Arabian oryx (*Oryx leucoryx*; **Fig. 18**). Hunting is also the main reason that larger birds are endangered. Among birds many bustard species are threatened (e.g., the houbara, *Chlamydotis* sp.) or are already extinct (e.g., the Arabian subspecies of the ostrich: *Struthio camelus syriacus*). Large predators have been and continue to be extensively hunted since they are perceived to be a threat to livestock (e.g., desert subspecies of the Old World leopards, *Panthera pardus jarvisi*). International efforts to save many of the larger endangered animals are currently ongoing; many of these efforts involve reintroductions.

Invasive species can have detrimental effect on threatened species as well. An example is the increased fire frequency caused by annual, non-native grasses, which is threatening populations of the desert tortoise (*Gopherus agassizii*) in the deserts of North America.

Desert Research

One of the major attractions of desert ecosystems for scientists lies in their simplicity. Spatial patterns of life are often visible and clear cut and ecologists tend to feel empowered by the sense of ecological understanding. As any desert scholar will have to attest though, this simplicity is only relative. In comparison to more complex systems, deserts seem to invite ecological questions with greater ease than for instance tropical rainforests would. Therefore much of basic ecological knowledge has been founded in desert research and these dry places more often than not were used as simplified models for the green and (forbiddingly) complex world. Thus it is no wonder that the desert has spawned many research efforts, notably among them large, coordinated ecological research enterprises. The permanent research sites established worldwide during the International Biological Program (IBP) are good examples; in the US, many of these continue to be monitored under the Long Term Ecological Research (LTER) program.

Dunes

P Moreno-Casasola, Institute of Ecology AC, Xalapa, Mexico

Published by Elsevier B.V.

Introduction

Coastal beaches and dunes have a worldwide distribution. They are common in both temperate and humid tropical areas, in arid climates, and in regions covered by snow during the winter. Beaches and dunes are considered two of the most dynamic systems. They are not permanent structures, but rather huge sand deposits that move and have an episodic supply of sand.

They can be found in deserts as well as on dissipative coasts with a plentiful supply of sediments and where there are strong onshore winds or winds that are parallel to the coastline. Sand dunes are eolian bedforms and beaches are marine geomorphic structures. Dunes form from marine sand delivered to the beach from the near-shore by waves. The exposed sediment is dried by the sun and the wind then transports sand inland to form incipient dunes and foredunes. Tidal range is important in this process since a high range exposes a large intertidal area that often dries out between the tides. These sediments constitute a major source of wind-blown sand given that sand-sized sediments are more easily transported by wind.

Dune size varies considerably. Some of the biggest dunes are found in deserts such as Badain Jaran Desert in the Gobi Desert in China (approximately 500 m), the Sossuvlei Dunes, Namib Desert (380 m), and the Great Sand Dunes National Park Preserve in Colorado, USA (230 m). Along the coast, on the Bassin d'Arcachon, France, is Europe's largest sand dune, the Dune du Pyla, nearly 3 km long, reaching 107 m in height, and moving inland at a rate of 5 m yr^{-1}.

Dune Origin and Formation

Wind is the main agent forming sand dunes. There is an exchange of sediments between beaches and dunes and this is part of a natural process that maintains both morphological stability and ecological diversity. Once exposed, sand is vulnerable to aerodynamic processes.

Wide beaches are formed in the summer and narrower beaches during the winter. Storms erode beaches and transport sand out of the system or to other beaches. Bonding, both by moisture and chemical precipitates, may cause surface adhesions, raising thresholds and reducing erosion. Sometimes salt forms a whitish crust on the sand surface, also bonding sand grains.

Sand grains come in a wide variety of shapes, colors, and densities, depending on their origin and on how long they have been rolling in water currents and wind. Silicate sand and calcium carbonate sand (formed by fractured shells and skeletons) are the more common components of coastal dunes. Sand texture, as well as shape and density, affect transport. Smaller particles are easier to move than larger ones. Sediment size is measured on the Wentworth scale. It is harder for angular grains to become airborne but they may move further once they have. Denser grains are harder to move and often accumulate as lag deposits on the upper beach.

Almost all wind-blown sand travels quite close to the ground, through a mechanism called saltation. Individual grains move in a series of continuous leaps. Once airborne, a grain describes a curve path, and lands hitting the ground at a low angle, but with sufficient force to rebound into the air again. It hits other sand grains that become airborne and do the same thing. In a short time, there is a considerable amount of sand in the air. Under most circumstances, deposition takes place within a short distance although sometimes sand may be transported long distances alongshore where the wind blows parallel to the coast. Deposition is favored by obstacles such as driftwood, clumps of vegetation, boulders, and plastic objects which perturb air flow and create a shelter zone. Small dunes are formed with their tails – called trailing ridges – stretching downwind.

Changes in wind strength and direction cause rapid resedimentation. Often a dune's surface changes by the hour, creating complex stochastic patterns. Over time, these processes create recognizable dune bedforms such as ripples, sand waves, and barchans.

Most coastal dunes form in the presence of vegetation. An important determinant of dune form is the drag imposed by the vegetation on the air flow. Dunes can be classified according to the percentage vegetation cover. At one extreme are dunes that have been stabilized by their vegetation cover (fixed, shore-parallel ridges and parabolic dunes) and at the other are the free wind forms (barchan or sand wave dunes, transverse dunes). Transitional forms are typified by a fragmented topography (hummock dunes).

There is a strong interaction between vegetation and dune form, and there are several patterns of incipient dunes. Plant form modifies sand deposition, forming a leading edge (as in the case of *Ammophila arenaria*), a trailing edge (*Spinifex hirsutus*), or intermittent deposition in clumped vegetation. Perennial grasses such as *Agropyron junceiforme* and *Elymus arenarius* as well as tropical long-branched creepers (*Canavalia rosea* and *Ipomoea pes-caprae*) grow laterally and vertically and are able to raise a dune a meter or two high.

Sand dunes act as a buffer to extreme winds and waves and they also shelter landward communities. They replenish the depleted beach and near-shore during and after storms, and are important in the retention of freshwater tables against salt intrusion. They filter rain water and are also important habitats for plants and animals. People have always appreciated their beauty and recreational value.

R. W. Carter wrote that ``Of all the coastal systems, sand dunes have suffered the greatest degree of human pressure.'' Many have been irreversibly altered by human activities such as tourist developments, golf courses, and urban growth.

Abiotic Factors

Dune ecosystems may be viewed as a series of gradients related to various environmental factors, which operate on different spatial and temporal scales. If we view a profile from the sea landward, we first have the beach (near-shore and back-shore), the embryo or incipient dunes, and the foredune. The first dune ridge (the next inland from the foredune) is normally the highest and forms a continuous sand structure. The second is an older dune ridge, frequently lower because of the reduction in sand supply and the gradual loss of sand. This formation occurs when we have a series of parallel ridges, formed by onshore winds, each ridge lower than the previous. Sand is trapped by vegetation and saltation cannot be initiated beneath the vegetation, unless a blowout forms. Older dune ridges become fragmented when blowouts and parabolic dunes develop. Parabolic dunes are formed when prevailing winds blow at right angles to the dune ridges. Poorly stabilized regions are rapidly eroded but the more vegetated areas on either side remain covered by plants for a longer time. As the bare sand of the central region moves inland, the two horns or tips of the parabola remain attached to the relatively stabilized sand of the trailing ridges. A slack (a dune depression where sand has been blown away until the water table is exposed) may be formed in the middle, between the parabola arms. Parabolic dunes can also be formed in transverse dunes.

Throughout the dune field, there are gradients in salinity, sedimentation, nutrients, flooding, and shelter. Dune vegetation forms a complex spatial mosaic, mainly because of variations in physical gradients which depend on the distance to the sea and topography. Disturbances also result in temporal successions that add another dimension of complexity to the spatial mosaic described.

Sand Movement

Dune movement has only been measured in a few dune systems and most of the published records are based on estimates from maps, the height of sand on fence posts, houses, and trees, etc. The results show that the rate of movement varies considerably among systems, varying from a few centimeters per year to 70 m per month, the latter in New Zealand (personal observation of Patrick Hesp). Dune formation depends on an adequate supply of sand and the wind to transport it. The interaction of wind and vegetation is of primary importance for dune growth. Colonization by plants accelerates dune growth, because surface roughness created by vegetation decreases wind flow and increases sand deposition. Several plants show an inherent capacity to bind sand and are able to develop extensive horizontal and vertical rhizome systems. The growth form and the ecological dynamics of dune plants are important contributors to foredune growth. Rhizomatous growth (as in the grass *Ammophila*) or stoloniferous growth (as in *Ipomoea* or *Spinifex*) can extend the foredune depositional area by 5–15 m in a few months. *Elymus arenaria* (Europe) develops vertical rhizomes 150 cm long and *Ipomoea pes-caprae* (pantropical) can have 25-m-long branches that are buried two or three times along their length. **Fig. 1** shows species that are able to survive and reproduce successfully under high rates of sand mobility in different parts of the world. In each region, sand-tolerating species have evolved, and they play a very important role in

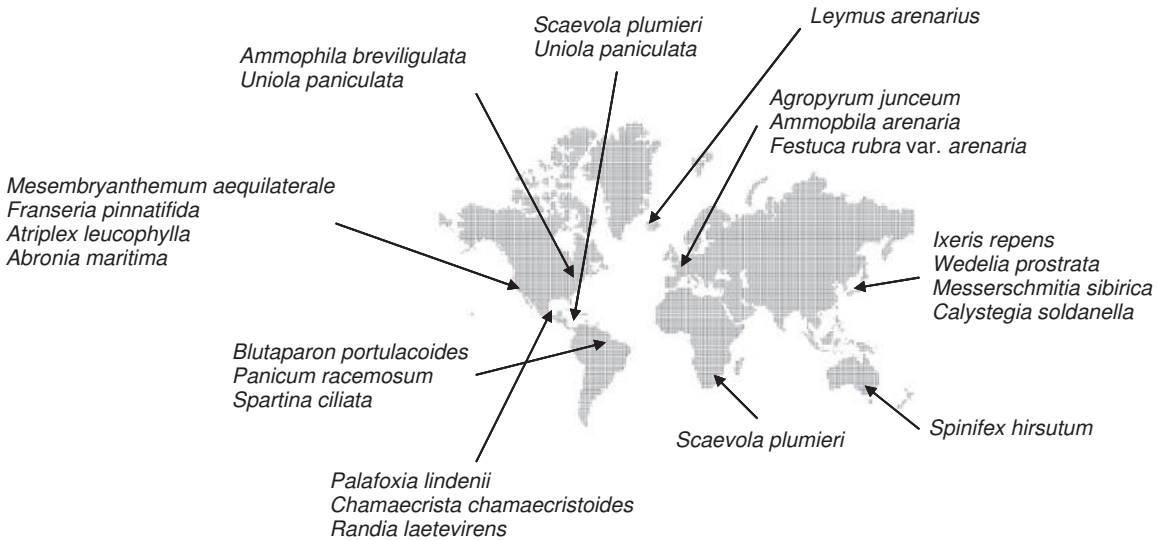

Fig. 1 Species that are able to survive and reproduce successfully under high rates of sand mobility in different parts of the world. Many regions have their own set of species that play important roles in stabilizing sand dunes locally.

dune formation. Sand deposition produces vigorous growth in some of these species; both plant height and plant cover increase, making these species excellent dune fixers. Many hypotheses have been suggested to explain this response of sand dune plants, but there are few studies in which the explanations are based on experimental evidence. Changes in soil temperature, increased space for root development, higher nutrient and moisture availability, a response to darkness, meristem stimulation, and interactions with endomycorrhizae and nematodes are probably factors that play an important role in this response.

Nutrients

There are great differences in the soil properties of young dunes (formed by recently blown sand), and those of more mature dunes in which vegetation has dominated. Newly blown sand from the beach is low in mineral nutrients. Dune soils show marked changes as they age. Pioneer species that initiate dune stabilization are able to live in very poor soils. On fully vegetated dunes, organic matter and nutrients accumulate, and the leaching effects of rainfall decrease. Leaching dissolves carbonate and moves it downward to the water table. With time, the organic matter of nutritionally poor soils of younger dunes increases, and pH decreases. The increase in organic matter content varies among dune systems, depending on the climate and colonizing species. In high-rainfall climates such as Southport (Lancashire, Great Britain), organic matter increases slowly at first but much faster after about 200 years. In Studland, Dorset, the early invasion of *Calluna* is largely responsible for a very rapid increase in organic matter. Primary productivity and the competitive abilities of coastal plants are frequently limited by nutrient availability, with nitrogen deficiency the most severe. As succession advances, plants increase their cover, communities change from grasslands to thickets, and then to tropical or temperate forests, adding nutrients and organic matter to soils. In dune depressions, where water is not a limiting factor for plant establishment, the accumulation of organic matter is faster. Experiments with dune plants have shown that many species are slow-growing and generally show growth responses characteristic of plants from infertile habitats.

Salinity

Soil salinity comes from salt spray and foam blown inland, and the amount of salt usually correlates well with the distance inland or degree of protection from the wind. In some regions with a Mediterranean climate, such as California, soil salinity follows a seasonal progression. Late summer additions by fog and salt spray result in high values at this time of the year. Winter rains leach salt away, salinity decreases, and in early spring reaches its lowest level. Salinity gradients affect species distribution, especially for those plants sensitive to salinity. Germination and growth might be difficult when soil salinity is high. Salts in the soil affect plants by making water less available, and high salinity is considered a physiological drought. Frequently, there are no shared species between the beach and the more sheltered or inland areas of the dunes. Experiments on sea rockets (*Cakile maritima*) and lupines (*Lupinus* spp.) which were sprayed with seawater showed that lupine seedlings were not tolerant of salt spray. The level of salt spray in a Californian beach may be 1 $mg\,cm^{-2}\,d^{-1}$ on a calm day, but is much higher on a windy day. On other beaches and dunes, where onshore winds are not as strong, airborne spray is very low and plants are not subjected to these conditions.

Water

The primary source of water for dune plants is rainfall. Radiation causes considerable diurnal and nocturnal temperature variations. These fluctuations in soil temperature are sufficient to cause the periodical condensation of water vapor in the soil. This produces an increase in water availability from dew that is sufficient to maintain plants in rainless periods. Fog can be another source of water, but in some areas it contains salt. Studies in open dune communities have shown that soil moisture increases to depths of about 60 cm below the dune surface and then tends to fall off. In closed dune communities, where the soil has some organic matter, rainfall is absorbed and held near the surface where it is available to roots. Experiments with *Chamaecrista chamaecristoides* seedlings, a species that thrives in mobile dunes, showed that they had the ability to withstand total lack of watering for more than 80 days. This probably allows them to survive during the dry months of the year in the dunes of the Gulf of Mexico.

In a wet year, there may be widespread flooding in dune depressions. Blowouts are wind hollows or basins of exposed sand within dunes, called slacks or depressions. They frequently arise through the erosion of deflated areas in poorly vegetated dunes. The deflation limit is reached owing to the presence of water, algae, or the accumulation of coarse immovable material. Deposition occurs around the borders of the blowout and vegetation may recolonize the area. The water table falls during the dry season and recovers during the rainy months and the composition of the plant community reflects this groundwater regime. When the soil is completely flooded, the prevailing anaerobic conditions can influence its chemical composition and the concentration of nutrients, affecting plant survival and growth. Flooding can cause the local extinction of some non-wetland species and facilitate the establishment of others.

The frequency and duration of slack inundation are factors that can alter the distribution of vegetation and plant community composition. When flooding takes place occasionally, on very wet years, many of the plants die, and when the water recedes, colonization takes place again. In wet slacks that flood every year, water-loving plants establish and a completely different set of species is found in these areas. Thus community composition will depend on the differential tolerance of plants to the environmental conditions associated with inundation, particularly anoxia. Species are good indicators of the water table depth. In

temperate areas, *Erica tetralix*, *Glyceria maxima*, *Carex nigra*, and *Juncus effusus* are some of the more common species. In Europe, slacks are very important for endemic and rare species. In tropical regions, *Cyperus articulatus*, *Lippia nodiflora*, *Hydrocotyle bonariensis* (Mexico) and *Paspalum maritimum*, *Fimbrisitylis bahiensis*, *Marcetia taxifolia* (Brazil) are frequently found in these depressions. Thickets are also common and in Mexico they are formed by *Pluchea odorata*, *Chrysobalanus icaco*, and *Randia laetevirens*. In Brazil, there is Ericaceae scrub dominated by *Humiria balsmifera*, *Protium icicariba*, and *Leucothoe revoluta*.

Temperature

On open sand dunes, there are considerable diurnal and nocturnal temperature variations. In California, on an August day, when the air temperature was above 15.5 °C 1 m above the ground, the soil surface was at 38 °C and soil 15 cm below the surface was at 19 °C. In a Nevada desert, the soil surface temperature reaches 65.5 °C and in Veracruz, in the coastal dunes in the central Gulf of Mexico, the soil surface also reaches 65 °C. These temperatures are critical for seed germination and seedling establishment. Some species, such as hard-coated legumes, need these temperature oscillations over several weeks to break the hard seed coat. They lie on the soil during the dry season, and the temperature fluctuations break the testa. When the rains come, they are ready to germinate. Vegetation cover reduces these temperature oscillations considerably. There are also temperature differences over short distances because of topography and orientation. In the dunes of temperate regions, there are temperature and vegetation differences depending on dune slope orientation.

Habitats

Coastal dunes are very dynamic systems offering a wide variety of habitats with different physical and biotic conditions, and this allows for the existence of species with very diverse life-history traits. They can be visualized as a permanently changing environment with distinct degrees of stabilization that is closely correlated with topography, the disturbance produced by sand movement, and distance to the sea. Dune habitats can be classified into three types: (1) those where sand movement dominates, sea spray is sometimes important, and nutritionally poor soils prevail (they are formed by the sandy beach, embryo or incipient dunes, foredunes, blowouts, and active dunes); (2) humid and wet slacks or depressions, that is, those habitats which become inundated during the rainy season when the water table rises and they sometimes may even form dune lakes with wetland vegetation; (3) stabilized habitats, which show no sand movement, conditions are less stressful, and there is more organic matter in the soil. Vegetation cover is more continuous – grasslands, thickets, woodlands, and tropical forests.

Fig. 2 shows a beach and dune topographic profile as well as the intensity of some of the abiotic factors mentioned and the areas where they affect the dune system.

Biological Factors

Dune plants are found all over the world, from the frosty regions of Canada and Patagonia, to the tropical areas of the Caribbean, Africa, and the South East, and the dry regions of Australia, Peru, and California. They are subjected to very different climatic conditions, they share few species, and life forms vary. Raunkaier developed an ecologically valuable system of plant classification, based on the position of the vegetative perennating buds or the persistent stem apices in relation to the ground level during the unfavorable season of the year, which can be either the cold winter or the dry summer. There is a strong correlation between the climate of an area and the life forms of the plants present. This system allows comparisons to be made between particular areas or regions. The biological spectrum found in a dune system is an expression of the number of species in each life-form class as a percentage of all the species present. A comparison of the biological spectrum of a dune system in Braunton Burrows (North Devon, Great Britain) and one in La Mancha (Veracruz, Gulf of Mexico) was made. Braunton Burrows is dominated by hemicryptophytic plants (perennating buds are at the surface of the sand) and therophytes (annuals that survive the unfavorable season as seeds); La Mancha is dominated by phanerophytic types (these grow continually, forming stems that often have naked buds projecting into the air, such as in *Hippophae rhamnoides* or *Chamaecrista chamaecristoides*).

Facilitation and Succession

Ecological succession refers to a more-or-less predictable and orderly change in the composition or structure of an ecological community. Facilitation is one of the mechanisms by which succession takes place. It occurs when plant establishment is favored or facilitated by previously established plant communities that ameliorate environmental extremes. Physical factors in dune environments produce a very harsh environment where few plants can survive. Several studies show that facilitation takes place in the early stages of colonization and succession in coastal dunes. As succession proceeds, pioneer species will tend to be replaced by more competitive species, the abiotic environment will become less harsh, and biotic interactions such as competition and predation will be more common.

Dune succession is comprised of a pioneer (also called yellow dunes, associated with the most seaward dunes that are still receiving a significant input of wind-blown sand), intermediate, and mature stages (gray dunes or inland dunes with little or no

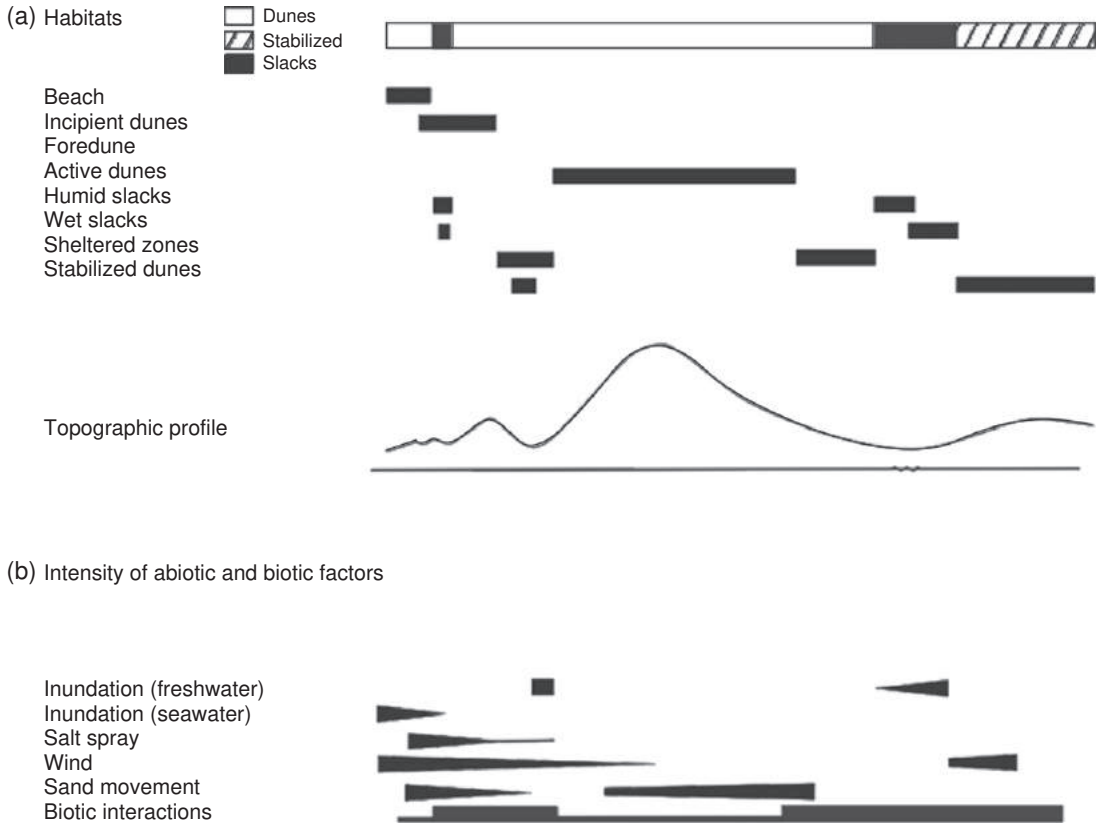

Fig. 2 (a) Beach and dune topographic profile showing each of the habitats. (b) Intensity, indicated by the width of the line, of some of the abiotic factors mentioned along with the areas where they affect the dune system. Reproduced with permission from Moreno-Casasola P and Vázquez G (2006) Las comunidades de las dunas. In: Moreno-Casasola P (ed.) *Entornos veracruzanos: La costa de La Mancha*. Xalapa, Mexico: Instituto de Ecología AC.

sand, a high humus content, and where soil development has occurred). The rate of succession varies with the harshness of the environment. This is related to the abiotic factors mentioned and the vegetation stock. Detailed studies have been undertaken in the Lake Michigan dunes, a salt-free system, in the coastal dunes of Newborough Warren, several sites in Holland, and La Mancha, among others.

Competition, Predation, Disease

Biotic interactions among plants are an important determinant of structure and dynamics. Competition is recognized as one of the most important forces structuring ecological communities. Competition is the interaction of organisms or species such that, for each, the birth or growth rate is depressed and the death rate increased by the presence of the other organisms (or species). Well-known examples of competition between plants growing on coastal dunes are grass and shrub encroachment and the invasion of exotic species.

Grass encroachment occurs when aggressive and competitive grasses spread over dune areas, reducing biodiversity because of the dominance of a few species. Grass encroachment is found in many dune areas, where grasslands become the dominant community type. Among the more aggressive species are *Calamagrotis epigejos*, *Ammophila arenaria*, and *Schizachyrium scoparium*. Shrub encroachment is also common, for example, in the Caribbean (*Coccoloba uvifera*).

Species introduction has been a common practice in dunes, both for dune stabilization and for cattle ranching activities. European marram grass was widely dispersed in other regions that were quite different from its native Europe, mainly to fix sand dunes. Several conifers have also been used for example in Doñana's dune system in southern Spain. African grasses (e.g., *Panicum maximum*) have been brought to America and used to replace local grass species because they have been considered better fodder.

Neither the effects of fauna nor those of grazing animals (especially rabbits) on dunes have received the attention they deserve. The importance of herbivory by rabbits was seen in Great Britain during the outbreak of myxomatosis, a viral disease which infects rabbits. The disappearance of rabbits led to profound changes in the structure of the vegetation, mainly the development of scrub in several dune areas. Rabbits also produce nitrogen and phosphorus enrichment beneath the scrub species under which they find shelter, causing N-fixing root nodules to invade.

Lethal yellowing is a specialized bacterium, an obligate parasite that attacks many species of palms, including the coconut palm (which has become the symbol of tropical beaches). Extensive coconut plantations in the Tropics have been abandoned because of coconut dieback, and shrub encroachment has taken place.

Symbiotic Relations

Symbiotic associations involving nitrogen fixation by microorganisms are frequent in dunes. There are nitrogen-fixing bacteria such as *Rhizobium*, which form a symbiosis with numerous forbs and shrubs in temperate and tropical dune systems. Some of the plants showing nodules are *Ulex europaeous*, *Trifolium* spp., *Lupinus arboreus*, and *Hippophae rahmnoides* in Europe, *Acacia* shrubs in South Africa, and *Chamaecrista chamaecristoides* in Mexico.

In foredunes and mobile dunes, pioneer grasses such as *Ammophila*, *Elytrigia*, and *Uniola* show different degrees of infection by vesicular-arbuscular mycorrhizae (VA). The major benefit to these grasses is probably enhanced phosphorus uptake under conditions of phosphorus limitation. They also help in the aggregation of sand particles. Tropical sand dune plants also frequently show symbiosis with mycorrhizae.

Sand dunes are harsh environments where abiotic factors act as filters that determine species survival. The interactions between abiotic and biotic factors in sand dunes change as dunes mature. They are delicate systems in which plant cover, formed by different vegetation structures and species assemblages, maintains the system in a stabilized condition. Higher diversity is found when there are different habitats. Today, these fragile systems are endangered and the urbanization of the coast is increasing. We must find ways to make our activities and dune conservation compatible.

Ecosystems☆

Brian D Fath, Towson University, Towson, MD, United States and International Institute for Applied Systems Analysis, Laxenburg, Austria

Introduction

Ecology is a broad and diverse field of study. One basic distinction in ecology is between autecology and synecology, in which the former considers the ecology of individual organisms and populations, mostly concerned with the biological organisms themselves; and the latter, the ecology of relationships among the organisms and populations, which is mostly concerned with communication of material, energy, and information of the entire system of components. In order to study an ecosystem, one must have knowledge of the individual parts; thus, it is dependent on fieldwork and experiments grounded in autecology. However, the focus is much more on how these parts interact, relate to, and influence one another including the physical environmental resources on which life depends. Ecosystem ecology, therefore, is the implementation of synecology. In this manner, the dimensional units used in ecosystem studies are usually the amount of energy or matter moving through the system. This differs from population and community ecology studies in which the dimensional units are typically the number of individuals (**Table 1**).

History of the Ecosystem Concept

The term ecosystem, which is ubiquitous today, both as scientific terminology and in common vernacular, was first used by Arthur Tansley in 1935 in a seminal paper in the journal *Ecology*, entitled "The use and abuse of vegetational concepts and terms." In fact, his reason for coining the term "ecosystem" was in response, as the title says, to a perceived abuse of community concepts by some, such as Clements, Cowles, and Phillips, who interpreted an ecological community as having overt organismal-like properties. The community as organism metaphor bothered Tansley to the extent that he wanted to provide a more scientific footing for the processes and interactions occurring during community development. Tansley describes the ecosystem thusly, "…the fundamental conception is… the whole system, including not only the organism-complex, but also the whole complex of physical factors forming what we call the environment of the biome—the habitat factors in the widest sense." The definition he proposed over 80 years ago sounds fresh today, since it has changed little if at all. The major tenets of this approach are the explicit inclusion of nonliving processes interacting with the biota—in this sense it is more along the Haeckelian lines of ecology than the Darwinian, with an additional emphasis on the system. The latter tied the field closer to the burgeoning disciplines of general system theory and system analysis, and later complex systems theory and socio-ecological metabolism.

While the conceptual underpinning of the ecosystem was now established, the introduction of this term was theoretical, lacking guidance as to how it might be applied as a field of study. There were around this time several whole system energy budgets being developed, particularly for lake ecosystems by North American ecologists such as Juday and Birge in Wisconsin, which were ideal test cases for the ecosystem concept. Building on this work, in 1942, Lindeman's study of Cedar Bog Lake also in Wisconsin was published, providing, for the first time, a clear application of the ecosystem concept. In addition to constructing the food cycle of the aquatic system, he developed a metric—now called the Lindeman efficiency—to assess the efficiency of energy movement from one trophic level to the next based on ecological feeding relations. His conceptual model of Cedar Bog Lake included passive flows to detritus, but these were not included in the trophic enumeration. Since then numerous additional studies have followed this same approach, applying it to many habitats such as terrestrial, aquatic, and urban ecosystems.

Defining an Ecosystem

As stated above, an ecosystem is comprised of the ecological community and its interactions with the nonliving environment. This is often referred to as the interaction of the biotic and abiotic aspects of the ecosphere, however, the term abiotic does a disservice to the overwhelming influence that life has on the planet it inhabits. Many examples of feedback and biotic conditioning of the environment exist such as soil formation and erosion, an oxygen atmosphere and the protective ozone layer, and a balanced carbon cycle. Even simple factors such as temperature, humidity, and soil pH are biologically-mediated leading one to consider that a better term for these features is *conbiotic* rather than abiotic (see entry in this volume). An ecosystem, as a unit of study, must be a bounded system, yet the scale can range from a puddle, to a lake, to a watershed, to a biome. Indeed, ecosystem scale is defined more by the functioning of the system than by any checklist of constituent parts and the scale of analysis should be determined by the problem being addressed. Whereas, individuals perish over time, and even populations cannot survive indefinitely—none can fix their own energy and process

Table 1 Typical dimensional units of study at different ecological scales

Ecological scale	*Dimensions*
Organismal ecology	d*E*/d*t*
Population ecology	d*N*/d*t*
Community ecology	d*N*/d*t*
Ecosystem ecology	d*E*/d*t*

d*E*/d*t*, change in energy over time; d*N*/d*t*, change in number over time.

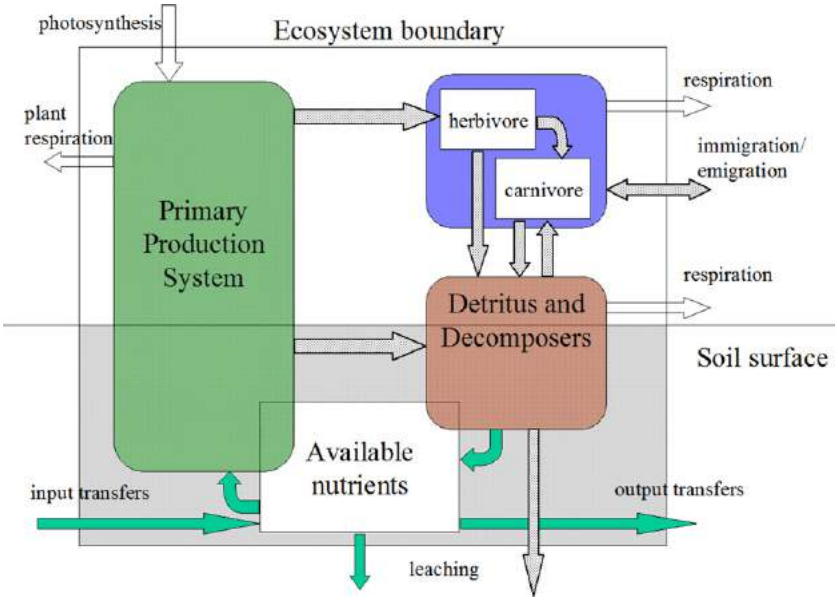

Fig. 1 Conceptual diagram of a simplified ecosystem.

their own wastes—every ecosystem contains the ecological community necessary for sustaining life: primary producers, consumers, and decomposers, and the physical environment for oikos (Fig. 1 shows a simple ecosystem model). It is this feature of ecosystems, that they are the basic unit for sustaining life over the long-term, which provides one of the main reasons for studying them for environmental management and conservation. The two main features of the ecosystem, energy flow and nutrient biogeochemical cycling, comprise the major areas of ecosystem ecology research.

Energy Flow in Ecosystems

The thermodynamic assessment of an ecosystem starts with the recognition that an ecosystem is an open system, in the sense of physics, such that it receives energy and matter input from outside its borders and transfers output back to this environment. Thus, every ecosystem has a system boundary and is embedded in an environment that provides low-entropy energy input and can receive high-entropy energy output. In addition to the external resource source–sink, there is another internal, within system boundary environment with which each organism directly and indirectly interacts. Patten proposed the concept of these two environments, one external and mostly unknowable—other than the input–output interactions, and the second internal and measurable—that is, external to the specific organismal component but within system boundary, as a systems approach to quantify indirect, yet within system interactions. This approach—called environ analysis—relying on the methodologies of input–output analysis, has developed into a powerful analysis tool for understanding complex interactions and dependencies in ecological networks. For now though, let us concern ourselves more generally with what occurs within the ecosystem boundary.

Energy flow in ecosystems begins with the capture of solar radiation by photosynthetic processes in primary producers. (Note, there are also chemoautotrophs that capture energy in the absence of sunlight, but while biologically fascinating, contribute negligible energy flux to the overall global ecological energy balance. Their significance may be in being evolutionarily earlier forms of energy capture.)

$$\text{Energy} + 6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6 + 6O_2 \quad (1)$$

The accumulated organic matter, first as simple sugars then combined with other elements to more complex molecules, represents the gross primary production in the system, some of which is released and used for the primary producers' growth and maintenance through respiration.

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{Energy} \quad (2)$$

The reminder, or net primary production is available for the rest of the ecosystem consumers including decomposers. Secondary production refers to the energetic availability of the heterotrophic organisms, which accounts for the energy uptake by heterotrophs and the energy used for their maintenance. Overall ecosystem production is supported by the primary producers, whereas ecosystem respiration includes the metabolic activity of all the ecosystem biota (**Table 2**). In this manner, plants provide the essential energetic-basis for all ecological food webs. Since it is often difficult to make direct measurements of ecological production, the change in biomass growth can be used as representative of production.

The captured energy moves through a reticulated network of interactions forming the complex dependency patterns known as food webs. In a simplified food chain, and as first described by Lindeman, the trophic concept is used to assess the distance away from the original energy importation, but in reality the multiple feeding pathways found in ecological food webs make discrete trophic levels a convenient yet inaccurate simplification. Elton observed that one typically finds a decreasing number of organisms as one proceeds up the food chain from primary producers to herbivores, carnivores, and top carnivores—leading him to propose a pyramid of numbers. One can control for the individual variation in body size by considering the biomass at each trophic level rather than the number of individuals—resulting in a pyramid of biomass. The trophic pyramid is a thermodynamically satisfying view of interactions since according to the Second Law energy must be lost during each transformation step; plus energy is used at each level for the maintenance of that level. Under this paradigm, the trophic levels apparently cap out around five or six levels. Fractional trophic levels have been employed to account for organisms feeding at multiple levels, but even these do not usually account for the role of detritus and decomposition, which extend the feeding pathways to higher numbers. However, instead of linking detritus as a source compartment in the ecosystem conceptual model, the standard paradigm is to envision two parallel food webs one with primary producers as the base, and the other with detritus as the base without any input from the rest of the web. If detritus were properly linked as both a source and sink in the ecosystem, then it would be clear that longer energy pathways are possible, if not common. The longer energy flow pathways observed in some studies are not in conflict with the laws of thermodynamics, but they show that ecosystems are more thorough at utilizing the energy within the system, mostly by decomposers, before it is lost as degraded, unavailable energy.

Energy resources flowing through the ecosystem are necessary to maintain all growth and development activities. Organisms follow a clear life history pattern, and while the time scales differ depending on the species, early-stage energy availability is usually used for growth, while later energy surplus is used for maintenance or reproduction. A similar pattern is visible in ecosystem-level growth and development. Net primary production is used to build biomass and physical structure of the ecosystem. The additional structure of photosynthetic material allows for the additional import of solar energy until saturation is reached at about 80% of the available solar radiation. At this point, the overall growth of the ecosystem begins to level off because although gross primary production is high, the overall system supports more and more nonphotosynthetic biomass both in terms of nonphotosynthetic plant material and heterotrophs. When the average gross production is entirely utilized to support and maintain the existing structure, net production is zero and the system has reached a steady state regarding biomass growth. However, the ecosystem continues to develop both in terms of the network organization and in the information capacity. In addition to being a dynamic steady state, it does not persist indefinitely because disturbances afflict the system setting it back to earlier successional stages in which the growth and development processes begins anew, possibly with different results. In this manner, the disturbance acts according to Holling's creative destruction (see entry on Holling Cycle) providing the system the opportunity to develop along a different pathway. Recent work on ecosystem growth and development has focused on the orientation of thermodynamic indicators such as energy throughflow, energy degradation, biomass, work energy capacity, and specific entropy. These orientors provide good system-level indicators of development during succession or restoration of impaired ecosystems.

Biogeochemical Cycles

A useful adage to remember regarding ecosystems is that there are no trashcans in nature. All material is source for some other process. Therefore, another major focus of ecosystem ecology is understanding how the chemical elements necessary for life persist and translocate in pools and fluxes within the ecosphere. The biosphere actively interacts with the three nonliving spheres (hydrosphere, atmosphere, and lithosphere) to provide the available concentration of each for life. This action has a significant impact on the relative distribution of these elements. The simple sugar products of photosynthesis, $C_6H_{12}O_6$, are the base for organic matter so carbon, hydrogen, and oxygen dominate the composition of life, and while oxygen is available in the

Table 2 Ecosystem energetics defined by net and gross production

Net primary production = gross primary production − respiration (autotrophs)
Net secondary production = gross secondary production − respiration (heterotrophs)
Net ecosystem production = gross primary production − ecosystem respiration (autotrophs + heterotrophs)
Net production = biomass (now) − biomass (before)

lithosphere, and hydrogen in the hydrosphere, carbon is actually quite scarce in the environment, making the disproportionate amount of carbon in biomass a hallmark of life. In fact, there are about 20 elements used regularly in living organisms, of which 9 are called the macronutrients as the major constituents of organic matter: hydrogen, oxygen, carbon, nitrogen, calcium, potassium, silicon, magnesium, and phosphorus. Some of these elements are readily available in the abiotic environment, in which case conservation through cycling of the elements is not paramount, however those in scarce supply, such as nitrogen and phosphorus, are reused many times before being released from the system (**Table 3**). These biogeochemical cycles provide the foundation to understand how human modification leads to eutrophication (N and P cycles) and global climate change (C cycle). Therefore, much effort has been made to study and understand these cycles, particularly the carbon, nitrogen, and phosphorus cycles, details of which are addressed elsewhere in this encyclopedia.

Ecosystem Studies

The ecosystem perspective achieved footing in the ecological academic community since it was central to Gene Odum's seminal textbook *Fundamentals of Ecology* first published in 1953. An early implementation of this approach at the institutional scale was attempted was in the International Biological Program (IBP), which was run from 1964 to 1974. The program had many successes in assessing and surveying the earth's ecosystems, but faced the difficulty of compelling a top–down, holistic research paradigm on individual scientific endeavors. As a result of this conflict, the program did not deliver as much as had been hoped, but set the stage for the next generation of ecosystem-scale research. One feature of the IBP that did continue was the use of computer simulation modeling as a tool to understand the complex ecological interrelations. The journal, *Ecological Modeling and Systems Ecology*, was started in 1975 and continues as an active outlet for mathematical and computer-based ecosystem research.

Subsequent to the IBP, the U.S. National Science Foundation officially established the Long-term Ecological Research Sites (LTER) in 1980 but research at several of the sites dates much earlier. Currently, there are 30 such sites ranging from the Coweeta Hydrological Lab in North Carolina, Hubbard Brook Ecosystem Study in New Hampshire, Sevilleta National Wildlife Refuge in New Mexico, and the Baltimore Ecosystem Study (lternet.edu/lter-sites). These projects rely on a vast team of scientists to study the many interactions at this spatial scale. Still, the difficulty lies in putting together all the pieces into an integrated whole picture of the ecosystem.

Smaller-scale, individual-led ecological research is commonly conducted using microcosm and mesocosm experiments. A mesocosm experiment uses designed equipment or enclosures in which environmental factors can be controlled and manipulated to approximate natural conditions. The prevalence of this approach created a wealth of small-scale experimentation but at the expense of larger observational studies, which sparked a fierce debate in the 1990s between the "field" versus "bottle" approach. Indeed, the usefulness of microcosm experiments for ecosystem ecology was brought into question, but the resolution has been that a multiplicity of approaches is useful to address ecological questions.

Biomes

Specific ecosystem characteristics are variable across the globe depending on the location and conditions. Tansley discussed in detail the factors that go into forming a climax community such as edaphic or physiographic. A simple formulation considers the regions' climatograph, a combination of temperature and precipitation and from those two variables gives a good indication of the terrestrial ecosystem (**Table 4**). These climatic conditions determine whether the regions are tropical or temperate, trees or grasses, providing a rich display of ecosystems across the globe.

Human Influence on Ecosystems

Humans have greatly altered and impacted the global biosphere. We recognize now the importance of maintaining functioning ecosystem services both out of our own necessity and for the obligation we have to the ecosphere. In 2000, the United Nations

50% of all the synthetic nitrogen fertilizer ever used has been used since 1985	20% of the world's coral reefs were lost and 20% degraded in the last several decades
60% of the increase in the atmospheric concentration of CO_2 since 1750 has taken place since 1959	35% of mangrove area has been lost in the last several decades
Approximately 60% of the ecosystem services evaluated are being degraded or used unsustainably	Withdrawals from rivers and lakes doubled since 1960

Table 6 Ecosystem approach principles of the convention on biological diversity

The following 12 principles are complementary and interlinked

Principle

1 The objectives of land, water, and living resource management are a matter of societal choices
2 Management should be decentralized to the lowest appropriate level
3 Ecosystem managers should consider the effects (actual or potential) of their activities on adjacent and other ecosystems
4 Recognizing potential gains from management, there is usually a need to understand and manage the ecosystem in an economic context. Any such ecosystem-management program should:
   (a) Reduce those market distortions that adversely affect biological diversity
   (b) Align incentives to promote biodiversity conservation and sustainable use
   (c) Internalize costs and benefits in the given ecosystem to the extent feasible
5 Conservation of ecosystem structure and functioning, in order to maintain ecosystem services, should be a priority target of the ecosystem approach
6 Ecosystem must be managed within the limits of their functioning
7 The ecosystem approach should be undertaken at the appropriate spatial and temporal scales
8 Recognizing the varying temporal scales and lag-effects that characterize ecosystem processes, objectives for ecosystem management should be set for the long term
9 Management must recognize the change is inevitable
10 The ecosystem approach should seek the appropriate balance between, and integration of, conservation and use of biological diversity
11 The ecosystem approach should consider all forms of relevant information, including scientific and indigenous and local knowledge, innovations, and practices
12 The ecosystem approach should involve all relevant sectors of society and scientific disciplines

Secretary General called for a global ecological assessment, which was recently published as the Millennium Ecosystem Assessment (MEA) (www.maweb.org/en/index.aspx). The report compiled by over 1350 experts from 95 countries found that humans have changed ecosystems more rapidly and extensively over the last 50 years than in any comparable period of time in human history, resulting in a substantial and largely irreversible loss in the diversity of life on Earth (other highlights from the report are presented in **Table 5**). The MEA operated within a framework that identified four primary ecosystem services needed by humans: supporting (nutrient cycling, primary production, soil formation, etc.), provisioning (food, water, timber, fuel, etc.), regulating (climate, flood, disease, etc.), and cultural (aesthetic, spiritual, educational, recreational, etc.). All have shown signs of stress and human pressures during the past century. One positive trend was the increase in food production (crops, livestock, and aquaculture), but this occurred with a concomitant loss of wild fisheries and food capture, along with a substantial increase in the resource inputs required to maintain the high agricultural production. While these observed changes to ecosystems have contributed to substantial net gain in human well-being and economic development, they have come at an increasing cost to the ecosystem health. The loss of this natural capital is typically not properly reflected in economic accounts.

Since the ecosystem provides the necessary functions for life, environmental management principles being devised and implemented today use the ecosystem concept as foundation. In particular, there have been several high profile international efforts such as with the Convention on Biological Diversity (CBD), a treaty initiated in 1992 and signed by 150 government leaders with the express aim to protect and promote biological diversity and sustainable development. The *Ecosystem Approach* adopted within this convention uses scientific methodologies regarding ecological interactions among organisms, their environment, and human activity to promote conservation, sustainability, and equity for managing natural resources. The approach deals with the complex socio-ecological-economic systems by promoting integrated assessment and adaptive management (see entry on Panarchy). The Ecosystem Approach of the CBD is outlined below in 12 principles (**Table 6**). Note particularly principles 5–8 that deal with ecosystem functioning, and taken in the context of the other principles assert how this ecological functioning provides opportunities and constraints for economic and social well-being. Better understanding these issues, such as ecosystem services, scale, time-lags, and dynamics are paramount research areas today.

At a national scale, in the United States, the Endangered Species Act of 1973 was critical legislation that puts into place a recovery plan for any species listed as endangered or threatened. What is impressive is that the legislation rests firmly on an ecosystem approach when it states: "The purposes of this Act are to provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved…" This holistic approach was already evident in the Organic Act of 1916, which codified the process of designating National Parks (the first, Yellowstone, was established in 1872) with the "purpose is to conserve the scenery and the natural and historic objects and the wild life therein and to provide for the enjoyment of the same in such manner and by such means as will leave them unimpaired for the enjoyment of future generations." The US Wilderness Act of 1964 provided additional protection to natural places stating they are areas "where the earth and its community of life are untrammeled by man, where man himself is a visitor who does not remain". It is encouraging to see scientific understanding and perspective referenced in legislation. Unfortunately, all of these protections are under threat from politics and businesses that undervalue ecosystems and their services.

Summary

Ecosystems are a unit of organization that include the interactions of the ecological community with its nonliving environment, primarily in terms of the energy flow and nutrient cycling. Research in ecosystem ecology has given us a much better understanding of the processes and functions necessary to sustain life. The work in the natural sciences has outpaced the ability of the social institutions to adapt and implement this knowledge. However, there is reason to be optimistic because the recent focus on the ecosystem approach in major international efforts recognizes that humans, with their cultural diversity, are an integral component of ecosystems.

The Boreal Forest Ecosystem☆

Donald L DeAngelis, University of Miami, Coral Gables, FL, United States

Introduction

The boreal biome is the largest of all terrestrial biomes, amounting to roughly 15×10^6 km^2, with estimated storage of about 195 billion (195×10^9) metric tons of carbon (C) in aboveground living pools, which is about one-third of the total terrestrial carbon. Approximately three times that amount is stored in soil. The boreal forest biome is also referred to as the "taiga" (Russian) for "swamp forest." Geographically, the boreal forest is located between latitudes 45° and 70° N, and virtually all of it in Canada, Alaska, and Siberia, with portions in European Russia and Fenno-Scandia. The boreal forest is bordered on the north by treeless tundra and on the south by mixed forest. The boreal forest is termed a "biome" by ecologists, a term that refers to a biogeographic unit that is distinguished from other biomes by the structure of its vegetation and dominant plant species. A biome is the largest scale at which ecologists classify vegetation. All parts of a biome tend to be within as the same climatic conditions, but because local conditions differ, a biome may encompass many specific ecosystems (e.g., peatlands, river floodplains, uplands) and plant communities. Despite this diversity within a biome, in referring to the boreal forest we will here use the terms "biome" and "ecosystem type" interchangeably.

Climate and Soils

The climate of the boreal forest is continental and, importantly for the growing season, there tend to be between 30 and 150 days of temperatures above 10°C. Temperature lows can fall below −25°C. Average annual precipitation is 38–50 cm, with the lowest amounts in the northern boreal forest, and greater frequency of precipitation during the summer season. Water is seldom limiting because of the generally flat topography and low rate of evaporation.

Permafrost can occur in the northern parts of this zone, the southern limit coinciding roughly with a mean air temperature of −1°C and snow depth of about 40 cm. The zone of permafrost generally starts at depths ranging from 1.5 to 3 m in the areas of the boreal forest where it occurs. Its occurrence limits soil processes to an upper active layer and impedes water drainage, leading to waterlogged soils. The soil decomposition rate in the taiga is slow, which leads to the accumulation of peat.

Several soil types characterize the boreal forest. The soils of a major part of the boreal forest, lying under a dense coniferous canopy, are heavily podzolized where the soil is permeable. These soils consist largely of spodosols. Intense acid leaching forms a light ash-colored eluvial soil horizon leached of most base-forming cations such as calcium. Thus taiga soils tend to be nutrient poor. Gelisols are common in the north, where permafrost occurs. These are young soils with little profile development. Histosols, which are high in organic matter, form in nonpermafrost wetlands, where decomposition is slowed by hypoxic conditions. These are often referred to as peatlands.

Biodiversity

Tree species richness is far smaller than that in the temperate forests to the south, where more than 100 species are typically observed in 2.5° × 2.5° quadrats in eastern United States. Species richness clearly declines from south to north in the taiga. Whereas 40 or more tree species can be found in the southern taiga in Canada, this declines to 10 or so species near the tundra boundary. Animal species also show strong gradients. Reptile and amphibian species are almost nonexistent above 55°. Mammal species richness declines from close to 40 species to about 20 going northward in the boreal forest biome in North America, while bird species decline from about 130 to less than 100.

Forest Structure and Species

Because many hardwood trees are both sensitive to low winter temperatures and require a long and warm summer, the true boreal forest begins where the few remaining hardwoods become a minor part of the forest. Four coniferous genera dominate a major

☆*Change History:* April 2017. Donald DeAngelis updated sections Introduction, Climate and Soils, Climatic variation and effects on vegetation, Landscape-scale vegetation differences, Herbivorous insect outbreaks, Difference in food webs due to climatic differences, Predator-prey cycling, Fire and its effects, Conservation and global issues Summary.

This is an update of D.L. DeAngelis, Boreal Forest, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 493–495.

part of the taiga; *Picea* (spruce), *Abies* (fir), *Pinus* (pine), and *Larix* (larch). The hardwoods, which largely occur in dwarf form, include *Alnus* (alders), *Populus* (poplars), *Betula* (birches), and *Salix* (willows). The hardwoods tend to be early successional species following disturbances such as fires or erosion/deposition processes on riverbanks, which are eventually shaded out by slower-growing spruces and firs. Much of the main boreal forest is dominated by a few spruce species. These form a dense canopy in the central and southern taiga, with a ground cover of dwarf shrubs, such as cranberries and bilberries, and mosses and lichens. In northern Siberia, huge areas are covered almost solely by larch, and the canopy is much less dense. Pine species, which can withstand a range of harsh conditions, grow in light, sandy soils and other dry areas. As the boreal forest-tundra boundary is approached, conifers thin out to a woodland with lichen and moss dominating the ground. Trees become more and more stunted.

The standing stock of biomass of the boreal forest ranges is estimated at 200 (range 60–400) metric tons per hectare ($t\ ha^{-1}$). This compares with an estimate of $350\ t\ ha^{-1}$ for the temperate deciduous forest and $10\ t\ ha^{-1}$ for the tundra ecosystems. The boreal forest differs from the temperate forest in having a much higher percentage of its total biomass as photosynthetic foliage (7% vs. 1%). It differs from the tundra in having a lower percentage of root biomass (22% vs. 75%).

Climatic Variation and Effects on Vegetation

There is a great deal of climatic variation within the boreal biome. Winter temperatures in the boreal forest of western North America are about 15–20°C colder than in northwestern Europe (Fennoscandia) with half as much precipitation. Across Russia, the climate changes from relatively mild and wet in the Baltic region to extreme continental climate in northeastern Siberia, with mean annual temperatures of -10°C and low precipitation.

The differences in climate between areas of forest at the continental scale bring about differences in vegetation. Typical areas of boreal forest of upland western North America are dominated by white spruce (*Picea glauca*), with lesser amounts of aspens and poplars (*Populus* spp.) in the canopy. In northwestern Europe, Scots pine (*Pinus sylvestris*), Norway spruce (*Picea abies*), and birches (*Betulus* spp.) make up most of the overstory layer. But the main differences are in the understory structure. In North America, there is a relatively tall shrub layer (0.6–2 m high) of willow (Salix spp.) and birches, whereas in northwestern Europe the tall shrub layer is absent. Instead there is a layer of dwarf shrubs (0–0.5 m), mostly ericaceous, such as bilberry (*Vaccinium* spp.). The difference has been attributed to greater tolerance to low winter temperatures of willow and birch shrubs, while smaller shrubs such as bilberry are poor at surviving cold temperatures without a deep snowpack for insulation. The extreme cold and dry conditions of eastern Siberia result in the deciduous needle-leaf conifer, larch (*Larix* spp.) being the most common component of the forest. The deciduous trait allows larches to avoid needle dessication from the extreme winter temperatures.

Landscape-Scale Vegetation Differences

The taiga of interior Alaska is a particular example showing the variability of vegetation communities at the landscape scale. Well-drained south-facing slopes are dominated by communities of white spruce and hardwoods such as birches and aspens, which are adapted to warmer conditions. Along a transect down gentle north-facing slopes, closed black spruce (*Picea mariana*) forest gives way to more open black spruce-*Sphagnum* muskeg with sedge tussocks dominating on areas of stream valley underlain with permafrost. It is also possible for alternative stable states of community to occur in some areas on the same site, depending on the history of that area. This is true of the white spruce and hardwood type community and black spruce community. These communities, both of which can potentially occupy the same sites in the taiga zone, are characterized by different nutrient cycling efficiencies. Black spruce ecosystems have mechanisms that conserve nutrients. Because the litter of black spruce is low in nutrients, it is slow to decompose; thus thick layers of organic matter accumulate on the forest floor under black spruce. This insulates the soil and thus reduces summer soil temperature. Rates of mineralization become even slower on these stands because of the low summer soil temperatures. If a fire disturbance occurs, it may burn off enough of the litter, so that summer soil temperatures are warmer and nutrient cycling is higher. Under these circumstances, white spruce, which needs greater nutrient availability, may be able to invade and dominate. However, any disturbance that reduces nutrient availability to the white spruce may allow some black spruce trees to invade. The black spruces will contribute more low quality (nutrient poor) litter to the ground, causing the insulation factor to increase again, and reducing soil summer temperatures. Eventually, the black spruces may dominate again.

Animals

Animal life in the boreal forest is far less diverse than in most temperate zone ecosystems. A number of bird species are adapted to being residents of the taiga. Grouses such as the capercaillie of the Old World, are adapted to year-round life in the taiga, as are some owls, woodpeckers, tits, nuthatches, crossbills, and crows. Small mammal herbivores of the boreal forest include the squirrels, chipmunks, voles, and snowshoe hares. These provide food for a small number of predators species, including the red fox (*Vulpes vulpes*) and members of the weasel family. The moose (*Alces alces*) (called elk in the Old World) has a wide geographic distribution in the taiga. They are prey for wolves (*Canis lupus*) and occasionally the brown bear (*Ursus arctos*).

One component of the taiga fauna, conspicuous for its frequent devastating effects on thousands of hectares of forest, is that of phytophagous insects. Populations of these insects, which include pine sawflies (*Neodiprion* spp.), spruce budworms (*Choristoneura fumiferana* (Clemens)), bark beetles, and many others that attack conifers, are capable of escaping natural enemies and building up to huge population densities. The large monospecific stands of the boreal forest may be especially vulnerable.

Herbivorous Insect Outbreaks

The boreal forest is known for the occurrence of severe outbreaks of herbivorous outbreaks insects like the spruce budworm. Patterns of outbreaks may be cyclic or irregular (irruptive). Environmental factors can affect outbreaks, and outbreaks of some species of insect have increased in recent times; perhaps due to logging practices and fire suppression, leading to greater densities of tree species preferred by particular insects; for example, there were nine outbreaks of eastern spruce budworm during the nineteenth century, whereas during the first 80 years of the 20th century there were 21, and they were more widespread.

Weather is an important factor in herbivorous insect outbreaks. An example is the spruce budworm, which feeds preferentially on foliage of white spruce and balsam fir (*Abies balsamea*). The caterpillars of this moth do not feed immediately after emergence from the egg, but are dispersed by wind and hibernate over winter. When they emerge in spring they start to feed on *old* fir needles; that is, they are senescence feeders, feeding on needles that are breaking down and releasing nutrients, that is, amino acids, in high concentrations during nutrient translocation. Outbreaks tend to occur when there are large numbers of old trees, where it is likely that many of the needles are old and not very vigorous, so they tend to break down quickly. But the presence of a large stand of old trees is not sufficient in itself to lead to a spruce budworm outbreak. The period of 1948 to 1958 in eastern Canada was a time of summer droughts interspersed with wetter than normal winters. This combination of drying of roots in the summer and waterlogging them in the winter caused dieback of crowns, with rapid aging of leaves and release of high concentrations of amino acids being translocated out of the dying leaves. The extra amino acid in the diets of the spruce budworm caterpillars was enough to increase caterpillar survival, which led to population explosions that predators and parasitoids could not control. DDT was sprayed to stop the outbreaks, but that just made things worse by saving the old stands trees and letting them get older and even more susceptible to outbreaks.

Insect herbivores are estimated to cause more timber losses than fires in the boreal zone. The spruce budworm is the most destructive boreal forest insect which caused as average annual loss during the period of 1982–1987 of 27.3×10^6 ha of forest in eastern North America. Among other defoliator insect pest of the boreal forest, the forest tent caterpillar (*Malacosoma disstria*) caused 2.4×10^6 ha, and the jack pine budworm (*Choristoneura pinus*) a 2.2×10^6 ha annual loss during the same period. Insect damage causes forests to become more susceptible to fire. However, the high numbers of insects during the warm months is a main explanation for the large numbers of birds that migrate from the south to breed in the taiga, especially large numbers of species of warblers and thrushes.

Difference in Food Webs Due to Climatic Differences

The differences in vegetation between western North America and northwestern Europe also lead to differences in the food webs. The tall shrubs of the former provide winter forage for snowshoe hares (*Lepus americanus*) in North American, while the voles (e.g., bank vole (*Myodes and Microtus* spp.)), which are key rodents in Fennoscandia, are better adapted to foraging on the shorter dwarf shrubs that are beneath the snow surface in winter. The snowshoe hare is the prey of relatively specialist predators like the lynx (*Lynx canadensis*), coyote (*Canis latrans*), and great horned owl (*Bubo virginianis*), while mustelids such as the weasel (*Mustela nivalis*) and stoat (*Mustela* ermine) are adapted to feeding on the voles and thus being key predators in northwestern Europe boreal forest. In addition, the snow characteristics differ in the two regions, with deeper and softer snow in western North America, which could have favored the Canadian lynx (*Lynx Canadensis*) as a specialist predator on the snowshoe hare, in contrast with the wetter snow, with hard surface, in northern Europe. The generalist red fox (*Vulpes vulpes*) is better suited to the latter hard-packed snow conditions, and so is an important generalist in northwestern Europe but not western North America. The moose (*Alces alces*)-wolf (*Canis lupus*) predator–prey relationship is important in both systems.

Predator–Prey Cycling

The interaction between a specialist predator and its prey can lead to population cycles, and this occurs between both the snowshoe hare and the Canadian lynx and voles and mustelids. The population cycle of the snowshoe hare is the best studied and most famous. Hare populations exhibit 9–11 year fluctuations in abundance that can be explained in terms of interactions with the lynx, although not all aspects of the cycling are understood. Fire may be an instigator of the cycle, as fires are followed a few decades later by very high levels of edible deciduous vegetation.

Ecosystem Dynamics

In keeping with its position between much warmer climate of the temperate zone and colder climate of the tundra, the boreal forest's indices of production are intermediate between those two ecosystem types. Annual net primary production in the boreal

forest has been estimated at 7.5 (range 4–20) metric tons per hectare ($t\,ha^{-1}\,year^{-1}$). This compares with 11.5 $t\,ha^{-1}\,year^{-1}$ for temperate forest and 1.5 $t\,ha^{-1}\,year^{-1}$ for tundra ecosystems. Mean boreal forest litterfall is estimated to be 7.5 $t\,ha^{-1}\,year^{-1}$, compared with 11.5 and 1.5 $t\,ha^{-1}\,year^{-1}$ for the temperature forest and tundra. Because low temperatures slow decomposition, the rate of litterfall decay in the boreal forest, 0.21 $year^{-1}$, is also intermediate between 0.77 and 0.03 for the temperate forest and tundra. This means that it takes roughly $3 \times (1/0.21) = 14$ years for 95% of a pulse of litter to decompose.

Fire and Its Effects

Fire is an inherent factor in the ecosystem dynamics of the boreal forest. Lightning-caused fires occur on a given area at intervals of 20–100 years in drier areas to 200+ years in wetter areas such as floodplains. Because nutrients tend to be tied up in slowly decomposing organic matter, fire may be important maintaining tree growth by releasing pulses of nutrients periodically. Many taiga plant species have adaptations to fires, such as serotinous cones and early sexual maturity of some conifers, and resprouting capacity of hardwood trees and many herbs and shrubs. Fires also reset the successional cycle, allowing shade intolerant species like birch and aspen to invade.

Fires destroy the highly flammable late successional evergreen forests that are dominated by the spruces (white spruce and black spruce), creating the habitat required by early successional deciduous trees and shrubs. The dominant early successional deciduous species include the trees quaking aspen (*Populus tremuloides*) and Alaska paper birch (*Betula neoalaskana*) and an assemblage of willows (*Salix* spp.). As post-fire succession proceeds, the vegetation becomes progressively dominated by evergreens such as spruces, and ericaceous shrubs (e.g., *Ledum* spp.), as well as green alder (*Alnus viridis* subsp. *fruticosa*). Fires create a mosaic of patches of deciduous and evergreen trees and shrubs created by fire and the subsequent post-fire succession.

Fire is important to the boreal forest. In boreal North America, fire is essential to the existence of most browsing mammal populations, and especially snowshoe hare populations. This is because fire creates most of the habitat mosaic required by these herbivores. Fire destroys late successional evergreen forests dominated by the slowly growing spruces *Picea mariana* and *P. glauca*, which are effectively defended against browsing by resins that contain toxic lipid-soluble secondary metabolites such as the monoterpene camphor that deters feeding by snowshoe hares. However, although spruce is a comparatively poor winter-food for boreal browsers, dense spruce thickets provide the protective cover that these herbivores use to evade their predators. The recently burned patches within an unburned spruce forest matrix are colonized by the more rapidly growing and comparatively poorly defended early successional deciduous species such as the willows (*Salix* spp.), quaking aspen (*Populus tremuloides*) and birches that in are the preferred winter-foods of most North American boreal browsing mammals. Thus, in boreal North America most of the optimal habitat for browsing mammals occurs at the edge of burns where browsers have ready access to both good predator escape cover (spruce forest) and good food (fast growing deciduous species in recently burned patches). For this reason in boreal North America the abundance of browsing mammals is often greatest in a landscape that contains patches of poorly defended early successional deciduous woody species within a late successional spruce matrix. And where the abundance of these browsing mammals is greatest, the intensity of their selective browsing on the recruitment of rapidly growing deciduous tree species such as *B. neoalaskana* and *B. papyrifera* is generally most intense.

Conservation and Global Issues

The boreal forest represents the single largest pool of living biomass on the terrestrial surface. It contains more than 30% of the total terrestrial pool, and it is therefore critically important in global carbon dynamics. Much of the carbon is stored in the ground layer. Currently, the taiga is thought to act as a net sink of carbon, with an estimated 0.54 billion metric tons stored per year. However, global climate change, in the form of higher temperatures, may cause significant changes in the carbon dynamics by increasing decomposition rates faster than photosynthetic rates. Fire frequencies may also increase with temperature, as precipitation is not expected to rise, which will further increase the release of carbon stored in the ground layer. According to some studies, the boreal forest will be a net contributor to CO_2 in the atmosphere under the projected climate changes.

Climate-induced changes in the boreal forest would also have an impact of migrant birds that use the region for reproduction. Changes in tree species composition may challenge the capacity of birds to adapt, as has already the increasing fragmentation of the forest due to clear-cutting in many areas within the biome.

Estuaries

RF Dame, Charleston, SC, USA

Introduction

Estuarine ecosystems are among the most complex and complicated systems in the biosphere. Because they are at the interface of terrestrial, freshwater, and marine systems, estuaries are subject to massive fluxes of materials and energy. Further, as a large percentage of the human population lives in close proximity to estuarine and coastal environments, anthropogenic impacts and stress are major driving factors in determining the health and functional status of estuarine ecosystems. In this section, the structure and function of estuarine ecosystems are examined.

Definitions of Estuarine Ecosystems

To set the stage for any discussion of estuarine ecosystems, a clear working definition is needed. One of the simplest and most utilized definitions of an estuarine ecosystem is:

> the zone where freshwater from land runoff mixes with seawater.

Another common definition is:

> An estuary is a semi-enclosed coastal body of water that has free connection with the sea where seawater is diluted by freshwater derived from land drainage.

The preceding definitions focus on the geomorphological and hydrological aspects of estuaries with no mention of the abiotic or physical driving sources of energy, that is, tides and solar insolation. Nor are any biotic components or processes utilized. Thus, the following definition is proposed:

> An estuarine ecosystem is a system composed of relatively heterogeneous biologically diverse subsystems, i.e., water column, mud and sand flats, bivalve reefs and beds, and seagrass meadows as well as salt marshes. These subsystems are connected by mobile animals and tidal water flows that are embedded in the geomorphological structure of creeks as well as channels, and together form one of the most productive natural systems in the biosphere.

Recent quantitative studies indicate that estuaries are ecoclines that are composed of gradients containing relatively heterogeneous subsystems that are environmentally more stable than ecotones (Fig. 1). Ecoclines are boundaries with more gradual, progressive change between freshwater and the sea. In this view, the organisms in the estuary are either from freshwater or from marine environments; there are no brackish water species. Each estuarine system will respond to at least a freshwater and a marine gradient as well as have its own particular combination of biological and physical components and processes. Thus, every estuarine ecosystem is unique.

Geomorphological Types of Estuaries

Bar-Built and Lagoonal

Bar-built or lagoonal estuaries form in the areas behind sandy barrier islands and usually drain relatively small watersheds. The exchange of water between the estuary and the sea occurs through tidal inlets. Astronomical tides and winds are the major forces controlling water circulation and water height. The areas behind barrier islands are generally subject to less wave action and this promotes the development of extensive wetlands. Bar-built estuaries are generally smaller than other estuarine types, suggesting that they have a higher surface area to volume ratio and, therefore, play a greater role in ecological processes than was previously thought. Well-studied examples of bar-built estuaries are found along the temperate and subtropical coasts of eastern North America, Europe, Asia, and the southern and eastern shores of Australia.

Riverine Estuaries

There are two fundamentally different riverine systems (Fig. 2). First, are those that arise in the piedmont, have extensive watersheds, receive substantial freshwater discharge, but only a small portion of their watershed is covered by wetlands. Chesapeake Bay and San Francisco Bay in North America as well as the Eastern Scheldt in Northern Europe are well-studied examples of

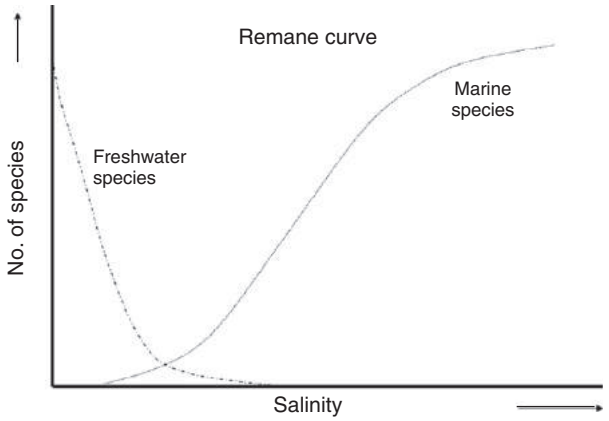

Fig. 1 A generalized Remane curve with number of species plotted versus estuarine salinity gradient.

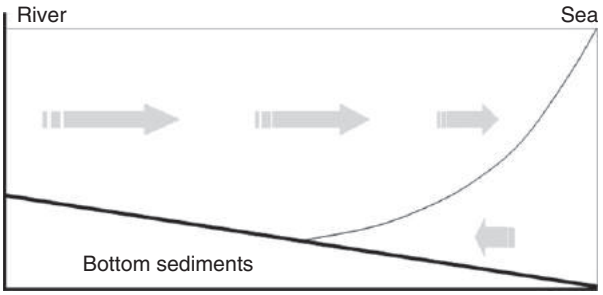

Fig. 2 Generalized material flux patterns in a Riverine estuary.

this type of riverine system. A second type of riverine system known as coastal plain estuaries are characterized by a much gentler slope with proportionally more wetlands than piedmont estuaries. Generally, these systems are less studied, smaller and have a lower, more sluggish flows.

Estuarine Ecosystems and Maturity

In an attempt to place a more ecosystems oriented emphasis on estuaries, the `geohydrologic continuum theory of Marsh-Estuarine ecosystem development' was proposed as a scheme for categorizing estuarine ecosystems. In this theory, the tidal channels of the estuarine ecosystem represent a physical or geohydrologic model of how the ecosystem adapts until there is a change of state. Mature portions of the system are at the ocean–estuary interface, mid-aged components are intermediate within the longitudinal distribution of the system, and young or immature areas are at the land–estuary interface. Mature systems export particulate and dissolved materials, mid-aged areas import particulate and export dissolved materials, and immature systems import both particulate and dissolved materials. Some estuarine ecosystems may have all three types while others may have only one or two.

Estuaries as Complex Systems

While it is generally acknowledged that ecosystems are complex systems, it is appropriate to describe estuarine ecosystems in the context of the complex systems approach. Complexity as used here can be defined by (1) the nonlinear relationships between components; (2) the internal structure created by the connectivity between the subcomponents; (3) the persistence of the internal structure as a form of system memory; (4) the emergence or the capacity of a complex system to be greater than the sum of its parts; (5) the reality that complex systems constantly change and evolve in response to self-organization and dissipation; and (6) behaviors that often lead to multiple alternative states. Thus, estuarine ecosystems are open nonequilibrium systems that exchange matter and energy as well as information with terrestrial and marine ecosystems as well as internal subsystems. These exchanges not only connect various components, but are the essential elements of feedback loops that generate nonlinear behavior and the emergence of structures and behaviors whose sum is greater than the whole. These systems do exhibit alternate states, for example, Chesapeake Bay appears to have a benthic state dominated by oysters and a water column state dominated by plankton.

Major Estuarine Subsystems or Habitats

The landscape approach to estuarine ecosystems focuses on subsystems or habitats as major components within estuaries. Because organisms respond to the amount of change in the physical (abiotic) environment, their reaction to their environment results in subsystems or habitats composed of specific groups of species that are adapted to that particular set of abiotic factors. In estuarine ecosystems, the major abiotic factors are salinity, water velocity, intertidal exposure, and depth.

Water Column

Water is the primary medium for the transport of matter and information in estuarine ecosystems. Freshwater enters the estuary either as precipitation or as an accumulation driven by gravity down-slope through streams and rivers to the estuary. Salt water enters the estuary from the sea via tidal forcing. The gradient of increasing salt concentration from freshwater to marine divides the estuary into zones of salt stress and subsequently into different pelagic subsystems (Fig. 2).

Phytoplankton are small chlorophytic eukaryotes that drift as single cells or chains of cells in estuarine currents. Diatoms and dinoflagellates are the dominant groups while species composition of a specific system is usually determined by salinity, nutrients, and light. They are a major component of the estuarine water column and provide food for many suspension-feeding animals. Planktonic primary production is seasonal and varies from distinct peaks in the arctic to spring and autumn blooms in temperate systems and almost no peaks in tropical estuaries. Average annual planktonic primary production in estuaries is about 200–300 gC m^{-2} yr^{-1} and is mainly a function of light, nutrient availability, and herbivore grazing.

There are two major categories of zooplankton: holoplankton that in most estuaries are dominated by calanoid copepods which spend their entire life in the planktonic state and the diverse meroplankton that only spend their larval state in the plankton. Most estuarine zooplankton are believed to be herbivores and play a major role in connecting carnivores to phytoplankton. They are also thought to be major sources of inorganic nutrients that are available to phytoplankton.

The microbial loop in estuaries is composed of micro- and nano-planktonic bacteria, protozoans, and flagellates. Initially, the microbial loop was thought to play a major role in recycling nutrients with dissolved organic matter (DOM) a major product. However, the recent finding that a sizable proportion of DOM is made up of viruses has forced a major change in the microbial loop model (Fig. 3). The current paradigm of the microbial–viral loop envisions the viruses (10^{10} l^{-1}) as 10 times more abundant than bacteria (10^{9} l^{-1}) and controllers of bacterial diversity and abundance. The viruses are small (20–200 nm), ubiquitous particles that use the process of cell lysis to attack and kill bacteria. As a result, more bacterial biomass is shunted into DOM and away from the macroplankton and suspension-feeding macrobenthos. The much more rapid viral recycling of nutrients also has the potential to generate more stability in the system.

Large mobile animals, birds, terrestrial and aquatic mammals, and fish, shrimps and crabs, are common residents as well as transients in estuarine systems. These animals transform and translocate materials both within the estuary and between the estuary and other systems. The nekton organisms, in particular, use the tidally forced water column as a pathway between deeper channels and intertidal habitats where they seek refuge, feed, and develop.

Marshes and Mangroves

Emergent vascular plant-dominated intertidal wetlands are major subsystems in most estuaries. The two most common habitats are geographically zoned latitudinally with marshes dominating the temperate zone and mangroves the frost free subtropical and tropical zones. Both are found in low-energy wave-protected, sedimentary, high-salinity, and intertidal environments near the

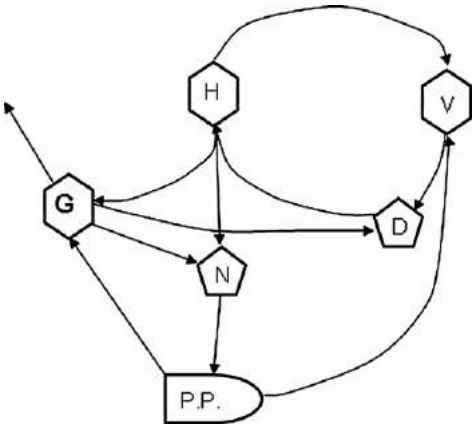

Fig. 3 A simple microbial–viral loop food web for an estuarine system. D, dissolved organic matter; G, grazers; H, heterotrophs; N, nutrients; P. P., primary producers; V, viruses.

Table 1 Primary production in estuaries

Primary producer	*Annual primary production(g C m^{-2})*
Macrophytes	
Spartina	400–2480
Rhizophora	696–2100
Microphytobenthos	50–200
Epiphytes	12–260
Phytoplankton	25–150

mouth of the estuary. While wetlands in the high-salinity portion of estuaries are low in species diversity (almost monocultures) of vascular plants, diversity is much higher in the freshwater reaches.

Salt marshes reach their greatest extent and productivity along the Gulf and southeast Atlantic coast of North America where the cord grass *Spartina alterniflora* dominates. This high production is the result of near ideal conditions of temperature, salinity, light, sediment texture, nutrients, and tidal range. Marsh grasses produce large quantities of both above- and belowground biomass that accumulates in the surrounding sediments (Table 1). The stems and leaves of the grasses also provide a structural base for an epiphytic community that further increases production. Decomposition processes in the organically rich sediments generate a strongly anaerobic reducing environment making the salt marsh a major center for nutrient cycling. The nutrient uptake mechanisms of vascular plants are poisoned by the reducing environment; however, air passages in the roots, rhizomes, and stems of these grasses aerate the surrounding sediments so that nutrient uptake can be maintained. The vertical stems and leaves of *Spartina* also serve as a passive filter that slows water flow, can remove via deposition suspended sediments from the water column, and allows many marshes to maintain their elevation with respect to rising sea level. This same environment provides food and refuge for many economically important nekton.

Mangroves are intertidal, tropical, and subtropical woody vascular plants that fill a niche similar to that of *Spartina*. In the high-salinity portions of the estuary, the red mangrove, *Rhizophora*, dominates. Red mangroves have prop roots that lift the plants above the reducing environment of the surrounding sediments. There is a gradient from high production in riverine swamps to low production in high-salinity scrub areas. On a global scale of increasing light with decreasing latitude, the closer a system to the equator, the higher the mangrove productivity. Nutrients have also been implicated as a major limiting factor on mangrove productivity. There is evidence that mangrove production is enhanced by flushing action of storms. In addition to being a nursery for many fish, shrimps, and crabs, the structural mass of mangroves may form a protective buffer to the impacts of storm surges and tsunamis on coastal and estuarine systems.

Seagrasses

Seagrasses are submerged vascular plants that are found in aerobic, clear-water, high-salinity systems with moderate water flow. Cold water systems are dominated by eel grass, *Zostera*, and in the tropics turtle grass, *Thalassia*, is the major group. These grasses are not found in estuaries with high suspended sediment loads, that is, Georgia and South Carolina where there is insufficient light penetration to support their growth. They are also limited to the upper 20 m of water because water pressure compresses their vascular tissues. Maximum seagrass production can approach 15–20 gC m^{-2} d^{-1}. The high productivity of the seagrass is almost equaled by the productivity of the epiphytes on their leaves; however, the sediment trapping abilities of seagrasses give them an advantage over phytoplankton and epiphytes in nutrient limiting conditions. The structure of the seagrasses provides feeding habitat for many mobile animals as well as deposit feeding and suspension-feeding benthos.

Invertebrate Reefs and Beds

Suspension-feeding benthic animals are common in most estuaries because of the high availability of suspended phytoplankton. A number of bivalves and a few worms can aggregate in very dense, high biomass beds or reefs. These structures are found both intertidally and subtidally in high to moderate salinities. The eastern oyster, *Crassostrea virginica*, in its intertidal form builds some of the most extensive aclonal reefs known. Intertidal beds of *Crassostrea* and *Mytilus* can have biomass densities exceeding 1000 gdb m^{-2}. Depending on the estuary, suspension feeders such as oysters and mussels have been shown to control phytoplankton populations in some systems and influence nutrient cycling by short-circuiting planktonic food webs and reducing the recycle time for essential nutrients. There is evidence that the presence of a significant bivalve suspension-feeder component in estuarine ecosystems enhances system stability.

Mud and Sand Flats

Mud and sand flats are common to the intertidal zone of most estuaries. The major biotic components of tidal flats are bacteria, microbenthic algae, small crustaceans, and burrowing deposit feeders. As in the water column, the microbial–viral loop is thought to play a major role in the decomposition of organic matter in tidal flat sediments. In some estuaries, the microbial–viral loop

utilizing a variety of electron acceptors may represent a significant sink for matter and energy. Thus, the prevailing processes on these flats can potentially redirect the fluxes of matter and energy away from macrofaunal food webs to those dominated by microbial processes. The occurrence of tidal flats was originally attributed to the hydrodynamics and sediment sources in tidal creeks; however, with the application of complexity theory to ecological systems, these flats are also being described as alternative states of salt marshes and bivalve beds.

Material Fluxes

Water Fluxes and Residence Times

Interest in the exchange of nonliving materials and organisms between estuarine ecosystems and the sea was initiated by the first quantitative metabolic studies on the high productivity of marsh dominated estuaries. These studies were first synthesized in simple energy budgets that were found to explain less than 50% of the productivity of estuarine ecosystems. Investigators speculated that the unaccounted-for energy must be exported from the estuarine ecosystem by tidal currents. This idea led to the `outwelling hypothesis' that states that estuarine ecosystems produce much more organic material than can be utilized or stored by the system and that the excess is exported to the coastal ocean where it supports near coastal ocean productivity. While the energy budget or mass balance approach is a cheaper and quicker method of determining the direction of material fluxes, in recent years the direct measurement of material fluxes is favored because this approach provides statistically meaningful results.

Another aspect to the fluxes of materials in estuarine systems is the time the water mass remains in the system or residence time (also known as flushing time or turnover time). Residence time can provide essential information to resource managers on the retention and dispersal of toxins, the incubation of invasive species, and the carrying capacity of a system for benthic suspension feeders (Fig. 4). Recent studies on the physics and geomorphology of water in estuarine tidal channels suggest that the residence time of water may vary greatly from place to place within some estuaries. Such variations have been used to explain growth variations in bivalves in different locations within the same estuary. Traditional estimates of an estuarine system's residence time can be computed from measurements of system volume, tidal prism, and water input to the system. The advent of fast computers and numerical models, however, now allows for much more modeling of these systems with the potential for more sophisticated spatial and temporal management strategies.

In riverine systems, river flow is the main physical cause of material and organismic transport from estuaries to the sea. Each of these systems are a unique and changing feature on the present landscape because rising sea level is drowning their basins and sediments are gradually filling their channels. For example in Chesapeake Bay, 35% of the particulate nitrogen and most of the phosphorus is buried in the sediments of the bay. Of the nitrogen in the bay water column, 31% was exported to the sea and 8.9% was removed from the system as commercial fish harvest. In general, the nutrients transported and exported by riverine estuaries are thought to be a significant source for generating new organic production in the coastal ocean. As many of these systems have dams or have them proposed, managers must take into account the direct and indirect effects of these structures on recreational and coastal fisheries.

In bar-built estuaries, tides are usually the major source of energy for the transport of materials into and out of the estuary. If the fastest currents are on the flooding tides, then the system tends to import suspended particulate material. In contrast, if ebbing tides have the fastest currents, then the system usually exports suspended particulate materials. The Wadden Sea of Northern Europe is a flood-dominated system and North Inlet in South Carolina is an ebb-dominated system.

In shallow, high-insolation, low-precipitation, warm systems, evaporation can dictate the direction of transport. This is the case in some small tropical systems where water loss due to evaporation is replaced by the influx of water and nutrients from the adjacent sea.

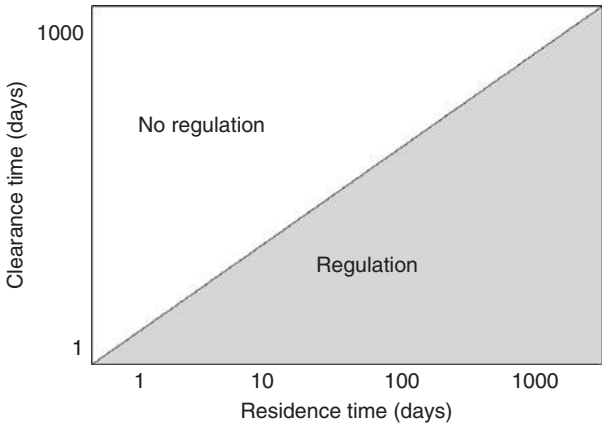

Fig. 4 A plot of water volume residence time versus bivalve clearance time showing areas of potential control by suspersion-feeders.

Organismic Transport

In addition to inanimate materials, the larval and adult stages of many organisms are exchanged between the estuary and the sea. Some organisms may be passively carried by estuarine currents while others may actively swim or take advantage of the direction of tidal flows to move across the estuary–ocean interface.

Primary producers, including phytoplankton and resuspended benthic microalge, depend on passive transport between estuaries and the sea. Most flux studies show that these organisms have a net seasonal or annual transport into the estuary from the coastal ocean. This import has been explained by passive filtration by estuarine wetlands and by active filtration by suspension-feeding animals within the estuary. Protozoans, bacteria, and viruses are also found in the estuarine water column and while they most certainly are passively transported by estuarine currents, the direction of their net flux is yet to be determined.

The exchange of invertebrate larvae between estuaries and the coastal ocean has been explained by two competing schools of thought, the passive and active hypotheses. In the passive hypothesis, the horizontal movements of larvae are mainly a function of current direction and velocity. The active transport school contends that invertebrate larvae swim both vertically and horizontally to take advantage of tidal currents. In one group that includes oysters, the early stage larvae stay high in the water column with later stages sinking to lower depths. This strategy allows downstream movement of early larvae with some exiting the estuary to the sea, while older larvae are entrained in inflowing bottom currents and effectively retained in the estuary. A second approach is used by larvae that migrate vertically in the water column in synchrony with tidal cycles. This strategy allows larvae to maximize upstream transport and retention. A third group has larvae that are immediately transported to the coastal ocean where they stay for weeks before returning into the estuary using wind and tidal currents. A final group uses the coastal ocean during their adult and larval life. In this case, the postlarvae enter the estuary maintaining their position by swimming against tidal currents.

Nekton organisms (fish, crabs, and shrimps) are mobile links between the various subsystems of estuarine ecosystems as well as links between the estuary and the sea. These animals feed and accumulate biomass while in the estuary and then move back to the coastal ocean, thus exporting biomass and inorganic wastes.

Global Climate

While seasonal and latitudinal climatic effects on coastal and estuarine systems have long been documented, the impacts of global climate change (warming or cooling) on estuarine systems have only recently been quantified. Major storms, El Nino-Southern oscillation (ENSO) events, seismic sea waves, or tsunamis and sea level rise (SLR) are global effects that can significantly influence water and material fluxes in estuaries.

Hurricanes and major storms generally influence estuaries through storm surges and short-term increases in precipitation. These enormous pulsed fluxes of water can change the geomorphology of estuaries and their watersheds, massively resuspend sediments, and flush materials off the landscape and into the estuary. Tsunamis can be even larger than storm surges and can have similar impacts to even greater areas of the coastal ocean and estuaries. However, extensive marsh and mangrove wetlands common to estuaries can buffer these pulses of water and reduce the damage they can cause to the coastal landscape.

ENSO events only affect some estuaries. The effect is usually a drought or higher than average precipitation. For example in some South Carolina estuaries, ENSO-induced precipitation and upland runoff can depress salinity up to 75% for as much as 3 months.

SLR is an example of global change on both seasonal and annual time scales that directly influences estuarine systems. Seasonal changes in sea level are the result of air pressure changes at the water's surface and the expansion or contraction of water mass due to heating and cooling. In estuarine systems, these changes are reflected in the depth of the system, but more importantly in the area and time of exposure or submergence in the intertidal zone. SLR will gradually force the transgression of estuaries upslope along the coastal plain. Eventually, SLR will compete with human development for the coastal landscape.

Estuarine Ecosystem Resilience and Restoration

Estuarine ecosystems and subsystems can and do exhibit alternate or multiple states of existence. The ability of an ecosystem to absorb disturbance and resist a change in state is termed ecological resilience, as opposed to engineering resilience, which is the time it takes a system to return to its original state. In the last decades of the twentieth century, ecologists observed that ecosystems were not static entities, but appeared to change in response to external and internal forces. In the Chesapeake Bay estuary, for example, some of the factors causing a state change were over-fishing, increased suspended sediment load, eutrophication, species invasion, and disease. The bay's responses to these forces were slow at first, but with the steady increase in the human population in the bay watershed and with its adherent development, the signs of a state change were dramatically evident. The oyster reefs, a major benthic subsystem or habitat that had dominated the bay for centuries, began to decline rapidly or crash. The benthic-dominated food web was replaced by a planktonic food web. Management efforts to restore the initial oyster-dominated system did not work, probably because they had a single species focus and because ecosystems are strongly nonlinear which means the

path to restoration is different from that leading to the initial change of state and many more components of the ecosystem are involved in addition to the oysters.

Introduction

Globally, floodplains may be of greater value to society than any other ecosystem type. This is because of the critical role that interactions between floodplains and associated streams play in maintaining supplies of clean water. While that role is conceptually simple, the processes which define interactions (i.e., floodplain functions) in aquatic–terrestrial ecotones are exceedingly complex. Consequently, it is necessary to develop some understanding of the ecological mechanisms behind those interactions in order to fully appreciate the importance of floodplain ecosystems. To that end, the goal of this article is to provide a first-iteration overview of floodplain form and function (Fig. 1).

A key concept is that floodplains and associated streams are both causes and reflections of the other's characteristics and functioning. As an example, the climate and geomorphology of a landscape will define the hydrology and initial chemistry of streams. Stream characteristics determine the hydrology, soil characteristics, flora and fauna, and biogeochemistry of the floodplain. In turn, biogeochemical feedback from floodplains to streams helps define the environment seen by aquatic flora and fauna. Thus, a strong interdependency exists between aquatic and terrestrial components of riparian ecotones.

It is critical to understand that land clearing and development, construction of dams and impoundments, pollutant export, and other human activities constitute major influences on streams and floodplains. In some cases, these will override the original hydrology, biogeochemistry, and ecology. As an example, the original hydrology of a riparian system could be dramatically altered by the construction of bermed roadways that cross streams without adequate provision for through flow. Since hydrology is the primary driver of all floodplain functions, corresponding changes in net primary productivity (NPP), species composition of animal and plant communities, and biogeochemistry could be expected to follow.

Geomorphic Origins

Streams in steep topography tend to undergo continual downcutting and, consequently, act as sources of fine and coarse material with little to no opportunity for deposition. Sediment loads are easily carried downstream because the high gradient of the channel imparts sufficient energy for water to retain particles. In many cases, as streams emerge from steeper terrain and move into flatter areas such as coastal plains, the gradient of the channel decreases and flows may spread and lose energy. This promotes the occurrence of overbank flow and creation of deposition surfaces or sediment sinks. However, a floodplain may shift between being a sediment sink or source depending on hydrologic changes induced by climate, anthropogenic activities, or other influences. Downcutting also occurs as older floodplains are abandoned by streams and become terraces which resemble stair steps in cross-section (Fig. 2).

Sedimentation occurs as particles settle during sheetflow and is highly variable both temporally and spatially. Sediment deposition or alluviation makes possible the high soil fertility that is generally associated with many floodplains although there

are notable exceptions. Rates of sediment accumulation vary markedly among floodplains and, in the southeastern United States for example, range from 1 to 6 mm yr^{-1}.

Deposition and scouring may often occur simultaneously on different portions of floodplains and at different times in individual locations. Consequently, the scale at which sedimentation is assessed is very important in gaining an accurate assessment of net changes. The result of the spatial irregularities is a pattern of swales and berms that generally runs parallel to the stream course. The convex and concave microrelief may represent elevation differentials of only a few centimeters. Nonetheless, those minor differences have major importance in defining soil environments for vegetation and in influencing the extent of contact between floodwaters and the floodplain surface. In many cases, the microtopography of major floodplains is somewhat predictable (Fig. 3) and, similarly, drives spatial patterns of species composition and NPP of vegetation communities. However, changes in microrelief may be much less apparent on some floodplains due to either prolonged or infrequent flooding.

Hydrology

Hydrology is the foremost determinant of vegetation species occurrence, NPP, biogeochemistry, floral and faunal habitat, and all floodplain functions and traits. Consequently, any insights into the nature of floodplain ecosystems and the basis of their societal

value are predicated upon an understanding of hydrology. The `flood-pulse' concept provides one framework within which to develop this understanding.

In this concept, the river and floodplain are considered as a single system and the `rhythm of the pulse' (i.e., the hydroperiod) is the controlling mechanism which regulates exchange of energy and material between the river and floodplain. An influx of sediment and nutrients and export of organic carbon from the floodplain will occur at intervals dependent on the pulse rhythm. Examples of common rhythms include single, long duration and multiple, short duration which might be stereotypic of high-order river floodplains and low-order headwater streams, respectively.

In general, flood frequency and duration may decrease and increase, respectively, as stream order rises. When headwaters originate in mountainous terrain, narrow V-shaped valleys form and hydroperiods may be characterized as flashy (i.e., frequent flooding, with sharp rises and drops associated with stage levels). Hydroperiods reflect the integration of rainfall patterns, water storage capacities, and many other factors across the associated catchments. Consequently, stage level rises and falls are slower due to the `buffering' that is provided by high storage capacities and the greater variability of other factors. Conversely, small catchments have much less storage capacity and, consequently, streams respond rapidly to precipitation events. As a result, floodplains of large rivers can stay flooded for significant portions of a year while low-order floodplains may be inundated frequently but for much shorter periods.

Interchange of water between floodplains and rivers is very complex and involves mutualistic influences. The nuances of those interactions form the basis of the role of floodplains as ecotones and regulators of energy and nutrient exchange. At low stage levels, water within swales and depressions may have originated with the river, precipitation, an upwelling of groundwater, or some combination. From a biogeochemical standpoint, the origin is significant in terms of the degree of spatial and temporal contact with the floodplain. At low stage levels, there is less opportunity for river water to contact the floodplain and, consequently, biogeochemical and dissolved organic carbon exchanges are minimal. As stage levels rise, the potential for the floodplain to influence the biogeochemistry of sheetflow increases as well. However, at some point, increasing floodwater volumes and higher velocities reduce contact with the floodplain. This is because a decreasing proportion of the sheetflow volume is in contact with the floodplain as volumes increase. Similarly, temporal contact is reduced as sheetflow velocities rise.

There is also significant interaction between the river and floodplain in terms of groundwater. Channel waters often generate a head pressure which declines with distance from the stream bank. Groundwater transmittance will decline as hydraulic conductivity of alluvium decreases (e.g., clays have reduced conductance compared to sands). In humid regions, groundwater near the channel moves under pressure and will contact and mix with water that has seeped into the alluvium from adjacent uplands. As a result, groundwater mixing can be quite active during periods of low evapotranspiration.

Biogeochemistry

Once considered purely as nutrient sinks, floodplains are now known to play multiple roles from a geochemical perspective. Based on the type of floodplain, associated vegetation, and the degree and nature of disturbance, floodplains may also serve as sources or transformation zones for nutrients. The widely held perception of floodplains as fertility hot spots belies the complexity associated with input–output budgets as well as the biogeochemical processes within the floodplain ecosystem. In particular, the impact of hydroperiod on biogeochemical processes sets floodplain biogeochemistry apart from that of non-wetland ecosystems. Periodic flooding makes possible nutrient exchange across the aquatic–terrestrial ecotone and controls the nature of decomposition, nutrient uptake and release by vegetation, and many other processes. As an example, the process of denitrification or the anaerobic conversion of nitrate to gaseous forms of nitrogen is very important on floodplains. In addition, the interaction of hydrology and biogeochemistry necessitates the development of unique approaches to the study of nutrient cycling in these ecosystems.

As previously mentioned, floodplains may serve as sinks, sources, or transformation zones for geochemical inputs of nutrients derived from inflow, precipitation, nitrogen fixation, and soil weathering. Multiple roles may proceed simultaneously on the same floodplain if spatial heterogeneity in hydrology, vegetation, disturbance, and nutrient influx so dictate. The use of a geochemical budget allows net inputs to be compared to net outputs and is based on the perspective of the ecosystem as an integrated system.

In general, the factors that promote nutrient sink activity on floodplains include (1) presence of aggrading vegetation; (2) wide carbon: nutrient ratios in living vegetation and detritus; (3) topographic positions conducive to somewhat frequent, short duration, and low-energy flooding; (4) basin geomorphology that promotes significant sediment loads in streams (e.g., redwater, brownwater, or whitewater based on the color of suspended clay); (5) high occurrence of nitrogen-fixers; and (6) until nutrient saturation is approached, association with a river subjected to high anthropogenic nutrient loadings.

Alternatively, rivers draining low gradient basins with sandy soils are often referred to as blackwater systems because their waters are stained with organic substances (Fig. 4). These tend to carry low sediment loads and, consequently, alluviation (i.e., sink activity) is less pronounced. Also, floodplains occupied by mature vegetation communities may act as transformers of nutrients (e.g., inorganic inputs of nitrogen converted to organic outputs) rather than a sink or source. The latter is a key facet of the `kidney function' of these systems and has great significance for maintenance of water quality. Sink activity, such as the filtration and accumulation of sediments (and associated nutrients) from sheetflow also plays a major role in cleansing water (Fig. 5). Finally, floodplains that have been altered in some way by disturbance may function as nutrient sources. The longevity of the source

activity could be short-term (e.g., a well-planned forest harvest followed by rapid forest regeneration) or long-term (e.g., conversion to agricultural or urban uses, impoundments, or climate change).

Similarly, all biogeochemical processes within floodplain ecosystems reflect the overriding influence of hydrology. As an example, the timing of litterfall is heavily affected by hydroperiod because different vegetation communities occur under different hydrologic regimes. In the southeastern United States, forest species associated with *Nyssa* may grow under wetter conditions than communities dominated by some species of *Quercus*. On wetter sites, *Nyssa* foliage tends to senesce earlier in the autumn than other floodplain tree species and, consequently, the senesced foliage is exposed to a different microenvironment than litter that falls later in the year. As a result, nutrient release and immobilization sequences are likely to differ among sites.

Mass loss and nutrient dynamics during decomposition are a function of both litter quality and the decomposition microenvironment. Litter quality (the biochemical composition of detritus) is defined by the conditions under which a plant is growing as well as genetics and has been shown to be closely linked to variation in hydroperiod. Also, the frequency and duration of flooding play a dominate role in determining biomass and composition of microbial populations. Key determinants of shifts between nutrient mineralization and immobilization include hydroperiod and nutrient inflow. In the southeastern United States, mass loss rates of foliar litter (with litter quality held constant) are maximized by moderate durations of flooding followed by several months of noninundation.

In general, rates of litter mass loss in forested floodplains exceed those of uplands. Globally, decay constants for temperate floodplain forests average approximately 1.00 while the mean for all temperate deciduous forests is less than 0.80. This differential is partly due to the greater availability of soil moisture (better habitat for microbial populations) during parts of the year. However, mass loss, as measured by disappearance of confined litter, includes both mechanical disintegration as well as metabolic conversion of organic carbon and, consequently, periodic inundation offers greater opportunities for disintegration and export.

The general perception that floodplains are very fertile has led to misconceptions regarding the degree to which insufficient nutrient availability may constrain floodplain NPP. In many cases, it is true that floodplain soils are more fertile than upland counterparts. However, vegetation species found in many floodplains often have higher annual nutrient requirements compared to species adapted to uplands. Consequently, forest vegetation on many floodplains is likely to be nitrogen deficient and, in some cases such as blackwater systems, deficient in phosphorus and base cations as well. An example would be the nutrient-demanding *Populus deltoides* Batr. plantations that grow in extraordinarily fertile soils of the Southern Mississippi Alluvial Valley, USA. In spite of fertile soils and high aboveground NPP (20–25 t ha^{-1} yr^{-1}), those systems would increase in NPP if supplied with additional nitrogen.

The degree to which a floodplain ecosystem is deficient or nondeficient for particular nutrients is critical in regard to that system's potential to act as a nutrient sink. As previously mentioned, the kidney function is enhanced if floodplain vegetation can assimilate incoming nutrients from sources such as polluted water or atmospheric inputs. Once a deficiency is eliminated, it is still possible for floodplain vegetation to assimilate particular nutrients such as nitrogen through luxury consumption. However, a level may be reached after which the vegetation's capacity to retain nutrients is saturated. The latter condition reflects a high degree of biotic stress and is a serious threat to floodplain vegetation associated with eutrophic streams.

Vegetation Community Structure and Composition

Vegetation communities in floodplain systems have developed over hundreds of years as a function of soil type, topography, and hydrology. The type of vegetation growing on a particular floodplain will be dominated by trees or shrubs adapted to the environmental conditions of that floodplain. Hydroperiod is the most important local environmental condition determining composition, and the species found respond to elevation differences relative to the river's flooding regime. Typical floodplain forests begin at the natural levee where coarse-grained deposits result in quickly draining soils and continue as surface elevations decrease away from the river and become more poorly drained.

Structural characteristics of floodplain forests vary depending upon location (**Table 1**). Stem density and basal area are generally greater in the southeastern United States and the humid tropics than in arid areas, but in arid areas basal area can still exceed 50 m^2 ha^{-1}. Basal areas in floodplain forests tend to be as high as or higher than that of upland forests. Almost without exception, the number of tree species increases as flooding decreases. The greatest number of tree species occurs in wet, tropical floodplains such as the Amazon. The understory of floodplain forests is generally lower in density and species numbers, probably due to reduced light levels and the extended flooding conditions.

Adaptations of Floodplain Vegetation

Due to the alternating wet–dry environment experienced by trees growing on floodplains, they have developed a variety of physiological and morphological adaptations that allow survival during flooding. Initially, stimulation of alcohol dehydrogenase (ADH), enzyme activity may provide a temporary means to support essential metabolic functions. The anaerobic pathway is less efficient than the aerobic pathway (39 moles ATP per mole hexose vs. 3 moles ATP per mole hexose), but provides an energy resource while anatomical changes are occurring.

Table 1 Mean structural and aboveground productivity characteristics of floodplain forests

Area	No. of species	Density (no. ha^{-1})	Basal area (m^2 ha^{-1})	Biomass (t ha^{-1})	Aboveground NPP		
					Leaf	Wood (t ha yr^{-1})	Total[a]
Southeastern USA	13	1242	45.0	302	5.36	7.78	13.26
Northeastern USA	10	970	26.1	150			
North Central USA	5	546	29.5				
Western USA	5	310	27.5				
Central USA	12	405	33.5	290	4.20	2.50	8.70
Europe		1237	26.5	314	3.48	17.88	
Central America	10	726	49.9	118	11.61		
Caribbean	27	3359	42.4	224	15.55

Africa	26						
Southeast Asia					9.15		
Australia	12	493		260			

[a]Total NPP does not always equal leaf plus wood as some sources only report total.

The seeds of floodplain tree species require oxygen for germination, and even those species that can grow in permanently to nearly permanent flooded conditions (e.g., *Taxodium* and *Nyssa*) require moist, but not flooded, soil for germination and establishment. Occasional drawdowns are necessary for the survival of tree species. Rapid stem elongation, such as been observed with *Nyssa aquatica*, allows the seedling to get its crown above the water surface of subsequent floods. The dispersal and survival of many wetland tree seeds is dependent upon hydrologic conditions. *Taxodium* and *Nyssa* seeds are produced in the fall and winter between the periods of lowest and highest streamflows, giving the seeds the widest possible range of hydrologic conditions. Overall, seed production of many wetland species seems to be linked to the timing and magnitude of hydrologic events.

Stem hypertrophy, commonly called butt swell or buttressing, is characterized by an increase in diameter of the basal portion of the stem and is common in *Taxodium*, *Fraxinus*, *Nyssa*, and *Pinus* species. Basal swelling can extend from just above the ground level to several meters depending upon the depth and duration of flooding. Swelling generally occurs along that portion of the trunk that is flooded seasonally. Increased air space in the swollen portion of the stem allows increased movement of gases within the plant. Ethylene production has been documented to play a regulatory role in altering growth and stem anatomy of woody plants, and has been found to be higher in flooded *Fraxinus* stems with well-defined hypertrophy than those without stem hypertrophy. Lenticel hypertrophy has long been associated with flooding and acts to increase internal gas transport from the stem to the roots. Duration of flooding does not appear to affect the number of lenticels formed but does affect the size. The formation of hypertrophied lenticels under anoxic conditions also appears to be induced by ethylene. Other commonly observed features in flooded environments include buttress roots and knees. Buttress roots appear as fluted projections at the base of mature trees and extend for several feet from the trunk outward and down into the soil. Because of the shallow nature of root systems in saturated or flooded soils, these buttress roots are thought to provide additional support to the tree. Knees are common in *Taxodium* spp. in the southeastern United States. Their function has not been confirmed, although there is some speculation that they also serve in stability of the tree. In Australia, *Melaleuca* trees on floodplain sites have modified bark structures such as papery bark with internal longitudinal air passages that allow them to tolerate flooded conditions.

Productivity

Riverine floodplains are typically characterized by high productivity. Productivity is enhanced in many floodplain areas by the continued import and retention of nutrient-rich sediments from headwater regions and lateral sources, increased water supply (especially in arid regions), and more oxygenated root zones as a result of flowing waters. The flood pulse advantage has long been recognized, with ancient Egyptians setting taxes based on the extent of the annual flood.

Primary productivity of unaltered, seasonally flooded ecosystems is generally higher than that of floodplain forests that are permanently flooded or those with stagnant waters. Despite the theoretical basis for increased floodplain productivity due to pulsing, it has been difficult to confirm. More recent studies tend to point toward the idea that seasonal flooding can be both a subsidy and a stress. In the southeastern United States, aboveground NPP was similar for upland hardwood, bottomland hardwood, and *Taxodium–Nyssa* forests. The reason for this may be that for some sites, subsidies and stresses occur simultaneously and cancel one another. As a result, flood intensity and duration affect soil moisture, available nutrients, anaerobiosis, and even length of growing season in a complex and nonlinear `push–pull' arrangement. When hydrology is altered rapidly, aboveground productivity is less than in natural forest communities with nearly continuous flooding (**Fig. 6**).

Aboveground biomass in floodplain forests ranges between 100 and 300 t ha^{-1}, although there is one report of a forest in Florida where biomass exceeds 600 t ha^{-1}. Leaves account for only 1–10% of the total aboveground biomass. Belowground biomass has been sampled rarely and varies greatly, but reported values tend to be somewhat lower than the 20% of

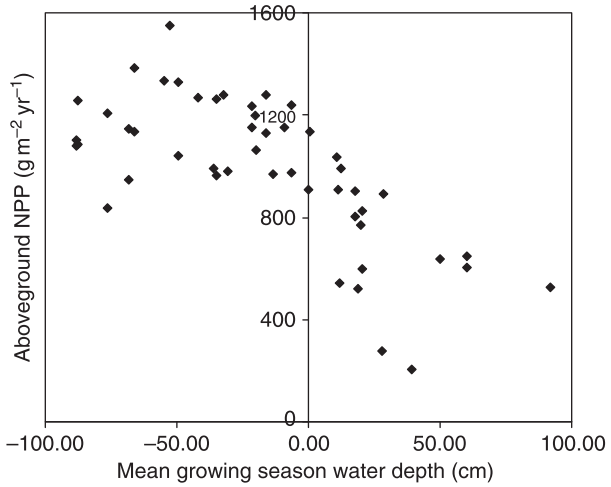

Fig. 6 Relationship between aboveground net primary productivity (NPP) of floodplain forests of the southeastern United States and mean water depth during the growing season.

total biomass often cited for upland species. Total aboveground biomass production (leaves plus stem wood) ranges from 668 to 2136 g m^{-2} yr^{-1}, with leaves accounting for approximately 47% of the production. Although it has been reported that there are no latitudinal patterns in NPP, litterfall production of *Taxodium* forests in the United States shows a curvilinear relationship with latitude with a maximum occurring at about 31.9° N. In northern Australia, litterfall in *Melaleuca* forests has been reported to be 2–3 times greater than that in forests in the southern part of the continent. Changes to natural hydrologic regimes decrease litter production by half. As a result of the high productivity, generally associated with floodplain forests, carbon sequestration is particularly important there.

Anthropogenic Impacts

Rivers and associated floodplains have been vitally linked to civilization throughout history for food production. In order to make farming easier and more productive, rivers have been diverted and floodplains have been deforested and drained or leveed to provide fertile land. A major consequence of the widespread use of floodplains and adjacent uplands for agriculture has been the generation of large sediment loads in associated streams and rivers. As a result, much sediment has been deposited on streambeds and floodplains with negative consequences for aquatic habitat and floodplain vegetation. More recently, impoundments have become commonplace for energy production and water storage and levees continue to be built to provide space for development as well as for farming. Globally, it is estimated that, at a minimum, 75% of total floodplain area has been lost.

Floodplain function is dependent on connectivity between the river and its riparian area. Unfortunately, many anthropogenic impacts eliminate or reduce that connectivity so that key functions such as water filtration are much reduced at the landscape level. Similarly, alterations in hydroperiod caused by human activity often drive changes in composition and productivity of vegetation communities as those species adapted to the former conditions decline and are replaced by others.

Additional impacts include fragmentation of riparian vegetation communities and stimulation of invasive non-native plant invasion. Fragmentation often results in reduced habitat quality while successful invasion by non-native species may cause major alterations in community composition, structure, and function. While ecological restoration of floodplains has attracted widespread interest, economic constraints have primarily limited restoration applications to localized areas. However, notable exceptions include restoration of the portions of the Pantanal River Basin in South America and the Kissimmee River Corridor in Florida, USA.

More recently, urbanization has led to significant and growing impacts on floodplains in many parts of the world. As catchments become developed, the concomitant rise in impervious surface drives major increases in runoff volume and velocity. As a result, rising limbs during flood events become much steeper, a condition that is often associated with higher in-channel velocities. Higher flow velocity increases the rate of channel incision resulting in a lowered groundwater table and reduced connectivity between the stream and floodplain. In addition, urbanization stimulates loadings of nutrients (particularly, nitrogen) and causes a considerable degree of water pollution in general.

Further anthropogenic impacts include channelization of river systems. Channelization has benefited farming and waterborne transportation by reducing flooding and removing obstacles to barge and other water traffic. However, water quality has suffered in many instances since there is again less opportunity for river waters to contact floodplain surfaces and undergo pollutant reduction.

Africa

The African continent has approximately 99 large wetlands, of which 43 are floodplain systems. Some of the larger floodplain systems include the Zaire Swamps (200 000 km^2), the Inner Niger Delta of Mali (320 000 km^2 when flooded), the Sudd of the Upper Nile (16 500 km^2 of permanent swamp and 15 000 km^2 of seasonal floodplain), and the Okavango (14 000 km^2 of permanent swamp and 14 000 km^2 of seasonal floodplain). These floodplain systems are in dynamic equilibrium with the constant flux of pulsing events occurring within them at different spatial and temporal scales. Goods and services resulting from pulsing events include floodplain recession agriculture, fish production, wildlife habitat, livestock grazing, ecotourism, and biodiversity, as well as natural products and medicine.

In semiarid and arid regions of Africa, floodplains are often the only source of year-round water. As in other floodplains around the world, vegetation distribution is strongly related to flooding frequency and duration and microtopography. Dense evergreen tree growth occurs on higher well-drained areas like levees and termite mounds, while grasslands tend to dominate lower, more frequently flooded areas. Typical grasses found growing in these frequently flooded areas (called swamp) include *Phragmites*, *Typha*, and *Polygonum*. Tree and bush genera in less frequently flooded areas include *Hyphanene*, *Borassus*, *Acacia*, *Ficus*, and *Kigelia*.

Floodplain areas are centers of high diversity of animal and plant life. These floodplain areas are of profound importance for fish production and probably serve as spawning and recruitment areas. Interannual fluctuations in fish production have been correlated with the flooding regime. Numerous bird species (over 400 in some floodplains) can be found in these areas, including bee-eaters, jacanas, malachite kingfishers, grey herons, egrets, African fish eagles, and Zaire peacocks. The birds share the floodplains with antelope (sitatunga, waterbuck, puku, and lechwe), hippopotamus, zebra, and buffalo; vegetation ranges from water lilies and papyrus to floodplain forests with minor topographical variations playing an important role in distribution of forest and grassland. Climatic variations are also important, with forest only occurring near rivers in drier areas while in wetter areas forests can extend for a considerable distance away from the river. River meanders tend to be cut off during flooding periods, adding diversity to the floodplain topography.

Unfortunately, very few studies of the ecology of many of the African floodplain systems have been carried out. The most studied floodplain system in Africa is the Okavango Delta. Annual floods travel uninterrupted down the Okavango River and inundate the Okavango Delta from April to September. River water is characterized by moderate levels of nutrients, but when it enters the floodplain it becomes strongly enriched by nutrients via leaching from soil, detritus, and feces. Organic carbon enrichment comes from leaching of floodplain leaf litter and soil, although dissolved organic carbon release from leaf litter is over 2 orders of magnitude greater than for leached soils. This nutrient enrichment has a major impact on aquatic productivity in the delta and illustrates the strong links between terrestrial and aquatic ecosystems.

African floodplains face a different set of challenges as opposed to those in developed countries. In Africa, floodplains generally occur in semiarid areas to arid regions, and flooding is the driving force behind the high productivity of these areas. From as early as the 900s, people have inhabited these areas, and pastoral and agricultural economies are dependent upon the continued presence of the floodplains. Continued pressures from agricultural practices within the floodplains themselves and population growth that demands the transfer of water to alleviate shortages outside of the floodplain need to be addressed to ensure survival of these important ecosystems.

Asia

In northern Asia, there are extensive productive wetlands along the floodplains of rivers. In western Siberia, the river Ob extends over 50 000 km^2 and supports what is called the largest waterfowl breeding and moulting area in Euroasia. The Ob Valley is a labyrinth of intricately arranged channels and floodplain lakes. As in other seasonal floodplains, the region is a land of fluctuating water levels, with seasonal and annual fluctuations in river discharge and flooding patterns. This area avoided any serious human impacts for centuries, but oil and gas exploration has resulted in significant pollution and transformation of the landscape.

The Indus River has long been the lifeblood of arid Pakistan. In earlier times, people used the river's water to cultivate the floodplain, but during the last 100 years, the river has been dammed and diverted into one of the largest and most complex irrigation systems in the world. In the absence of a drainage system to remove irrigation water, evaporation leaves salt in the soil. As a result of this salinization of the soil, combined with waterlogging, over 400 km^2 of irrigated land is lost each year.

Many of the large river systems in South Asia display considerable annual variation in discharge and, during the rainy season, may flood very large expanses of land (e.g., approximately 200 km on each side of the Ganges). In some cases, entire deltaic areas may be inundated. The prolonged, monomodal flooding promotes extensive spatial and temporal contact with floodplains and, consequently, dominates the socioeconomics of the large human populations near those systems. Agricultural activities often cause significant sediment export from upper reaches of many rivers and, as a result, delta tributaries may become clogged. Due to the subsequent reduced flow, salinity can increase in soils and alter species composition in the delta forests.

About 80% of Bangladesh (115 000 km^2) is formed by floodplains of the Ganges, Brahmaputra, and Meghna rivers. In major floods, 57% of the country can be flooded. Availability of water during the dry season makes it possible to grow three crops a year in some areas. Deposition of waterborne sediments keeps the soils fertile and algal growth enriches the soil by fixing nitrogen. As in many parts of the world, forest vegetation of South Asian floodplains strongly reflects variations in hydroperiod and soil. In the Ganges and Brahmaputra River Valleys, within areas with heavy clay soils where flooding occurs for most of the year or

permanently, forest vegetation may be only 5–10 m in height and occur in conjunction with numerous vines. However, combinations of similar flooding regimes and lighter, fertile soils may increase canopy heights by 10 m or more. Many of these riverine forests exhibit a prevalence of evergreen or semievergreen species, although at higher altitudes alders may dominate. Some lowlands, in particular many river deltas such as those of the Ganges–Brahmaputra and Irrawady, are occupied by mangrove forests.

In China, 95% of the population is concentrated in the eastern half of the country, mainly in the vast alluvial plains of the major rivers, the Yellow and Yangtze Rivers primarily. High population densities coupled with high growth rates, rapid urbanization, and industrialization play a major role in most Asian countries. Water resources in this region are under increasing pressure as the demand for domestic supplies, agricultural use, and hydroelectric power increases. Past water resource and agricultural management practices have resulted in rapid loss and degradation of natural wetlands throughout the region. The regulation of rivers and streams through embankments and dams has eliminated floodplains and reduced groundwater recharge. Changing hydrological regimes have increased flooding during the rainy season and reduced availability during dry periods. Water resource management has often resulted in numerous man-made wetlands such as reservoirs and paddy fields that have very different functions and values than natural wetlands, and are in no way a substitute for natural wetlands, particularly floodplain wetlands. In short naturally occurring floodplains in these regions are threatened by numerous human activities, including mining, aquaculture, unsustainable forestry or fisheries practices, and conversion of forests to urban or agricultural land.

Australia

Australia is distinctive in that there are few permanent wetlands due to high evaporation rates and low rainfall. Most wetlands on the continent are intermittent and seasonal. Common features of floodplains are waterholes and lagoons called billabongs that retain water seasonally or permanently, providing important habitat for many animals at different times of the year. Floodplain wetlands tend to be sites of extraordinary biological diversity of waterbirds, native fish, invertebrate species, aquatic plants, and microbes. Key drivers of this biodiversity are the lateral connectivity to the river of the floodplain wetland and the unpredictable flows that create wide ranges of temporally and spatially different aquatic ecosystems.

Humid coastal areas are drained by short, perennial streams, while much of the streamflow in the rest of the country is intermittent or nonexistent because of low and unreliable rainfall, high evaporation, and flat topography. Even under these conditions, forested wetlands can be found throughout Australia, but they can only be classed as true forests in the wettest localities. The largest area of floodplain forested wetland (over 60 000 ha) occurs on the Murray River. Floodplain forests are generally composed of *Melaleuca* or *Eucalyptus* species, but they cannot survive very long periods (>5 months) of flooding. If flooding exceeds several weeks during the growing season, forest canopy cover declines to between 10% and 70%, creating open woodlands.

Tropical floodplain wetlands are found across northern Australia, covering an estimated 98 700 km^2. Vegetation of these wetlands has been mapped at various scales, but there are few specific or long-term analyses of the distribution or successional changes of the plants. The Ord River floodplain in northern Australia encompasses approximately 102 000 ha and is a large system of river, tidal mudflat and floodplain wetlands that supports extensive stands of mangroves, large numbers of waterbirds, and significant numbers of saltwater crocodiles. In southeastern Australia, the Murray–Darling river system drains 14% of the continent and contains the greatest amount of floodplain wetlands on the continent.

In recent years, floodplain areas have undergone considerable change because of animal (buffalo, pigs, cane toads) and plant (mimosa, salvinia, paragrass) invasions, changes in fire regimes, water resource management, and saline intrusion. Dams and the cumulative impact of diversions and upstream river management have turned many floodplains into terrestrial ecosystems. The effect of this change in flooding has not been well studied and data exist only for a fraction of the area affected. Floodplain loss will continue until there is a better understanding of the long-term ecological effects of dams and diversions.

Europe

Floodplains in Europe have been influenced by humans for thousands of years. Civilizations often were established near rivers and frequently utilized floodplain resources for food (agriculture or hunting), power (wood or water mills), and shelter. As communities grew there was an increased need to control the flooding that naturally occurred in the floodplains with the use of dams, dikes, and ditching. These structures altered the hydrology which in turn has altered the forest composition in these areas. Furthermore, channel straightening has caused major hydrologic changes resulting from faster flow and increased groundwater depth. In some of the Danube watersheds, there has been an 80% decrease in first-order streams from 1780 to 1980.

In many areas, depth to groundwater has increased due to the `drying' of the floodplains and this has driven shifts in the composition of vegetation communities. In particular, species such as *Quercus robur*, *Fraxinus* spp., and *Ulmus* spp. are becoming rarer due to the altered hydrology. Forestry practices have induced a further shift from natural systems to faster growing *Populus* clones in many of the floodplains across central Europe. However, reestablishment of the more traditional forest composition of uneven-aged oak, ash, and maple mixes has been achieved in some areas as recently as the past 50 years. Large portions of the forests remain monocultures of even-aged *Acer* or *Fraxinus*.

The Danube Delta represents one of the largest wetlands in Europe and is undergoing eutrophication as a result of increasing nutrient inputs, decreased riparian vegetation, and loss of the filtration function. One major difference between European floodplains and others worldwide is that increased flow and flooding often occurs in the spring as a result of snowmelt in high altitudes.

North America

In the dry climate of the Western United States, water is a limited resource not only for the wildlife but also for the human inhabitants. Although wetland areas comprise a very small portion of total land area (i.e., less than 2%), over 80% of wildlife is dependent on their presence. Rainfall in this region varies from less than 15 cm yr^{-1} in the desert regions to greater than 140 cm in the mountains. In the mountainous regions, rainfall and snowmelt are greater than losses and, therefore, wetlands rarely dry out. However, evapotranspiration in the basin areas is 3–4 times greater than precipitation and, consequently, soil salinization is a stress to which vegetation must adapt. In the driest regions soil salinization prevents vegetative establishment. Ephemeral drains are prevalent in the intermountain west with snow melt and high rain contributing to their flow.

At higher elevations in the United States, where soils are semipermanently inundated or saturated, associations of *Populus*, *Salix*, and *Acer* are found. Floodplain areas flooded or saturated 1–2 months during the growing season are comprised of a wide array of hardwood trees. Common species in the United States include *Fraxinus* spp., *Tilia* spp., *Ulmus* spp., *Liquidambar* spp., *Celtis* spp., *Acer* spp., *Plantanus* spp., and some *Quercus* spp. At the highest elevations, flooding occurs for less than a week to about a month during the growing season. Typical tree species include a variety of *Quercus* spp. and *Carya* spp., with some *Pinus* spp.

Floodplains of the southeastern United States occur within three physiographic regions: (1) coastal plains, (2) piedmont, or (3) Appalachian Mountains. Rainfall is sufficiently prevalent during all seasons except for brief periods of drought. Successional patterns of southern forested floodplains are often dictated by hurricanes, tornados, catastrophic ice storms, and extended drought. Soils are typically acidic, with the exception of near neutral pH soils across much of the Southern Mississippi Alluvial Floodplain and the Selma Chalk geologic region of Alabama and Mississippi. In many floodplains, as one moves in a direction perpendicular to the river, soil textures range from coarse sands near stream channels, fine sands in natural levees, to loams and clays in backwater areas. This separation pattern is a result of particle size and sheet flow velocity.

The lowest elevation, nearly always flooded sites on floodplains in the southeastern United States are occupied by *Taxodium–Nyssa* swamps. In other parts of the world, it appears there are no similar tree species that can survive permanent or long periods of inundation. As long as the floodplain channel remains stable and flooding frequency remains constant, these species should dominate the stands indefinitely.

South America

Much of our current knowledge about forested floodplains has been derived from extensive studies performed in the sub-basins of the Amazon River. In particular, our understanding of floodplain biogeochemistry, NPP, vegetation dynamics, geomorphology, and faunal relationships has been greatly influenced by Amazonian research.

In comparison to river basins in other parts of the world, the water balance of Amazonia lowlands is roughly evenly divided between evapotranspiration and runoff. This contrasts with systems in Asia where runoff dominates due to generally steeper terrain and many African systems where broad floodplains and high potential evapotranspiration result in low runoff. Floodplain forests in South America are typically composed of a small number of fast-growing, early-successional species capable of surviving periodic floods and large amounts of sediment deposition (e.g., *Salix* and *Inga* spp.).

The `flood pulse' concept was originally conceptualized in relation to the Amazon and similar floodplains and can be applied worldwide. The major river floodplains of South America such as the Amazon, Orinoco, and the Parana display singular, river-borne flood pulses of large amplitude and duration. In contrast, inundation on floodplains situated within large depressions such as the Pantanal is generally rainfed (as opposed to overbank flow from rivers), and also displays a singular periodicity but with lower amplitude. Finally, multiple flood pulses that are less predictable in terms of occurrence and amplitude are characteristic of floodplains associated with smaller order streams.

Some of the classic research that defined global variation among floodplains took place in Amazonia and was associated with contrasts between blackwater versus brownwater or whitewater rivers. Similar types of floodplain systems occur in many parts of the world. The color of the river waters is reflective of the geomorphology of particular systems and is a strong indicator of floodplain biogeochemistry, vegetation dynamics, and NPP. Whitewater rivers in the Amazon Basin derive their color from white clay sediments that originate in the Andes. The suspended clays contain higher levels of nutrients (particularly base cations) which, when deposited, often create fertile floodplains labeled varzea.

In contrast, blackwaters are stained by fulvic acids and other organic compounds and are more acidic than whitewater counterparts (pH <5.0 vs. >6.0 for blackwater and whitewater, respectively). Due to the low sediment loads, floodplains associated with blackwater streams are often nutrient poor and are referred to as igapo. Consequently, forest litterfall production on varzea floodplains is often considerably higher than that of the igapo (approximately 10 vs. 5 t ha^{-1} yr^{-1} for the respective system types). Also, the standing crop of fine roots is much higher in igapo soils compared to varzea, a reflection of greater

belowground allocation of biomass as would be expected in resource-poor soils. Such adaptations increase the likelihood of nutrient capture from decomposing igapo litter. The distinctions in hydrology and biogeochemistry between the igapo and varzea also drive major differences in vegetation species occurrence, root, shoot, and reproductive phenology, and community structure.

Distinctions between floodplains types are also important in regard to animal populations. This is particularly true for fish which depend on interactions with inundated floodplains for resource acquisition, reproductive habitats, and other factors. As an example, the lower NPP on igapo floodplains may translate to lower food resources for fish. While the amount of plant detritus exported from varzea floodplains is higher, phytoplankton production also depends on settling of the clay sediments so that sufficient light can penetrate the waters. Although more difficult to document in riverine systems, fish catches are generally much lower in igapo lakes compared to varzea counterparts.

As is the case in much of the world, South American floodplain ecosystems are under pressure from an array of human activities. As an example, the lower reaches of the Parana' River have undergone changes in hydrology due to construction of dams and upstream expansion of agriculture. The altered hydrology, along with increased concentrations of sediment and other contaminants have resulted in heavy impacts to fish populations and concomitant economic declines in local fishing communities. Although there is a growing voice for conservation and protection of natural resources, it is unclear to what extent anthropogenic impacts may be curtailed.

Summary

As pathways between aquatic and terrestrial ecosystems, floodplains perform a myriad of functions that are critical to humanity and all other components of the biosphere. Because of the vital need of all organisms for clean water, the kidney or filtration function is the most important attribute of healthy floodplain systems.

The filtration function entails sediment and nutrient deposition and, consequently, has long made floodplains very attractive for exploitation as agricultural sites. It is ironic that the very function that makes floodplains so important attracts major disturbances which, in turn, result in destruction of the kidney function in those systems. Globally, that destruction is reflected in the magnitude of floodplain loss (i.e., 75%).

While the primary cause of floodplain destruction is shifting from agriculture to urban development, it would be unrealistic to expect that the general magnitude of anthropogenic pressures on these systems will abate. Consequently, an answer to the critical question of whether adequate supplies of clean water exist will become increasingly uncertain. In order to provide a positive answer and, subsequently, protect human health and well-being, it is vital that we more clearly understand how these ecotones operate so that functional floodplains can be maintained and integrated into evolving landscapes.

Forest Plantations

D Zhang, Auburn University, Auburn, AL, USA
J Stanturf, Center for Forest Disturbance Science, Athens, GA, USA

Between the extremes of afforestation and unaided natural regeneration of natural forests, there is a range of forest conditions in which human intervention occurs. Previously, forest plantations were defined as those forest stands established by planting and/or seeding in the process of afforestation or reforestation. Within plantations, there is a gradient in conditions. At one extreme is the traditional forest plantation concept of a single introduced or indigenous species, planted at uniform density and managed as a single age class (the so-called monoculture). At the other extreme is the planted or seeded mixture of native species, managed for nonconsumptive uses such as biodiversity enhancement. To further complicate matters, many forests established as plantations come to be regarded as secondary or seminatural forests and no longer are classed as plantations. For example, European forests have long traditions of human intervention in site preparation, tree establishment, silviculture, and protection; yet they are not always defined as forest plantations.

Further refinement of the plantation concept is necessary in order to encompass the full range of actual conditions. A useful typology is based on purpose, stand structure, and composition of plantations. Thus, an industrial plantation is established to provide marketable products, which can include timber, biomass feedstock, food, or other products such as rubber. Industrial plantations usually are regularly spaced with even age classes. Home and farm plantations are managed forests but at a smaller scale than industrial plantations, producing fuelwood, fodder, orchard, and garden products but still with regular spacing and even age classes. A wide range of agroforestry systems exist, distinguishable as a complex of treed areas within a dominantly agricultural matrix. Environmental plantations are established to stabilize or improve degraded areas (commonly due to soil erosion, salinization, or dune movement) or to capture amenity values. Environmental plantations differ from industrial plantations by virtue of their purpose; they may still be characterized as regularly spaced with even age classes. Efforts to restore forest ecosystems are increasing and often utilize the technology of plantation establishment, at least initially.

Recently, FAO defined `planted forests' as forests in which trees have been established through planting or seeding by human intervention. This definition is broader than plantations and includes some seminatural forests that are established through assisted natural regeneration, planting or seeding (as many planted forests in Europe that resembled natural forests of the same species mix) and all forest plantations which are established through planting or seeding. Planted forests of native species are classified as forest plantations if characterized by few species, straight, regularly spaced rows, and/or even-aged stands. Forest plantations may be established for different purposes and were divided by FAO into two classes: protective forest plantations which are typically unavailable for wood supply (or at least having wood production as a secondary objective only) and often consist of a mix of species managed on long rotations or under continuous cover; and productive plantation forests which are primarily for timber production purposes.

Fig. 1 shows that, in 2005, some 36% of global forests (about 4 billion ha, covering 30% of total global land area) are natural forests, 53% are modified natural forests, 7% are seminatural forests, and the remaining 4% are forest plantations. Of these forest plantations, productive forest plantations account for 78% and protective forest plantations account for 22%. While natural forests and modified natural forests declined between 1990 and 2005, seminatural forests and forest plantations increased (Fig. 2).

This article provides an overview and economic explanation of global forest plantation development. It also presents factors influencing global forest plantation development and lists the usefulness of forest plantations, including their roles in the conservation of natural forests. Finally, it summarizes the impact of forest plantations on biodiversity and other ecological functions.

An Overview and Economic Explanation of Global Forest Plantation Development

Currently, there are about 109 million ha of productive forest plantations in the world. Productive forest plantations represented 1.9% of global forest area in 1990, 2.4% in 2000, and 2.8% in 2005. The Asia region accounted for 41%; Europe 20%; North and Central America 16%; South America and Africa 10% each; and Oceania 3%.

Forest plantations have been increasing at an increased rate. The area of forest plantations increased about 14 million ha between 2000 and 2005 or about 2.8 million ha per year, 87% of which are in the productive class. The area of productive forest plantations increased by 2.0 million ha per year during 1990–2000 and by 2.5 million ha per year during 2000–05, an increase of 23% compared with the 1990–2000 period. All regions in the world showed an increase in plantation area, with the highest plantation rates found in Asia, particularly in China. The ten countries with the greatest area of productive forest plantations accounted for 79.5 million ha or 73% of the total global area of productive forest plantations (Fig. 3). China, the United States, and the Russian Federation together accounted for more than half of the world's productive plantations.

Forest plantations, productive or protective, develop in response to a relative scarcity of timber and other goods and services associated with forests. In the early part of modern human history, population was sparse, forests were abundant, and survival, economic development, and territorial control were the primary concerns of governments and society. As forest resources declined, assuring an adequate timber supply gradually caught the attention of rulers and planners and became state policy. Often, the very

first policy implemented would be to regulate timber harvesting schedule and intensity. Society also responded by moving to frontiers farther and farther away from population centers, which in economic terms is called a shift in the extensive margin of timber production. In a nutshell, the production and consumption of forest products were all from natural forests in the early part of human history, and forest plantations were not needed.

When the increase in timber consumption caught up with the ability of a country or a region to produce timber in naturally regenerated forests, citizens and governments would become interested in tree planting. While tree planting occurred at least several thousands of years ago in the Middle East, China, and Europe, and nearly 200 years ago in the Americas, the areas planted with trees through afforestation (planting land that was formerly in a nonforest cover) and reforestation (planting land on which a former forest had been harvested) were relatively insignificant in size before AD 1800. It was only after the industrial revolution that timber consumption increased drastically, due to increasing human population and industrial use of wood – initially as charcoal, then lumber, other solid wood products including mine props and railroad ties, and pulp and paper, and finally for conservation uses – that large-scale forest plantations started to emerge in Europe, North America, Asia, and other regions in the last century, especially in the last few decades.

Thus, forest plantations develop primarily in response to economic necessity. Timber depletion drives the transition of human consumption of natural forests to artificial forests. Early in the development of North America, for example, timber prices were low, and forest lands were more valuable for other uses, especially the production of food. So trees were removed, forest lands were converted to other use, and timber inventory declined. As the standing inventory declines, timber becomes increasingly scarce and timber prices start to rise. As the prices continue to rise for timber in natural forests, the purposeful husbandry of planted forests becomes economically attractive, and productive forest plantations begin to emerge.

Further, timber depletion affects the supply and demand balance for environmental services from natural forests, whether or not these services go through formal markets. Related to this balance is the fact that the demand for most environmental services such as clean water, clean air, and esthetics, which are often produced from or protected by forests, is highly correlated with personal income. As personal income increases, society demands more environmental services from forests, as well as more wood commodities. When natural forests are depleted to the extent that they cannot adequately provide these services, protective forest plantations emerge. In some developing countries, subsistence farming requires forests to protect farming and grass land from potential flooding, dust storms, soil erosion, and desertification, and trees are thus planted for protective purposes whether or not their personal incomes actually grow over time.

Factors Influencing Forest Plantation Development

As mentioned earlier, rising timber prices, caused by timber scarcity, lead to forest plantation development. Thus, timber prices are the primary factor that influences forest plantation development. Holding everything else constant, whenever a country or a region experiences a long period of rising timber prices, forest plantations would develop quickly.

Tree planting also requires land, labor, and capital. The cost of these production factors thus influence forest plantation development. Further, high timber prices, high land costs, and high labor costs force innovation in tree-growing technologies in conventional silvicultural treatments and biotechnologies. A recent report shows that the growth rate of pine plantations in Alabama, a southern state in the US increased about 25% in a decade (from 8.20% in the period from 1982 to 1990, to 10.17% in the period of 1990–2000). This increase in growth rate is attributed to advancement in tree-growing technologies as well as an increase in management intensity.

Government policies influence forest plantation developments as well. Taxes on land and forest-related income, cash subsidies to plant trees, regulations on land use and labor, and free education and extension services to forest farmers all have an impact, positively or negatively, on tree planting. In general, the primary motivation for the private sector to plant trees is to generate financial (or other) benefits from their investment. In some cases, government policies (positive or pervasive incentives in taxes, subsidies) provide or take away a significant proportion of the financial benefits from forest plantation development. Where governments own land, they could conduct afforestation and reforestation activities directly, for purely financial reasons or for social and environmental benefits or both.

The US South is perhaps an important region in timber supply as it produces some 18% of the world's industrial round wood with just 2% of the world's forestlands and 2% of the world's forest inventory. Some 90% of forest lands in the southern US are owned by nonindustrial private and industrial owners, and timber markets are competitive. A study of tree planting showed that tree planting by both forest industry and nonindustrial private landowners was positively related to the availability (measured as previous-year harvest) and the price of land. Planting by forest industry and nonindustrial private landowners was responsive to market signals, positively to softwood pulpwood prices and negatively to planting costs and interest rates. Finally, government subsidy programs, which increase the total plantation area, might have substitution effects on nonindustrial private tree planting. The federal income tax break for reforestation expenses promoted reforestation in the southern US.

Since forests often have a long production cycle, perhaps the most important government policy in promoting forest plantation development is to provide long-term and secure property rights (private property or land tenure) to private landowners or forest farmers. Many theoretical and empirical studies substantiate that long-term and secure property rights promote tree planting activities in both developed and developing countries. For example, in British Columbia, Canada tree planting was done more

often and more promptly following harvest when forest property rights were secure. In Ghana, reforestation was significantly influenced by the form of forest tenure, and more intensive resource management was fostered by more secure forms of tenure.

Forest Plantations and Conservation of Natural Forests

Plantation forests can provide most goods and services that are provided by natural forests. These include timber, nontimber forest products, protection of clean water and clean air, soil erosion control, biodiversity, esthetics, carbon sequestration, and climate control. Nonetheless, as the value of environmental services from natural forests is higher than that from forest plantations, the demand for conservation of natural forests is stronger. It is possible that a division of land, with some land specialized in timber production and other land in providing environmental services, would produce more forest-related goods and services to society. Because forest plantations grow much faster than natural forests, forest plantations are seen as an increasingly important source of timber supply. Should more forest plantations be developed, more natural forests might be saved.

In 1995, natural forests contributed some 78% of global industrial timber supply, and the remaining was from forest plantations. With growing concerns about the status and loss of natural forests, the rapid expansion of protected areas, and large areas of forest unavailable for wood supply, plantations are increasingly expected to serve as a source of timber. The general trend of the sector is for timber supply to shift from natural forests to plantations.

A simple simulation of global timber supply and demand, allowing forest plantations and their productivity to extend at the current rate, has shown that logging on natural forests could fall by half, from about 1.3 billion m^3 in 2000 to about 600 million m^3 in 2025. Thus, forest plantations will have an increasingly significant role in substituting products from natural forests, even if they cannot replace harvests from natural forests for a long period of time.

One side impact of forest plantation development is that the supply of large quantities of low-cost timber could perhaps undermine the value of natural forest stands, leading to more rapid destruction, especially where legal frameworks and law enforcement are inadequate. Therefore from a global perspective, the transition from natural forests as the primary source of timber supply to forest plantations will take a long time. Nonetheless, the transition has been completed in some countries such as New Zealand and Chile.

Direct Ecological Effects of Forest Plantation

Forest plantations have direct ecological effects in addition to the positive impact of reducing pressure on natural forests. Generalizations are difficult, however, in part because plantation management regimes are diverse and the appropriate comparison is not always to unmanaged natural forests. In worst-case scenarios, natural forests or savannas on fragile soils are converted to plantations of exotic species that lower groundwater tables, decrease biodiversity, and develop extreme nutrient deficiencies in successive rotations. While this scenario overstates the impact of plantations, their generally monoculture nature and intensive management raises concerns about the effect of plantations on biodiversity, water, long-term productivity and nutrient cycling, and susceptibility to insects and diseases.

Biodiversity illustrates the complicated ecological impact of forest plantations; although biodiversity encompasses genetic, species, structural, and functional diversity, much of the focus in discussions about diversity has been at the genetic, species, and local ecosystem levels. As has occurred in agriculture, the introduction of genetically improved exotic or native species in forestry increases productivity and carbon-fixation efficiency. In some regions, this introduction has also increased interspecies diversity at landscape and regional scales. In France, compared with 70 natural forest tree species, 30 introduced species that are commonly used in forest plantations have helped increase the interspecies genetic diversity of forests at the local level. In Europe, at least, there is no doubt that the introduction of new tree species has increased the species richness of forests. Nevertheless, exotic species, even those long naturalized species such as Douglas-fir (*Pseudotsuga menziesii*) are unacceptable in nature conservation schemes.

Exotic species can have negative impacts on native species and communities. For example, fast-growing species can replace native forest species because of their natural invasive potential, as have been observed with *Eucalyptus* in northwestern Spain and Portugal. As the introduction of exotic species has potential risks, confirmation of long-term adaptation to local environmental conditions and pest resistance is necessarily the first step for the use of exotic species in extensive plantation programs.

Plantations tend to be even-aged and managed on relatively short rotations; thus, simple stand structures are common. When repeated across a landscape, large areas of similar species and low structural complexity result in a loss of habitat for taxa that require the kind of conditions provided by naturally regenerated stands or old forests. It has been reported that the bird fauna of single-species plantation forests is less diverse than that of natural and seminatural forests. In other cases, however, bird species diversity in plantation forests is comparable with that in naturally generated stands. For example, cottonwood (*Populus deltoides*) plantations in the Mississippi River Valley in the southern United States are intensively managed (rotation lengths of 10–15 years), reaching crown closure in 2 years. In comparison to natural stands, bird species diversity and abundances are similar for all guilds except cavity nesters.

Where avian diversity is decreased in managed forests generally, loss of structure following harvest is usually the cause. In plantations, simplified structure may be exacerbated further by use of exotic species or by monoculture. Because plantations are harvested at or near economic optima, rather than at biological maturity, plantations seldom develop much beyond the stem

exclusion stage of stand development and do not re-establish characteristics of old forests or complex stand structures such as snags and coarse woody debris. Strategies to compensate for the simplifying tendencies of plantations and integrate biodiversity considerations include complex plantations composed of multiple species, varying planting spacing, thinning to variable densities, and retaining uncut patches and snags after harvest. Such biological legacies should benefit invertebrates such as saproxylic beetles as well as fungi, small mammals, and birds.

Silvicultural and site management practices of site preparation, competing vegetation control, and fertilization may reduce understory and groundcover vegetation diversity, although the effects of previous land use such as agriculture may play a larger role. For example, in southern United States industrial pine plantations, understory diversity was correlated with previous land use; lower diversity of native forest species occurred in plantations established on former farmland and higher diversity in plantations on cutover forest land.

Some species can benefit from forest plantations. For example, clear-cutting and short rotations favor the occurrence of ruderal plant species over some long-lived climax species. Forest plantations accommodate edge-specialist bird species and generalist forest species such as deer. Some rare and threatened species have been found to occupy forest plantations, especially when they lost most of their habitat to agricultural and urbanized land uses. For example in the UK, the native red squirrel is out-competed in native woodlands by the gray squirrel introduced from North America but the red squirrel thrives in conifer plantations, which are poor habitat for the gray squirrel.

Spatial considerations play a role in maintaining biodiversity at the landscape scale. Landscape diversity can meet the habitat needs of wildlife and be achieved by varying the size and shape of plantations and incorporating adjacency constraints into harvest scheduling models (i.e., a plantation adjacent to a recently harvested or young stand cannot be harvested until the adjacent stand reaches a certain age or crown height). Retaining areas of naturally regenerated forest, riparian buffers, or open habitat creates a landscape mosaic that combined with prescribed burning in fire-affected ecosystems, adds to landscape diversity. Landscape connectivity that provides dispersal corridors for mobile species is fostered by careful placement of forest roads and firebreaks.

Concerns about plantations and water are as varied as the issues surrounding biodiversity but generally relate to water use, water quality, or alteration of natural drainage. Species of *Eucalyptus* planted outside their native Australia have attracted the most negative attention for their putative excessive water use, especially in Africa and India but *Populus* species have similarly been accused in China of lowering local water tables and adding to drought. Species such as *Eucalyptus camaldulensis*, *E. tereticornis*, and *E. robusta* (and hybrids of these and other eucalypts) are drought tolerant and able to transpire even under considerable moisture stress. On balance they probably do not use more water than adjacent natural forests but certainly use more of the available water than grasslands or agricultural crops. There is little evidence that they can abstract groundwater; however, there is no recharge below the root zone. In the Wheatbelt of Western Australia, removal of the deep-rooted native vegetation including eucalypts and conversion to cereal crops has caused water tables to rise with subsequent salinization of soils and surface water bodies. Plantations of oil mallee crops (*E. polybractea*, *E. kochii* subsp. *plenissima*, and *E. horistes*) are planted to restore natural hydrology and counteract salinization.

Negative effects of plantations on water quality and aquatic resources are more due to intensive management than to use of exotic species. Intensive mechanical site preparation, especially on sloping sites, can result in sediment movement into streams. Chemical herbicides are used to control competing vegetation at various stages in the plantation growth cycle, but usually for site preparation in place of mechanical treatments or early in the life of the stand to release crop species from competitors. Less intense site preparation, formulations of herbicides that are not toxic to insects or other aquatic organisms and break down in soil, careful placement of chemicals to avoid direct application to water bodies, and designation of riparian buffers all have contributed to protection of water quality.

Harvesting practices, especially placement and construction of harvest roads and layout of skidding trails, potentially can degrade water quality. In developed nations, forest practices such as site preparation, harvesting, use of herbicides, and even choice of species may be regulated to some extent. In the United States, best management practices (BMPs) to address nonpoint source pollution and protect water quality have been codified by state agencies and landowners follow them voluntarily. Research shows generally high rates of compliance. Certification schemes substitute the coercive power of the marketplace for that of government; the various certification bodies differ in how they regard plantations, especially with regard to the use of herbicides, exotic species, or genetically modified trees.

Use of inorganic fertilizers to overcome fertility deficiencies, promote rapid growth, and sustain biomass accumulation generally has been found to have little impact on aquatic systems unless fertilizers are applied directly to streams, lakes, rivers, or adjacent riparian zones. Greater attention has focused on nutrient removals in harvests and the potential for intensive management to reduce site fertility and cause a fall-off in productivity of subsequent rotations. Claims of later-rotation productivity declines have been hard to substantiate, however, as general improvements in seed and seedling quality, genetic makeup, site preparation and competition control, and more careful harvesting that conserves site fertility have raised, rather than lowered yields. Nevertheless, there exist documented cases of lowered fertility caused by export of nutrients in the harvested wood. These localized cases have been caused by low initial fertility, often of phosphorus, potassium, or micronutrient deficiencies inherent in the soil parent material that are easily overcome by application of inorganic fertilizers.

In the most intensive management of pine plantations for pulpwood in the southern United States, some companies routinely apply complete nutrient mixes containing all macro- and micronutrients as a precaution, despite lack of demonstrated deficiency of most nutrients except phosphorus and a responsiveness to added nitrogen. A stand may be fertilized with nitrogen up to five times in a 25-year rotation, sometimes in combination with phosphorus. These stands occur mostly on relatively infertile Ultisols

and Spodosols developed on old marine sediments. On better soils (Alfisols, Entisols, and Vertisols), cottonwood plantations managed on 10-year rotations receive only an initial application of nitrogen at planting to promote rapid height growth to better compete with herbaceous competitors. Management of site nutrients in intensive plantations is critical to high yields as well as to protect long-term productivity and may require attention to retaining soil organic matter, especially on sandy soils. Factors to consider include inherent soil fertility (nutrient stocks as well as transformations and fluxes), plant demand and utilization efficiency, and nutrients export in products removed as well as leakages.

It is common wisdom that monoculture plantations are more susceptible than natural forests to insect and disease attacks, yet there is little evidence this is generally true. On the one hand, single-species stands occur naturally and some of these natural vegetation types are the product of periodic, catastrophic disturbances such as pine bark beetles or spruce budworm. On the other hand, one explanation for the often greater productivity of exotic tree species than attained in their native habitat is the lack of yield-reducing insects and diseases. But diversity in the abstract is not a guarantor of lessened risk; diverse, multiple-species stands themselves are not immune to devastating attack by introduced pests, a situation likely to increase in frequency as a result of globalization of trade in timber products.

Often the practices associated with intensive management are the causes of insect and disease problems. For example, the desire to maximize wood production may set the level of tolerable damage from native pests lower than the stable equilibrium levels for the pest; attempts to control the pest at lower levels may cause unstable population growth cycles. The potential risks of plantations stem from their uniformity: the same or a few species, planted closely together, on the same site, over large areas. Pests and pathogens adapted to the dominant species may build up quickly due to food supply and abundant sites for breeding or infection. Proximity of the branches and stems in closely spaced stands may favor buildup of species with low dispersal rates or small effective spread distances. Conversely, the same uniformity of plantations that contributed to the risks of insects and diseases also confers some advantages. Species can be chosen that have resistance to diseases, for example, the greater resistance of loblolly pine (*Pinus taeda*) compared to slash pine (*P. elliottii*) to *Cronartium* rust was one reason loblolly was favored by forest industry in the US South. The shorter rotation length of plantations relative to naturally regenerated stands means trees are fallen before they become overmature and become infected. The compact shape and uniform conditions in plantations facilitate detection and treatment of economically important pests and pathogens.

Plantations may negatively impact adjacent communities – because of invasive natural regeneration of planted trees in adjacent habitat or alteration of local and regional hydrologic cycles and poor management practices may damage aquatic systems. Plantations are certainly simpler and more uniform than naturally regenerated stands or native grasslands, and may support a less diverse flora and fauna. Nevertheless, plantations can contribute to biodiversity conservation at the landscape level by adding structural complexity to otherwise simple grasslands or agricultural landscapes and by fostering the dispersal of forest-dwelling species across these areas.

Further, comparisons of plantations to unmanaged native forests or even naturally regenerated secondary forests are not necessarily the most appropriate comparisons to make. Although the conversion of old-growth forests, native grasslands, or some other natural ecosystem to forest plantations rarely will be desirable from a biodiversity point of view, in that forest plantations often replace other land uses including degraded lands and abandoned agricultural areas. Objective assessments of the potential or actual impacts of forest plantations on biological diversity at different temporal and spatial scales require appropriate reference points. Forest plantations can have either positive or negative impacts on biodiversity at the tree, stand, or landscape level depending on the ecological context in which they found. Impacts on water quantity and quality can be minimized if sustainable practices are followed; similarly with soil resources and long-term site productivity. Both complex plantations for wood production and environmental plantations can beneficially impact local and regional environments.

Lastly, managing forest plantations to produce goods such as timber while at the same time enhancing ecological services such as biodiversity involves tradeoffs; this can be made only with a clear understanding of the ecological context of plantations in the broader landscape. Tradeoffs also require agreement among stakeholders on the desired balance of goods and ecological services from plantations. Thus, there is no single or simple answer to the question of whether forest plantations are `good' or `bad' for the environment.

Freshwater Lakes

Sven E Jørgensen, Copenhagen University, Copenhagen, Denmark

Introduction

Freshwater lakes and reservoirs are basins filled with freshwater. Only 2.53% of the global water is freshwater; 1.76% of the global water is stored in ice caps, glaciers, and permafrost, while all fresh groundwater makes up 0.76% of the global water. It leaves 0.01% only for the surface freshwater, of which 70% or 0.007% of the global water is stored in the freshwater lakes. As surface water is easily accessible water, the storage of water in lakes and reservoirs becomes very important for the water supply and represents a large proportion of the world's readily accessible water (see Figs. 1 and **2**). Lake water is not only used for human consumption. Other water uses include industrial applications and processes and transportation and generation of hydropower.

The World's Freshwater Lakes

Table 1 gives an overview of 12 important freshwater lakes, including the deepest lake, the lake with the largest surface area, and the lake with the biggest volume. The lakes are not equally distributed in the world. About 10% of the total land is occupied by lakes in Scandinavia, while lakes occupy less than 1% of the land area in Argentina and China.

Importance of Lakes

The lake and reservoir water uses are becoming more intensive and multipurpose, particularly for lakes in heavily populated areas and intensively utilized regions. We can distinguish nine functions of lakes and reservoirs:

1. drinking water supply,
2. irrigation,
3. flood control,
4. aquatic production and fishery,
5. fire and ice ponds,
6. transportation,
7. hydropower,
8. conservation of biodiversity, and
9. recreation.

The multipurpose and extensive use of lakes and reservoirs can often lead to abuse and conflicts. There are numerous examples of such conflicts which are often rooted in inappropriate and insufficient water management.

Water Quality Problems of Lakes and Reservoirs

Nine problems associated with the extensive use of lakes and reservoirs can be identified.

Eutrophication

This is the most pervasive water quality problem on a global scale, being a primary cause of lake deterioration. Eutrophication (nutrient enrichment) represents the natural aging process of many lakes in which they gradually become filled with sediments and organic materials over a typically geologic timescale. Human activities in a drainage basin can, however, dramatically accelerate this process. Its primary cause is the excessive inflow of nutrients (mainly phosphorus, sometimes nitrogen, sometimes both) to a water body from municipal wastewater treatment plants and industries, as well as drainage or runoff from urban areas and agricultural fields. Most lakes in densely inhabited regions of the world suffer from eutrophication, both in industrialized and developing countries. The impacts of the eutrophication process include heavy blooms of phytoplankton in a water body. These blooms will inevitably result in (1) reduced water transparency; (2) decreased oxygen concentration in the water column, particularly in the bottom layer (hypolimnion), which can cause fish kills and the remobilization or resuspension of heavy metals and nutrients into the water column; and (3) significant declines in the biodiversity of the lakes, including the disappearance of

Fig. 1 Lake Baikal, the deepest lake in the world. The volume of Lake Baikal corresponds to almost 20% of all global surface freshwater.

Fig. 2 Crater Lake, Oregon State, the lake famous throughout the world for its clarity. The Secchi disk transparency is 42 m.

sensitive aquatic species. In shallow lakes, eutrophication can also cause an enormous increase in the growth of submerged and emergent rooted aquatic plants, as well as floating plants. This can lead to dramatic changes in the ecosystem structure.

If the sources of nutrients are removed or reduced significantly, the eutrophication problems can be fully controlled (see **Figs. 3** and **4**). Lake Constance, also known as Bodensee, gives very illustrative examples. After the Second World War, the phosphorus concentration in the lake was about 0.01 mg l^{-1} and the lake was oligotrophic. In the year 1980, the lake was mesotrophic to eutrophic and the phosphorus concentration was about 0.08 mg l^{-1}. Due to a massive reduction in the discharge of phosphorus from all sources, wastewater, agricultural drainage water, and septic tanks, it has been possible to reduce the phosphorus concentration to about 0.013 mg l^{-1} today. Lake Biwa, Japan, is illustrative of a partial solution of the problem (**Fig. 5**). The discharge of phosphorus from wastewater has been significantly reduced since the 1970s, but due to almost no reduction in the phosphorus coming from agricultural drainage water, it has only been possible to stabilize the eutrophication level at a phosphorus concentration about 0.035 mg l^{-1}. If on the other hand, the phosphorus in wastewater would not have been reduced, the eutrophication level would have increased.

Table 1 Major freshwater lakes

Lake	Volume (km^3)	Area (km^2)	Max. depth (m)
Lake Baikal	22 995	31 500	1 741
Lake Tanganyika	18 140	32 000	1 471
Lake Superior	12 100	82 100	170
Lake Malawi	6140	22 490	706
Lake Michigan	4920	57 750	110
Lake Huron	3540	59 500	92
Lake Victoria	2700	62 940	80
Lake Titicaca	903	8 559	283
Lake Erie	484	25 700	64
Lake Constance	48.5	571	254
Lake Biwa	27.5	674	104
Lake Maggiore	37.5	213	370

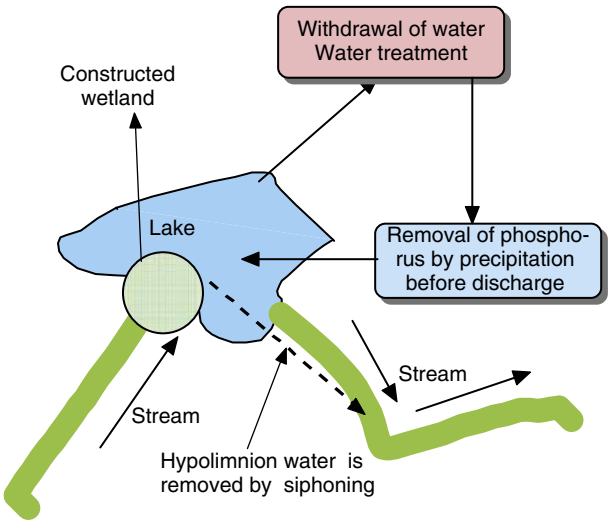

Fig. 3 Abatement of eutrophication requires often the use of several methods at the same time, as shown here: removal of phosphorus from wastewater, construction of wetland to remove phosphorus from the inflowing tributary, and removal of hypolimnic (bottom) water by siphoning.

Fig. 4 Lake Bled, where restoration by siphoning hypolimnic water has been applied.

Acidification

This process of lake deterioration is caused mainly by acid precipitation and deposition. The nitrogen and sulfur compounds that cause this problem are emitted by industrial activities and by the consumption of fossil fuels, and fall to the land surface. The water in a lake can become acidic over time if its drainage basin does not contain the appropriate soil and geologic characteristics to neutralize the acidic water prior to its inflow into the lake. The primary consequence of acidification of lake water is the significant

Fig. 5 Lake Biwa in Japan is a very important recreational area for the population. A museum has been erected to present for the population all aspects of the lake: the culture, the limnology, the geology, and the history.

reduction of species diversity, the extinction of fish populations, and the disruption of lake ecosystem equilibrium. Other causes of lake acidification also exist, including water discharges from mining activities and the direct discharge of industrial waste effluents containing acidic components. Natural sources of acidifying substances include volcanic activities and natural emissions of gases. This problem, because of the geological characteristics, has been a major problem in Scandinavia (except the most southern Scandinavia) and the northeastern United States.

Toxic Contamination

This problem can have direct and dramatic impacts on both human and ecosystem health. Toxic substances originate not only from industrial activities and mining, but also as a result of intensive agriculture practices. Identification of the number of lakes and reservoirs exhibiting toxic contamination will doubtlessly increase in future years as we obtain more information on their concentrations in the environment, particularly in developing countries. Major impacts of toxic substances include the disappearance of sensitive species, as well as their accumulation in lake sediments and biota. The latter can directly and indirectly impact human health. Because the number of risk assessments applied to already-existing chemicals is currently extremely low ($\sim$500), a complete solution of this problem will take many years.

Water-Level Changes

Significant changes in water levels, particularly dropping levels, can be caused by

1. excessive withdrawal of water from lakes and/or their inflowing or out flowing rivers, and
2. the diversion of the inflowing water.

The consequences of water-level changes include: decrease in lake volume and/or surface area; unstable shoreline area communities; changes in lake ecosystem structure; reduced fish spawning areas; increased water retention time (decreased flushing rate), which can accelerate other negative lake processes (e.g., eutrophication, retention of toxic substances); and increased salt concentration, leading to reduced water quality for human uses.

Lake Aral is probably the most illustrative example of this problem. Due to uncontrolled use of the inflowing river water for irrigation, the water level in the lake was reduced by almost 20 m. The lake was divided in two lakes, Large and Small Aral, with together less than half of the original lake area and with a salinity 10 times what it was 40 years ago.

Salinization

This process is an increase in the concentration of salts (all ions, not just sodium and chloride) in lake water, caused by such factors as (1) decreased in-lake water levels; (2) overuse of water in the drainage basin (e.g., cooling water, irrigation); and (3) global climate change. The effects of water salinization include (1) dramatic changes in lake biological structure; (2) lower fish production; and (3) reduced biodiversity. Human utilization of lake water with a high salt concentration also can become very problematic. This problem, however, can at least be partly addressed with the implementation of appropriate environmental management and agricultural practices in a lake's drainage basin.

Siltation

Accelerated soil erosion, resulting from such activities as the overuse or misuse of arable land, mining and/or deforestation in a drainage basin, can lead to the excessive loading of suspended solids (sediment) to lakes. The consequences of these increased loads include the rapid accumulation of sediment within the lake basin, and the increased turbidity (decreased transparency) of the water in the lake. The immediate impacts can be a significant reduction in the number of living organisms in a lake, decreased biodiversity, and reduced fisheries.

Introduction of Exotic Species

The intentional introduction of exotic (nonresident) species has become an almost common practice in some fisheries to increase the production of commercially important species. The introduction of Nile perch into Lake Victoria is a primary example. However, the intentional or unintentional (or sometimes illegal) introduction of exotic species can cause very serious problems in a given lake. The accidental introduction of zebra mussels in Lake Erie and water hyacinths in several lakes of China provides a dramatic example of this phenomenon. The introduction of exotic species can provoke very dramatic changes in the ecosystem structure not only at the biological community level, but also in a lake's chemical–physical environment. The major negative consequences of exotic species include the (1) disappearance of native species; (2) alteration of trophic equilibrium; (3) significant reduction in species diversity; and (4) reduction of water transparency and changes in algae bloom patterns, via chemical–physical feedback processes in a lake.

Overfishing

Unsustainable fishing practices, sometimes combined with other problems, can lead to the collapse of fisheries. It seems to be an increasing problem for many African lakes, particularly Lake Victoria.

Pathogenic Contamination

This problem is caused by discharge of untreated sewage or runoff from livestock farms, a problem in both developing and developed countries. A *Cryptosporidium* outbreak in Lake Michigan (Milwaukee) sickened 400 000 people in the early 1990s. It is likely that many deaths in developing countries are due to consumption of dirty lake water.

Freshwater Marshes

P Keddy, Southeastern Louisiana University, Hammond, LA, USA

Wetlands are produced by flooding, and as a consequence, have distinctive soils, microorganisms, plants, and animals. The soils are usually anoxic or hypoxic, as water contains less oxygen than air, and any oxygen that is dissolved in the water is rapidly consumed by soil microorganisms. Vast numbers of microorganisms, particularly bacteria, thrive under the wet and hypoxic conditions found in marsh soils. These microbes transform elements including nitrogen, phosphorus, and sulfur among different chemical states. Therefore, wetlands are closely connected to major biogeochemical cycles. The plants in wetlands often have hollow stems to permit movement of atmospheric oxygen downward into their rhizomes and roots. Many species of animals are adapted to living in shallow water, and in habitats that frequently flood. Some of these are small invertebrates (e.g., plankton, shrimp, and clams), while others are larger and more conspicuous (fish, salamanders, frogs, turtles, snakes, alligators, birds, and mammals).

Six Types of Wetlands

There are six major types of wetlands: swamp, marsh, fen, bog, wet meadow, and shallow water (aquatic). These six types are produced by different combinations of flooding, soil nutrients, and climate. A seventh group, saline wetlands, which includes salt marshes and mangroves, is often treated as a distinct wetland type. Saline wetlands occur mostly along coastlines, but also occasionally in noncoastal areas where evaporation exceeds rainfall, such as in arid western North America, northern Africa, or central Eurasia.

Swamps and marshes have mineral soils with sand, silt, or clay. Swamps are dominated by trees or shrubs, whereas marshes are dominated by herbaceous plants such as cattails and reeds (Fig. 1). Such wetlands tend to occur along the margins of rivers (Fig. 2) or lakes, and often receive fresh layers of sediment during annual spring flooding. Marshes are among the world's most biologically productive ecosystems. As a consequence, they are very important for producing wildlife, and for producing human food in the form of shrimp, fish, and waterfowl.

Fens and bogs have organic soils (peat), formed from the accumulation of partially decayed plants. Most peatlands occur at high latitudes in landscapes that were glaciated during the last ice ages. In fens, the layer of peat is relatively thin, allowing the longer roots of the plants to reach the mineral soil beneath. In bogs, plants are entirely rooted in the peat. As peat becomes deeper (the natural trend as fens become bogs), plants become increasingly dependent upon nutrients dissolved in rainwater, eventually producing an `ombrotrophic' bog. The large amounts of organic carbon stored in peatlands help reduce global warming.

Wet meadows occur where land is flooded in some seasons and moist in others, such as along the shores of rivers or lakes. Wet meadows often have high plant diversity, including carnivorous plants and orchids. Examples of wet meadows include wet prairies, slacks between sand dunes, and wet pine savannas. Pine savannas may have up to 40 species of plants in a single square meter, and hundreds of species in a hundred hectares.

Aquatic wetlands are covered in water, usually with plants rooted in the sediment but possessing leaves that extend into the atmosphere. Grasses, sedges, and reeds emerge from shallow water, whereas water lilies and pondweeds with floating leaves occur

Fig. 1 Marshes occur in flooded areas, such as this depression flooded by beavers in Ontario, Canada. As the photo illustrates, marshes form at the interface of land and water. Courtesy of Paul Keddy.

 doi:10.1016/B978-0-444-63768-0.00338-3

in deeper water. Aquatic wetlands provide important habitat for breeding fish and migratory waterfowl. Animals can create aquatic wetlands: beavers build dams to flood stream valleys, and alligators dig small ponds in marshes or wet meadows.

The Distribution of Marshes

Wetlands can occur wherever water affects the soil. Not only are there therefore many kinds of wetlands, but their size and shape is very variable. Wetlands can include small pools in deserts and seepage areas on mountainsides, or they can be long but narrow strips on shorelines of large lakes (Fig. 3), or they may cover vast river floodplains (Fig. 4) and expanses of northern plains. The two largest wetlands in the world (both $>750\,000\ km^2$) are the West Siberian lowland and the Amazon River basin. The West Siberian Lowland consists largely of fens and bogs, but marshes occur along rivers, particularly in the more southern regions (Fig. 5). The Amazon is a tropical lowland with freshwater swamps and marshes containing more kinds of trees and fish than any other region of the world.

Water as the Critical Factor

Water is a critical factor in all marshes. The duration of flooding is the most important factor determining the kind of wetland that occurs. Water can arrive as short pulses of flooding by rivers, as rainfall, or as slow and steady seepage. Each mode of arrival produces different kinds of wetlands. In order to better understand marshes, let us consider four examples of wetlands with very different flooding regimes.

Floodplains. Wetlands along rivers are often flooded by annual pulses of water. These pulses may deposit thick layers of sediment or dissolved nutrients that stimulate plant growth. In floodplains, animal life cycles are often precisely determined by the timing of the flood. Fish may depend upon feeding and breeding in the shallow warm pools left by retreating floodwaters. Birds

may time their nesting to be able to feed their young on the fish and amphibians left behind by receding water. Marshes are often intermixed with swamps, depending upon the duration of flooding (**Fig. 6**). Early human civilizations developed in this type of habitat, along the Nile, Indus, Euphrates and Hwang Ho, where the annual flooding provided fertilized soil and free irrigation.

Peat bogs. Some peat bogs receive water only as rainfall. As a consequence, the water moves slowly, if at all, and contains very few nutrients. Hence, these types of wetlands often are dominated by slow growing mosses and evergreen plants. Most such wetlands occur in the far north in glaciated landscapes. Humans have developed a number of uses for the peat – in Ireland, the peat is cut into blocks and used for fuel. In Canada, the peat is harvested and bagged for sale to gardeners. In Russia, peat is used to fuel electrical plants. Marshes may form on the edges of bogs where nutrients accumulate from runoff, or along river courses where nutrients are more available.

Seepage wetlands. In gently sloping landscapes water can seep slowly through the soil. In northern glaciated landscapes, such seepage can produce fens, which have distinctive species of mosses and plants, and may develop in distinctive parallel ridges. In more southern landscapes, seepage can produce pitcher plant savannas or wet prairies. Often these seepage areas are rather small (only a few hectares in extent) but are locally important because of the rare plants and animals they support. Seepage areas can be larger, and when the water flow is sufficiently abundant, shallow water can move across a landscape in a phenomenon known as sheet flow. The vast Everglades, with its distinctive animals, is a product of sheet flow of water from Lake Okeechobee in south central Florida southward to the ocean.

Temporary wetlands. In many parts of the world, small temporary (or ephemeral) pools form after heavy rain or when snow melts. These pools can go by a variety of local names including vernal pools, woodland ponds, playas or potholes. The aquatic life in these pools is forced to adopt a life cycle that is closely tied to the water levels. Many species of frogs and salamanders breed in such pools, and the young must metamorphose before the pond dries up. Wetland plants may produce large numbers of seeds that remain dormant until rain refills the pond.

Since water has such a critical effect on wetlands, where water levels change, plant and animal communities will change as well. A typical shoreline marsh will often show distinct bands of vegetation (`zonation'), with each kind of plant occupying a narrow

Fig. 6 Southern marshes on the coastal plain of North America may be dominated by a single grass, maidencane (*Panicum hemitomon*). This marsh occupies an opening within a baldcypress swamp, Louisiana, USA. Courtesy of Cathy Keddy.

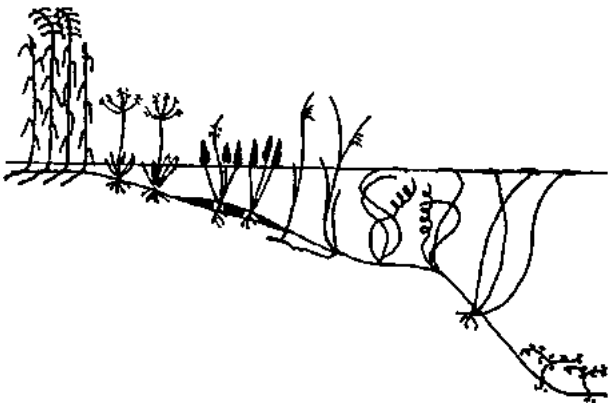

Fig. 7 Different marsh plants tolerate different water levels. Hence, as the water level changes from shallow water (left; seasonally flooded) to deeper water (right; permanently flooded), the plants appear to occur in different zones. Courtesy of Rochelle Lawson.

range of water depths (Fig. 7). Most kinds of animals, including frogs and birds, also have their own set of preferred water depths. Wading birds (egrets, ibis, herons) may feed in different depths of water depending upon the length of their legs. Ducks, geese, and swans can feed at different water depths depending upon the length of their necks. Some water birds (Northern Shoveler, flamingos) strain microorganism from shallow water, while others (cormorants, loons) dive to feed further below the surface. Some ducks prefer wetlands that are densely vegetated, while others prefer more open water. Hence, even small changes in the duration of flooding or depth of water can produce very different plant and animal communities.

Many marsh plants adapt to flooding by producing hollow shoots, which allow oxygen to be transmitted to the rooting zone. The tissue that allows the flow of oxygen is known as aerenchyma. Not only can oxygen move by diffusion, but there are a number of methods in which oxygen moves more rapidly through large clones of plants, entering at one shoot and leaving at another. Consequently, plants can play an important role in oxidizing the soil around their rhizomes, allowing distinctive microbial communities to form. Some marsh plants also have floating leaves (e.g., water lilies) or even float entirely on the surface (e.g., duckweeds). The largest floating leaves in the world (Fig. 8) are those of the Amazon water lily (*Victoria amazonica*). The gargantuan leaves can be 2 m in diameter with an elevated lip around the circumference. There are two gaps in the lip to allow water to drain, and large spines to protect the underwater sections of the foliage.

Other Environmental Factors Affecting Marshes

Nutrients

The main nutrients that affect the growth of marsh plants, and plants in general, are nitrogen and phosphorus. As described above, flood pulses that carry sediment down river courses can produce particularly fertile and productive marshes. Floodplains can therefore be thought of as one natural extreme along a gradient of nutrient supply. At the other end of the gradient lie peat bogs, which depend partly or entirely upon rainfall, and which therefore receive few nutrients. Sphagnum moss is well adapted to

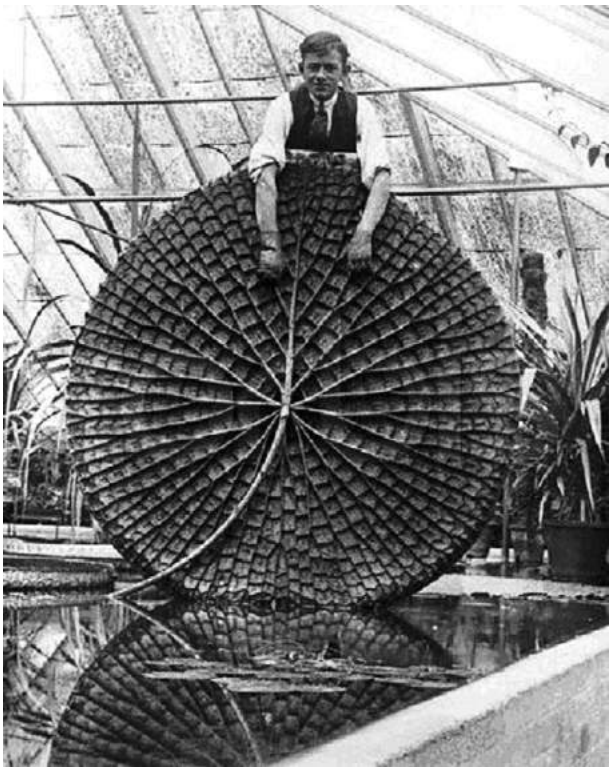

Fig. 8 The Amazon water lily has the largest floating leaves of any wetland plant. Note the prominent ribs on the underside of the leaf. Courtesy of Corbis.

peatlands, and often comprises a large portion of the peat. In between the natural extremes of river floodplains (high nutrients) and peat bogs (low nutrients), one can arrange most other types of wetlands. The type of plants, and their rate of growth, will depend where along this gradient they occur, but most marshes generally occur in more fertile conditions.

While nutrients enhance productivity, paradoxically they can often reduce the diversity of plants and animals. Often, the high productivity is channeled into a few dominant species. One finds large numbers of common species, while the rarer species disappear. Humans often increase nutrient levels in watersheds and wetlands, thereby changing the species present and reducing their diversity. Carnivorous plants are known for tolerating low nutrient levels, because they can obtain added nutrients from their prey. Common examples include pitcher plants (*Sarracenia* spp.), bladderworts (*Utricularia* spp.), and butterworts (*Pinguicula* spp.). Cattails (*Typha* spp.) and certain grasses (*Phalaris arundinacea*) are particularly well known for rapid growth and an ability to dominate marshes at higher nutrient levels.

Disturbance

A disturbance can be narrowly defined as any factor that removes biomass from a plant. In marshes, sources of disturbance may include waves in lakes, fire, grazing, or (in the north) scouring by winter ice. One of the principal effects of disturbances is the creation of gaps in the vegetation, allowing new kinds of plants to establish from buried seeds. Most marshes have large densities of buried seeds, often more than 1000 seeds m^{-2}. After disturbance, marsh plants can also re-emerge from buried rhizomes. Hence, cycles of disturbance play an important role in creating marshes.

Although the presence of fire in wetlands may seem paradoxical, fire can often occur during periods of drought. Northern peatlands, cattail marshes on lakeshores, wet prairies, and seepage areas in savannas can burn under the appropriate conditions. In northern peatlands, a fire can remove thousands of years of peat accumulation in a few days, even uncovering boulders and rock ridges that were buried beneath the peat. In marshes, fire can selectively remove shrubs and small trees, preventing the marsh from turning into a swamp. In the Everglades, burning can create depressions that then cause marshes to revert to aquatic conditions.

Animals that feed upon plants often cause only small and local effects. Think of a moose grazing on water lilies, a muskrat feeding on grasses, or a hippopotamus feeding on water hyacinth. Often the small patch of removed foliage is quickly replaced by new growth. But when herbivores become overly abundant, they can destroy the marsh vegetation entirely. In northern North America along Hudson Bay, Canada geese (*Branta canadensis*) are now so abundant that they remove all vegetation from expanses of coastal marsh. In southern North America, along the Gulf of Mexico, an introduced mammal, nutria (*Myocastor coypus*), similarly can strip marsh vegetation to coastal mudflats. To some extent, disturbance by herbivores is a natural phenomenon, one

Fig. 9 Marshes provide essential habitat for many kinds of wading birds including flamingos, Jurong Bird Park, Singapore. Courtesy of Corbis.

that has occurred cyclically throughout history. However, in the above two examples, one suspects humans may be the ultimate cause of the large-scale overgrazing (see the next section).

Periodic droughts may at times function like a natural disturbance by killing adult plants, and allowing new species to re-establish from buried seeds. Vernal pools and prairie potholes both have plant and animal species that are adapted to this kind of cyclical disturbance.

Plant and Animal Diversity in Wetlands

Wetlands are important for protecting biological diversity. Their high productivity provides abundant food, and the water provides an important added resource. Hence, wetlands often have large populations of animals and wading birds. The Camargue in Southern Europe, for example, is considered to be the European equivalent of the Everglades. Both have species of wading birds such as storks and flamingos (Fig. 9). Large numbers of other kinds of species including fish, frogs, salamanders, turtles, alligators (Fig. 10), crocodiles, and mammals require flooded conditions for all or at least part of the year. If the wetlands are drained, all of the species dependent upon them will disappear.

All wetlands, however, do not support the same species. Often, as already noted in the section entitled `Disturbance', small differences in water level or nutrient supplies will produce distinctive types of wetlands. Hence, wetlands that are variable in water levels and fertility will frequently support more kinds of species than wetlands that are uniform. Along the Amazon River floodplain, for example, different kinds of swamp, marsh, grassland, and aquatic communities form in response to different flooding regimes, and each has its own complement of animal species. In the Great Lakes, different flood durations similarly produce different types of wetlands, from aquatic situations in deeper water, to marshes and wet meadows in shallower water. Some types of frogs, such as bullfrogs, require deeper water, while others, such as gray tree frogs, require shrubs.

Human Impacts

Humans have had, and continue to have, serious impacts upon wetlands in general, and marshes in particular. Some human impacts include draining, damming, eutrophication, and alteration of food webs. Let us consider these in turn.

One of the most obvious ways in which humans affect wetlands is by draining them. When the wetlands are drained, the soil becomes oxidized, and terrestrial plants and animals replace the wetland plants and animals. Often, drainage is followed by conversion to agriculture or human settlement, entirely removing the marshes that once existed. Vast areas of farmland in Europe, Asia, and North America were once marshes and have now been converted to crops for human consumption. Many countries now have laws to protect wetlands from further development, although the degree of protection provided, and the degree of enforcement, varies from one region of the world to another. Wetlands are also often included in protected areas such as national parks and ecological reserves.

Construction of dams can also have severe negative effects upon wetlands. The dams may be built for flood control, irrigation, or generating electricity. The wetland behind the dam may be destroyed by the prolonged flooding, whereas the wetlands downstream are disrupted by the lack of normal flood pulses. A single dam can therefore affect a vast area of wetlands. The degree of damage depends upon the pattern of water level fluctuations in the reservoir behind the dam, but in general large areas of marsh are lost both upstream and downstream from the dam. Sediment that would have expanded and fertilized wetlands during periodic floods becomes trapped behind the dam. Most of the world's large rivers have now been significantly affected by dams. To protect wetlands, it is necessary to identify rivers that are still relatively natural and to prevent further dams from being constructed. In other cases, it is possible to remove dams and allow natural processes to resume. An artificial levee can be considered a special type of dam that is built parallel to a river to prevent it from flooding into adjoining lands. Levees harm marshes by preventing the annual flooding, and by allowing cropland and cities to move into floodplains.

Humans can also affect wetlands by changing the nutrients in the water. Sewage from cities provides a specific `point source' of nutrients, particularly nitrogen and phosphorus, that enter water courses then spread into wetlands. Activities such as agriculture and forestry provide `diffuse sources' of nutrients, where runoff from large areas carries dissolved nutrients, and nutrients attached to clay particles, into the water and into adjoining marshes. The added nutrients can stimulate plant growth, which may seem to be beneficial – but it often leads to significant changes in the biota. Rarer plants and animals that are adapted to low fertility are replaced by more common plants and animals that exploit fertile conditions. Rapid growth of algae, followed by decay, can eliminate oxygen from lakes, causing fish kills. Protecting the quality of marshes therefore requires two sets of actions. First, it is necessary to control the obvious point sources of pollution by building sewage treatment plants. Second, it is necessary to use entire landscapes with care, with the broad objective of reducing nutrients in runoff. This can involve carefully timing the fertilization of crops, maintaining areas of natural vegetation along watercourses, fencing cattle away from stream valleys, minimizing construction of new logging roads, and avoiding construction on steep hill sides.

Herbivores are common in wetlands, and a natural part of energy flow from plants to carnivores. Common examples of large herbivores include moose, geese, muskrats, and hippopotamuses. Humans can disrupt wetlands by disrupting the natural balance between herbivores and plants. Herbivores can increase to destructive levels in several ways. When humans introduce new species of herbivores, rates of damage to plants may increase greatly – for example, nutria introduced from South America are causing significant damage to coastal wetlands in Louisiana. When humans reduce predation on herbivores, they may also increase to higher than natural levels. Killing alligators may damage wetlands by allowing herbivores such as nutria to reach high population densities; similarly, the loss of natural predators may be one of the reasons that Canada geese have multiplied to levels where they can destroy wetlands around Hudson Bay. There is also evidence that when humans harvest blue crabs, snails that the crabs normally eat begin to multiply and damage coastal marshes. These types of effects are difficult to study, since the effects may be indirect and take place over the long term.

Road networks are a final cause of damage to wetlands. The obvious effects of roads include the filling of wetlands, and the blocking of lateral flow of water into or out of wetlands. But there are many other effects. When amphibians migrate across roads to breeding sites, vast numbers can be killed by cars. In northern climates, the road salt put on roads as a de-icer can flow into adjoining wetlands. Snakes may be attracted to the warm asphalt and killed by passing cars. Invasive plant species can arrive along newly constructed ditches. Overall, roads change a landscape by accelerating logging, agriculture, hunting, and urban development. As a consequence, the quality of the marshes in a landscape is linked to two factors: the abundance of roads (a negative effect) and the abundance of forest (a positive effect). Although it may not be obvious, halting road construction (or removing unwanted roads) and protecting forests (or replanting new areas of forest) may have important consequences for all the marshes in a landscape.

Wetland Restoration

Humans have caused much damage to wetlands over the past thousand years, and the effects have increased as human populations and technological power have grown. We have seen some examples of damage in the preceding section. In response to such past abuses, humans have also begun consciously re-creating wetlands. There are a growing number of efforts to create new wetlands and enhance existing wetlands. Along both the Rhine River and the Mississippi River, some levees have been breached, allowing floodwater to return and marshes to recover. Depressions left by mining, or deliberately constructed for wetlands, can be flooded to recreate small marshes in highly developed landscapes. Construction of dams and roads has been more carefully regulated.

Table 1 The world's largest wetlands (areas rounded to the nearest 1000 km^2)

Rank	Continent	Wetland	Description	Area (km^2)	Source
1	Eurasia	West Siberian Lowland	Bogs, mires, fens	2 745 000	Solomeshch, chapter 2
2	South America	Amazon River basin	Savanna and forested floodplain	1 738 000	Junk and Piedade, chapter 3
3	North America	Hudson Bay Lowland	Bogs, fens, swamps, marshes	374 000	Abraham and Keddy, chapter 4
4	Africa	Congo River basin	Swamps, riverine forest, wet prairie	189 000	Campbell, chapter 5
5	North America	Mackenzie River basin	Bogs, fens, swamps, marshes	166 000	Vitt *et al.*, chapter 6
6	South America	Pantanal	Savannas, grasslands, riverine forest	138 000	Alho, chapter 7
7	North America	Mississippi River basin	Bottomland hardwood forest,swamps, marshes	108 000	Shaffer *et al.*, chapter 8
8	Africa	Lake Chad basin	Grass and shrub savanna, shrubsteppe, marshes	106 000	Lemoalle, chapter 9
9	Africa	River Nile basin	Swamps, marshes	92 000	Springuel and Ali, chapter 10
10	North America	Prairie potholes	Marshes, meadows	63 000	van der Valk, chapter 11
11	South America	Magellanic moorland	Peatlands	44 000	Arroyo *et al.*, chapter 12

Modified from Fraser LH and Keddy PA (eds.) (2005) *The World's Largest Wetlands: Ecology and Conservation*. Cambridge: Cambridge University Press.

The future of marshes will likely depend upon two human activities: our success at protecting existing marshes from damage and our success at restoring marshes that have already been damaged. The list of the world's largest wetlands in **Table 1** provides an important set of targets for global conservation.

Summary

Marshes are produced by flooding, and, as a consequence, have distinctive soils, microorganisms, plants, and animals. The soils are usually anoxic or hypoxic, allowing vast numbers of microorganisms, particularly bacteria, to transform elements including nitrogen, phosphorus, and sulfur among different chemical states. Marsh plants often have hollow stems to permit movement of atmospheric oxygen downward into their rhizomes and roots. Marshes are some of the most biologically productive habitats in the world, and therefore support large numbers of animals, from shrimps and fish through to birds and mammals. Marshes are one of six types of wetlands, the others being swamp, fen, bog, wet meadow, and shallow water. Humans can affect marshes by changing water levels with drainage ditches, canals, dams, or levees. Other human impacts can arise from pollution by added nutrients, overharvesting of selected species, or building road networks in landscapes.

Greenhouses, Microcosms, and Mesocosms

WH Adey, Smithsonian Institution, Washington, DC, USA

Introduction

An ecosystem is an assemblage of organisms living together and interacting with each other and their environment. An element of biodiversity and biogeochemical time stability is implied, although dimensions are optional, ranging from the biosphere subset, the biome, to perhaps a field or pond. Ecosystems with their complex food webs and biotic physical/chemical relationships are self-organizing due to the genetic information existing in the genome of each species. Even when spatially well bounded, ecosystems are not closed. At the very least, they are subject to energy input and energy and materials exchange with adjacent ecosystems. Often, ecosystems demonstrate biotic exchange with adjacent ecosystems that can be complex and include reproductive and seasonal phases.

The development of an ecosystem in a greenhouse implies that the ecosystem is solar driven, and thus no deeper than the photic zone of the ocean, although the basic principles discussed could generally apply to deep ocean ecosystems. Greenhouse placement generally requires spatial limitation, and scaling of model to analog is necessary for many physical and biotic factors. In some cases, it is intuitive, and in others must be empirically demonstrated by trial and error in comparison with analog function. All of the following case studies demonstrate aspects of this necessary scaling exercise. Normal, biogeochemical, and biotic exchange with adjacent ecosystems must also be simulated.

The reasons for placing or developing ecosystems within greenhouses for research or educational purposes have varied enormously and have ranged from the strongly funded, multiscientist research endeavors, to the classroom aquarium or terrarium. Even the naming of the research field of endeavor has varied widely: to name a few, synthetic ecology, ecological engineering, controlled ecology, closed systems ecology, ecosystem modeling, etc. The systems themselves are called living systems models, microcosms, mesocosms, macrocosms, ecotaria, living machines, closed ecological life support systems (CELSS), etc.

In this article, we limit our discussions to those serious research efforts in which significant effort is expended to match biodiversity, food web and symbiotic relationships, as well as biogeochemical function to analog wild ecosystems. By definition, such systems cannot be closed; however, the known interchanges, biotic and biogeochemical, with adjacent ecosystems must be known, studied in the wild, and be simulated so that the essential functional characteristic of the analog ecosystem can be maintained.

Hundreds, perhaps thousands, of microcosm studies of liter or few liter dimensions of a very limited biodiversity have been undertaken to elucidate component ecosystem function, often related to toxic compound effect. Rarely could these studies be regarded as the modeling of an ecosystem. At the other extreme, perhaps the most complex ecosystem modeling effort ever undertaken was the Biosphere II project in Arizona during the 1980s and 1990s. Biosphere II was an ecologically well-conceived collection of interacting terrestrial marine and freshwater ecosystems. However, it was intentionally operated as a closed system because of its planned space station future. Several decades ago, it was widely regarded among ecologists that even though greenhouse enclosure provided a critical element of control over variables, the difficulties inherent in enclosure and operation were too great to allow ecosystem modeling. As the examples we provide below show, this judgment was only minimally correct and perhaps no more severe than the breakup of wild ecosystems by development or farming expansion. Human expansion and perturbation has severely altered many of the ecosystems on Earth, and has altered all ecosystems in at least minor ways. The entire biosphere has been in effect placed in a poorly operated greenhouse, with the atmosphere serving as its upper `glass' roof. There can be no valid argument against greenhouse enclosure of ecosystems for research and education. It is simply one end of a complex spectrum of interacting biota and biogeochemistry that we seek to understand. Indeed, in many ways, such model ecosystems may be `purer' than their wild counterparts.

Physical/Chemical Control Parameters

The Enclosure

The shape of an ecosystem relative to its controlling physical and energy parameters can be crucial. In the case of aquatic systems, the relative thickness of the water mass and its relationship to the bottom establish the basic character of an ecosystem. A large body of water would be dominated by true plankters, normally living most of their lives suspended in mid and surface waters, with little benthic (or bottom) influence, whereas the shallow stream or narrow lagoon of a few meters in depth is benthic dominated. Light enters only through the air–water interface of a water ecosystem, and the shape of the containing body of water relative to depth, as well as water turbidity, determines the photosynthetic versus heterotrophic character of the ecosystem. The direction of current flow and wave action through an aquatic system relative to the position and orientation of its communities is

Fig. 1 Florida Everglades mesocosm during construction. The butyl rubber-lined concrete block walls were used to constrain the entire system as well as to physically separate the salinity subcomponents thereby creating a salinity gradient. The plastic box at the lower right contains the tide controller, which determines the tide level in the estuary (center tank and the four smaller units behind).

critical to simulate in any model. The direction, frequency, and strength of wind relative to forest or field size can also be critical to systems function, as can be the physical dimension and density of such ecosystems.

The all-glass or acrylic aquarium box, ranging from about 40 l (10 gallons) to 1000 l (250 gallons), is a standard piece of equipment in terrestrial and aquatic modeling, and by drilling holes to attach pipes and linking all-glass tanks in complex arrays, many aspects of wild ecosystems can be modeled with reasonable accuracy.

The construction of molded fiberglass tanks or poured concrete or concrete block tanks, sealed with a wide variety of newer sealants, has considerable advantages for larger systems.

Ideally, the ecosystem envelope would be like that of the boundary of the mathematical modeler, a theoretical boundary allowing the controlling of exchange but not having any inherent characteristics. Walls, whatever their nature, unless rather esoteric measures are used to prevent organisms and organic molecules from using their surfaces, or blocking wind or current, are intrusions into the model ecosystem that may or may not be acceptable. For a small model of a planktonic system, the presence of uncleaned walls may prevent the system from being plankton dominated. To some degree, walls also interact with the water and atmosphere of the ecosystem they contain. For most purposes, glass and many plastics are ideal in this respect.

Greenhouse walls and roofs can block ultraviolet light and, for most ecosystem models, a component of artificial light is probably essential to achieve both the intensity and spectral veracity of natural light. Reinforced cement block or concrete can be valuable construction materials for large systems; however, concrete interacts with both water and atmosphere, being one of the limiters of veracity in of Biosphere II (as we describe below), and must be sealed with epoxy or other, carefully considered resins (Fig. 1).

Many chemical elements and compounds used in construction are toxic. Some of these are only mildly poisonous and are often required by organisms as elements in small quantities and only become toxic in excess. Others are always toxic and only concentration determines effect. Glass, acrylics, epoxies, polyesters, polypropylenes, polyethylenes, nylons, Teflon, and silicones, among others, are structural materials commonly used in model/greenhouse construction. When properly cured these materials are generally inert, nonbiodegradable, and nontoxic. Many metals and organic additives easily find their way into construction processes and must be avoided or sealed off.

Physical/Chemical Environment

Many of the physical/chemical parameters of ecosystem, such as temperature, salinity, pH, hardness, and oxygen, are more or less obvious and generally accepted as crucial. Others such as light, wind, tides, currents, and wave action, have often been neglected or at least minimally considered in their effects on ecosystem models.

Light

Whole communities or parts of ecosystems, where plants are major components, typically capture a maximum of 6% of the incident light energy in photosynthesis. Nevertheless, full light is often required to achieve that peak transfer of energy. Also much higher capture efficiencies are possible when forcing energy such as wind and wave are present. In many cases, if greenhouse roofs cannot be opened, artificial lighting will have to be introduced to achieve the correct spectrum and intensity to drive the primary production characteristics of an analog ecosystem.

Water Supply/Water Environment

Whether a terrestrial or aquatic ecosystem is planned, the supply and internal transfer of water is critical. Air- and water-handling systems need to be carefully designed to prevent water contamination. Since water sequestration and loss is more or less inevitable,

Fig. 2 Red mangrove community in the Florida Everglades mesocosm from the engineering control pad. The large fan in the upper center provides wind for the mangrove communities. The box in the lower right is one of a bank of five algal turf scrubbers (ATSs) that control water quality (nutrients, pH, O_2) in the coastal system.

the water quality of both initial water and later top-ups must be carefully controlled. Rarely would tap water be acceptable. Water is the universal solvent, whether in liquid or gaseous form, and often `sequesters' gases. Most ecosystems in greenhouses require the dedicated monitoring and control of atmospheric and water quality. Managed aquatic plant systems, such as algal turf scrubbers (ATSs), have been successfully used to manage water quality of adjacent ecosystems interaction, as we describe in some of the examples. Such systems can also control atmospheric quality (Fig. 2).

Water and Air Movement

In virtually all water ecosystems, the water flows, and in most shallow water systems it oscillates (surges) as well. In models, this flow and surge are developed, at least initially by pumps. However, standard impellor pumps destroy or damage many plankters, particularly larger zooplankton and swimming invertebrate larvae. Several approaches are available to solve this problem, including using slow-moving piston pumps, membrane pumps, and Archimedes screws (Fig. 3). All of these devices can work well, though relative performance is not fully quantified.

In terrestrial environments, fans for wind and air handlers for heat and air conditioning, as well as the cooling or heating surfaces employed have the same effect on flying insects and birds. On the other hand, in the wild, ultraviolet light, wind, and rain have critical controlling effects on many plant predators. These factors cannot be omitted.

Biotic Parameters

Ecosystem Structuring Elements

Some communities of organisms are structured by physical elements – a sandy beach, or rock, for example. However, in most terrestrial environments and in many shallow aquatic environments, plants and algae are the structuring elements. They not only provide the food and water and atmospheric chemistry but also greatly increase surface for attachment and cover. In general, plants also provide a spatial heterogeneity (spatial surface) that does not exist in the physical world. Particularly in the marine environment, where calcification is enhanced, many animals join plants to provide a community structure that consists of reef or shell framework. This framework is calcium carbonate (or other organic solid such as chiton) instead of (or along with) plant cellulose. In constructing any living ecosystem, it is essential that these structuring elements be first developed as `colonial' stages soon after the physical environment is formed.

Ecosystem Subunits

In the construction of greenhouse ecosystems, subunit installation can be utilized. However, it would be impossible to individually extract and emplace the tens to hundreds of species amounting to hundreds to millions of individuals that occur in these subunits. Installation of sub-blocks of wild ecosystem includes the microspecies and keeps their relationships intact. For example, soil blocks, or in the marine or aquatic habitat, mud or rock blocks, can be introduced into the preexisting physical/chemical elements of the model ecosystem.

Repeated efforts must be taken to install rock, soil, mud, or `planktonic blocks'. These injections should be periodically carried out during system stocking; at completion of development, they should be followed by several final injections. The process of cutting out, or otherwise extracting, an ecological block or ecosystem subunit and transporting it to the waiting model can be stressful to the community of organisms within the block. Even in the model, the block meets conditions that at least initially

Fig. 3 Engineering/control pad in the Florida Everglades mesocosm. The green diagonal tube in the center is an Archimedes screw that lifts water from the coastal tank (far right) for distribution to the estuary (back right), the ATS (left-foreground), and the wave generator (out of view to lower right).

Fig. 4 Salt marsh community 1 year after establishment of the Florida Everglades mesocosm. Young white mangrove tree to left. After 5 years of self-organization the system followed a succession to a white mangrove/buttonwood swamp.

consist of the raw physical/chemical environment unameliorated by the effects of a functioning community of organisms. The first block injections are likely to lose species. However, with each addition, the diversity of reproductively successful species increases.

All ecological communities are patchy. An island, coral reef, a large salt marsh, a field, even a forest, all differ from place to place. Chance factors of organism settlement, negative and positive interaction between species, the local effect of environment, and real differences of environment (wave exposure, current, etc.) all lead to patchiness within a community. The model itself, no matter how accurate, is a patch, or several patches, that the modeler hopes represents a `mean' of most wild patches.

After the structuring elements are established, and the entire pool of available species from the type community given a chance at immigration into the model, the model will self-organize. In the form of the genetic codes of its constituent species, the ecosystem carries a tremendous quantity of information with regard to its structure and function. Particularly since we know and understand only a small part of this information, we should be loath to subvert ecosystem self-organization (**Fig. 4**).

Care in adhering to wild density levels will help prevent overstocking, overgrazing, and overpredation until the model is better understood. Single members of species guilds can be selected to perform a function, and thus reproductive density is achieved without exceeding ecosystem density requirements. In general, the larger the population of any single species, the more likely it is that breeding success will be achieved.

Ecosystem Interchange

However, one arbitrarily draws the boundary, no ecosystem occurs in total isolation. In many cases when such boundaries are arbitrary, major survival effects must be provided by adjacent ecosystems. For example, coral reefs and most shallow benthic communities are greatly dependent on the effects of adjacent open bodies of water for food, oxygen, and wave and current `drive'. Typically, filters, the core element of aquarium science, have been devised to fill the need for the larger, less animal-dense body of adjacent open water that has been `filtered' by the settling or loss of organic particles to deep water. However, such filters to a large extent usurp the role normally

provided by plants in most of the communities that are modeled. Unfortunately, in so doing they do not add oxygen as the plants do, and they raise nutrient levels. Both bacterial and foam fractionation methods remove organic particulates and swimming plankters, including reproductive stages that should be part of ecosystem function. Managed aquatic plant systems, such as ATSs, have been successfully used to manage water quality of adjacent ecosystems interaction, as we describe in some of the examples.

Although terrestrial systems, in general, may be less difficult in this regard, simulation of biotic interchange may be crucial. For example, birds and mammals often change ecosystems seasonally and even diurnally and the effects may be critical. Many insects are seasonal, some for very short periods, and often cross ecosystem boundaries. In some cases, it may be possible to provide these interactions through a human manager; however, a refugium, or alternate ecosystem may be necessary to achieve veracity.

The Operational Imperative

Successful enclosed ecosystem operation requires the monitoring of a large number of physical and chemical factors. To a large extent, this can be automated with electronic sensors, and the data can be logged and the system computer controlled. Some chemical parameters require wet chemistry, though a once-a-week analysis is usually sufficient in a well-run system. Like any piece of complex laboratory equipment (a scanning electron microscope, for example) a dedicated and highly trained technician is needed to manage the monitoring equipment, though in a well-tuned system, considerable time can be available for other duties.

An operational feature that is rarely discussed, and in practice is mostly anecdotal is that of population instability. A mesocosm, in effect, is a few-square-meter patch of a larger ecosystem. In the wild, ecosystem patches of a few square meters can be subject to considerable short-term variability, though stability is achieved to some extent by the smoothing effect of the larger ecosystem that may be measured in square kilometers.

Microcosms and mesocosms require an ecologist, fully acquainted with `normal' community structure of the `wild-type' system. Effectively, that ecologist/operator performs as the highest, and most omnivorous, predator. In the cases of algal or insect `explosions' the operator's function is obvious, a once-a-week cropping or `grazing' (i.e., hand harvest) until the explosion tendency subsides. In other cases, the short-term introduction of predator to carry out the limited cropping or grazing role can be quite successful. These `managed predators' can be kept in a refugium unit where they are readily available for such service.

Case Study: Coral Reef Microcosm

The Caribbean coral reef ecosystem model shown in Fig. 5 received natural sunlight from one side, south-facing at 37.5° N latitude; the metabolic unit had six 160 W VHF flourescent lamps (to match tropical intensity), step-cycled to bring mid-day peak intensity to approximately 800 uE m^{-2} s^{-1} and total incoming light to 220 Langleys/day (Fig. 6). The ATS, lighted at night, had three 100 W metal halide lamps. The discussion presented represents data accumulated throughout the 9th year of 10 years of operation.

The physical and chemical components of the microcosm were measured in the metabolic unit and closely match those of the St. Croix analog (Table 1). The pH of the microcosm ranges from 7.96 ± 0.01 ($n = 62$) in the morning to 8.29 ± 0.10 ($n = 39$) in the late afternoon. Because of linked interacting photosynthesis and calcification in the ecosystem, calcium concentrations and

Alkalinity (meq l^{-1})	2.88 ± 0.04 (n = 59)	2.47[b]
Light[e] (Langleys d^{-1})	220	430 (surface); 220 (5 m deep infore-reef)

[a]The St. Croix data is from Adey and Steneck (1985).
[b]Tropical Atlantic means from Millero and Sohn (1992); no data available for St. Croix.
[c]Values from Enewetak and Moorea (Odum and Odum, 1955; Gattuso *et al.*, 1997).
[d]Tropical Atlantic means from Sverdrup *et al.* (1942); no data available for St. Croix.
[e]The light levels of the system were measured with a pyranograph. All of the physical and chemical components of the microcosm are compared to the fore-reef of St. Croix since light levels are equivalent (Kirk, 1983; Adey and Steneck, 1985). For references, see Small A and Adey W (2001) Reef corals, zooxanthellae and free-living algae: A microcosm study that demonstrates synergy between calcification and primary production. *Ecological Engineering* 16: 443–457.

alkalinity continually fall during the day and are stable or rise slightly at night. Calcium was added each morning as a solution of aragonite dissolved in HCl at approximately 24 000 mg l^{-1}. To keep microcosm concentrations above 420 mg l^{-1}, after a full day of calcification, the mean concentration of calcium in the system was maintained at 491 ± 6 mg l^{-1}. Bicarbonate, was added as either $NaHCO_3$ or $KHCO_3$ dissolved in distilled water. The mean alkalinity was 2.88 meq l^{-1} (n = 59), in order to maintain levels above 2.40 meq l^{-1}. Water quality (nutrients, oxygen, and pH) of the system was controlled by algal turf scrubbing.

The mean oxygen concentration of the microcosm as shown in **Fig. 6** is very close to that of the analog St. Croix reef. Net primary productivity (NPP) and respiration (R) were calculated based on the rate of oxygen increase and decrease, respectively, across the point of saturation (6.5 mg 1^{-1} O_2), to avoid atmospheric fluxes. This gave a mean gross primary productivity (GPP) of 14.2 ± 1.0 gO_2 m^{-2} d^{-1}, as compared to the mean GPP for the analog fore-reef at 15.7 gO_2 m^{-2} d^{-1}. The difference between the microcosm and reefs *in situ* can be accounted for by the difference in spatial heterogeneity; topographic relief on the St. Croix fore-reef typically ranges from 1 to 2 m, while in the microcosm only 10–30 cm is possible.

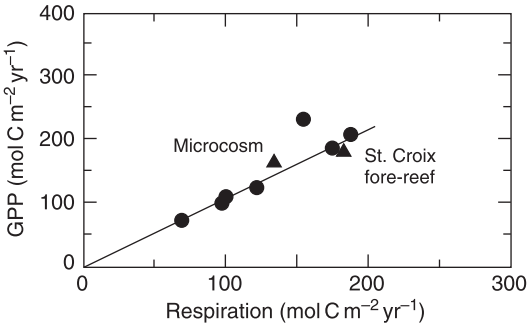

Fig. 7 GPP as a function of respiration in the coral reef microcosm and its wild analog reef in comparison with selected worldwide reefs.

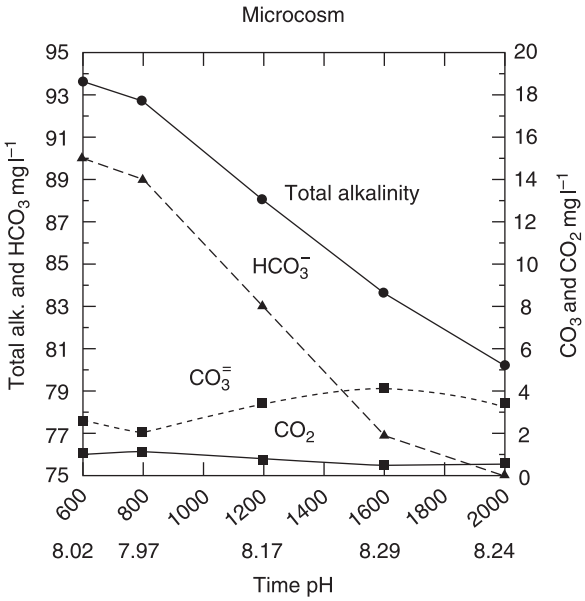

Fig. 8 Mean daytime carbonate cycle in coral reef microcosm calculated by namograph from pH and total alkalinity data.

In Fig. 7, GPP versus R for the microcosm and its analog are plotted, showing that both are well within the range of typical wild reefs. Even though primary productivity of the microcosm is very close to the wild analog, the fact that respiration is somewhat lower probably relates to the proportionally lower spatial heterogeneity in the microcosm.

Whole ecosystem calcification in the coral reef model, at 4.0 ± 0.2 kg $CaCO_3$ m^{-2} yr^{-1}, is related to its primary components (stony coral 17.6%, *Halimeda* 7.4%, *Tridacna* 9.0%, algal turf, coralline and foraminifera 29.4%, and miscellaneous invertebrates 36%). Through analysis of the microcosm's daily carbonate system, it is demonstrated that bicarbonate ion (Fig. 8), not carbonate ion, is the principal component of total alkalinity reduction in the water column.

This coral reef microcosm contained 534 identified species within 27 phyla (Table 2), with an estimated 30% unaccounted for due to lack of taxonomic specialists. Because of the length of time that this model system was closed to biotic interchange, virtually all of the biotic composition of the system (over 95%) had to be maintained by reproduction. Based on standard species/area relationships ($S = kA^z$, where S = species richness and A = area), the predicted pan tropic coral reef biodiversity calculated from the model biodiversity (at three million species) exceeds that of recent estimates for wild coral reefs.

Case Study: Florida Everglades Mesocosm

This greenhouse-scale mesocosm is a 98 500 l butyl-lined, concrete block tank divided into seven connected sections of varying salinity (Fig. 9). Each section contains water, algae, animals, sediments, and wetland–coastal plants representative of habitats along a transect from the full salinity Gulf of Mexico through the estuarine Ten-Thousand Islands and into the freshwater Florida Everglades (Fig. 10).

As in the wild analog, the Gulf Shore and estuary are part of the same dynamic water mass. Here, the estuarine salinity gradient is created by pump-driven tidal inflow interacting through open weir constrictions and against downstream freshwater flow. Tank

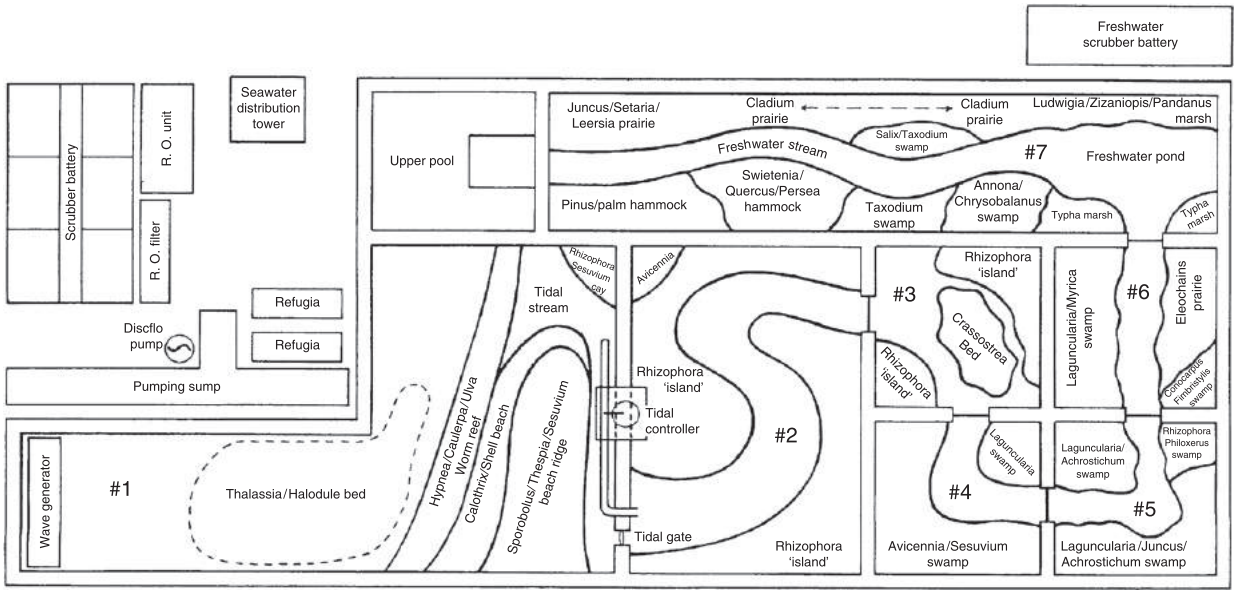

Fig. 9 Plan view of the Florida Everglades mesocosm and its critical engineering components.

#1, the Gulf Shore, acts as a tidal reservoir for the estuary, thereby saving the need for a blank reservoir (Fig. 11). The primary pump is an 800 lpm, Discflo™ unit that utilizes a rotating disk, rather than plankton-destructive impellers. The freshwater is derived from rain and from reverse osmosis extraction from the Gulf Shore (the equivalent of Gulf evaporation and resulting

Fig. 10 Florida Everglades mesocosm approximately 4 years after construction showing salt marsh, black mangrove, and red mangrove communities (from front to background at left) and lower freshwater stream at right. At this point the greenhouse roof is providing a significant constraint to community succession by limiting vertical growth of mangrove and hammock trees.

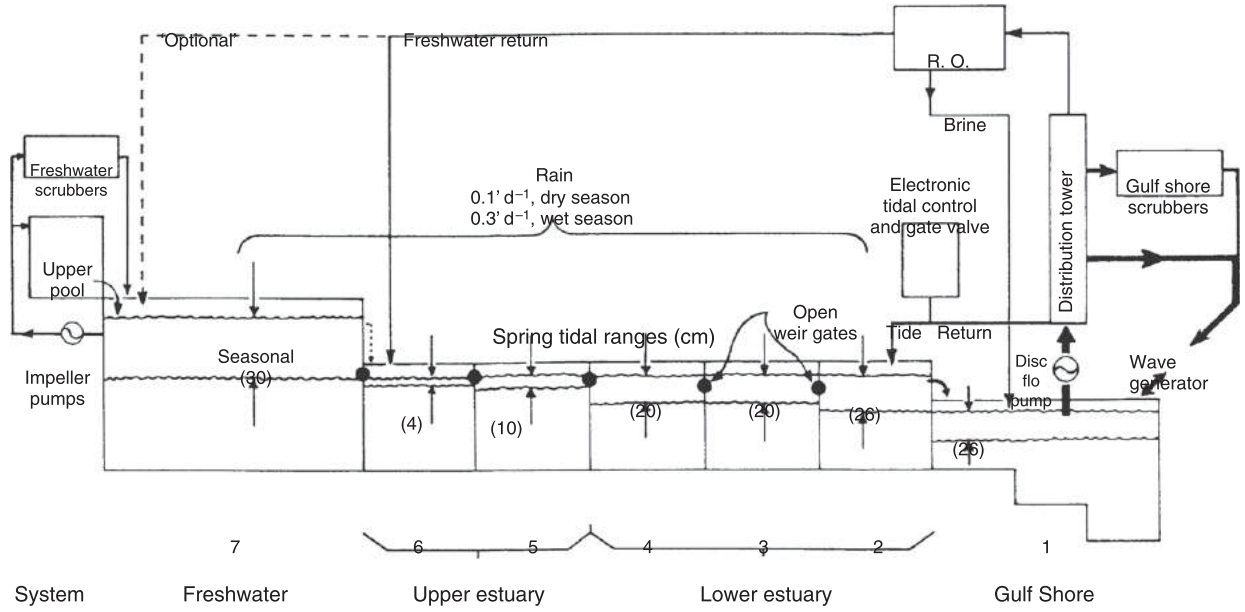

Fig. 11 Vertical/longitudinal section through Florida Everglades mesocosm showing water management system and tide levels.

rainfall in the wild). All aquatic organisms, including adult invertebrates, can move from the estuary to the Gulf Shore. All organisms that can survive Discflo™ pumping (including small fish) can return to the estuary via tidal inflow. The freshwater system, at times, flows directly into the uppermost estuary and technically all organisms can enter the estuary from freshwater.

The initial stocking of the mesocosm was completed in mid-1988, and small collections continued to be injected through 1990. During this period, partial censuses for key organisms were undertaken, and, where required, additional stocking was carried out. From late 1990 to late 1994, the system was operated as a biotically closed system, with minor human interaction, functioning as an omnivorous predator.

Major physical/chemical parameters are shown in **Table 3**. Dissolved nitrogen was monitored as nitrite plus nitrate in each of the community units (tanks); these were typically at levels of 5–8 μM ($NO_2 + NO_3$) through the middle of the estuary, and at 3–5 μM ($NO_2 + NO_3$), in the Gulf (#1) system. Levels average a few μM higher in winter than in summer. Nutrient flow-through is achieved by algal export, in the ATS banks. When levels drop below 1–2 μM in the Gulf (#1) system (typically in summer), the dried scrubber algae are redistributed to the system.

After 4 years of biotically closed operation, the Florida Everglades mesocosm was censused for organisms. The abundance of the principal higher plants, algae, invertebrates, and fish are shown in **Figs. 12–14**. A total of 369 species (not including bacteria, fungi and the minor `worm' phyla) was tallied. Excluding algae, protists, and small invertebrates, which could not be censused during introduction, it can be estimated that approximately 20–40% of the introduced species survived through the 4 years of

Table 3 Physical/chemical parameters of the Florida Everglades mesocosm

Parameter	Tank #1	Tank #2	Tank #3	Tank #4	Tank #5	Tank #6	Tank #7

biotic closure. In most cases these were the dominating species in the analog ecosystems. At the time of termination of the system as a carefully monitored mesocosm, only 15–30% of the originally introduced species were reproductively maintaining populations. However, in most cases, as Figs. 12–14 show, these were the species that provided primary structure and metabolism in the analog ecosystem.

Case Study: Biosphere 2

Biosphere 2, located near Tucson, AZ, USA, is the largest greenhouse system ever built with nearly three acres (1.2 ha) of enclosed space. It is unique in surpassing any other greenhouse ecosystem in size, complexity, and duration of operation. The system was originally intended as a model of the Earth's biosphere (e.g., biosphere 1) with several tropical and subtropical ecosystems, an agricultural area, wastewater treatment wetlands, and a human habitat, along with a factory-sized machinery area for maintaining physical–chemical conditions. It was built to develop bioregenerative technology for future space travel, to educate the public about biosphere-scale issues and for basic ecological research. Atmospheric

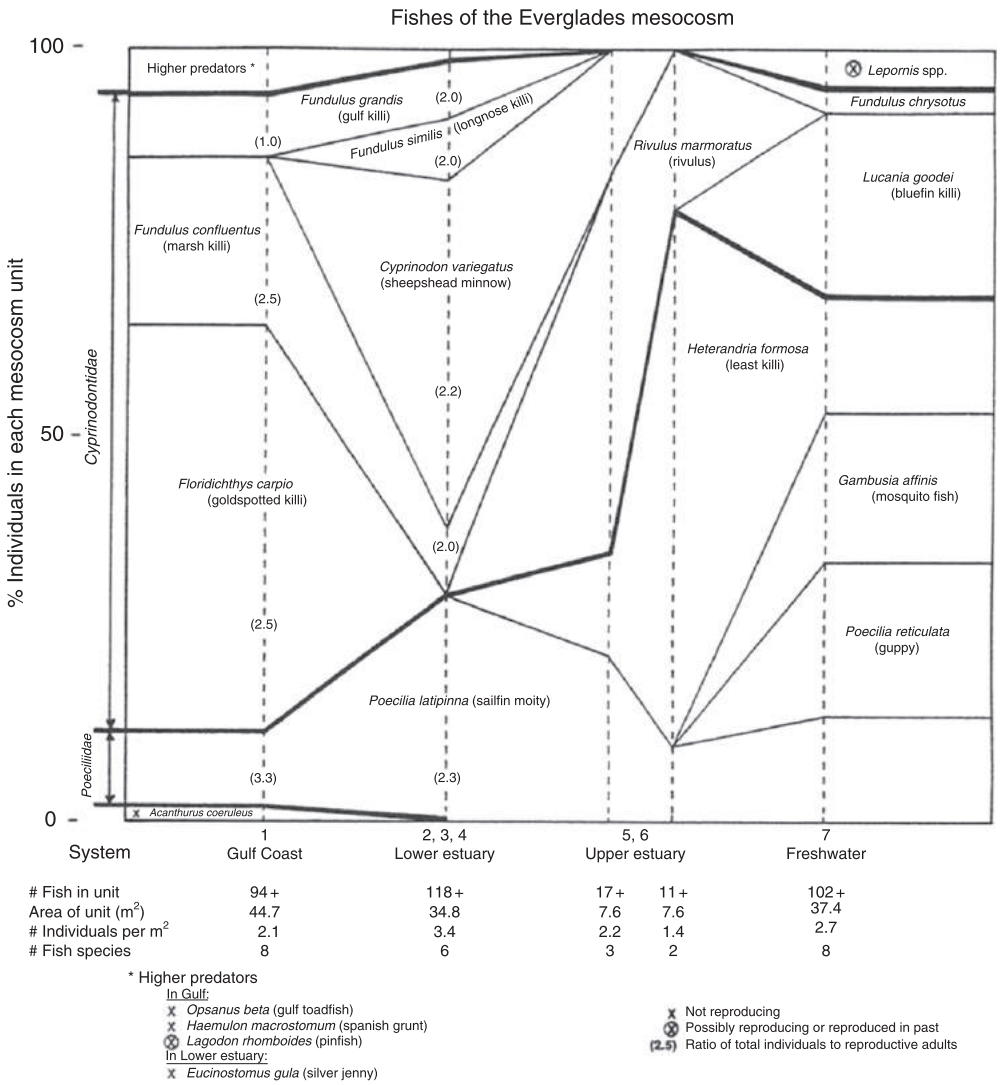

Fig. 14 Distribution of fish (% of total) in Florida Everglades mesocosm.

closure of gas cycles was part of the system design, which was tested with a prototype module of 11 000 ft^3 (312 m^3) from 1988 to 1990.

A number of ecologists were consulted for the creation of the greenhouse's ecosystems which included plots of rainforest, desert, savanna, mangrove estuary, and ocean with coral reef. Thousands of species were added to the greenhouse intentionally and unintentionally (i.e., in ecosystem sub-blocks, as described above), from existing tropical systems as distant as Venezuela and from the local Arizona desert. After construction the ecosystems self-organized and many of the added species went extinct within the system as expected. Success, in terms of replication of the analog ecosystems in nature, has varied among the different model ecosystems, but most have developed and sustained a significant degree of ecological integrity.

Two experiments were conducted in Biosphere II during which humans were enclosed inside the system: the first for 2 years (1991–93) and the second for 6 months (1994). These experiments tested concepts of sustainability at a very basic level since the humans had to rely on the overall greenhouse system for life support function. However, changes in the gas cycles within the greenhouse caused the human experiments to be modified and ultimately terminated. During the first human experiment oxygen concentration in the atmosphere decreased dramatically because high rates of soil respiration released more carbon dioxide than was taken up in photosynthesis; some of the carbon dioxide was absorbed as carbonates in the concrete of the greenhouse foundation. Oxygen had to be pumped into the system to maintain the humans so that the 2-year test could be completed. During the second human experiment, buildup of noxious concentrations of nitrous oxide in the atmosphere from microbial metabolism caused the experiment to be shut down ahead of the planned schedule.

At least two of the basic principles of ecosystem modeling discussed in the introduction were violated in this system. Incoming light was greatly reduced, due to the glass and significant support structure, resulting in insufficient photosynthesis and primary productive to balance respiration. This could have been offset by introducing a subset of highly efficient photosynthesis (such as

provided by an ATS), using artificial lighting; indeed, some ATS systems were used, but only as a minor element of control on the ocean system. Monitored exchange with the external environment could also have been employed. Also, the concrete as an atmospheric reactant should have been sealed with a nonreactive material, such as glass or plastic.

Much controversy developed during these human experiments. Colombia University took over management of the system from 1996 to 2003. During this time period the research program changed from human enclosure experiments to work on global climate change.

Lagoons

G Harris, University of Tasmania, Hobart, TAS, Australia

Background

Coastal lagoons are estuarine basins where freshwater inflows are trapped behind coastal dune systems, sand spits, or barrier islands which impede exchange with the ocean. They are most frequent in regions where freshwater inflows to the coast are small or seasonal, so that exchange with the ocean may not occur for months or years at a time. Many occupy shallow drowned valleys formed when the sea level was lower during the last ice age and subsequently flooded by postglacial sea level rise. The tidal range is usually small. Accordingly, coastal lagoons are frequently found in warm temperate, dry subtropical, or Mediterranean regions along moderately sheltered coasts. Lagoons are infrequent in wetter temperate and tropical regions where freshwater inflows are sufficient to scour out river mouths and keep them open. Here estuaries are dominated by salt marshes in temperate and mangroves in tropical climes. A particularly good example is the series of coastal habitats on the southern and eastern coastline of Australia which change from open temperate estuaries and salt marshes in the wetter southern regions of Tasmania, through a series of coastal lagoons of varying sizes and ecologies along the south and east coasts, to open subtropical and tropical estuaries, reefs, and mangroves in the warmer and wetter north. A similar, although inverted, sequence can be seen running south along the east coasts of Canada, and the northeastern, central, and southeastern coasts of the USA. The resulting lagoons have varying water residence times, depending on volume, climate, freshwater inflow volumes, and the tidal prism.

Some lagoons are predominantly freshwater or brackish, while others are predominantly marine; so the dominant organisms in coastal lagoons reflect the balance of freshwater and marine influences. All are influenced by the local biogeography. Thus, the dominant species in Northern Hemisphere lagoons are quite different from those in their Southern Hemisphere equivalents. Different coastal regions of the globe differ in their biodiversity; for example, the endemic biodiversity of seagrasses is very high in Australian waters. Nevertheless, two points are worthy of note. First, there is great functional similarity between systems despite differing in the actual species involved. Second, human activity is quickly moving species around the world so that there are large numbers of what might be called `feral' introduced species in coastal waters close to ports and large cities.

Coastal lagoons are ecologically diverse and provide habitats for many birds, fish, and plants. The interactions between the species in estuaries and coastal lagoons produce valuable ecosystem services. Indeed, the value of ecosystem services calculated for such systems by Costanza *et al*. was the highest of any ecosystem studied. Lagoons are also esthetically pleasing and desirable places to live, providing harbors, fertile catchments, and ocean access for cities and towns; thus, they have long been the sites of rapid urban and industrial development. Habitat change and other threats to lagoons now compromise these valuable services. All around the world they are threatened by land-use change in their catchments, urbanization, agriculture, fisheries, transport, tourism, climate change, and sea level rise. Coastal waters and lagoons are therefore definitive examples of the problems of multiple use management. Rapid population growth in coastal areas is common in many western countries (particularly the common `sea-change' phenomenon, in which there is a trend toward rapid population growth along coasts), so the threats and challenges are increasing rapidly. Climate change and sea level rise are also becoming issues to be dealt with. In tropical and subtropical regions there is both evidence of rapid coastal habitat loss and population growth as well as an increased frequency of severe hurricanes. Modified systems impacted by severe hurricanes and tsunamis appear to be more fragile in the face of extreme events and certainly do not degrade gracefully.

Research and the management of coastal systems require a synthesis of social, economic, and ecological disciplines. Around the world there are a number of major research and management programs which aim to apply ecosystem knowledge to the effective management of coastal resources. Current examples include work in Chesapeake Bay and the Comprehensive Everglades Restoration Plan in the USA. In Italy the lagoon of Venice is a classic example. In Australia major programs have been undertaken in coastal embayments and lagoons in Adelaide (Gulf of St. Vincent), Brisbane (Moreton Bay), and Melbourne (Port Phillip Bay). (For details on these programs and useful links, see www.chesapeakebay.net, www.evergladesplan.org, and www.healthywaterways.org.) Land-use change (both urbanization and agriculture) in catchments, together with the use of coastal lagoons for transport and tourism, has led to a combination of changes in physical structures (both dredging and construction of seawalls and other barriers), altered hydrology and tidal exchanges, increased nutrient loads, and inputs of toxicants. The resulting symptoms of environmental degradation include algal blooms (which may be toxic), loss of biodiversity, and ecological integrity (including the loss of seagrasses and other important functional groups), anoxia in bottom waters, loss of important biogeochemical functions (denitrification efficiency), and the disturbances caused by introduced, `feral' species from ships and ballast water.

Inputs – Catchment Loads

Land-use change in catchments changes the hydrology of rivers and streams and increases nutrient loads to lagoons. Rivers draining clear catchments, or those with extensive urbanization, show `flashier' flow patterns with water levels rising and falling

quickly after rainfall. The hydrological balance and water residence times of the lagoons are altered as a result. While nutrient loads are generally proportional to catchment area (Fig. 1), loads from cleared agricultural or urban catchments are higher than those from forested catchments, the nutrient loads being proportional to the amount of cleared land or the human population in the catchment. Carbon, nitrogen, and phosphorus loads all increase; C loads from wastewaters may lead to biochemical oxygen demands (BODs) and anoxia, while increased N and P loads stimulate algal blooms and the growth of epiphytes in seagrasses. A further problem is the fact that forested catchments tend to export organic forms of N and P (which are less biologically active in receiving waters), whereas cleared and developed catchments tend to export biologically available inorganic forms of N and P. Thus, both nutrient loads and the availability of those loads increase when catchments are cleared and developed.

N is in many cases (particularly in warmer coastal waters) the key limiting element in lagoons because of high denitrification efficiencies in sediments and long water residence times in summer. In temperate waters N and P may be co-limiting or the limitation may vary seasonally and on an event basis. Overall the climate regime, geomorphology, and biogeochemistry of coastal lagoons seem to lead to extensive N limitation and denitrification is an important process which determines many ecological outcomes. The effect of land-use change on N loads is therefore a key area of concern. A considerable amount of work has been done on the export of N from catchments around the world. Catchments tend to retain on average about 25% of the N applied to them and export about 75%. There are both latitudinal and seasonal factors which affect this figure. Catchment exports on the eastern coast of North America show an effect of latitude, with warmer, southern catchments with perennial vegetation exporting about 10% of applied N and more northerly catchments with seasonal vegetation growth exporting as much as 40% of applied N, particularly in winter. P exports tend to come primarily from sewage and other wastewater discharges, and also from erosion and agricultural runoff. Catchment loads show evidence of self-organized pattern and process in catchments – nutrient loads and stoichiometries change over time at all scales and the distribution of inflowing nutrients may be fractal.

Fates and Effects – Physics and Mixing

Water movement and mixing are driven by the effects of wind and tide on coastal lagoons. The basic hydrodynamics of coastal systems are well represented by physics-based simulation models of various kinds. A number of two- and three-dimensional (2D and 3D) models now exist (both research tools and commercially available products) which can adequately represent wind-induced wave patterns and currents, tidal exchanges and circulation, and changes in surface elevations due to tides and winds. (For an introduction to a variety of models, see www.estuary-guide.net/toolbox or www.smig.usgs.gov; models by Delft Hydraulics at www.wldelft.nl and DHI www.dhigroup.com/. Input data required are basic meteorological data: wind speed and direction, plus solar insolation, and a detailed knowledge of the morphometry and bathymetry of the lagoon in question. Based on the conservation of mass and momentum and various turbulence closure schemes, it is possible to adequately model and predict both velocity fields and turbulent diffusion in the water column. Calibration and validation data are obtained from *in situ* current meters and pressure sensors. Bottom stress, sediment resuspension, and wave-induced erosion can also be represented. It is thus possible to model the effects of various climate and engineering scenarios, everything from sea level rise to construction projects of various kinds. These models are widely used to develop environmental impact statements (EIS) for major projects and to manage major dredging projects around the world. Only some of these models are capable of long-term predictions of water balance and

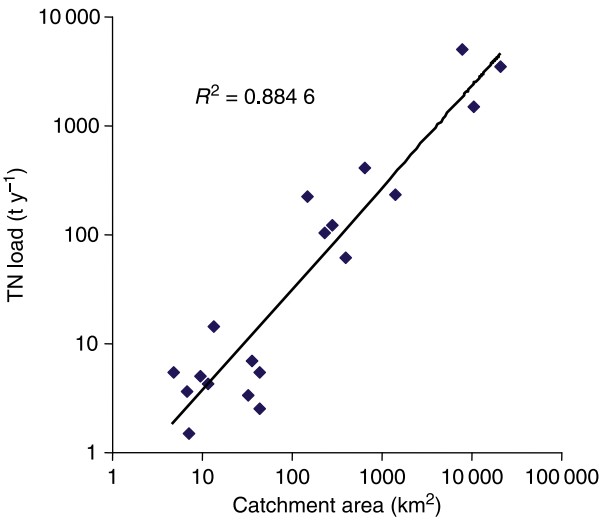

Fig. 1 The empirical relationship between catchment area (km^2) and the total nitrogen load (tonnes per year) to their associated coastal lagoons. Data from the catchments of 19 coastal lagoons on the east coast of Australia. Details of data sources are given in Harris, G.P., 1999. Comparison of the biogeochemistry of lakes and estuaries: Ecosystem processes, functional groups, hysteresis effects and interactions between macro- and microbiology. Marine and Freshwater Research 50, 791–811.

of water residence times. Such predictions require careful analysis of long-term meteorological records and good predictive models of inflows and evaporation. Nevertheless such models also exist.

Fates and Effects – Ecological Impacts and Prediction

Given the nature of the threats, the value of ecosystem services delivered, and the importance of ecosystem management, there have been many studies of ecosystems in coastal lagoons. As noted above some of the ecosystem studies have been in the form of major multidisciplinary programs. The knowledge obtained has then frequently been encapsulated in various kinds of predictive ecological models which attempt to provide answers to `what if' questions from environmental managers and engineers seeking to implement catchment works or reductions in wastewater discharges. The ecological models are driven by the hydrodynamic models described above – the physical setting provides the basic context for the ecological response. In many cases the knowledge has also been built into a variety of EIS and risk assessments which attempt to judge the possible detrimental effects of land-use change, port construction, harbor dredging, and other engineering developments in urban and industrial areas.

Empirical Knowledge and Models

Despite the pandemonium of interactions between species in coastal marine systems (or perhaps because of it), there are some high-level empirical relationships which can be used for diagnosis and management. Much as Vollenwieder discovered in lakes there are some predictable high-level properties of coastal marine systems. For example, the total algal biomass (as chlorophyll *a*) responds to N loads just as lakes respond to P loads. This is further evidence of the importance of N as a limiting element in marine systems, and for the key of P as the limiting element in freshwater systems. The differing biogeochemistry of marine and freshwater ecosystems is explicable on the basis of the evolutionary history and geochemistry of the two systems. The existence of a relationship between N and algal biomass is evidence for a kind of `envelope dynamics' of these diverse systems. N does not limit growth rates of the plankton so much as the overall biomass. As a result of high growth rates, grazing, and rapid nutrient regeneration in surface waters, the total community biomass reaches an upper limit set by the overall rate of supply of N. This is a form of `extremal principle' of these pelagic ecosystems which indicates that with sufficient biodiversity then an upper limit to maximum nutrient use efficiencies can be reached. A similar model of high-level ecosystem properties has been developed in which some fundamental physiological properties of phytoplankton (the slope of the P vs. I curve at low light and the maximum photosynthetic rate) are used to develop a production model based on biomass, photosynthetic properties, and incident light. This amounts to saying that even in shallow coastal systems it is possible to get some reasonable empirical predictions of the physiological (photosynthetic parameters and nutrient uptake efficiencies) and ecosystem responses to some driving forces (nutrient loads and incident light).

A second form of empirical determinant of system function is set by the stoichiometry and biogeochemistry of these systems. The characteristic elemental ratios in the key organisms (algae, grazers, bacteria, macrophytes) and the ratios of elemental turnover set limits on the overall system performance. The predominant element ration in pelagic marine organisms is the Redfield ratio (106C:15N:1P). This aspect of the biogeochemistry of coastal lagoons has been used in a global comparison of the biogeochemistry of these systems by the IGBP LOICZ program. Knowing the loading rates of major nutrients, the concentrations of nutrients in the water column, and the rates of tidal exchange allows simple mass balance models of C, N, and P to be constructed. The salt and water budget of these systems can be used to obtain bulk hydrological fluxes. Making stoichiometric assumptions via the Redfield ratio about fluxes of C, N, and P (as well as oxygen) in the plankton and across the sediment interface allows estimates to be made of the overall autotrophic–heterotrophic balance of the system as well as nitrogen fixation and denitrification rates (essentially by estimating the `missing N' based on the C, N, and P stoichiometry). These techniques have made it possible to do global comparisons of the biogeochemistry of lagoons around the world and to examine the effects of inflows, tidal exchanges, and latitude or climate. This has been a major contribution to the knowledge of the ways in which major elements are processed and transported from the land to the ocean through the coastal zone.

The overall impression is that pristine lagoons (loaded by largely organic forms of C, N, and P) are mostly net heterotrophic and strong sinks for N through denitrification. More eutrophic systems with higher N and P loads (and more of those in inorganic forms) tend to be net autotrophic and, if dominated by cyanobacterial blooms, net N fixing systems. Decomposition of these blooms may be sufficiently rapid to cause anoxia in bottom waters and lead to the cessation of denitrification and the export of N (as ammonia) on the falling tide. Warm temperate and subtropical lagoons – with low hydrological and nutrient loads – seem to have higher denitrification efficiencies than temperate systems. They are often heterotrophic and strongly N limited systems. An extreme is Port Phillip Bay in Melbourne which has low freshwater inflows, high evaporation, a long water residence time (*c.* 1 year), high denitrification efficiency (60–80%) and is so N limited that it imports N from the coastal ocean on the rising tide. Temperate lagoons and estuaries have higher freshwater and nutrient inflows, are more eutrophic (autotrophic), and are exporters of N. Temperate systems are therefore more likely to show occasional P limitation. Overall, the cycling of the major elements is driven by the stoichiometry of the major functional groups of organisms.

Thus in biodiverse ecosystems it is possible to obtain some high-level state predictors from a knowledge of key drivers and the basic physiology and stoichiometry of the dominant organisms. The predictions so produced are not perfect but they do capture a large fraction of the behavior of these systems. At this level these models can be used for the management of nutrient loads to coastal lagoons.

Detailed Simulation Models of Ecosystems, Functional Groups, and Major Species

Many of the questions that are asked of ecologists studying coastal systems are of a more detailed nature and relate to loss or recovery of major species, functions, or functional groups – ecosystem services and assets if you like. Examples would be dominant algal groups, seagrasses, macroalgae, denitrification rates, benthic biodiversity, fish recruitment, etc. At this level a large number of dynamical ecological simulation models of shallow marine systems have been constructed. There is much more uncertainty in the ecological models than there is in the physical models. Much of the required ecological detail is unknown, key parameters can be ill-defined, the data are usually sparse in space and time, and the computational resources are not adequate to the task of a complete simulation of the entire system. Ecological models are therefore abstractions which attempt to represent the major ecological features and functions of the greatest relevance to the task at hand. Nevertheless, 30 years of research in lagoons and coastal systems around the world have uncovered a number of major functional groups and ecosystem services which, when coupled together in models, give some guide as to the overall ecological responses.

The generic models of coastal systems use two basic functional components. A nutrient, phytoplankton, zooplankton (NPZ) model for the water column, and a benthic model incorporating the necessary functional groups – macroalgae, zoo- and phyto-benthos, seagrasses – with the groups chosen to represent the particular system of interest. All functional groups are represented by their basic physiologies and stoichiometries and the interconnections (grazing, trophic closure, decomposition, and denitrification rates) are represented by established relationships. The NPZ models adequately predict the average chlorophyll of lagoons and, when coupled with 3D physical models, can give predictions of the spatial distribution of algal biomass in response to climate and catchment drivers. For reasons which will become clear below, these models only predict average biomass levels and cannot predict all the dynamics of the various trophic levels. The coupling between the plankton and the benthos in lagoons is nonlinear and results in some strongly nonlinear responses of the overall system to changes in nutrient loads. Basically, there is competition between the plankton and the benthos for light and nutrients which can drive switches in system state. Thus, lagoons, much like shallow lakes, may show state switches between clear, seagrass-dominated states and turbid, plankton-dominated states.

The major driver of the state switches is the high denitrification efficiencies exhibited by the diverse phyto- and zoobenthos in lagoons with strong marine influences. As long as there is sufficient oxygen in bottom waters, diverse zoobenthos burrow and churn over the sediments causing extensive bioturbation and 3D structure in the sediments. Clams, prawns, polychaete worms, crabs, and other invertebrates set up a complex system of burrows and ventilate the sediments through feeding currents and respiratory activity. Given sufficient light at the sediment surface the phytobenthos (particularly diatoms, the microphytobenthos, MPB) photosynthesize rapidly and set up strong gradient of oxygen in the top few millimeters of the sediment. These gradients, together with the strong 3D microstructure of the sediments set up by the zoobenthos, favor the co-occurrence of adjacent oxic and anoxic microzones which are required for efficient denitrification. N taken up by the plankton sinks is actively denitrified by the sediment system. In marine systems the abundance of sulfate in seawater ensures that P is not strongly sequestered by the sediments. Thus, the basis of the LOICZ models lies in the efficiency of denitrification of N in sediments and the more or less conservative behavior of P in these systems. These ecosystem services are supported by the high biodiversity of the coastal marine benthos.

In lagoons with higher nutrient loads, the entire ecosystem may switch to an alternative state. Increased N loads stimulate the growth of plankton in the water column and shade off the MPB. The increased planktonic production sinks to the bottom depleting oxygen and reducing the diversity of zoobenthos, restricting the community structure to those species resistant to low oxygen concentrations. Active decomposition in anaerobic sediments together with reduced bioturbation leads to the cessation of denitrification and the release of ammonia from the sediments. So instead of actively denitrifying and eliminating the N load, the system becomes internally fertilized and algal production rises further. This is analogous to the internal fertilization of eutrophic lakes through the release of P from anoxic sediments. In both cases the switch is caused by a change in redox conditions and the change in performance of suites of microbial populations. Once switched to a more eutrophic state (algal bloom dominated), these lagoons do not easily revert to their clear and macrophyte dominated state. Loads must be strongly reduced to get them to switch back – something which may not be possible if the catchment has been modified by urban or agricultural development. There is thus evidence for strong hysteresis in the response of these ecosystems to various impacts.

The overall biodiversity and nutrient cycling performance of coastal lagoons therefore depends on the relative influences of marine and freshwaters, the differing biodiversity of marine and freshwater ecosystems, the relative C, N, and P loads to the plankton and the benthos, and on seasonality, latitude, and climate drivers. Nevertheless, at least the broad features of their behavior can be explained and predicted on the basis of sediment geochemistry, and the stoichiometry and physiology of the major functional groups in these ecosystems. Empirical work on a number of lagoons up the east coast of Australia allowed Scanes *et al.* to effectively determine the response of `titrating' these systems with nutrients. As the N load to the lagoons was increased, seagrasses were lost and algal blooms were stimulated. Even at a crude level of visual assessments it was possible to rank these systems in order of loading and to show that the pattern of response was entirely similar to that predicted by the models (**Fig. 2**). Thus, despite difference in biogeochemistry and biodiversity, shallow lakes and coastal lagoons have broadly similar response to increased nutrient loads and other forms of human impact. Even broad indicators of system state reveal consistent patterns of change.

So oligotrophic lagoons with a Mediterranean climate (warm temperatures in summer and long water residence times) and strong marine influences can be strong sinks for N, whereas cooler, temperate lagoons and estuaries with larger freshwater inflows and higher productivity may export N and be frequently P limited. As the LOICZ program intended, we have managed a broad understanding of the ways in which the coastal zone influences the transport of major elements from land to ocean.

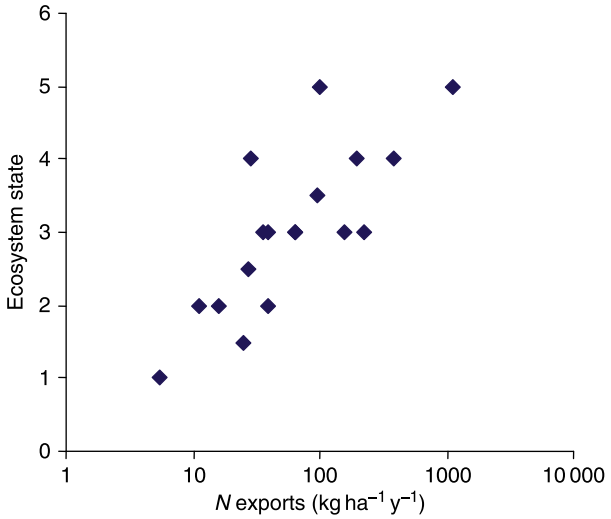

Fig. 2 The empirical `ecosystem titration' relationship between catchment N exports and the resulting ecosystem state in 17 coastal lagoons on the east coast of Australia. Ecosystem state is defined as 1, pristine; 3, showing marked seagrass loss and the growth of macrophytic algae; 5–6, dominated by nuisance algal blooms (some of which may be toxic). Data from personal observations and reworked from Scanes, P., Coade, G., Large, D., Roach, T., 1998. Developing criteria for acceptable loads of nutrients from catchments. In: Proceedings of the Coastal Nutrients Workshop, Sydney (October 1997). Artarmon, Sydney: Australian Water and Wastewater Association, pp. 89–99. Artarmon, Sydney: Australian Water and Wastewater Association.

Nonequilibrium Dynamics

If more detailed descriptions and predictions are required (e.g., the diversity and abundance of individual species and other specific ecosystem services and assets), then the predictive ability is less. One of the reasons for this is the fact, alluded to above, that these are nonequilibrium systems which respond to individual events (storms and engineering works) over long time periods. The elimination and invasion of species may take decades and the responses of freshwater lagoons, for example, to salt incursions may also take decades. A particularly good example is Lake Wellington in the Gippsland Lakes system in Victoria, Australia. The entire system is slowly responding to the ingress of salt made possible by the opening of the lagoon system mouth (Lakes Entrance) in 1883. Lake Wellington, the lake farthest inland, remained fresh until after the 1967 drought when a combination of high N and P loads from agriculture, the extraction of water from the inflowing La Trobe River for power station cooling and irrigation, and the incursion of salt killed all the freshwater macrophytes in the Lake. In a few years the lake switched from its previous clear and macrophyte dominated state to being turbid and dominated by toxic algal blooms. It does not appear to be possible to switch it back.

The response of these lagoon systems to climate and other perturbations is nonlinear and complex because of the interactions between the major functional groups and because the timescales of response of the major groups differ strongly. Phytoplankton may respond to changes in loads and water residence times in a matter of days, whereas seagrasses take decades or longer to recover. By perturbing a simple coupled plankton-benthos model with storm events and `spiked' N loads, Webster and Harris showed that the threshold load for the elimination of seagrasses could be altered considerably depending on the characteristics of the input loads. So the response of the system was a function of the overall load and the frequency and magnitude of events. Climate change and catchment development both alter the overall C, N, and P load to lagoons as well as the characteristics of that load, so that ecological responses by lagoons are highly complex and change over time depending on a variety of modifications and management actions. Consequently, lagoons are always responding to the last storm or intervention and the abundance of key species drifts to and fro over time as the entire plankton–sediment system responds.

The picture is made more complex by the evidence for strong trophic cascades in marine as well as freshwater systems. Coastal ecosystems are frequently over-fished; larger predators and grazers are removed by human hand. Removal of the `charismatic megafauna' of coastal systems, together with beds of shellfish and other edible species, has changed the ecology of many lagoons and estuaries. Coastal ecosystems around the world have also been strongly modified by the removal of natural physical structures (mangroves and reefs) which confer resilience in the face of extreme events. We have removed both larger fish and benthic filter feeders from many systems compromising function and the ability to respond to changes in catchment loads. Overall there has been a consistent simplification of both physical and ecosystem structures (removal of reefs and macrobiota, simplification of food chains, etc.) and a trend toward more eutrophic (nutrient rich) and simplified systems dominated by microbiota, especially algae and bacteria. We know less about the response of ecosystems to changes in the `top down' trophic structure than we do about the responses to `bottom up' catchment drivers; nevertheless, there is good evidence for similar nonlinearities and state switches in response. A nonequilibrium view of coastal lagoons changes the way we look at them. Overall there is a need to pay attention to

the `precariousness' of these systems and manage them adaptively for resilience and response to natural and anthropogenic impacts. Despite being over-fished and highly modified, there is still a need for the ecosystem services they produce.

Emerging Concepts – Multifractal Distributions of Species and Biomass

The underlying complexity of interactions and species distributions is displayed when detailed (high-frequency) observations are made of the spatial and temporal distributions of biomass and species. There is now much evidence to show that the underlying distribution of the plankton and the MPB are fractal or multifractal. Similarly, high-frequency observations in catchments show similar multifractal and even paradoxical properties of hydrological and nutrient loads. So underlying all the generalizations discussed above lies a pattern of behavior which gives strong evidence of self-generated complexity which arises from the pandemonium of interactions between species and functional groups. Indeed, we can probably argue that the kinds of general, system level, responses described above would not occur if it were not for the underlying complexity. While making high-level statements about ecosystem behavior possible, these small-scale, multifractal properties (and the possibilities created by emergence) cause problems when we wish to make predictions at the meso-scale level of dominant species and functional groups. Because of the work that has been done across the levels of organization, coastal lagoons are very good examples of a new kind of ecology – an ecology of resilience and change, rather than an ecology and equilibrium and stasis.

One fundamental problem that these new insights reveal is that most of the data we presently use for the analysis of coastal lagoons are collected too infrequently to be useful for anything other than the analysis of broad trends. Data collected weekly or less frequently are strongly aliased and cannot reveal the true scales of pattern and process. It is just possible to analyze daily data for new insights and processes but high-frequency data – collected at scales of hours and minutes – reveal a wealth of new information. Aliased data combined with frequentist statistical techniques that `control error' actually remove information from multifractally distributed data and raise the possibility of serious type I and II errors in ecological interpretations. Most importantly, there is information contained in the time series of multivariate data that can be collected from coastal systems. Most analyses of ecological data from ecological systems use univariate data and because of the infrequent data collection schedules – including gaps and irregular time intervals – time series analyses are not possible.

We are just beginning to find new technologies and techniques to study the high-frequency multivariate behavior of these systems using moorings and other *in situ* instruments. New electrode technologies make on-line access to data possible and throw up new possibilities for new kinds of observations of system state. We are beginning to realize that in addition to the `top down' causation of climate and trophic interactions, there is also a `bottom up' driver of complexity and the strong possibility of the emergence of high-level properties from the interactions between individuals. New forms of statistical analyses display information in time series of complex and emergent systems. This emerging understanding of complexity and emergent properties changes the ways in which we should approach EIS and risk assessments. We now know that interactions and self-generated complexity, together with hysteresis effects at the system level, can cause surprising things to happen as a result of anthropogenic change. Coastal lagoons are now classic examples of this. That means that risk assessments and EIS cannot look at impacts and changes in isolation; somehow we must develop integrated risk assessment tools that examine the interactive and synergistic effects of human impacts on coastal ecosystems. A further level of complexity is contained in the similar complex and emergent properties of the interactions between agents in the coupled environmental and socioeconomic (ESE) system in which all coastal lagoons are set. Multiple use management decisions are set in a complex web of ESE interactions across scales. Decisions made about industrial and engineering developments for financial capital reasons influence both social capital and ecological (natural capital) outcomes. Feedbacks ensure that this is also a highly nonlinear set of interactions. What we do know is that the prevalent practices of coastal management and exploitation are not resilient in the face of extreme events and that they do not degrade `gracefully' when impacted by hurricanes and tsunamis. New management practices will be required.

Mangrove Wetlands

RR Twilley, Louisiana State University, Baton Rouge, LA, USA

Introduction

Mangroves refer to a unique group of forested wetlands that dominate the intertidal zone of tropical and subtropical coastal landscapes generally between 25° N and 25° S latitude. These tropical forests grow along continental margins between land and the sea across the entire salinity spectrum from nearly freshwater (oligohaline) to marine (euhaline) conditions. The coastal forests also inhabit nearly every type of coastal geomorphic formation from riverine deltas to oceanic reefs – another example of the tremendous `biodiversity' of mangrove ecosystems. Mangroves are trees considered as a group of halophytes with species from 12 genera in eight different families. A total of 36 species has been described from the Indo-West-Pacific area, but fewer than ten species are found in the new world tropics. The term mangroves may best define a specific type of tree, whereas mangrove wetlands refers to whole-plant associations with other community assemblages in the intertidal zone, similar to the term `mangal' introduced by Macnae to refer to swamp ecosystems. In addition, the habitats of tropical estuaries consist of a variety of primary producers and secondary consumers distributed in bays and lagoons that have the intertidal zone dominated by mangrove wetlands. These may be referred to as mangrove-dominated estuaries.

There are numerous reviews and books that describe the ecology and management of mangroves around the world, including references describing techniques to study the ecology of mangrove wetlands.

Ecogeomorphology of Mangroves

The environmental settings of mangroves are a complex behavior of regional climate, tides, river discharge, wind, and oceanographic currents (Fig. 1). There are about 240×10^3 km^2 of mangroves that dominate tropical continental margins from river deltas, lagoons, and estuarine settings to islands in oceanic formations (noncontinental). The landform characteristics of a coastal region together with geophysical processes control the basic patterns in forest structure and growth. These coastal geomorphic settings can be found in a variety of life zones that depend on regional climate and oceanographic processes. Hydroperiod of mangroves resulting from gradients in microtopography and tidal hydrology (Fig. 1) can influence the zonation of mangroves from shoreline to more inland locations forming ecological types of mangrove wetlands. Lugo and Snedaker identified ecological types of mangroves based on topographic location and patterns of inundation at local scales (riverine, fringe, basin, and dwarf; Fig. 1) that Woodroffe summarized into basically three geomorphic types (riverine, fringe, and inland). A combination of ecological types of mangroves can occur within any one of the geomorphic settings occurring at a hierarchy of spatial scales that can be used to classify mangrove wetlands.

Various combinations of geophysical processes and geomorphologic landscapes produce gradients of regulators, resources, and hydroperiod that control mangrove growth (Fig. 2). Regulator gradients include salinity, sulfide, pH, and redox that are non-resource variables that influence mangrove growth. Resource gradients include nutrients, light, space, and other variables that are consumed and contribute to mangrove productivity. The third gradient, hydroperiod, is one of the critical characteristics of wetland landscapes that controls wetland productivity. The interactions of these three gradients have been proposed as a constraint envelope for defining the structure and productivity of mangrove wetlands based on the relative degree of stress conditions (Fig. 2). At low levels of stress for all three environmental gradients (such as low salinity, high nutrients, and intermediate flooding), mangrove wetlands reach their maximum levels of biomass and net ecosystem productivity.

Soil nutrients are not uniformly distributed within mangrove ecosystems, resulting in multiple patterns of nutrient limitation. Along a microtidal gradient in carbonate reef islands, trees were generally N-limited in the fringe zone and P-limited in the interior or scrub zone. Fertilization studies demonstrated that not all ecological processes respond similarly to or are limited by the same nutrient. It is also apparent that mangrove forests growing in other ecogeomorphic settings are also prone to P-limitation associated with different geophysical processes. One of the most critical regulator gradients (Fig. 2) controlling mangrove establishment, seedling survival, growth, height, and zonation is salinity, depending on their ability to balance water and salt. Interspecific differential response of mangrove propagules to salinity occurs at salinities from 45 to 60 g kg^{-1}. The δ^{13}C and δ^{15}N signatures of mangrove leaf tissue can indicate stress conditions such as drought, limited nutrients, and hypersalinity across a variety of environmental settings.

Biodiversity

Mangrove ecosystems support a variety of marine and estuarine food webs involving an extraordinarily large number of animal species and complex heterotrophic microorganism food web. In the New World tropics, extensive surveys of the composition and ecology of mangrove nekton have found 26–114 species of fish. In addition to the marine and estuarine food webs and associated

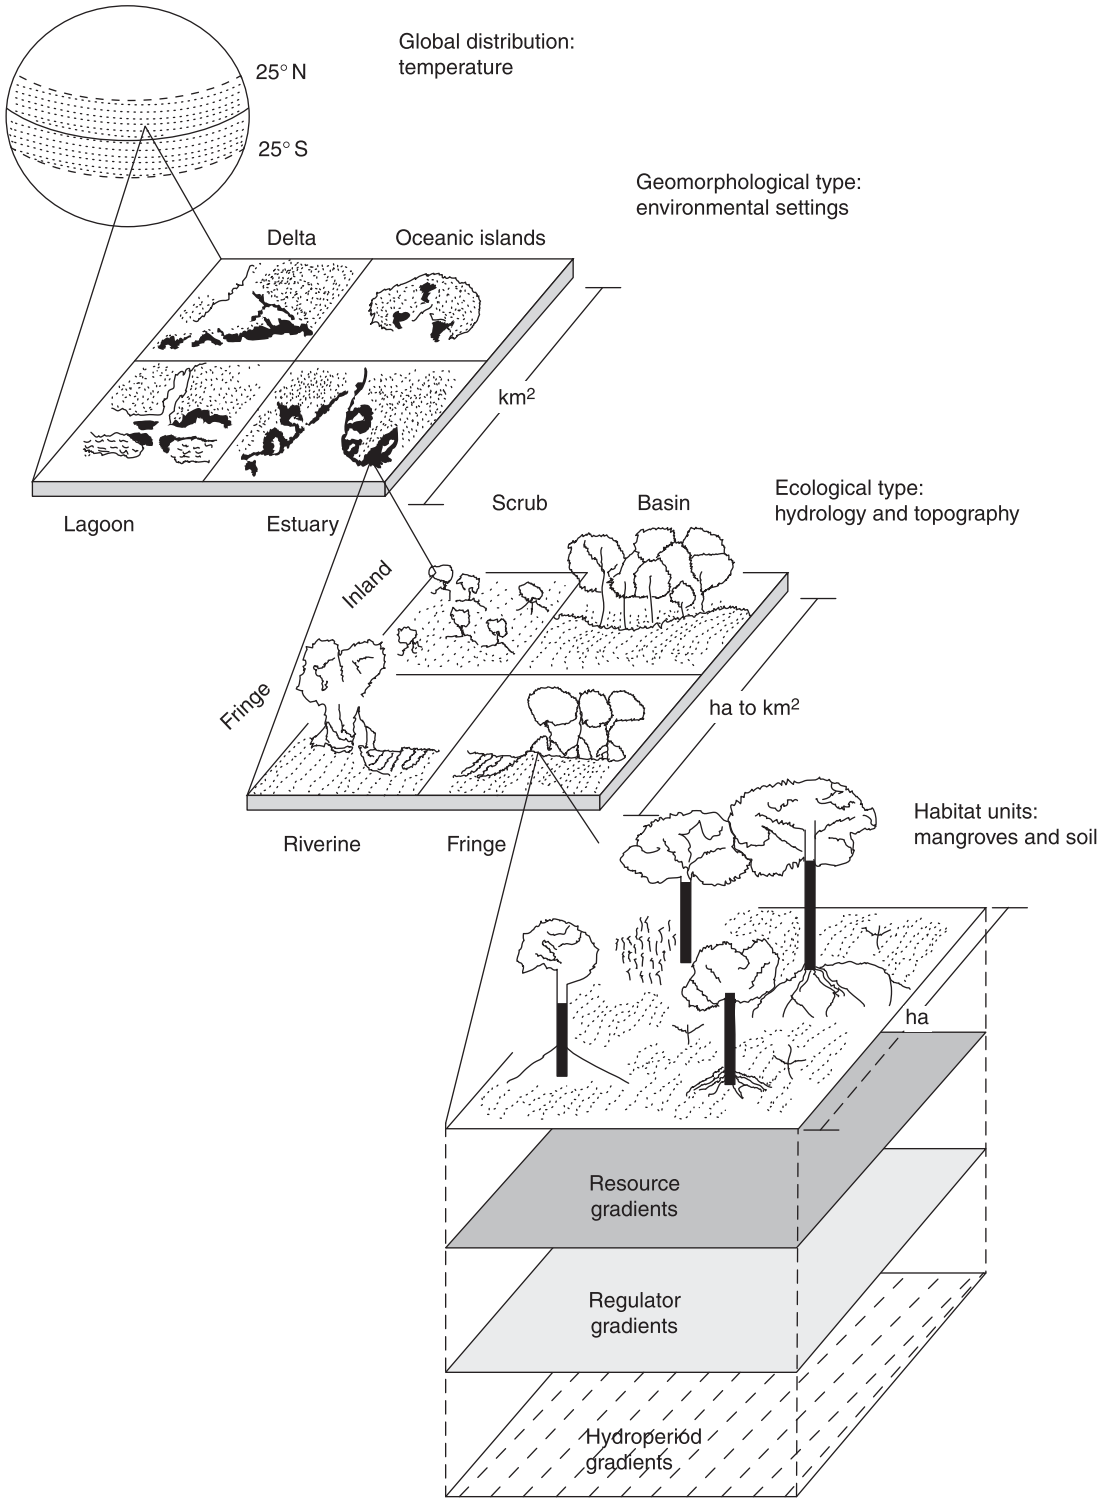

Fig. 1 Hierarchical classification system to describe patterns of mangrove structure and function based on global, geomorphic (regional), and ecological (local) factors that control the concentration of nutrient resources and regulators in soil along gradients from fringe to more interior locations from shore. Modified from Twilley RR, Gottfried RR, Rivera-Monroy VH, Armijos MM, and Bodero A (1998) An approach and preliminary model of integrating ecological and economic constraints of environmental quality in the Guayas River estuary, Ecuador. *Environmental Science and Policy* 1: 271–288 and Twilley RR and Rivera-Monroy VH (2005) Developing performance measures of mangrove wetlands using simulation models of hydrology, nutrient biogeochemistry, and community dynamics. *Journal of Coastal Research* 40: 79–93.

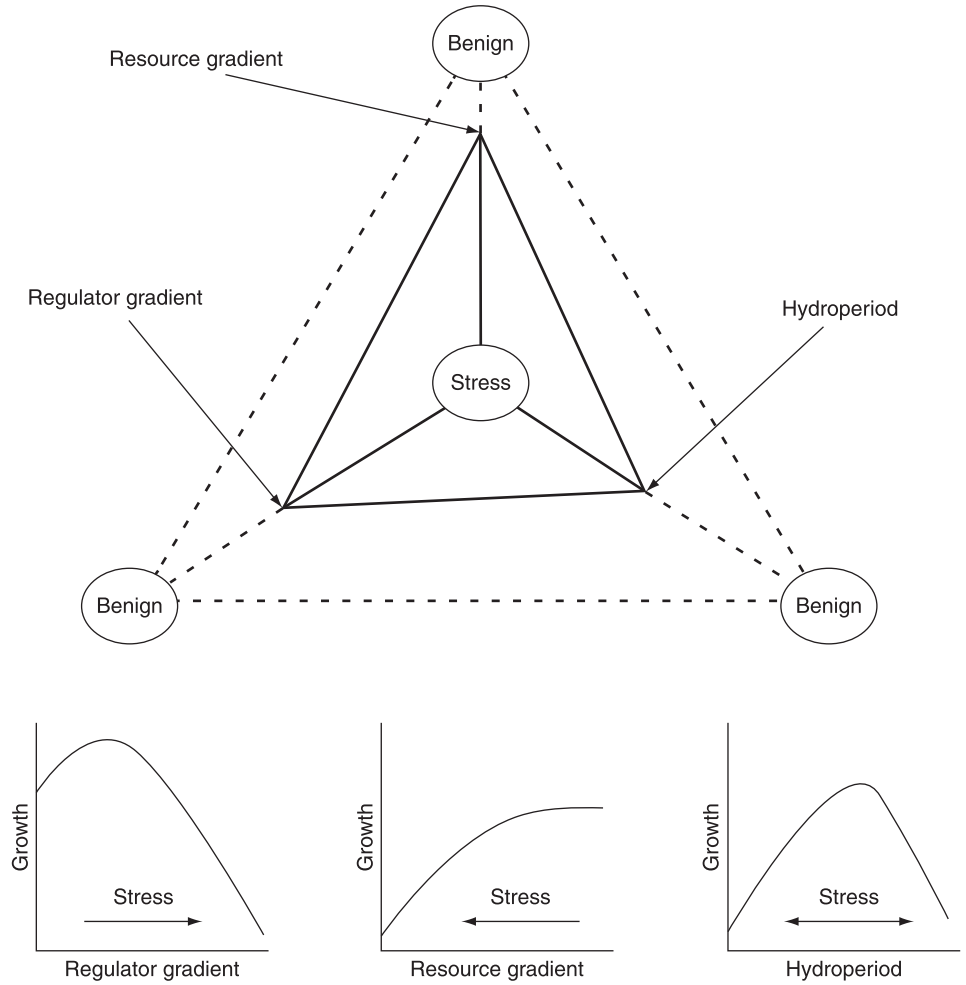

Fig. 2 Interaction of three factors controlling the productivity of coastal wetlands, including regulator gradients, resource gradients, and hydroperiod. The bottom panel defines stress conditions associated with how gradients in each factor control growth of wetland vegetation. From Twilley RR and Rivera-Monroy VH (2005) Developing performance measures of mangrove wetlands using simulation models of hydrology, nutrient biogeochemistry, and community dynamics. *Journal of Coastal Research* 40: 79–93.

species, there are a relatively large number and variety of animals that range from terrestrial insects to birds that live in and/or feed directly on mangrove vegetation. These include sessile organisms (such as oysters and tunicates), arboreal feeders (such as foliovores and frugivores), and ground-level seed predators. Sponges, tunicates, and a variety of other forms of epibionts on prop roots of mangroves are highly diverse, especially along mangrove shorelines with little terrigenous input. Over 200 species of insects have been documented in mangroves in the Florida Keys, similar to the richness of insects and faunal biota observed in other parts of the Caribbean. One of the most published links between mangrove biodiversity and ecosystem function may be the presence of crabs in mangrove wetlands. Crabs can influence forest structure, litter dynamics, and nutrient cycling of mangrove wetlands, suggesting that they are a keystone guild in these forested ecosystems.

Ecosystem Processes

Succession

Succession in mangroves has often been equated with zonation, wherein `pioneer species' would be found in the fringe zones, and zones of vegetation more landward would `recapitulate' the successional sequence toward terrestrial communities. Zonation in mangrove communities has variously been accounted for by a number of biological factors, including salinity tolerance of individual species, seedling dispersal patterns resulting from different sizes of mangrove propagules, differential consumption by grapsid crabs and other consumers, and interspecific competition. Snedaker proposed the establishment of stable monospecific zones wherein each species is best adapted to flourish due to the interaction of physiological tolerances of species with environmental conditions. Geological surveys of the intertidal zone of Tabasco, Mexico, demonstrated that the zonation and structure

of mangrove wetlands are responsive to eustatic changes in sea level, and that mangrove zones can be viewed as steady-state zones migrating toward or away from the sea, depending on its level. Thus, both monospecific and mixed vegetation zones of mangrove wetlands represent steady-state adjustments rather than successional stages. Many models of mangrove succession are based on how gap dynamics influence spatial patches of community dynamics across the landscape.

Productivity and Litter Dynamics

Tree height and aboveground biomass of mangrove wetlands throughout the tropics decrease at higher latitudes, indicating the constraint of climate on forest development in the subtropical climates. In addition, mangrove biomass can vary dramatically within any given latitude, an indication that local effects of regulators, resources, or hydroperiod may significantly limit the potential for forest development at all latitudes. The primary productivity of mangroves is most often evaluated by measuring the rate of litter fall, as recorded for other forested wetlands. Regional rates in litter production in mangroves are a function of water turnover within the forest, and rank among the ecological types is as follows: riverine > fringe > basin > scrub.

The dynamics of mangrove litter, including productivity, decomposition, and export, can determine the coupling of mangroves to the secondary productivity and biogeochemistry of coastal ecosystems. Patterns of leaf-litter turnover have been proposed to vary among ecological types of mangroves with greater litter export in sites with increasing tidal inundation (riverine > fringe > basin). However, several studies in the Old World tropics in higher-energy coastal environments of Australia and Malaysia have emphasized the influence of crabs on the fate of mangrove leaf litter, rather than geophysical processes. In these coastal environments, crabs consume 28–79% of the annual leaf fall. A similar biological factor was observed in the neotropics where the crab *Ucides occidentalis*s in the Guayas River estuary (Ecuador) processed leaf litter at similar rates observed in Old World tropics. Differences in litter turnover rates among mangrove wetlands are a combination of species-specific degradation rates, hydrology (tidal frequency), soil fertility, and biological factors such as crabs.

Nutrient Biogeochemistry

The nutrient biogeochemistry of mangrove wetlands as either a nutrient source or sink depends on the process of material exchange at the interface between mangrove wetlands and the estuary, which is largely controlled by tides (tidal exchange, TE, in Fig. 3). Nutrient exchanges may occur either with coastal waters (TE) or with the atmosphere (atmosphere exchange, AE), depending on whether the nutrient has a gas phase or not (Fig. 3). Substantial amounts of carbon and nitrogen can exchange with the atmosphere, resulting in very complex mechanisms both at the interface with coastal waters and with the atmosphere that influence the mass balance of these nutrients. In addition, there are internal processes, including root uptake (UT), retranslocation (RT) in the canopy, litter fall (LF), regeneration (RG), immobilization (IM), and sedimentation (SD) (Fig. 3). The balance of these nutrient flows will determine the exchanges across the wetland boundary.

There are very few comprehensive budgets of carbon, nitrogen, or phosphorus for mangrove ecosystems. Mangrove sediments have a high potential in the removal of N from surface waters, yet estimates of denitrification have a large range from a low of 0.53 μmol m^{-2} h^{-1}, to 9.7–261 μmol N m^{-2} h^{-1} in mangrove forests receiving effluents from sewage treatment plants. Small amendments of $^{15}NO_3$ followed by direct measures of $^{15}N_2$ production have shown that denitrification accounts for <10% of the applied isotope suggesting that NO_3 is accumulated in the litter via immobilization on the forest floor rather than a sink to the atmosphere. The other nutrient sink in mangrove wetlands is the burial of nitrogen and phosphorus associated with sedimentation. A survey of sedimentation and nutrient accumulation among five sites in south Florida and Mexico indicates patterns associated with the ecological types of mangroves, with rates of about 5.5 g m^{-2} yr^{-1}. This rate is higher than nitrogen loss via denitrification, indicating the significance of burial as nitrogen sink in mangrove ecosystems. Intrasystem nutrient recycling mechanisms in the canopy may be a site of nitrogen conservation in mangroves and, together with leaf longevity, could influence the nitrogen demand of these ecosystems. The significance of this ecological process to the nutrient budget of different mangrove wetlands has not been determined.

Surveys of nitrogen exchange demonstrate some of the principles of determining the function of mangrove wetlands as a nutrient sink. The largest nitrogen flux of nitrogen from sites in Mexico and Australia is export of particulate nitrogen, consistent with organic carbon representing the largest flux from most mangroves (Fig. 3). Compared to other flux studies of mangroves, there seems to be a pattern of net inorganic fluxes into the wetlands and corresponding flux of organic nutrients out. The best summary may be that mangrove wetlands transform the tidal import of inorganic nutrients into organic nutrients that are then exported to coastal waters. Carbon export from mangrove ecosystems ranges from 1.86 to 401 g Cm^{-2} yr^{-1}, with an average rate of about 210 g Cm^{-2} yr^{-1}. Carbon export from mangrove wetlands is nearly double the rate of average carbon export from salt marshes, which may be associated with the more buoyant mangrove leaf litter, higher precipitation in tropical wetlands, and greater tidal amplitude in mangrove systems studied.

Mangrove Food Webs

The function of mangrove wetlands as a source of habitat and food to estuarine-dependent fisheries is one of the most celebrated values of forested wetlands. There are several excellent reviews that describe the secondary productivity of tropical mangrove

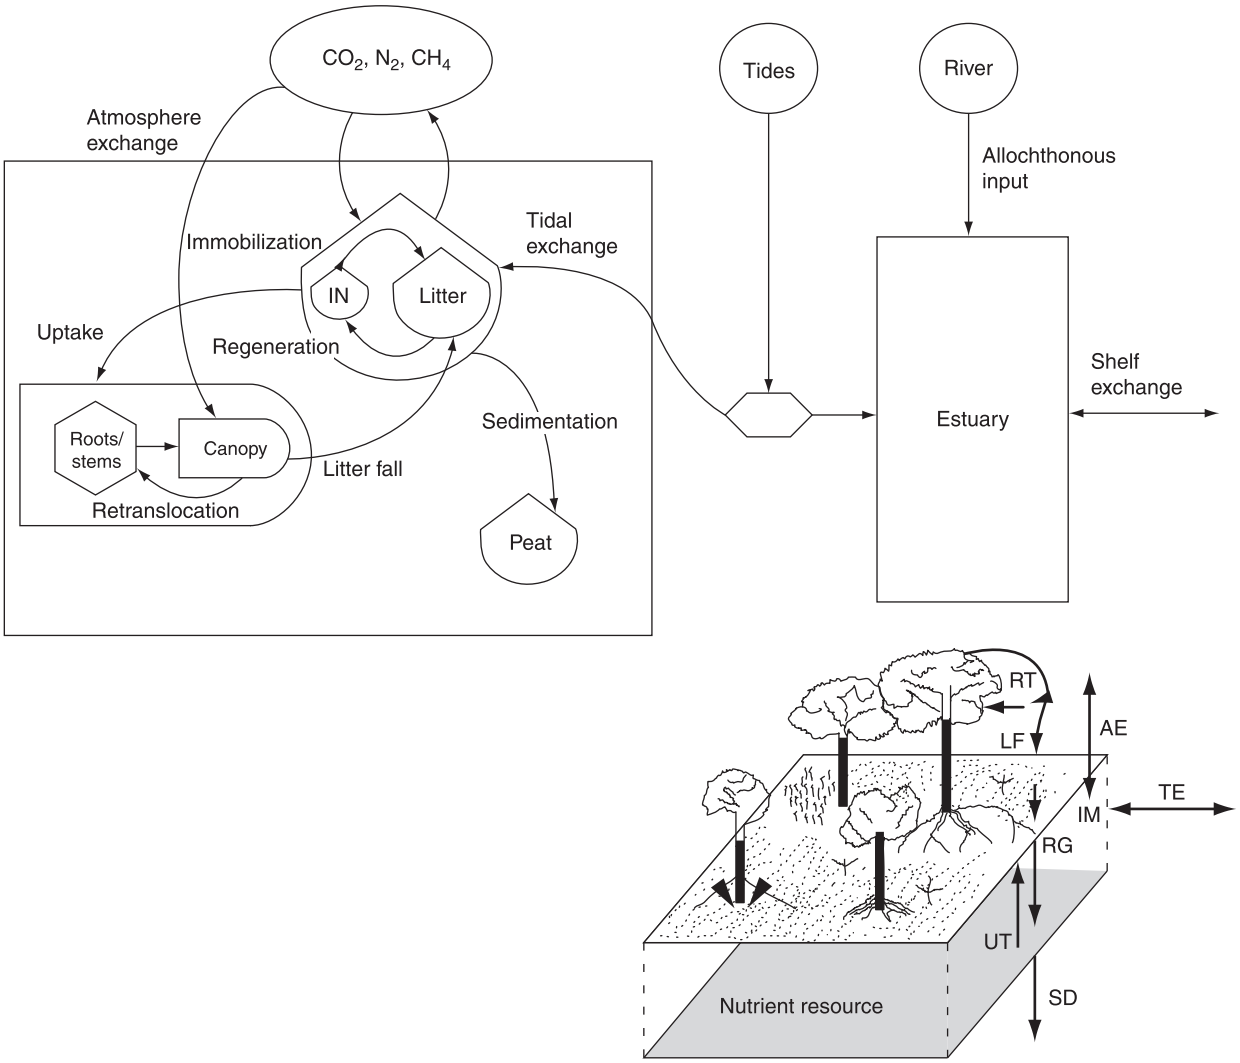

Fig. 3 Upper panel: Schematic of the various fluxes of organic matter and nutrients in a mangrove ecosystem, including exchange with the estuary (IN = inorganic nutrients). Lower panel: A diagram of a mangrove wetland with soil nutrient resources describing the various processes associated with intrasystem cycling and exchange. From Twilley RR (1997) Mangrove wetlands. In: Messina M and Connor W (eds.) *Southern Forested Wetlands: Ecology and Management*, pp. 445-473. Boca Raton, FL: CRC Press.

ecosystems. The original `outwelling hypothesis' of mangroves has been revised from the original paradigms based on comparisons among different mangrove estuaries using natural isotope abundance to trace mangrove organic matter through estuarine food chains. There are seasonal and spatial differences in the amount of mangrove detritus that can be measured in shrimp and fish that inhabit mangrove estuaries. If the distance from the source of mangrove detritus increases, the proportion of carbon in the tissue of shrimp from mangrove detritus decreases as the signal of carbon phytoplankton increases. The seasonal timing of mangrove export of detritus relative to the migration of estuarine-dependent fisheries may also dilute the contribution of mangrove detritus from the food webs among diverse sites. The migratory nature of many of the nekton communities and the seasonal pulsing of both organic detritus input and *in situ* productivity result in very complex linkages of mangroves with estuarine-dependent fisheries. In addition, mangrove detritus low in nitrogen relative to carbon may be modified by the microbial community and then utilized by higher trophic levels, masking the direct utilization of this organic matter as an energy source.

Impacts of Environmental Change

Mangroves are arguably an excellent indicator of how ecosystems will respond to the manifold impacts of global environmental change and land-use disturbance. Given present patterns, the combined effects of climate and land-use change will be noticeably evident in reduced goods and services of mangroves to human systems throughout the tropics in the twenty-first century. For example, accelerated rates in sea-level rise have been speculated as the most critical environmental change affecting the continued

existence of mangrove ecosystems. Numerous processes contribute to vertical accretion of mangroves at a rate that balances the increase in regional sea-level rise. Critical rates in sea-level rise have been estimated above which there is a projected collapse of mangrove ecosystems. While some speculation suggests that mangroves cannot sustain existence at sea-level rise >1.2–2.3 mm yr^{-1}, there is evidence that mangroves located in particular environmental settings existed through periods of accelerated sea level rise. Mangroves in Australia can keep pace with changes in sea-level rise with rates ranging from 0.2 to 6 mm yr^{-1} in the south Alligator tidal river. Also, mangrove forests in many estuaries in northern Australia tolerated sea-level rise of 8–10 mm yr^{-1} in the early Holocene. Many of these mangroves receive terrigenous sediments and exist in macrotidal environments, with critical rates that are much different than for mangroves in microtidal and carbonate environments. In addition, mangrove areas can be sustained along the coastline by migrating inland under conditions of increased sea-level rise. But this inland migration will depend on whether suitable inshore landscapes are available. The most significant recent restriction to mangrove colonization is human land use of available landscapes.

Mangroves in many coastal regions such as Gulf of Mexico and Caribbean are distributed in latitudes where the frequency of hurricanes and cyclones is high, resulting in strong effect on mangrove forest structure and community dynamics. Several patterns have been observed in Florida, Puerto Rico, Mauritius, and British Honduras. Species attributes and availability of propagules are important factors along with the severity of storm and sediment disturbance in projecting recovery patterns. Frequent storm disturbance tends to favor species capable of constant or timely flowering, abundant seedling or sprouting, fast growth in open conditions, and early reproductive maturity. Woody debris resulting from these disturbances have an important role in biogeochemical properties of disturbed mangrove forests. Although mangrove trees show these `traits', it is important to consider the cumulative impact of human activities on these ecosystems in conjunction with the complex natural cycle of regeneration and growth of mangrove forests. Cyclonic disturbance in areas with higher rates of sea-level rise has been demonstrated to cause sediment collapse (drop in surface elevation) that reduces the ability of mangroves to recolonize disturbed areas. Yet this potential impact may vary across ecogeomorphic types of mangroves.

River (and surface runoff) diversions that deprive tropical coastal deltas of freshwater and silt result in losses of mangrove species diversity and organic production, and alter the terrestrial and aquatic food webs that mangrove ecosystems support. Freshwater diversion of the Indus River to agriculture in Sind Province over the last several hundred years has reduced the once species-rich Indus River delta to a sparse community dominated by *Avicennia marina*. It is also responsible for causing significant erosion of the seafront due to sediment starvation and the silting-in of the abandoned spill rivers. A similar phenomenon has been observed in southwestern Bangladesh following natural changes in river channels of the Ganges and the construction of the Farakka barrage that reduced the dry season flow of freshwater into the mangrove-dominated western Sundarbans. Freshwater starvation, both natural and human-induced, has had negative impacts on the biodiversity of mangroves in the Ganges River delta as well along the dry coastal life zone of Colombia (the Cíenaga Grande de Santa Marta lagoon).

Deforestation of mangrove wetlands is associated with many uses of coastal environments, including urban, agriculture, and aquaculture reclamation, as well as the use of forest timber for furniture, energy, chip wood, and construction materials. Two reclamation activities that have contributed to examples of massive mangrove deforestation are agriculture and aquaculture enterprises. Agriculture impacts on mangroves are most noted in West Africa and parts of Indonesia. Many of the large agricultural uses are found in humid coastal areas or deltas where freshwater is abundant and intertidal lands are seasonally available for crop production. Mariculture use of the tropical intertidal zones, in the construction and operation of shrimp ponds, has become one of the most significant environmental changes of mangrove wetlands and water quality of tropical estuaries in the last several decades.

Oil spills represent contaminants to mangroves that can alter the succession, productivity, and nutrient cycling of these coastal forested wetlands. These impacts have been well documented in ecological studies in Puerto Rico, Panama, and Gulf of Mexico. An oil slick in a mangrove wetland will cause a certain mortality of trees depending on the concentration of hydrocarbons and species of trees, as well as the edaphic stress levels already existing at the site. Thus, those mangroves in dry coastal environments may be more vulnerable to oil spills than those in more humid environments.

Management and Restoration

Mangroves produce a variety of forest products, support the productivity of economically important estuarine- dependent fisheries, and modify the water quality in warm-temperate and tropical estuarine ecosystems. These goods and services lead to increased human utilization of mangrove resources that vary throughout the tropics depending on economic and cultural constraints (**Fig. 4**). Economic constraints are usually in the form of available capital to fund land-use changes in coastal regions, as well as river-basin development. Cultural constraints are complex and determine the degree of environmental management and natural resource utilization. However, the sustainable utilization of coastal resources, to a large degree, is controlled by these two social conditions of a region. Human use and value of mangrove wetlands are therefore a combination of both the ecological properties of these coastal ecosystems together with patterns of social exploitation. Therefore, any best management plan designed to provide for the sustainable utilization of mangrove wetlands has to consider both the ecological and social constraints of the region. Humans are part of all ecosystems, and management of natural resources is a combination of policies that seek to regulate the actions of societies within limitations that are imposed by the environment. Recent emphasis has been placed on comprehensive ecosystem restoration programs that represent changes in management of landscapes to reduce impacts on natural processes that enhance system recovery.

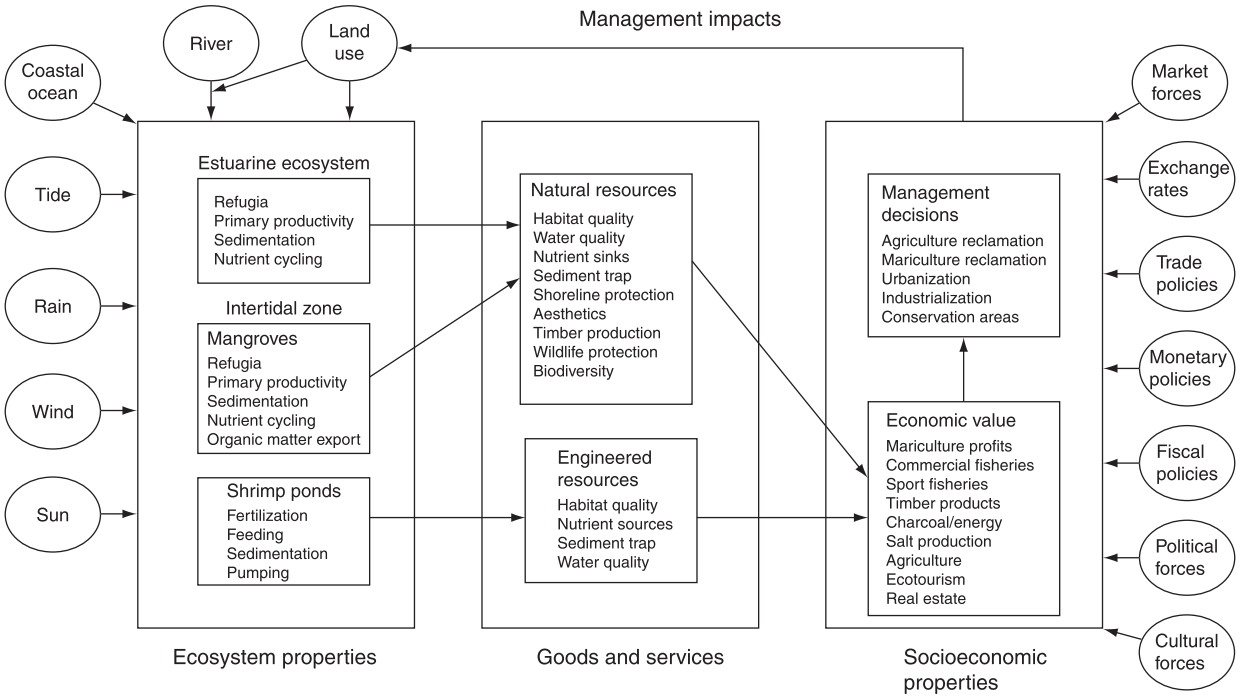

Fig. 4 Conceptual framework constraints of environmental setting and human activities on ecosystem properties, ecological functions, and uses of mangrove ecosystems that determine management decisions in coastal environments. From Twilley RR, Gottfried RR, Rivera-Monroy VH, Armijos MM, and Bodero A (1998) An approach and preliminary model of integrating ecological and economic constraints of environmental quality in the Guayas River estuary, Ecuador. *Environmental Science and Policy* 1: 271–288.

There have been several reviews of mangrove restoration, which collectively have alluded to the concept that since these forested wetlands are adapted to stressed environments, they are relatively amenable to restoration efforts. The success of mangrove restoration is the establishment of the proper environmental settings that control the characteristic structure and function of mangrove wetlands. The goal of ecological restoration is to return a degraded mangrove site back to either the natural condition (restoration) or to some other new condition (rehabilitation). The rates of change in the ecological characteristics of mangrove wetlands between natural, degraded, and some rehabilitated condition will depend on the type of environmental impact, the magnitude of the impact, and the ecogeomorphic type of mangrove wetland that is impacted. The success of any mangrove restoration project depends on the establishment of proper site conditions (geophysical processes and geomorphic features) along with ecological processes of the site such as the availability of propagules and the recruitment of these individuals to sapling stage of development. Some of the key parameters of a restoration project include the elevation of the landscape to provide the proper hydrology of the site, recognizing the significance of natural processes to sustaining the restored condition, and proper planting techniques to enhance recruitment. Several models of different properties of mangroves have been developed during the last decade to help facilitate planning and design of mangrove restoration projects and improve our management of these critical features of coastal landscape.

Peatlands☆

DH Vitt, Southern Illinois University, Carbondale, IL, USA

Introduction

Peatlands, or mires as they are sometimes called, are characterized by often deep accumulations of incompletely decomposed organic material, or peat. Peat accumulates when carbon that is sequestered in plant biomass through the process of photosynthesis exceeds the long-term loss of this carbon to the atmosphere via decomposition plus losses of carbon dissolved in water removed from the peatland through hydrological flow. Globally, peatlands contain about 30% of the world's terrestrial soil carbon, while covering only about 3–4% of the Earth's surface, and as such their carbon storage is considerably greater than their land surface area might indicate. Peatlands, in general, are relatively species poor when compared to upland communities in the same geographic region. However, due to the specialized environmental conditions often associated with peatlands, plants, and animals found only in these ecosystems are sometimes present. Peatlands are especially known for the presence of carnivorous plants such as *Sarracenia* and *Drosera* and for the occurrence of a large number of species of peat mosses (the genus *Sphagnum*).

Occurrence

Globally, peatlands occupy about 4 million km^2, with the boreal and subarctic peatland area estimated to be approximately 3 460 000 km^2, or about 87% of the world's peatlands. Six countries have greater than 50 000 km^2 of peatland and these account for 93% of the world's peatlands – five of these countries are predominantly boreal. Russia contains 1.42 million km^2, Canada 1.235 million km^2, the US 625 000 km^2, Finland 96 000 km^2, and Sweden 70 000 km^2; Indonesia has an estimated 270 000 km^2 as well. Although peat-forming plant communities occur in most of the world's nine zonobiomes, they are most prevalent in zonobiome VIII (cold temperate), or more commonly termed the boreal forest or taiga (Figure 1). The world's largest peatland complex is located in western Siberia (especially noteworthy is the Great Vasyugan Mire located between the Ob and Irtysh Rivers at about 58° N and 75° W). Two other large peatland complexes are the Hudson Bay Lowland in eastern Canada and the Mackenzie River Basin in northwestern Canada. Although peatlands have long been associated with cool, oceanic climatic regimes such as those in Britain and Ireland and indeed peatlands are common in these areas, in fact peatlands are most abundant in areas where the regional climate is continental with short cool summers and long cold winters, where the vegetation is coniferous and evergreen, and the upland soils are podzolic.

Environmental Limiting Factors

The initiation, development, and succession of peatland ecosystems are influenced by a number of regional, external factors. Especially important are hydrological and landscape position, climate, and substrate chemistry. These regional allogenic factors

☆*Change History:* June 2013. DH Vitt introduced small edits in the text of the article including sections Environmental Limiting Factors and Nutrient Sequestration (Oligotrophication), and changed Figure 3.

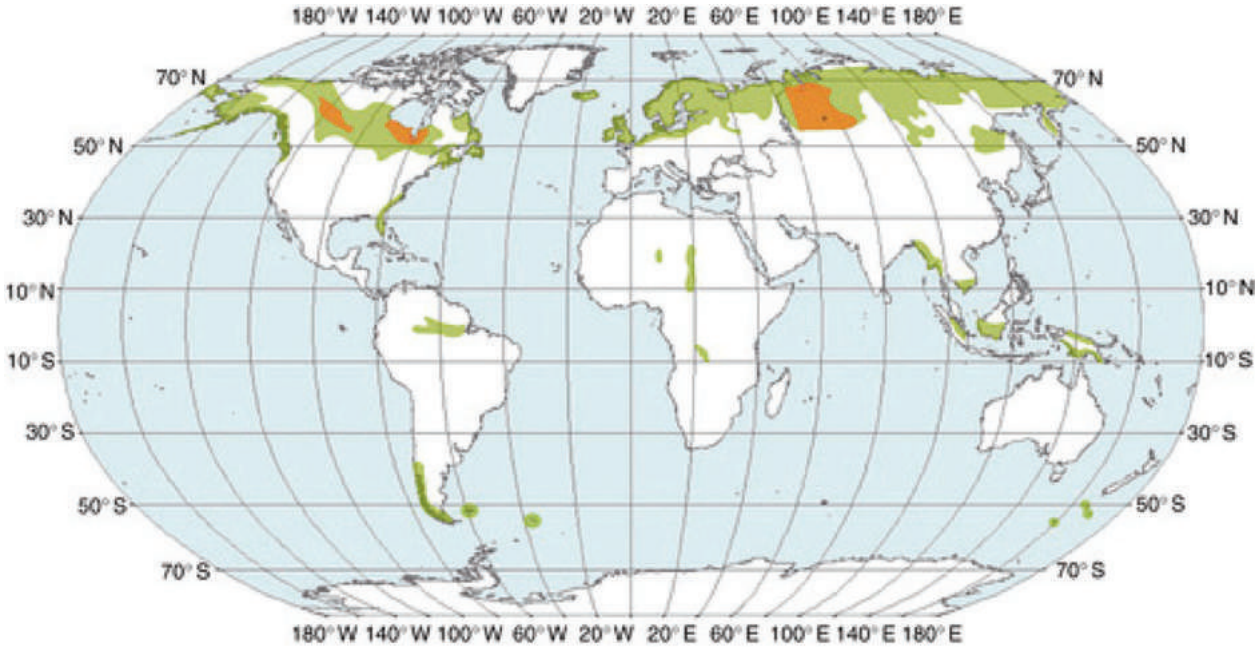

Figure 1 Estimated global distribution of peatlands. Areas colored in light green are those having >10% peat cover. The orange areas in North America and Siberia are the world's largest peatland complexes. The dot in western Siberia is the location for the Vasyugan peatland.

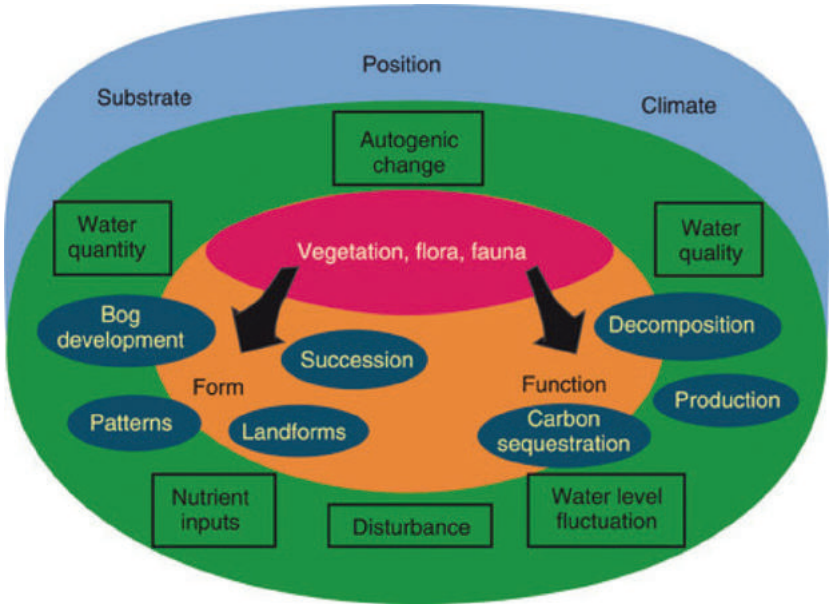

Figure 2 Substrate, position, and climate are regional factors that influence six local factors that are shown in boxes in the diagram. These local drivers direct both the form and function of bogs and fens. Adapted from Vitt DH (2006) Peatlands: Canada's past and future carbon legacy. In: Bhatti J, Lal R, Price M, and Apps MJ (eds.) *Climate Change and Carbon in Managed Forests*, pp. 201–216. Boca Raton, FL: CRC Press.

determine a number of site-specific factors that influence individual peatland sites. These local factors include rate of water flow, quantity of nutrient inputs, the overall chemistry of the water in contact with the peatland, and the amount of water level fluctuation. Additionally, there are a number of internal, or autogenic, processes that help regulate peatland form and function (Figure 2). These allogenic and autogenic factors operate in an ever-changing world of disturbance that includes natural disturbances, especially wildfire, as well as anthropogenic disturbances such as mining, forestry, and agriculture.

Peatland form and function are dependent on the process of peat accumulation and the pattern of loss or gain of carbon from habitats. Peat accumulation is dependent on the input of organic matter produced by photosynthesis. This organic matter is first accumulated in the upper, aerobic (or acrotelm) peat column wherein relatively rapid rates of decomposition occur. The rate at which this partially decomposed organic matter is deposited into the water-saturated, anaerobic peat column (the catotelm), wherein the rate of decomposition is extremely slow, largely determines the amount of carbon that will accumulate at a given site. Thus, the amount of carbon, and hence the quantity of peat, that is deposited at a peatland site is dependent on photosynthesis, aerobic decomposition within the acrotelm, and subsequent anaerobic processes in the catotelm, including methanogenesis and sulfate reduction. Recent examination of many peat cores across the northern high latitudes provides evidence that the carbon accumulated over the past 1000 years is related to contemporary growing season length and photosynthetically active radiation. This analysis suggests that net primary production is more important than decomposition in long-term carbon accumulation.

Peatland Types

Peat-forming wetlands are in general ecosystems that have accumulated sufficient organic matter over time to have a well-developed layer of peat. In many soil classifications, this is defined as soils having greater than 30% organic matter that forms deposits greater than 30–40 cm in depth. Non-peat-forming wetlands such as marshes (wetlands without trees) and swamps (wetlands dominated by a tree layer) mostly have less than 30–40 cm of accumulated organic material and over time have not been able to sustain continued accumulation of a carbon-rich peat deposit. Numerous classifications have been proposed that distinguish between various peatland types. For example, peatlands have been classified based on the source of water that has the primary influence on the peatland. Thus, peatlands that are influenced by water that has been in contact with soil or lake waters are termed geogenous and are divided into three types. Peatlands may be topogenous (influenced by stagnant water, mostly soil water, but also nonflowing water bodies as well), limnogenous (influenced by flood water from water courses resulting in lateral flow away from the direction of stream flow), or soligenous (influenced by flowing water, especially sheet flow on gentle slopes, including seepages and springs). Contrasted to these geogenous types of peatlands, others may be ombrogenous (influenced only by rain water and snow).

Peatlands are extremely variable in vegetation structure; they may be forested (closed canopy), wooded (open canopy), shrub dominated, or sedge dominated. Ground layers may be moss dominated, lichen dominated, or bare. Finally, peatlands vary as to where they occur on the landscape: in association with streams, lakes, springs, and seeps or isolated at higher elevations in the watershed. Peatlands often occur on the landscape as 'complex peatlands', wherein several distinctive peatland types occur together (**Figure 3**). Finally, and perhaps most universally utilized, is a classification that combines aspects of hydrology, vegetation, and chemistry into a functional classification of peat-forming wetlands. In general, this view of peatlands would consider hydrology as fundamental to peatland function and recognize two peatland types – fens and bogs.

Fens are peatlands that develop under the influence of geogenous (or minerogenous waters) waters that influence the peatland after being in contact with surrounding mineral, or upland, substrates). Waters contacting individual peatlands have variable amounts of dissolved minerals (especially base cations (Na^+, K^+, Ca^{2+}, Mg^{2+}) and associated anions (HCO_3^-, SO^{2-}, Cl^-), and may also vary in the amount of nutrients (N and P) as well as the number of hydrogen ions. Further complicating this minerotrophy is variation in the flow of water, including amount of flow and as well as source of the water (surface, ground, lake, or stream). Peatlands receiving water only from the atmosphere via precipitation are hydrologically isolated from the surrounding landscape. These ombrogenous peatlands, or bogs, are ombrotrophic ecosystems receiving nutrients and minerals only from atmospherically deposited sources.

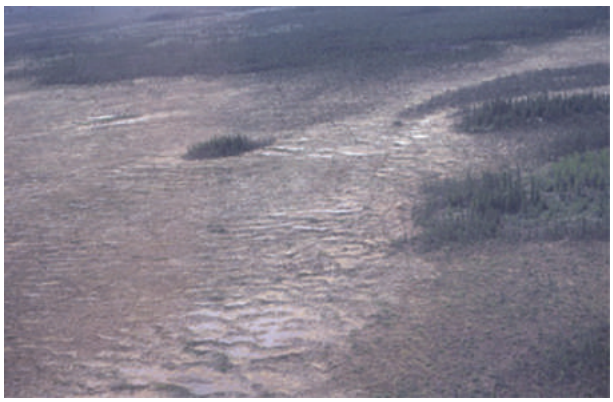

Figure 3 Peatland complex in northern Alberta, Canada. Patterned fen in left foreground, bog island with localized permafrost (large trees) and melted internal lawns to left, and curved treed bog island to right background. Small tree-covered, oval island in center is upland.

In summary and from a hydrological perspective, in fens water flows into and through the peatland after it has been in contact with surrounding materials, whereas in bogs water is deposited directly on the peatland surface and then flows through and out of the bog directly onto the surrounding landscape. Thus, fens are always lower in elevation than the surrounding landscape, while bogs are slightly raised about the connecting upland areas.

The recognition that hydrology is the prime factor for dividing peatlands into fens and bogs dates back to the early 1800 s. However, in the 1940s, Einar DuReitz recognized that vegetation composition and floristic indicators could be used to further characterize bogs and fens. Somewhat later, Hugo Sjörs associated these floristic indicators with variation in pH and electrical conductivity (as a surrogate for total ionic content of the water). The results of these early field studies in Sweden provided an overarching view of how hydrology, water chemistry, and flora are associated, and more recent studies delineate how these combined attributes together form a functional classification of northern peatlands that provides an ecosystem perspective.

Bogs

Bogs are functionally ombrotrophic. At least in the Northern Hemisphere, they have ground layers dominated by the bryophyte genus *Sphagnum* (**Figure 4**). Sedges (*Carex* spp.) are absent or nearly so. The shrub layer is well developed and trees may or may not be present. Nearly, all of the vascular plants have associations with mycorrhizal fungi. Microrelief of raised mounds (hummocks) and depressions (hollows) is generally well developed. The peat column consists of a deep anaerobic layer (the catotelm), wherein decompositional processes are extremely slow and a surficial layer of 1–10 dm of the peat column that occupies an aerobic zone (the acrotelm). The acrotelm extends upward from the anaerobic catotelm and is mostly made up of living and dead components of *Sphagnum* plants, wherein vascular plant roots and fallen vascular plant aboveground litter occur. Well-developed acrotelms are unique to ombrotrophic bogs and provide opportunities to study atmospheric deposition and ecosystem response to such deposition.

Bogs are acidic ecosystems that have pH's of around 3.5–4.5. Base cations are limited owing to the ombrogenous source of water and to the cation exchange abilities of *Sphagnum* (see below). Bicarbonate is lacking in bogs and carbon is dissolved in the water column only as CO_2. The lack of geogenous waters limits nutrient inputs to those derived only from atmospheric deposition, and thus nitrogen and phosphorus are in short supply.

Bogs appear to be limited in distribution to areas where precipitation exceeds potential evapotranspiration. In many oceanic regions of the Northern Hemisphere (especially Britain, Ireland, Fennoscandia, and coastal eastern Canada), bogs form large treeless expanses. In Europe, the Ericaceous shrub, *Calluna vulgaris*, forms a characteristic component of these treeless landscapes. Many of these oceanic bogs are patterned, with a series of pools of waters separated by raised linear ridges. This sometimes spectacular pool/ridge topography forms either concentric or eccentric patterns (**Figure 5**), with water flowing from the highest raised center of the bog to the lower surrounding edges. Runoff from the surrounding upland (and from the raised bog itself) is concentrated at the margins of these raised bogs and due to increased nutrients, decomposition processes are greater and peat accumulation somewhat less. Thus, the central, open, raised 'mire expanse' part of a bog is surrounded by a wetter, often shaded lagg, or moat, and this 'mire margin' zone may be dominated by plants indicative of fens. Some oceanic bogs have a rather flat mire expanse, with occasional pools of water. Whereas the mire expanse surface of these raised bogs is flat, the dome of water contained within the bog peat is convex and thus the driest part of the bog is at the edges just before contact with the fen lagg. This marginal, relatively dry upslope to the mire expanse is usually treed and is termed the 'rand'.

In continental areas, bogs have a very different appearance (**Figure 6**). These continental bogs have a conspicuous tree layer and abundant shrubs (mostly *Ledum* spp. or *Chamaedaphne calyculata*) while pools of water are not present. In North America, the endemic tree species, *Picea mariana*, dominates these continental bogs, while in Russia bogs have scattered individuals of *Pinus sylvestris*. Farther north in the subarctic and northern boreal zones, peat soils contain permafrost. When entire bog landforms are frozen, the bog becomes drier and dominated by lichens (especially species of the reindeer lichen, *Cladina*). Unfrozen or melted

areas contained within these peat plateaus are easily recognized features termed collapse scars (Figure 7). Peat plateaus form extensive landscapes across the subarctic zone of both North America and Siberia. Farther south in the boreal zone, bog landforms may contain only scattered pockets of permafrost (frost mounds), that over the past several decades have been actively melting. Recent melting of the raised frost mounds results in collapse of the mound and active revegetation by fen vegetation to form wet, internal lawns with associated dead and leaning trees (Figure 8).

Fens

Fens are peatlands that are minerotrophic that when compared to bogs have higher amounts of base cations and associated anions. All fens have an abundance of *Carex* and *Eriophorum* spp. and water levels at or near the surface of the peat (thus acrotelms are poorly developed). Unlike bogs that are characterized by high microrelief of hummocks and hollows, fens feature a more level topography of extensive carpets and lawns dominated by species of mosses (Figure 9). Depending on the characteristics of the surrounding water, fens can by divided into three types.

Poor fens

These *Sphagnum*-dominated peatlands are associated with acidic waters (pH 4.5–5.5) that contain the least amount of base cations and little or no bicarbonate alkalinity.

Rich fens

True mosses dominate the ground layer of rich fens, especially a series of species that are red-brown in color and often termed 'brown mosses'. Examples of important genera would be *Drepanocladus*, *Hamatocaulis*, *Warnstorfia*, *Meesia*, *Campylium*, *Calliergon*, and *Scorpidium*. Waters have pH varying from 5.5 to more than 8.0 and base cations are relatively abundant, especially calcium. Alkalinity varies from very little to extremely high amounts of bicarbonate. Rich fens occur as two types centered on the chemistry of the pore waters. 'Moderate-rich fens' have pH values between 5.5 and 7.0, with little alkalinity. Both brown mosses and some mesotrophic species of *Sphagnum* (e.g., *S. obtusum*, *S. subsecundum*, *S. teres*, and *S. warnstorfii*) dominate the ground layer. 'Extreme-

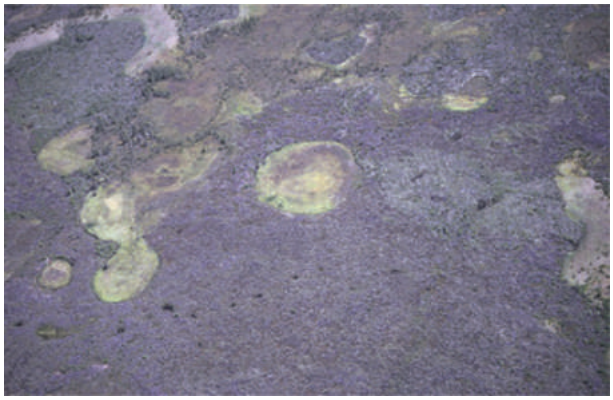

Figure 7 Extensive peat plateaus with permafrost (whitish areas dominated by the reindeer lichens in the genus *Cladina*), with isolated collapse scars (without permafrost – greenish circular to oblong areas), and with lush growth of *Sphagnum* species and sedges.

Figure 8 Bog dominated by *Picea mariana* in background, with dead snags in foreground, indicating recent permafrost collapse and the formation of an internal lawn and dominated by carpet and lawn species of *Sphagnum*.

rich fens' are bicarbonate-rich peatlands, often with deposits of marl (precipitated $CaCO_3$) and pH ranging from around neutral to over 8.0. Species of *Scorpidium*, *Campylium*, and *Hamatocaulis* dominate the ground layer.

Whereas water quality (= chemistry) is the main factor controlling fen type and flora, water quantity (= flow) controls vegetation structure and surface topography. Fens, whether poor or rich, are vegetationally extremely variable, ranging from sites having abundant trees (dominated by *Larix laricina* in North America), to sites dominated by shrubs (mostly *Betula*, *Alnus*, and *Salix*), to sites having only sedges and mosses. Topographically, fens may be homogeneous and dominated by lawns and carpets. However, as water flowing through the fen increases, the surface vegetation develops a reticulation of wet pools and carpets separated by slightly raised ridges. Further increase in flow of water directs the patterns into linear pools (some filled with floating vegetation = carpets), sometimes termed flarks, alternating with linear ridges (termed strings; **Figure 10**). These pool/string complexes are oriented perpendicular to water flow, with smaller pools always upstream from the larger ones. Especially prevalent in Scandinavia and Russia, these patterned fens and associated bog islands form extensive peatlands termed aapamires.

Important Processes in Peatlands

Acidification

Sphagnum species have cell walls rich in uronic acids that in aqueous solution readily exchange a hydrogen ion for a base cation. The base cations that are in solution in bogs and poor fens are received by the peatland from atmospheric deposition or inflowing water and are always associated with an inorganic anion (HCO_3^-, SO_4^{2-}, Cl^-). When the base cation is exchanged for the organically produced H^+, acidity of the peatland waters is produced. This acidity thus originated through the exchange of an inorganic base cation for an H^+ produced by *Sphagnum* growth – hence this is termed inorganic acidity. Inorganic acidity relies on the presence of base cations and can only produce acidity when base cations are present in the pore water to exchange. Inorganic acidity is an extremely powerful process when abundant base cations are present such as in rich fens transitional to poor fens and in poor fens. In bogs, with limited supplies of base cations due to their ombrogenous water supply, inorganic acidity is less important.

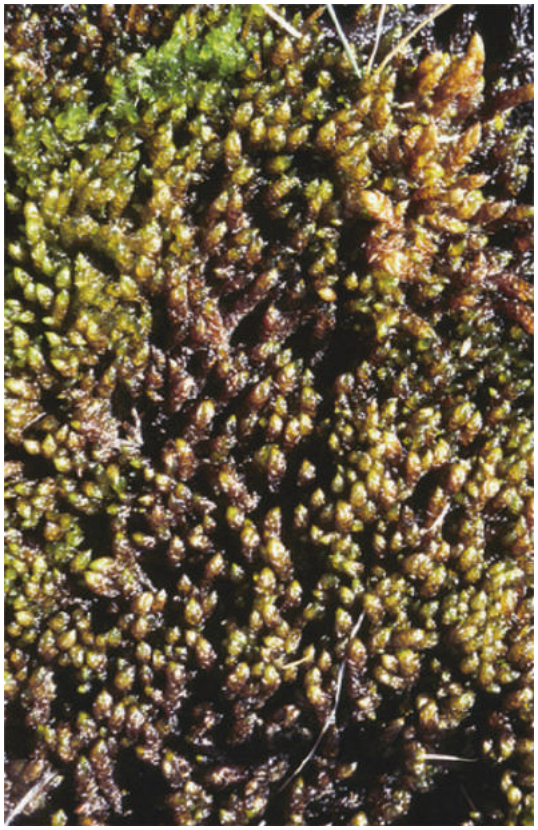

Figure 9 A carpet of the brown moss, *Scorpidium scorpioides*, a characteristic species of rich fens.

Figure 10 A patterned fen in western Canada characterized by elongate pools (flarks) separated by raised ridges (strings), oriented perpendicular to water flow.

Organic material produced by plants is decomposed and carbon mineralized through bacterial and fungal respiration. Under aerobic conditions, bacteria break down long cellulose chains and in doing so eventually produce short-chained molecules that are small enough to be dissolved in the pore waters. This dissolved organic carbon (DOC) may be lost to the peatlands via runoff or may remain suspended in the pore waters for some length of time. These decompositional processes produce acidity through dissociation of humic acids, acidity that is completely produced via organic processes; hence, peatland acidity produced via decompositional processes, and extremely important in ombrotrophic bogs, is termed organic acidity.

Rich fens, with pH above 7.0, also accumulate deep deposits of peat and are well buffered by large inputs of bicarbonate alkalinity. With continued inputs of bicarbonate, rich fens may remain stable for millennia, dominated by brown mosses that have less capacity for inorganic acidification, but strong tolerance for the alkaline peatland waters. However, as rich fens accumulate peat to depths of several meters, there is the possibility that the active surface layer will become more isolated from the bicarbonate inputs and alkalinity may decrease to the point that some tolerant species of *Sphagnum* may invade. If *Sphagnum* species establish,

then cation exchange proceeds, acidity increases while alkalinity decreases, and rich fen plant species are replaced by poor fen species tolerating acidic conditions. This acidification of rich fens has been documented in the paleorecord wherein the change from rich fen to poor fen vegetation takes place extremely rapidly, perhaps in the order of 100–300 years. As a result, these transitional rich fen–poor fen communities are short-lived on the landscape and among the most rare of peatland types.

Water Retention

The surface of a peatland lies on a column of water contained within the peat column. The peatland surface consists of a nearly complete cover of mosses (either peat mosses (*Sphagnum*) or true mosses (brown mosses)) that are continually pushed upward by the accumulating peat. This upward growth is limited only by the abilities of the peat and living moss layer to maintain a continuous water column that allows the living moss layer to grow. The vascular plants that grow in this water-soaked peat column produce roots that are largely contained in the small upper aerobic part of the peat. The mosses, however, alive and growing only from their uppermost stem apices, must maintain contact with the water column; thus, wicking and retaining of water above the saturated water column is paramount for maintenance of the moss layer. Peatland mosses have special modifications that help in this regard. Although some brown mosses have adaptations for water retention, such as the development of a tomentum of rhizoids along the stems, numerous branches along the stem that provide small spaces for capillarity, and leaves that have enlarged bases that retain water, it is in species of *Sphagnum* where water retention (up to 20 times dry plant weight) is greatly enhanced through a number of morphological modifications. *Sphagnum* has unistratose (one-celled thick) leaves consisting of alternating, large, dead, hyaline cells and small, partially enclosed, living, green cells. The walls of the hyaline cells are perforated with pores and are strengthened by the presence of cross-fibrils. Stems and branches are often encased in an outer layer of one or more rows of dead, enlarged cells. All of these hyaline cells have lost their living cell contents very early on in development and as a result the ratio of carbon to nitrogen is high. In addition to the features that allow the plants to hold water internally, the entire *Sphagnum* plant is a series of tiny spaces that serve as reservoirs for capillarity. The branches are surrounded by numerous, overlapping, very concave branch leaves (one-cell thick). The branches are attached to the stem in fascicles of three to five branches, half of which hang along the stem and half extend outward at more or less 90°. The fascicles of branches originate at the stem apex, and slowly develop while still close together at the apex of the stem. This group of maturing branches, the capitulum, along with the top 1–5 cm of mature stem and associated branches form a dense canopy. In total, this canopy (**Figure 11**) consists of numerous small spaces of different sizes and, along with the dead hyaline cells of the leaves and branches, provides the mechanism for wicking and retention of capillary water far above the actual water table, which in turn provides the framework for the aerobic peat column that is so characteristic of bogs.

Nutrient Sequestration (Oligotrophification)

Peat forms due to slow decompositional processes that allow organic materials to be deposited as peat. As organic material is deposited, it contains within its carbon matrix nutrients, especially nitrogen and phosphorus, which were originally incorporated in the cell structure of the living plants, especially those of *Sphagnum* and brown mosses. Relatively rapid decomposition in the acrotelm mineralizes only a portion of the total nutrients tied up in the plant material, making these available for further plant growth as well as fungal and bacterial processing. However, upon entry to the catotelm, almost all decompositional activity stops and the nutrients become tied to organic materials in unavailable forms. Thus, rather than being recycled and remaining available

Figure 11 A longitudinal view of the canopy of *Sphagnum*; each stem is terminated by a capitulum of young branches. The branches along the stem are covered with numerous overlapping leaves and organized into fascicles that have branches that hang down along the stem as well as branches that spread outward from the stem allowing the individual stems to be evenly spaced from one another.

for new plant growth, nitrogen and phosphorus become part of long-term unavailable nutrient pools. The lack of ability to utilize this unavailable pool of nutrients causes peatlands over time to become more oligotrophic at their surface yet also having large amounts of stored nitrogen and phosphorus. For example, *Sphagnum* peat is generally about 1% nitrogen; however, almost all of this catotelmic nitrogen is unavailable for plant and microorganism use while in place in the peat deposit. When exposed to the atmosphere (e.g., as a garden amendment), the carbon is oxidized to CO_2 and the nitrogen is mineralized to NO_3^- and NH_4^+ and available for plant uptake. Although the actual percent of nitrogen, and other nutrients, may not be as high as that in inorganic soils, the total amount in the soil within any one square meter surface area of the peatland is greater in peat soils due to the depth of the peat present. This oligotrophification, and consequently nutrient storage, is autogenetically enhanced through the buildup of the peat column, placing the peat surface farther from the source of minerotrophic inputs. The long-term result of oligotrophication is the regional storage of large pools of carbon and nitrogen, with stored nitrogen estimated at 9–16% of the global terrestrial soil pool. In ombrotrophic bogs, these high amounts of stored nitrogen are seemingly paradoxical to nitrogen inputs only from the atmosphere, mostly in areas where pristine bogs receive some of the lowest atmospheric inputs globally (about 1 kg N ha^{-1} yr^{-1}). Across Canada, these ombrotrophic peatlands contain approximately 8–40 times more nitrogen in their upper peat columns than can be explained by atmospheric inputs alone. Recently, this missing pool of nitrogen has been accounted for by high rates of N-fixation from prokaryotes associated with *Sphagnum* canopies.

Methane Production

Methane is a highly potent greenhouse gas that originates from both natural and anthropogenic origins. On a weight basis, methane is 21 times more efficient at trapping heat and warming the planet than carbon dioxide. Methane emissions from wetlands account for more than 75% of the global emissions from all natural sources. Methane is a highly reduced compound produced as the end product of anaerobic decomposition by a group of microorganisms called methanogens, which phylogenetically belong to *Archaea*. These strict anaerobes can utilize only a limited variety of substrates with H_2–CO_2 and acetate being the most important too. The H_2–CO_2 dependent methanogenesis is considered the dominant pathway of methane production in boreal peatlands. However, acetate-dependent methanogenesis sometimes dominates in fens. In rich fens, higher nutrient availability promotes the growth of vascular plants (primarily sedges). Roots of these vascular plants penetrate deep into the peat column and therefore transport potential carbon-rich substrates, such as acetate, into the anaerobic layer. Rapid decomposition of organic matter also provides abundant substrates for methanogens. Poor fens, with lower vascular plant cover than that of rich fens, generally have lower potentials for CH_4, and a higher portion of the produced CH_4 comes from H_2–CO_2. Similar to poor fens, *Sphagnum*-dominated bogs also have a higher proportion of CH_4 produced from H_2–CO_2, and it may be that the dominance of mosses (without roots) and mycorrhizal vascular plants (without deep carbon-rich roots), along with the reduced abundance of sedges with well-developed deep roots, prohibit movement of labile carbon substrates to the anaerobic peat layer. Low decomposition rates in acidic bogs also limit the amount of acetate that can be produced during peat decomposition, which in turn limits the acetoclastic pathway. Methanogen diversity in bogs is very low and the composition of the methanogen community in bogs also differs greatly from that characteristic of fens. In general, higher CH_4 production is found in peatlands with higher vascular plant cover, and higher water tables are found in rich fens.

Sulfate Reduction

In peatlands, sulfur occurs in several different redox states (S valences ranging from +6 in SO_4^{2-} to −2 in hydrogen sulfide (H_2S), S-containing amino acids, and other compounds), and conversions between these states are the direct result of microbially mediated transformations. In bogs, the sole sulfur input is via atmospheric deposition, while in fens atmospheric deposition can be augmented by surface and/or groundwater inputs, which may contain sulfur derived from weathering of minerals in rock and soil. Regardless of the sulfur source, when sulfur enters a peatland, there are a variety of pathways through which it can cycle. In the aerobic zone, sulfate can be adsorbed onto soil particles, or assimilated by both plants and microbes. In the anaerobic zone, sulfate can also be adsorbed onto soil particles, assimilated by plants or microbes, or reduced by sulfate-reducing bacteria through the process of dissimilatory sulfate reduction. Dissimilatory sulfate reduction is a chemoheterotrophic process whereby bacteria in at least 19 different genera oxidize organic matter to meet their energy requirements using sulfate as the terminal electron acceptor. Thus, this process is one way in which carbon is lost from the catotelm. If the sulfate is reduced by sulfate-reducing bacteria, the end product (S^{2-}) can have several different fates. In the catotelm, where $S^{2-}$is formed, it can react with hydrogen, to produce H_2S gas, which can diffuse upwardly into or through the acrotelm where it can be either oxidized to sulfate, or lost to the atmosphere. Alternatively, H_2S can react by nucleophilic attack with organic matter to form organic or C-bonded sulfur (CBS). If Fe is present, S^{2-}can react with Fe to form FeS and FeS_2 (pyrite), which is referred to as reduced inorganic sulfur (RIS). The RIS pool tends to be unstable in peat and can be reoxidized aerobically with oxygen if the water table falls, or anaerobically probably using Fe_3^+ as an anaerobic electron acceptor. If Hg is present, and combines with $S^{2-}$to form neutrally charged HgS, then Hg sulfide is capable of passive diffusion across cell membranes of bacteria that methylate Hg. Alternatively, bacteria can transfer the methoxy groups of naturally occurring compounds, such as syringic acid, to S^{2-}, and form methyl sulfide (MeSH) or dimethyl sulfide (DMS), although the exact mechanisms by which this occurs are still unknown.

Initiation and Development of Peatlands

Peatlands initiate in one of four ways. The first, the most common, appears to through paludification (or swamping), wherein peat forms on previously drier, vegetated habitats on inorganic soils and in the absence of a body of water, generally due to regional water table rise and associated climatic moderation. Additionally, local site factors also have strong influences on paludification. Second, peat may form directly on fresh, moist, nonvegetated mineral soils. This primary peat formation occurs directly after glacial retreat or on former inundated land that has risen due to isostatic rebound. Third, shallow bodies of water may gradually be filled in by vegetation that develops floating and grounded mats – thus terrestrializing the former aquatic habitat. Both lake chemistry and morphometry as well as species of plants in the local area influence the rates and vegetative succession. Fourth, peat may form and be deposited on shallow basins once occupied by extinct Early Holocene lakes. These former lake basins, lined with vegetated impervious lake clays, provide hydrologically suitable sites for subsequent peat development.

Across the boreal zone, peatland initiation appears to be extremely sensitive to climatic controls. For example, in oceanic areas, peatlands often initiated soon after glacial retreat some 10 000–12 000 years ago. Many of these oceanic peatlands began as bogs and have maintained bog vegetation throughout their entire development. In more continental conditions, most peatlands were largely initiated through paludification. In areas where the bedrock is acidic, most of these early peatlands were poor fens, whereas in areas where soils are base rich and alkaline, rich fens dominated the early stages. Like oceanic peatlands, subcontinental peatlands initiated soon after glacial retreat; however, throughout most of the large expanses of boreal Canada and Siberia, peatland initiation was delayed until after the Early Holocene dry period, initiating 6000–7000 years ago. Many of these peatlands initiated as rich or poor fens and have remained as fens for their entire existence, whereas others have undergone succession and today are truly ombrotrophic bogs. A recent study in western Canada correlated peak times of peatland initiation to Holocene climatic events that are evident in US Midwest lakes, North Atlantic cold cycles, and differing rates of peat accumulation in the one rich fen studied in western Canada.

Peatlands as Carbon Sinks

Peat is about 51% carbon and peatlands hold about 270–370 Pg (petagram) of carbon or about one-third of the world's soil carbon. For example in Alberta (Canada), where peatlands cover about 21% of the provincial landscape, the carbon in peatlands amounts to 13.5 Pg compared to 0.8 Pg in agricultural soils, 2.3 Pg in lake sediments, and 2.7 Pg in the province's forests. Estimates for apparent long-term carbon accumulation in oceanic, boreal, and subarctic peatlands range from around 19 to 25 g C m^{-2} yr^{-2}. However, disturbances can have a dramatic effect on carbon accumulation. Wildfire, peat extraction, dams and associated flooding, mining, oil and gas extraction, and other disturbances all reduce the potential for peatlands to sequester carbon, while only permafrost melting of frost mounds in boreal peatlands has been documented to have a positive effect on carbon sequestration. One recent study has suggested that effects from disturbance in Canada's western boreal region have reduced the regional carbon flux (amount of carbon sequestered in the regional peatlands) from about 8940 Gg (gigagram) C yr^{-1} under undisturbed conditions to 1319 Gg carbon sequestered per year under the present disturbance regime, yet only 13% of the peatlands have been affected by recent disturbance. These data suggest that although for the long-term peatlands in the boreal forest region have been a carbon sink and have been removing carbon from the atmosphere, at the present time, due to disturbance, this capacity is greatly diminished. Furthermore, when disturbance is examined in more detail, it is wildfire that is the single greatest contributor to loss of carbon sequestration, both from a direct loss as a result of the fire itself as well as from a loss of carbon accumulation due to post-fire recovery losses. If wildfire greatly increases as is predicted by climate change models, then the effectiveness of peatlands to sequester carbon may be greatly reduced and it has been proposed that an increase of only 17% in the area burned annually could convert these peatlands to a regional net source of carbon to the atmosphere. If boreal peatlands become a source for atmospheric carbon, then the carbon contained within the current boreal peatland pool, in total, is approximately two-thirds of all the carbon in the atmosphere.

Polar Terrestrial Ecology

TV Callaghan, Royal Swedish Academy of Sciences Abisko Scientific Research Station, Abisko, Sweden

The polar regions are situated at latitudes beyond which the Earth's angle to the Sun is shallow and the input of thermal radiation is low. During the winter period, the Sun is below the horizon and there are prolonged periods of darkness. The resulting low-temperature regimes dominate ecological processes, either directly by affecting plant growth, microbial activity, animal behavior, organism reproduction and survival, or indirectly by controlling the length of the snow- and ice-free periods in which most primary production and dependent biological activity occurs, the availability of water in liquid form, and the expansion and contraction, and other active layer properties in generally primitive soils underlain by permafrost. Feedback mechanisms from polar regions and their ecological systems to the climate system affect local, regional, and global climate. The balance between greenhouse gas emissions from decomposition, particularly soil microbial respiration, and photosynthesis has resulted in a large net accumulation of carbon in arctic soils while ice and snow that cover low, tundra vegetation reflect incoming radiation. Both mechanisms lead to cooling. In contrast, global ocean circulation leads to the redistribution of the Earth heat by cooling the tropics and warming the high latitudes.

Both the Arctic and the Antarctic are characterized by vast wilderness areas that are generally young, as most land areas, with some extensive exceptions in the Arctic, were glaciated in the Pleistocene. Polar regions host some of the Earth's most extreme environments and organisms such as snow algae, lichens that inhabit the crevices within crystalline rocks, and the simple communities of soil fauna in the dry valleys of Antarctica.

Polar environments vary between the Arctic and the Antarctic and also within each region (Figs. 1 and 2).

The Arctic is dominated by a polar ocean surrounded by continental land masses and islands, whereas the Antarctic is dominated by a polar, largely ice-covered, land mass surrounded by oceans. Terrestrial ecosystems are extensive (7.5 million km^2) and varied and stretch from the closed canopy northern boreal forests in the south, through the latitudinal treeline ecotone and tundra wetlands to the polar desert in the north. Along this latitudinal gradient, mean July temperature varies from about 12 °C in the south to 2 °C in the north, total annual precipitation varies from about 250 to 75 mm (mainly as snow), and net primary production varies from about 1000 to 1 g m^{-2} yr^{-1}. Approximately 6000 animal and 5800 plant species inhabit arctic lands (3% and 5% of global biodiversity, respectively). Biodiversity decreases geometrically along this gradient. Although plant biodiversity is low in comparison with many biomes, it is surprisingly high per square meter because of the small scale of plants, and over 6000 species of animals and plants have been cataloged in and around Svalbard at about 79° N. There is also large environmental variation associated with the climatic effects of northern ocean currents: in arctic Norway, Sweden, and Finland, forests grow north of the Arctic Circle (66.7° N) because of the warming effect of the northward-flowing Gulf Stream, whereas polar bears and tundra

Fig. 1 Ecosystems of the Arctic.

Fig. 2 Coastal ecosystem, sub-Antarctic South Georgia.

vegetation are found at about 51° N in eastern Canada because of the cooling influence of southward-flowing cold ocean currents. In the Arctic, indigenous and other arctic peoples have been part of the ecosystem for millennia.

The large land masses of the Arctic have great connectivity with land masses further south: great rivers flow from low latitudes to the Arctic Ocean, and mammals and hundreds of millions of birds migrate between the summer breeding grounds in the Arctic and overwintering areas in boreal or temperate regions. Food chains in the Arctic are more complex than those in the Antarctic and at the top of the chain are mammalian carnivores such as the polar bears, wolves, and arctic foxes. Population cycles characteristic of arctic animals together with relatively few species in each trophic level can result in ecological instability and ecological cascades: increasing numbers of snow geese in arctic Canada have denuded vegetation resulting in habitat hypersalinity.

The Antarctic land mass covers some 12.4 million km^2 but less than 1% is seasonally ice free. In the Antarctic, the major environmental variation is associated with the relatively moist and `warm' maritime climate of the west coast of the Antarctic Peninsula (temperatures are between 0 and 2 °C for 2–4 months in summer) contrasted with the cold, dry polar desert climate of the continental land mass. Consequently, most biological activity and most species are found on the west coast of the Antarctic Peninsula. Vegetation is dominated by relatively simple plant communities of lichens, mosses, and liverworts that support simple soil invertebrate communities. Only two species of higher plant and higher insects occur. Terrestrial mammals are absent and this short trophic structure, together with the isolation of the land mass, has enabled the establishment of a highly specialized, and commonly endemic fauna of ground-nesting birds (e.g., penguins) and seals that depend on the coastal land areas for breeding and moulting, and the sea, for food. Nutrients for plant growth in these areas are mainly derived from the sea and are deposited on land by wind or birds. In contrast, over much of the tundra, low nutrient availability to plants limits primary production. There are no indigenous peoples in the Antarctic and human activities there have been restricted to the past 200 years.

Human activity has, until recently, influenced both Arctic and Antarctic ecosystems less than most biomes on Earth. However, the polar amplification of global climate change together with the inherent sensitivity of polar ecological systems to invasion by species from warmer latitudes has resulted in the vulnerability of polar ecosystems which are now under threat of rapid change.

The Future: Polar Regions and Climate Change

The polar regions are undergoing rapid climate change. There is a general amplification of global warming in the Arctic: surface air temperatures have warmed at approximately twice the global rate, although there are local variations. The average warming north of 60° N has been 1–2 °C since a temperature minimum in the 1960s and 1970s with the largest increase (*c.* 1 °C per decade) in winter and spring. Continental arctic land masses together with the Antarctic Peninsula are the most rapidly warming areas of the globe. Precipitation in the Arctic shows trends of a small increase over the past century (about 1% per decade), but the trends vary greatly from place to place and measurements are very uncertain. There are reductions in Arctic sea ice, river and lake ice in much of the sub-Arctic, and Arctic glaciers. Reduction in Arctic sea ice has occurred at a rate of 8.9% per decade for September relative to the 1979 values and there was an un-predicted extreme reduction in 2007. Permafrost has warmed. Although changes in the active layer depth have no general trend, in some sub-Arctic locations, discontinuous permafrost is rapidly disappearing and changes in permafrost are driving changes in hydrology and ecosystems. In Arctic Russia, ponds are drying in the continuous permafrost zone and waterlogging is occurring where there is discontinuous permafrost.

In Antarctica, temperature trends show considerable spatial variability: the Antarctic Peninsula shows significant warming over the last 50 years, whereas cooling has occurred around the Amundsen-Scott Station at the South Pole and in the Dry Valleys. Consequently, there is no continent-wide polar amplification of global change in Antarctica.

Current polar warming is leading to changes in species' ranges and abundance and a northward and upward extension of the sub-Arctic treelines. Forest is projected to displace considerable areas of tundra in some places. Species tend to relocate, as they have in the past, rather than adapt to new climate regimes. However, this process is likely to lead to the loss of some species: polar

bears and other ice-dependent organisms are particularly at threat. In other areas, where rates of species relocation are slower than climate change, the incidence of pests, disease, and fire is likely to increase. Changes in vegetation, particularly a transition from grasses to shrubs, have been reported in the North American Arctic, and satellite imagery has indicated an increase in the `normalized difference vegetation index' (a measure of photosynthetically active biomass) over much of the Arctic. This index has increased by an average of about 10% for all tundra regions of North America, probably because of a longer growing season. However, such increases in productivity and changes in plant functional types have been shown experimentally to displace mosses and lichens that are now major components of Arctic vegetation.

In Antarctica, warming has caused major regional changes in terrestrial and marine ecosystems. The abundances of krill, Adelie, and Emperor penguins and Weddell seals have declined but the abundances of the only two native higher plants has increased. On continental Antarctica, climate change is affecting the vegetation composed of algae, lichens, and mosses. Introductions of alien species, facilitated by increased warming and increased human activity, are particular threats to southern ecosystems. Recent studies on sub-Antarctic islands have shown increases in the abundance of alien species and negative impacts on the local biota. In contrast, cooling has caused clear local impacts in the Dry Valleys where a 6–9% reduction in lake primary production and a 10% per year decline in soil invertebrates has occurred.

The responses of polar environments to climatic warming include feedbacks to the global climate system and other global impacts. Increased runoff from arctic rivers could affect the thermohaline circulation that redistributes the Earth's heat, thereby causing cooling in the North Atlantic and further warming in the tropics. Reductions in sea ice extent and snow cover together with a shift in vegetation from tundra to shrubs or forests are likely to reduce albedo (reflectivity of the surface) and lead to further warming despite the increased uptake of carbon dioxide by a more productive vegetation. Thawing permafrost is likely to release methane, a particularly powerful greenhouse gas, and evidence of this is already available from various arctic areas.

Not all impacts of climate warming in polar regions are disadvantageous to society: the reduction of sea ice in the Arctic is likely to lead to increased marine access to resources and new fisheries and reduced length of sea routes, while warming on land will probably lead to increased productivity and increased potential for forestry and agriculture.

Riparian Wetlands

KM Wantzen, University of Konstanz, Konstanz, Germany
WJ Junk, Max Planck Institute for Limnology, Plön, Germany

Introduction

The riparian zone of running water systems is a site of intensive ecological interactions between the aquatic and the terrestrial parts of the stream valley. Wetlands that occur in this zone exchange water with the aquifer and with the main channel during flood events (Fig. 1). Riparian wetlands are buffer zones for the water budget of the landscape: they take up excess water from flood events and release it gradually afterwards.

Modern ecological theory recognizes the important role riparian wetlands play for biodiversity and for the energy and matter budgets along the whole range of river courses. The carbon and nutrient budgets are influenced by dissolved and particulate substances from the bordering terrestrial ecosystems, by the autochthonous production from the wetland plants, and by allochthonous organic matter delivered by the floodwater. The proportions between these sources are defined by the hydrological patterns, landscape morphology, and climatic conditions.

The crossover between humid and dry conditions creates habitats for organisms coming from either aquatic or terrestrial ecosystems, and for those biota that are specialized on wetland conditions. As the transversal dimension of streamside wetlands is generally small, their overall importance for landscape ecology, biogeochemistry, and biodiversity is often overlooked. However, the total size of these wetlands can be considerable in areas with dense stream networks. Moreover, the corridor-shaped extension of riparian wetlands makes them perfect pathways for the gene flow between remote populations of aquatic and terrestrial biota. Many ecological services are uniquely provided by riparian wetlands, including erosion control, filtering of nutrients and pesticides from adjacent cropland, mitigation of floods, and recreation, which increases their conservation value in a socioeconomic context.

There is a large array of environmental conditions that vary between the different types of riparian wetlands, especially climatic region and prevailing vegetation type, and landscape morphology and hydrologic patterns. This article deals with the different types of riparian wetlands, their deterministic environmental conditions, prevailing ecological processes, typical biota, and aspects of conservation.

Definitions and Concepts

There are many definitions of riparian wetlands. A hydrological definition defines riparian wetlands as

> lowland terrestrial ecotones which derive their high water tables and alluvial soils from drainage and erosion of adjacent uplands on the one side or from periodic flooding from aquatic ecosystems on the other (McCormick, 1979)

A functional definition states that

> riparian areas are three-dimensional ecotones of interaction that include terrestrial and aquatic ecosystems, that extend down to the groundwater, up above the canopy, outward across the floodplain, up the near-slopes that drain to the water, laterally into the terrestrial ecosystem, and along the water course at a variable with (Ilhard *et al.*, 2000).

Both definitions point to the ecotonal character of riparian wetlands between water bodies on one side and the upland on the other. Riparian wetlands can be, at the smallest scale, the immediate water's edge where some aquatic plants and animals form a distinct community, and pass to periodically flooded areas of a few tens of meters width. At medium scale they form bands of vegetation, and at the largest scale they form extended floodplains of tens of kilometers width along large rivers. In this case, complexity of the riparian wetlands increases so much that many scientists give them the status of specific ecosystems.

There are several concepts that deal with different aspects of stream and river ecology but two of them are of specific interest to rivers and riparian zones. The `river continuum concept' (RCC) of Vannote *et al.*, describes the longitudinal processes in the river channel and the impact of the riparian vegetation on the physical and chemical conditions and as carbon source to the aquatic communities in the channel. The `flood pulse concept' (FPC) of Junk *et al.* stresses the lateral interaction between the floodplain and the river channel and describes the specific physical, chemical, and biological processes and plant and animal communities inside the floodplain. The predictions of the RCC fit well for rivers with narrow riparian zones but with increasing lateral extent and complexity of the riparian zone the FPC becomes more important. Here, we restrict our discussion to riparian wetlands along streams and low-order rivers. Since lateral extent of the riparian zone along low-order rivers can vary considerably in different parts of the same river or between different rivers of the same river order, the applicability of the concepts may also vary.

Black arrows indicate organic matter inputs, white arrows indicate water exchange pathways, spirals indicate nutrient spiralling or downriver transport, and circular arrows indicate sites of organic matter turnover *in situ*. Curly brace indicates water-level fluctuations during flood events. Modified from Wantzen, K.M., Yule, C., Tockner, K., Junk, W.J., 2006. Riparian wetlands. In: Dudgeon, D. (Ed.), Tropical Stream Ecology. Amsterdam: Elsevier, pp. 199–217.

Environmental Conditions Determining Riparian Wetlands

Riparian habitats are integral parts of a larger landscape and therefore influenced by factors operating at various special and temporal scales. The physical setting that determines rivers and streams basically defines the riparian wetlands; however, some environmental features have specific importance on the wetlands that will be dealt with in the following.

Spatial and Temporal Scales

At the regional scale, geomorphology, climate, and vegetation affect channel morphology, sediment input, stream hydrology, and nutrient inputs. At the local scale, land use and related alteration to stream habitats, but also the activity of bioengineers such as beavers, can be of significant influence. At short timescales, individual heavy rainfall events affect the riparian systems; at an annual basis climate-induced changes in light, temperature, and precipitation trigger important cyclic biological events, such as autochthonous primary and secondary production, litterfall, decomposition, and spawning and hatching of animals. On multiannual timescales, extreme flood and drought events, debris-torrents, landslides, heavy storms or fire can have dramatic effects on the riparian zone and its biota.

Climatic Region

Climate controls the availability of the water in the wetlands and the activity period of the organisms. If the flooding and activity periods match, the floodborne resources can be used by the adapted floodplain biota (e.g., during summer floods). On the other hand, winter floods are generally less deleterious for little-flood-adapted tree species.

In the boreal and temperate regions, freezing and drought in winter and snowmelt floods in spring are predictable drivers of the interplay between surface water and groundwater in riparian wetland hydrology. Ice jams may cause stochastic flood events in winter. Normally, stream runoff is reduced during winter, and groundwater-fed riparian wetlands discharge into the stream channel as long as possible. In wetlands with organic sediments, this water is often loaded with large amounts of dissolved organic carbon. In shallow streams that freeze completely during winter, riparian wetlands may serve as refuges for the aquatic fauna, for example, for amphibians and turtles. Spring snowmelt events generally provoke prolonged flood events that exceed the duration of rain-driven floods. These long floods can connect the riparian wetland water bodies to the stream, so that organic matter and biota become exchanged. At the same time, there is often an infiltration (downwelling) of surface water into the riparian groundwater body.

In seasonal wet-and-dry climates (both Mediterranean and tropical savanna climates) water supply by rainfall is limited to a period of several months during which very strong rainstorms may occur. These events, albeit short, are of great importance for the release of dissolved substances and for the exchange of organic substances and biota between wetland and main water course. Moreover, energy-rich organic matter (e.g., fruits) may become flushed from the terrestrial parts of the catchment into riparian wetlands. On the other hand, flash-floods can cause scouring and erosion of fine sediments (including organic matter). During the dry season, groundwater levels are lower and may cause a seasonal drought in the riparian wetlands. In these periods, the aquatic biota either estivate or migrate into the permanent water bodies, and large parts of the stocked organic matter become mineralized.

However, even in strongly seasonal zones, like the Brazilian Cerrado, groundwater supply may be large enough to support permanent deposition of undecomposed organic matter.

The distribution of water-conductive (coarse) and impermeable substrate (bedrock and loam) of the valley bottom influences the thickness of the stagnant water body in the riparian zone and thus the extension of organic matter layers. Permanently humid conditions are found in many riparian wetlands of the boreal zone and in the humid tropics. These permanent riparian wetlands can accumulate large amounts of organic carbon. In tropical Southeast Asia (Malayan Peninsula and parts of Borneo), a special case of riparian wetland occurs, the peat swamps. These swamps develop when mangrove forests proceed seawards, and the hinterland soils lose their salt content. Here, large amounts of organic matter from the trees become deposited and the streams flow within these accumulations.

Valley Size, Morphology, and Connectivity

The common textbook pattern of steep valleys in the upper sections of the streams and open, shallow floodplains in the lower river sections holds true only for very few cases in nature. Rather, we find these two valley types interspersed in an alternating pattern like `beads on a string'. Shallow areas are more likely to bear extended riparian wetlands; however, if groundwater levels are high enough, even steep valleys may be covered with wetlands. The morphology of riparian wetlands can be described by the entrenchment ratio (i.e., the ratio of valley width at 50-years flood level to stream width at bankfull level) or by the belt width ratio, that is the distance between opposing meander bends over a stream section to stream width at bankfull level. Fifty-years flood often intersect the terrace slope.

Riparian wetlands of different catchments may be linked with each other through swamp areas (e.g., in old eroded landscapes of the Brazilian and Guyana Shields in South America) so that biogeographical barriers can be overcome by aquatic biota even without a permanent connection between the water courses. The term connectivity describes the degree by which a floodplain water body is linked to the main channel. Riparian wetlands may also be connected to the stream, either in a direct connection by a short channel, or indirectly by a longer channel which may be intercepted by a pond. In some cases, these channels can be cryptic/hidden when they are formed by macropores in the organic soils. Alluvial riparian wetlands may be connected to the stream via the hyporheic interstitial zone provided that the sediments are coarse enough to conduct water. Wetlands without any of these pathways exchange water, biota, and organic matter with the main channel during overbank flow of the stream. Purely aquatic organisms depend on the existence of connection channels to migrate between wetland and main water body. For example, amphibia are especially sensitive to fish predation, so that the highest biodiversity of amphibia is found at riparian wetland habitats with the lowest accessibility for fish.

Hydrology and Substrate Type

The slope of the landscape and the rock characteristics of the catchment define the physical habitat characteristics of the stream–wetland system. Riparian wetlands provide habitats with different hydraulic and substrate conditions than the stream channel. Although flooding in streams is generally shorter, less predictable and `spikier' than in large rivers, there is a large number of exchange processes between the main channel and the riparian zone during these flood events. Major flood events, albeit rare, act as `reset mechanism' in the floodplain that rejuvenates the sediment structure and the successional stage of the vegetation. Between these rare events, riparian wetlands act as sinks for fine particles and organic sediments that were washed out of the stream channel, the terrestrial zone of the catchment, or derive from an autochthonous biomass production.

Vegetation

Vegetation bordering to and growing within riparian wetlands fulfils many functions: it delivers both substrate for colonization and food resources for aquatic animals, it strips nutrients from the incoming water, and it provides raw material for the organic soils. It retards nutrient loss, filters nutrient input from the upland, reduces runoff by evapotranspiration, and buffers water-level fluctuations. Shading by tree canopies reduces light conditions for algal and macrophyte primary production and it equilibrates soil temperatures. Therefore, riparian wetlands differ completely according to their vegetation cover.

Unvegetated riparian wetlands occur at sites where establishment of higher plants is hampered by strong sediment movement (e.g., high-gradient and braided rivers), low temperatures (high elevation and polar zones), rocky surfaces, or periodical drought (desert rivers). The lack of shading and nutrient competition by higher plants favors growth of algae on the inorganic sediments, and productivity may be high, at least periodically.

High altitudes and/or elevated groundwater levels may preclude tree growth but allow the development of grass or herbal vegetation on riparian wetlands. Hillside swamp springs (helokrenes) can coalesce and form extensive marshes far above the flood level of the stream channel, so that the distinction between `riparian' and `common' wetland is difficult.

The tree species of forested riparian wetland are adapted to periodical or permanent waterlogging of the soils. They contribute an important input of organic carbon to the stream system. Large tree logs shape habitat structure by controlling flow and routing of water and sediment between stream channel and wetland. Tree roots increase sediment stability, sequester nutrients, and form habitats.

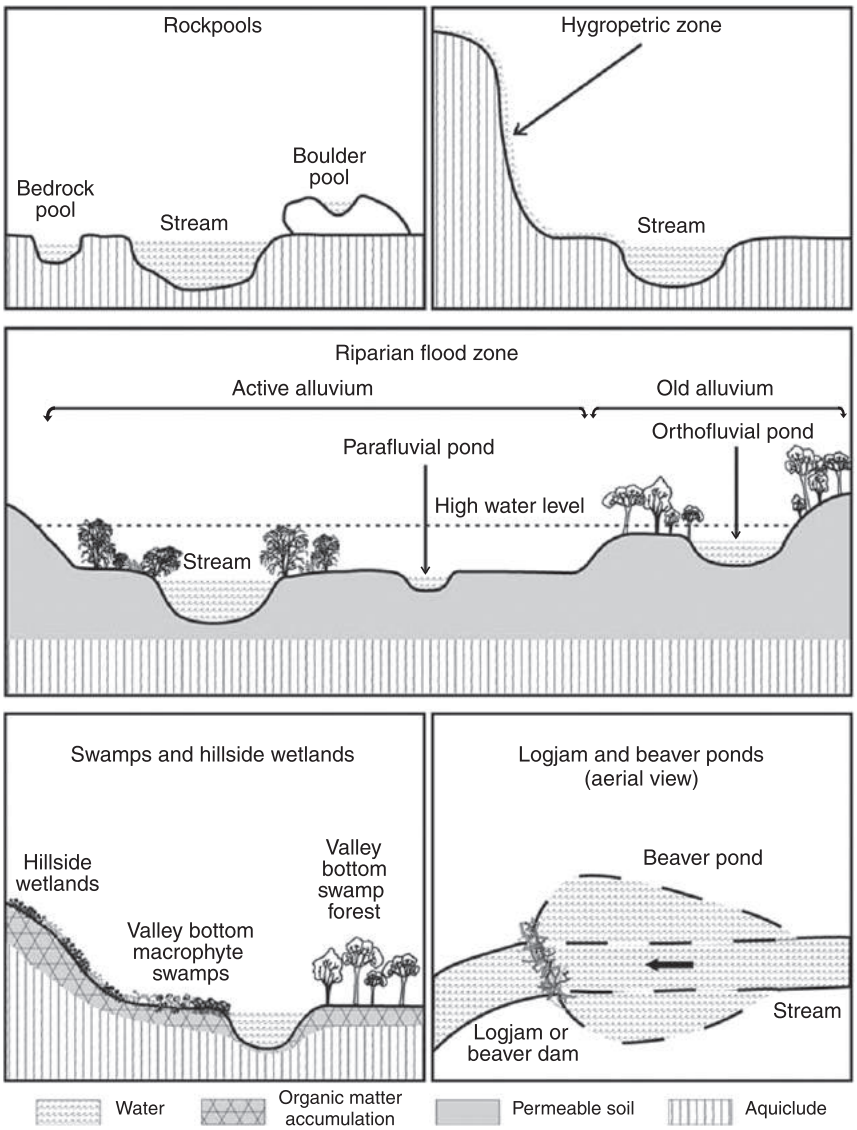

Fig. 2 Types of riparian wetlands.

Types of Riparian Wetlands

Riparian wetlands are very variable in size and environmental characteristics. In the following, we list the most common types according to their hydrological and substrate characteristics (Figs. 2 and **3**).

Hygropetric Zone

At sites where groundwater outflows run over rocky surfaces, hygropetric zones develop. In the thin water film, there is a vivid algal production and a diverse, however, less-studied fauna of invertebrates (mostly aquatic moths, chironomids, and other dipterans). Biota of the hygropetric zone need to be adapted to harsh environmental conditions such as periodical freezing and drying of the surfaces.

Rockpools

Many streams run through bedrock or large boulders which have slots that fill with flood or rain water. Biota colonizing these pools have to be adapted to relatively short filling periods, high water temperatures, and solar radiation. High algal production and low predator pressure (at least at the beginning of the filling period) attract many invertebrate grazers.

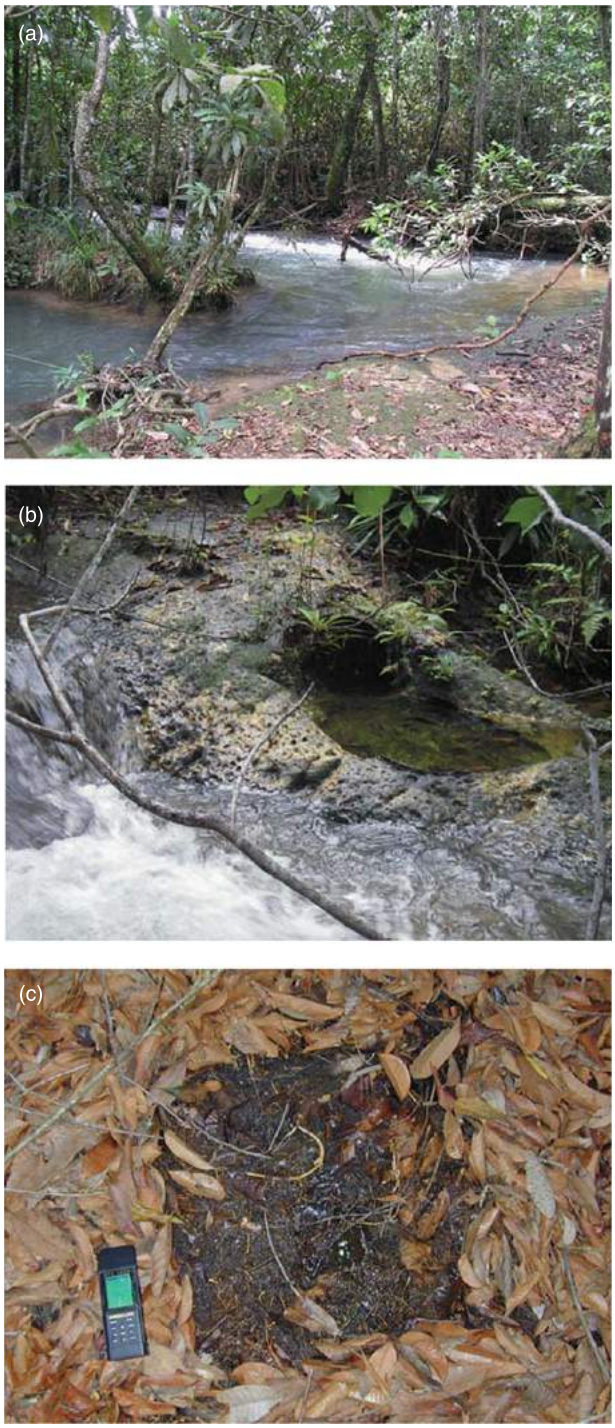

Fig. 3 Photographs of riparian wetlands (Tenente Amaral Stream, Mato Grosso, Brazil): (a) Stream channel with hygropetric zone (foreground) and floodplain forest (background), (b) Rockpool carved into the sandstone bedrock, (c) moist organic soil colonized by many aquatic invertebrate taxa. Leaf litter was removed. All photographs by K. M. Wantzen.

Parafluvial and Orthofluvial Ponds

In alluvial stream floodplains, permanent or temporary ponds develop from riverine dynamics either within the active channel (parafluvial pond) or in the riparian zone (orthofluvial pond). They are fed by both surface water and groundwater. In coarse-grained sediments, these ponds are connected to the main channel by the hyporheic interstitial zone, that is, an ecotone between groundwater and surface water that extends below and at either side of the stream channel. In fine-grained sediments (including organic soils), the contribution of groundwater is much more important, and these ponds are often brownish from dissolved

organic matter (humic acids and yellow substances). Para- and orthofluvial ponds contribute disproportionately to total species richness along riparian corridors.

Riparian Flood Zones

Even if no basin-like structures are present, flooding events create wetted zones on either side of the stream, independent of sediment type. Extension and permanence of the wetted zone depends on the valley shape, the porosity of the sediments, and eventual backflooding from tributary streams. In temporarily flooded forests with thick organic layers and in stranded debris dams, the moisture conditions may be long enough to bridge the gap between two flood events, so that many aquatic biota such as chironomids and other midges can complete their larval development in these semiaquatic habitats.

Riparian Valley Swamps

Swamps occur on soils that are waterlogged for most of the year. The lack of oxygen in the sediments allows accumulation of organic matter and selects for tree or herb species that have specific adaptations to these conditions, for example, pressure ventilation in the roots. The vegetation consists of either macrophytes or trees. Due to the shading and oxygen consumption during decomposition of organic matter, some of these riparian wetlands are hostile environments for aquatic metazoa that depend on dissolved oxygen. Some trees such as the Australian gum (*Melaleuca* sp.) shed bark which release secondary compounds that influence biota.

Hillside Wetlands

In areas where the aquiclude extends laterally from the stream, the riparian swamps can merge into hillside wetlands far above the flood level. Given that waterloggedness is permanently provided, these ecosystems tend to develop black organic soil layers from undecomposed plant material. The anoxic conditions in these soils favor denitrification and nitrogen may become a limiting factor for plant growth. Carnivorous plants (Droseraceae, Lentibulariacea, Sarraceniaceae) that replenish their nitrogen budget with animal protein are commonly found in these habitats. At sites where drainage is better, woody plants invade these natural meadows. The soft texture of the soils and their position in hill slope gradients makes these ecosystems highly vulnerable to gully erosion.

Logjam Ponds and Beaver Ponds

Falling riparian trees are stochastic events which may have dramatic consequences for the hydraulics of a stream system. Many tree species are soft-wooded, and tree dynamics are generally high in riparian wetlands. A fallen log blocks the current and creates a dam that accumulates fine particles. These natural reservoirs often extend far into the riparian zone.

Dams built by beaver (*Castor* sp.) can significantly alter the hydrological and biogeochemical characteristics of entire headwater drainage networks in Northern America and Eurasia. Fur trade led to the regional extinction of beavers. Few decades after reintroduction of beavers on a peninsula in Minnesota, they converted a large part of the area into wetlands, which led to a manifold increase in the soil nutrient concentrations. The activity of beavers considerably enhances the biodiversity of wetland-depending species. Beavers increase regional habitat heterogeneity because they regularly abandon impounded areas when the food supply is exhausted and colonize new ones, thereby creating a shifting mosaic of patches in variable stages of plant succession.

Typical Biota and Biodiversity in Riparian Wetlands

The importance of riparian wetland habitats for the conservation of biodiversity is well documented for several watersheds. Riparian areas generally have more water available to plants and animals than adjacent uplands. This is of specific importance in regions with a pronounced dry season, where lack of water affects plant growth. Abundance and richness of plant and animal species tend to be greater than in adjacent uplands because they share characteristics with the adjacent upland and aquatic ecosystems and harbor a set of specific riparian species. Because of their richness and their spatial distribution, the relative contribution of riparian ecosystems to total compositional diversity far exceeds the proportion of the landscape they occupy.

Apart from beavers, several other biota act as `ecological engineers' that create and modify riparian wetlands. African hippopotamus deepen pools and form trails that increase the ponding of the water. Several crocodilians maintain open water channels. Digging mammals, freshwater crabs, and insects like mole crickets increase the pore space in riparian soils and enhance the water exchange between wetland and stream channel. Similar macropores develop from fouling tree roots. Plants also strongly modify the habitat characteristics in riparian wetlands, either actively, by influencing soil, moisture, and light conditions or, passively, by changing the hydraulic conditions through tree fall or organic debris dams.

Typical wetland species are adapted to the amphibious characteristics of the habitats. They are either permanent wetland dwellers that cope with aquatic and dry conditions or they temporarily colonize the wetlands during either the dry or the wet phase. There are many animal species that permanently colonize riparian wetlands, especially anurans, snakes, turtles, racoons, otters, and many smaller mammals, like muskrats, voles, and shrews. Aquatic insects have developed special adaptations to survive periodical droughts, for example, by having short larval periods or drought resistance. Many birds profit by the rich food offered from the aquatic habitats like dippers, kingfishers, jacamars, warblers, and rails. Periodical colonizers from terrestrial ecosystems are bats, elks, moose, and several carnivorous mammals and birds. Many aquatic species like fish and aquatic invertebrates periodically colonize riparian wetlands. Riparian wetland biota belong to the most threatened species as they suffer from both the impacts on the terrestrial and aquatic systems, and many riparian species are threatened with extinction. The effects of extinction of a species are especially high if it is an ecological engineer or a keystone species, for example, a top predator. Extinction of wolves in the Yellowstone National Park in the US led to overbrowsing of broad-leaved riparian trees by increased elk populations.

Ecological Services of Riparian Wetlands

Riparian wetlands are intrinsically linked to both the stream and the surrounding terrestrial ecosystems of the catchment. In many places of the world, however, riparian zones have remained the only remnants of both wetland and woody habitats available for wildlife. They are surrounded by intensively used areas for either agriculture or urban colonization. The performance of riparian wetlands to provide ecological services becomes reduced by the same degree as these bordering ecosystems become degraded. However, even in degraded landscapes, the beneficial effects of the riparian wetland ecosystems are astonishingly high. For humans, healthy riparian wetlands are vital as filters and nutrient attenuators to protect water quality for drinking, fisheries, and recreation.

Nutrient Buffering

Riparian wetlands are natural traps for fine sediments and for organic matter, but they may vary from a nutrient sink to a nutrient source at different times of a year depending on high or low water levels. Particle-bound nutrients, such as orthophosphate ions, become deposited in the riparian wetlands during spates and may accumulate there. This may increase the amount of phosphate that becomes released during the following flood event. Therefore, technical plans for phosphorus retention in artificial wetlands in agricultural landscapes include a hydraulic design which hampers the release of particles from the wetland, for example, by providing continuous, and sufficiently broad wetland buffer strips along the streams.

For the removal of nitrogen inputs from floodwater and from lateral groundwater inputs, riparian wetlands are very efficient. Generally it can be taken for granted that the slower the water flow (both ground and surface water) the higher is the nitrate uptake rate; however, the precise flow pathways in the sediments have to be considered. In anoxic soils, reduction and denitrification processes transform inorganic nitrogen forms into nitrogen gas which is then released into the atmosphere. Once the nitrate has been completely reduced, sulphate is also reduced in the anoxic sediments. Nitrogen also becomes immobilized by bacterial growth and/or condensation of cleaved phenolics during the aerobic decay of organic matter. Aquatic macrophytes and trees growing in the riparian wetlands are very efficient in nitrogen stripping by incorporating mineral nitrogen forms into their biomass. They can represent the most important nitrogen sinks in riparian systems. Some riparian wetland plants (e.g., alder, *Alnus* sp., and several leguminous trees) have symbiotic bacteria associated to their roots that can fix atmospheric nitrogen when this nutrient is scarce in the soils. Thus, not all riparian wetlands exclusively remove nitrogen.

Carbon Cycle

Like other wetlands, riparian wetlands are important players in the carbon cycle of the watershed. They accumulate large amounts of coarse particulate organic matter (CPOM) and they release dissolved organic matter into the stream and gaseous carbon-compounds into the atmosphere (**Fig. 1**).

In the boreal zone, the spring snowmelt runoff contributes to more than half of the annual total organic carbon (TOC) export. The larger the riparian wetland zone, the bigger the amount of exported TOC. On the other hand, riparian wetlands receive large amounts of dissolved carbon from litter leachates from the surrounding forests, especially during the leaf-fall period. These leachates can be an important source for phosphorous and other nutrients, as well as for labile carbon compounds. These substances enhance heterotrophic microbial (bacterial and fungal) activity.

Spring snowmelt also carries large amounts of fine particulate organic matter (POM). Riparian wetlands often provide surface structures that act like a comb to accumulate these particles (e.g., macrophytes), and enhance the production of detritivores. Additional POM is produced by riparian trees. The general trend for litter production to increase with decreasing latitude (valid in forests) is overlain by species-specific productivity and physiological constraints due to the waterloggedness in riparian wetlands. Here, the litter production is generally higher in periodically flooded, than in permanently flooded, wetlands. Depending on the oxygen content of the soils, the chemical composition of the leaves, and the activity of detritivores, more or less dense layers of `leaf peat' can accumulate in the sediments. This organic matter stock can be increased by undecomposed tree logs and bark. A

reduction of the water level in the riparian wetlands leads to an increased mineralization of the carbon stocks and enhances the release of carbon dioxide.

Hydrological Buffering and Local Climate

Riparian wetlands have an equilibrating effect on hydrological budgets. Riparian vegetation dissipates the kinetic energy of surface flows during spates. Riparian wetlands store stormwater and release it gradually to the stream channel or to the aquifer between rainstorm events. Moreover, they are important recharge areas for aquifers. Several current restoration programmes try to increase this recharge function of riparian wetlands in order to stabilize the groundwater stocks for drinking water purposes.

Riparian wetland trees and macrophytes contribute considerably to evapotranspiration and to local and regional climate conditions. The rate of vapor release depends on the plant functional group which needs to be considered for basin-scale water budgets.

Corridor Function for Migrating Species

Riverine wetlands represent a web of ecological corridors and stepstones. In intense agricultural areas they can be considered as `green veins' that maintain contact and gene flow between isolated forested patches. Providing shadow, balanced air temperatures and moisture, shelter, resting places, food and water supply, they cover the requirements of a great deal of amphibian, reptile, bird, and mammal species. These not only use the longitudinal connection but also migrate laterally and thus reach the next corridor aside. Moreover, long-range migrating birds use the green corridors of riparian zones in general as landmarks for migration. Networks of riparian corridors also facilitate the movement of non-native species. In some US riparian zones, their richness was about one-third greater in riparian zones than on uplands and the mean number and the cover of non-native plant species were more than 50% greater than in uplands.

Refugia and Feeding Ground for Riverine Biota

During flood, drought, and freezing events, but also during pollution accidents in the stream channel, connected riparian wetland habitats represent refugia for riverine animals. In extreme cases, residual populations from the wetlands may contribute to the recolonization of defaunated stream reaches. Riparian wetlands also act as traps and storage sites for seeds both from the upstream and from the uphill areas. The seed banks contain propagules from plants that represent a large range of moisture tolerances, life spans, and growth forms. These seeds may also become mobilized and transported during spate events.

Riparian wetlands offer a large variety of food sources. Connected wetland water bodies `comb out' fine organic particles including drifting algae from the stream water, they receive aerial and lateral inputs of the vegetation, and they have a proper primary productivity which profits by the increased nutrient input and storage from the surroundings. Many riverine fish and invertebrate species are known to migrate actively into the riparian wetlands in order to profit by the terrestrial resources that are available during flood periods. In analogy to the `floodpulse advantage' of fish in large river floodplains, stream biota that temporarily colonize riparian wetlands have better growth conditions than those that remain permanently in the stream channel. For example, the macroinvertebrate community of riparian sedge-meadows in Maine (USA) is dominated by detritivorous mayfly larvae (over 80% of the invertebrate biomass) during a 2-month period in spring. The larvae use the stream channel as a refuge and use the riparian wetland as feeding ground where they perform over 80% of their growth.

Reciprocal Subsidies between Aquatic and Terrestrial Ecosystems

Many aquatic species profit by the terrestrial production and vice versa. Apart from leaf litter, large quantities of fruits, flowers, seeds, as well as insects and feces fall from the tree canopies into the streams where they represent important energy and nutrient sources for the biota. In Amazonian low-order rainforest streams, terrestrial invertebrates make up a major portion of the gut content of most fish species. Fruits and seeds are preferred food items for larger fish species that colonize medium- and high-order rivers. Riparian wetlands increase the area of this active exchange zone, and they retain these energy-rich resources for a longer period than a stream bank alone would do.

Aquatic organisms also contribute to the terrestrial food webs. For example, bats are known to forage on the secondary production of emerging insects in riparian wetlands, and the shoreline harbors a large number of terrestrial predators, such as spiders, tiger beetles, and riparian lizards. Experimental interruption of these linkages (e.g., by covering whole streams with greenhouses) has shown that the alteration of riparian habitats may reduce the energy transfer between the channel and the riparian zone.

Recreation

The sound of the nearby stream, the equilibrated climate, and the occurrence of attractive animal and plant species render riparian wetlands highly attractive for recreation purposes such as hiking, bird-watching, or meditation. These can be combined with `in-

channel' recreation activities such as canoeing, rafting, or fishing, and represent an economically valuable ecosystem service, that should be considered in management and conservation plans.

Conservation

Water is becoming scarce in many areas worldwide. Water mining reduces water levels, but high and stable groundwater tables are a prerequisite for the existence of riparian wetlands. In addition to direct water withdrawal, predictions about climatic changes include other threats. Increased stochasticity of the runoff patterns and reduced snowmelt floods are severe threats to the existence of riparian wetlands. The riparian zones of streams and rivers have been sought after by humans since early days. High productivity, reliable water supply, and climatic stability make these ecosystems suitable for a range of human-use types, such as wood extraction, hunting, aquaculture, and agriculture. In areas of intensive agriculture, riparian zones including their wetlands have shrunk to narrow strips or have completely vanished. On the other hand, the ecosystem services are good socioeconomical arguments to restore and enlarge riparian wetlands.

For conservation planning, it is very important to bear in mind that riparian wetlands are very diverse and have typical regional characteristics. Secondly, the whole riparian zone is very dynamic. Many tree species are relatively short-lived and well adapted to changes in the floodplain morphology or in the hydrology of the wetland. The existence of variable hydrological patterns is a prerequisite for the coexistence of annually varying plant and animal communities. Often, large-scale projects restore riparian zones including wetlands according to a single pattern that does not consider these dynamic changes in habitat and species diversity. If large flood events are precluded by dam constructions in the upstream region, the natural habitat dynamics are blocked and the vegetation will develop towards a late-successional stage without pioneer vegetation, and with a reduced range of moisture tolerance. Several studies could prove that once the hydrological fluctuations become reduced by water-level regulation, exotic species can invade river valleys more efficiently.

While many animal species depend exclusively on the specific habitat conditions of wetlands, most riparian amphibians and reptiles migrate into the drier zones of the aquatic–terrestrial ecotones for a part of their life cycle. This makes them vulnerable to increased mortality in the neighboring ecosystems, especially if these have been converted into agricultural or urban use. Therefore, a buffer zone considering the home range of these species is needed to fully protect these species.

Glossary

Allochthonous Organic inputs to lotic ecosystems that originate from plants and animals of terrestrial or marine origin.

Autochthonous Organic inputs that are generated within a lotic ecosystem through photosynthesis of autotrophic members of the aquatic community.

Autotroph An organism that synthesizes organic matter from inorganic materials using sunlight or chemical energy. Important autotrophs in lotic ecosystems include vascular plants, mosses and liverworts, periphyton and phytoplankton, some bacteria and protists. Autotrophic ecosystems are those in which trophic pathways are predominantly fueled by in-stream (autochthonous) primary production.

Ecotone A transition zone between two adjacent ecological communities.

Flocculation The process in which colloids come out of suspension and aggregate or precipitate to form particulate matter.

Heterotroph An organism that cannot fix carbon from inorganic sources; its energy derives from consumption of living or dead organic matter. Important heterotrophs in streams and rivers are microbes, protozoans and micrometazoans, macroinvertebrates, and vertebrates. Heterotrophic ecosystems are those in which energy transfers are dominated by community respiration (of microbes plus aquatic plants plus macroinvertebrates).

Hyporheos The groundwater interface in streams where a mixture of surface water and groundwater can be found, located both beneath the active stream channel and within the riparian zone of most streams and rivers.

Invertebrate functional feeding group Collection of macroinvertebrate taxa with similar morphological and behavioral mechanisms for procuring food.

Nutrient spiraling The interdependent processes in lotic ecosystems of nutrient cycling and downstream transport.

Paradigm A widely accepted conceptual model or theory.

Introduction

Research scientists, watershed managers, and conservationists alike agree that following an ecosystem perspective is the most productive way to examine streams and rivers. The integration of physical–chemical with biological processes, which is the study of ecosystems, has largely replaced single physical factor or single-species approaches to management and rehabilitation of running waters. In the discussion that follows, fluxes of energy and matter into, through, and out of lotic ecosystems are the basic processes embraced by integrating paradigms (conceptual models) that continue to underlie inquiry into the structure and function of streams and rivers.

Energy Flux

Energy Sources

Streams and rivers are driven almost entirely by two alternate energy sources: (1) sunlight that fuels the in-stream growth of aquatic plants (primary production), and (2) plant litter from stream-side (riparian) vegetation. The relationship between these two energy drivers is essentially inverse. The heavier the riparian cover over the stream/river channel, the greater the plant litter inputs and the greater the limitation of light reaching the water and therefore in-stream algae and vascular plant growth. In contrast to non-filamentous algae, very few stream/river consumers utilize macrophytes, filamentous algae, and rooted vascular plants. Rather, macrophytes enter the energy transfer to consumers as detritus after they die. Stream and river systems in which the

☆*Change History*: October 2017. KW Cummins and MA Wilzbach introduced small edits in the text of the article and in figure captions; added a sixth functional feeding group category in the section Feeding Roles and Food Webs; added new references and deleted others; added a table (Table 2) to compare use of biomass versus numeric data on functional feeding group ratios as surrogates for lotic ecosystem attributes; and added a Glossary to define technical terms.

This is an update of K.W. Cummins and M.A. Wilzbach, Rivers and Streams: Ecosystem Dynamics and Integrating Paradigms, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3084–3095.

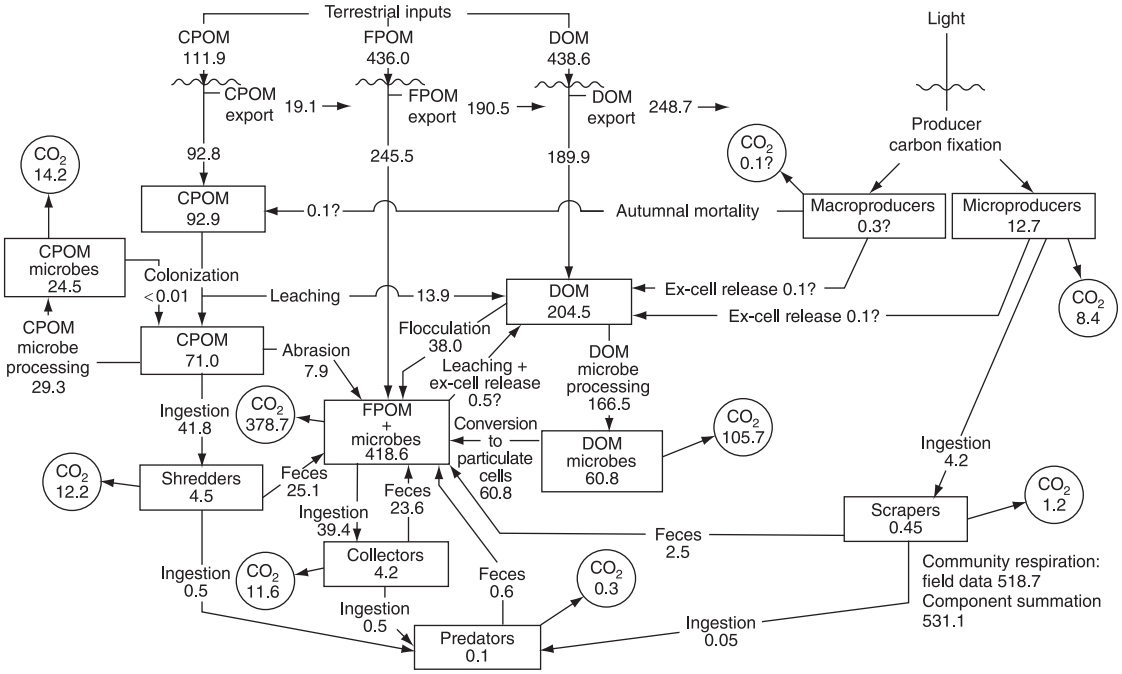

Fig. 1 Example of an energy budget for a small woodland stream ecosystem (Augusta Creek watershed, Michigan, USA). All values are in grams ash-free dry mass m^{-2} $year^{-1}$. *Squares* represent pools of organic matter in various states; *arrows* represent transfers and *circles* represent respiratory consumption of organic matter. From Saunders GW, *et al.* (1980) In: LeCren ED and McConnell RH (eds.) The functioning of freshwater ecosystems. Great Britain: Cambridge University Press

majority of the energy transfer is from in-stream plant growth to consumers are termed autotrophic. Those systems dominated by the detrital pathways of energy transfer are heterotrophic. As discussed in the "river continuum concept" (RCC), the relative importance of these two energy sources changes with stream size. Smaller streams in forested catchments are usually dominated by litter energy sources and wider, mid-sized stream segments are dominated by plant growth in the water. Larger rivers are dependent upon organic matter (OM) delivered from the upstream tributary network.

A model of energy flux, that is, the transfer of energy between trophic levels of plants and animals, was produced by Lindeman in the early 1940s and various forms of this model have more or less been the basis for the investigation of energy flux in running waters ever since. These studies most frequently take the form of energy budgets; an accounting of the energy in and the energy out of a given ecosystem (Fig. 1) or biological population (Fig. 2) or community within the system. OM budgets are useful in identifying the sources, magnitude, and fates of energy and provide insight into internal dynamics of lotic ecosystems. At the system level, inputs include autotrophic production plus energy originating from the surrounding terrestrial environment (allochthonous) that is brought in by various physical vectors. Outputs include community respiration and losses by downstream transport. Energy retained within a stream reach over a given time interval is referred to as storage. Comparisons of energy flux among and between trophic levels commonly express biomass as caloric equivalents. Animal ingestion, egestion, and growth (increase in mass) are all measured as biomass. Respiration (metabolism) is readily converted to calories consumed using an oxy-calorific equivalent. Tables are available that provide conversions of mass to calories for freshwater organisms.

Feeding Roles and Food Webs

Feeding studies of benthic macroinvertebrates have shown that, based on food ingested, most taxa are omnivorous. For example, invertebrates that chew riparian-derived leaf litter in streams, termed "shredders," ingest not only the leaf tissue and associated microbiota (e.g., fungi, bacteria, protozoans, and micro-arthropods), but also diatoms and other algae that may be attached to the leaf surface, as well as very small macroinvertebrates (e.g., first-instar midge larvae). For this reason, trophic-level analysis does not lend itself well to simple trophic categorization of stream macroinvertebrates.

An alternate classification technique, originally described by Cummins in the early 1970s, involves the functional analysis of stream/river invertebrate feeding. The method is based on the combined morphological and behavioral mechanisms of food acquisition used by the invertebrates and five fundamental categories of their food found in running waters (Fig. 3). There is a direct correspondence between the availability of categories of nutritional resources and the relative abundance of invertebrate populations that are adapted to efficiently harvest a given food resource. In 1974, five invertebrate functional feeding groups (FFG) were proposed. These include shredders, filtering collectors, gathering collectors, scrapers, and predators. These groups partition five food resource categories in running waters that are defined on the basis of particle size and type: (1) coarse particulate organic

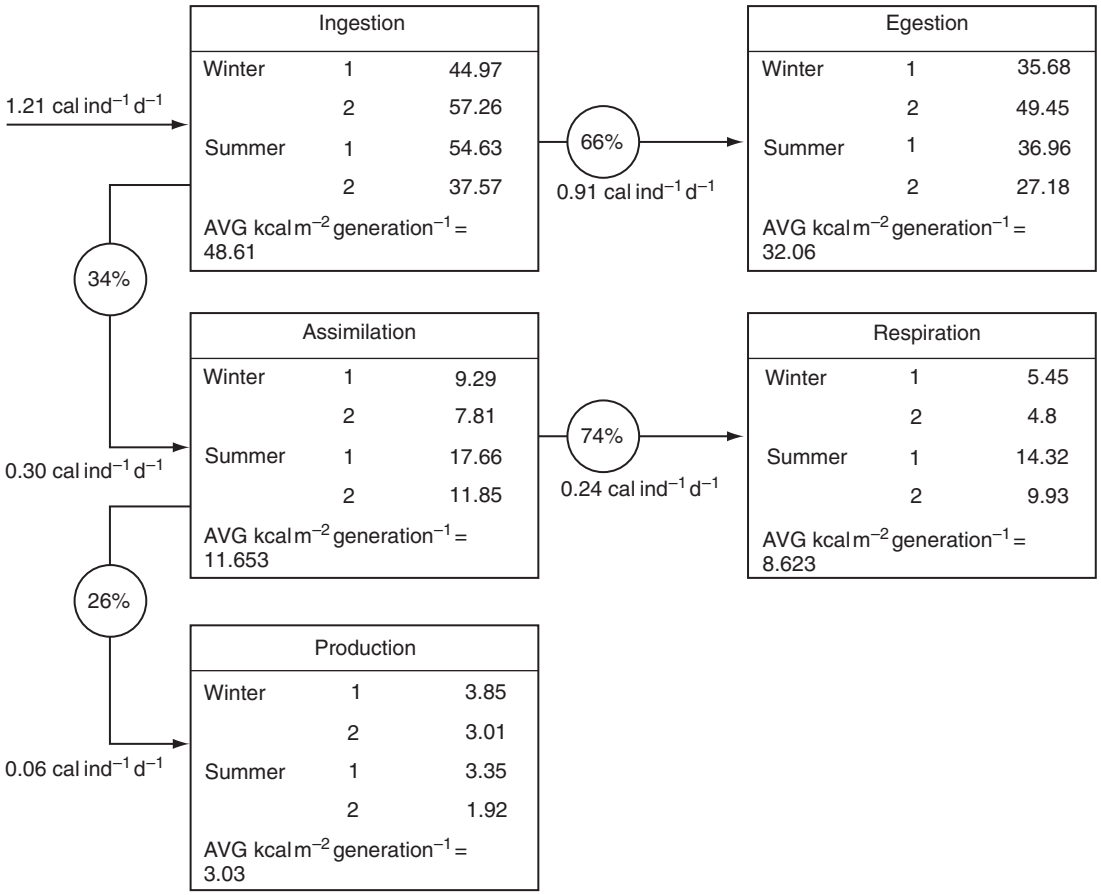

Fig. 2 Example of an energy budget constructed over 2 years of study for a population of a stream invertebrate (*Glossosoma nigrior*, Trichoptera) from Augusta Creek, Michigan, USA. The budget is based on independent measurements of ingestion, production, and respiration. Modified from Cummins, K.W., (1975). Macroinvertebrates. In: Whitton BA (ed.) River Ecology. Berkeley: University of California Press.

matter (CPOM), which is primarily riparian plant litter that has been conditioned, that is, microbially colonized, within the stream; (2) fine particulate organic matter (FPOM), which are particles generally smaller than 1 mm in diameter that are largely derived from the biological and physical breakdown of CPOM and whose surfaces are colonized and metabolized by bacteria; (3) periphyton, that is, tightly accreted algae and associated organic material; (4) live vascular aquatic plants; and (5) prey, that is, invertebrate species or larval/nymphal stages small enough to be captured and consumed by invertebrate predators. Recently, two other categories were added: herbivore shredders and herbivore piercers. Herbivore shredders are macroinvertebrates that are adapted to consume live aquatic vascular plant tissue. Herbivore piercers, which are limited to some species within the caddisfly family Hydroptilidae, pierce individual algal cells to suction their cell contents.

As the relative availability of the basic food resources changes, there is a concomitant change in the corresponding ratios of the FFGs of freshwater invertebrates adapted to specific resource categories.

Obligate and facultative members occur within each FFG. These can be different species or different stages in the growth period of the life cycle of a given species. For example, it is likely that most aquatic insects, including predators, are facultative gathering collectors as first-instars newly hatched from the egg. It is with obligate forms that linkages between invertebrates with their food resource categories are most reliable. The distinction between obligate and facultative status is best described by the efficiency with which a given invertebrate converts the resource acquired to growth; that is, obligate forms are more efficient consumers of a given food resource, such as conditioned leaf litter, than are facultative forms. For example, shredders feeding on litter consume the fungal-rich leaf matrix, whereas scrapers only abrade the much less microbially colonized, and therefore less nutritious, leaf cuticle. The high efficiency of obligate forms feeding on a particular resource category is in contrast with the wider array of food types consumed by facultative forms, but with lower efficiency. Facultative forms are more flexible, and often exhibit a greater affinity for one of the five food resource categories. The same morpho-behavioral mechanisms can result in the ingestion of a wide range of food items, the intake of which constitutes herbivory (consumption of living algal and vascular plants), detritivory (consumption of dead OM), or carnivory (consumption of live animal prey).

Although intake of food types changes from season to season, habitat to habitat, and with growth stage, limitations in food acquisition mechanisms have been shaped over evolutionary time and these are relatively more fixed than the food items ingested.

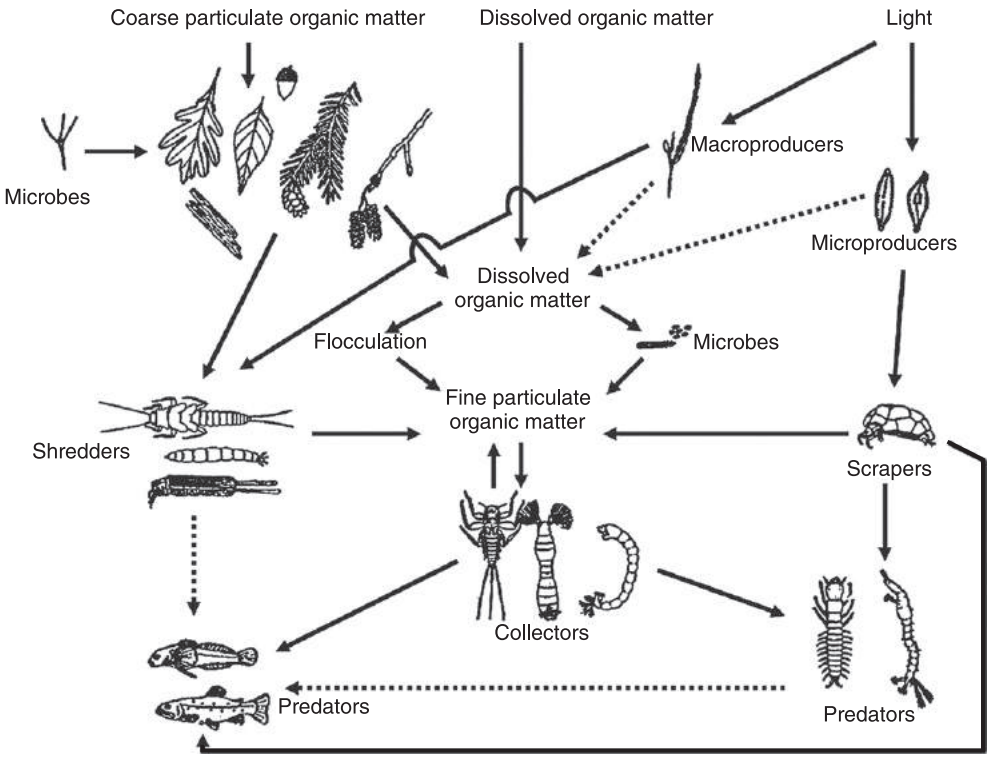

Fig. 3 Conceptual model of invertebrate functional feeding groups and their food resources in a small, forested stream ecosystem. *Dashed lines* indicate additional or alternate pathways. Modified from Cummins K.W., (1974). Structure and function of stream ecosystems. Bioscience 24: 631–641.

Morphological structures that enable aquatic insects to harvest a given food resource category exhibit significant similarities across diverse taxa. This convergent or parallel evolution lies at the heart of the FFG classification method. For example, larvae of the 26 North American caddisfly (Trichoptera) families are spread among the six major FFGs. The less highly evolved mayflies (Ephemeroptera) and stoneflies (Plecoptera) are adapted to acquire fewer food resource categories (**Table 1**).

An advantage of the FFG procedure is that it does not require detailed taxonomic separations of the invertebrates. Broad, easily distinguished characteristics allow FFG classification, preferably in the field with live specimens. Separations usually involve systematic distinctions at the level of family or higher, and cut across taxonomic lines. As an example, two groups of case-bearing larval caddisflies (Trichoptera) are sufficient to separate FFG categories at better than 90% efficiency. All families, or genera within families, of Trichoptera that construct mineral cases are FFG scrapers; those that construct organic cases are FFG shredders.

Given the coupling of FFGs with food resource categories, ratios of the different FFG groups can serve as surrogates for ecosystem attributes. For example, the ratio of the functional groups linked to in-stream primary production (scrapers plus those shredders that may harvest live plant tissue) to those groups dependent upon the CPOM and FPOM heterotrophic food resources (shredders of detrital material plus gathering and filtering collectors) provides an index of the ratio of autotrophy to heterotrophy at the lotic ecosystem level. When measured directly, an ecosystem ratio of autotrophy/heterotrophy >1 indicates an autotrophic system. A surrogate FFG ratio of >0.75 has been experimentally measured in such autotrophic stream/river systems. The interpretation of FFG ratios as surrogates for lotic ecosystem attributes, such as autotrophy versus heterotrophy, can differ somewhat whether the data are expressed numerically (the usual case) or gravimetrically (**Table 2**). The conversion of numbers to biomass equivalents can readily be accomplished using the relationship:

$$Y = aX^b$$

where Y = dry mass in mg, X = body length in mm, a = Y intercept, and b = slope of Y on X (Benke *et al.*, 1999).

Flux of Matter

Nutrient Cycles and Spiraling

The limnological study of standing waters has always been dominated by a conceptual model of closed ecosystems, in which nutrients recycle seasonally, totally within the system. The unidirectional flow of running waters necessitated modifying this view of closed cycles in lakes to an open-cycle model; that is, the open nutrient cycles in streams and rivers follow a spiraling pattern in

Table 1 Total number of families and number of families assigned to each functional feeding group of three major orders of benthic aquatic insects found in North America

Order	*Number of families by dominant functional feeding group*

Assignment of functional group based on largest number of species in the family listed as in that functional group.

which nutrients generated (or delivered) at one point along a stream or river complete the recycling to their initial state at a displaced location downstream (Fig. 4). Total spiral length represents the sum of the distance traveled by an element as an inorganic solute or organic particle until its uptake by the biota, plus the distance traveled within the biota until its release back into the water column. If nutrients such as nitrogen or phosphorous are cycled rapidly, the spirals are "tight," that is, the downstream completion of the cycle is short. If cycling is slow, the closing of the loop is displaced a longer distance downstream and the spirals are more open. The tighter the loops of nutrient spirals, the more retentive (conservative) is the stream or river reach.

Transport and Storage of OM

The transport and storage of OM in running-water ecosystems involves complex interactions between (1) the state of the OM, (2) the source of the OM, and (3) the physical, chemical, and biological retention potential for any given reach of stream or river.

State of the OM

OM can be partitioned into three broad categories: (1) dissolved (DOM, size range $<0.45\,\mu m$); (2) fine particles (FPOM, size range $>0.45\,\mu m$ to 1 mm); and (3) coarse particles (CPOM, size range >1 mm). Although FPOM particles are colonized primarily on the surface by bacteria, CPOM is colonized by fungi, bacteria, and microzoans that penetrate the matrix of the plant material. Aquatic hyphomycete fungi usually penetrate the CPOM leaf and needle litter first. Bacteria and microzoans follow the fungal hyphal tracks into the matrix of the CPOM. The OM in solution (DOM) includes a full range of molecules from simple very labile ones such as sugars and amino acids to complex recalcitrant ones such as phenolic compounds.

Sources of the OM

A major source of OM in streams (orders 0–5, where stream order 0 represents headwater tributaries that are intermittent or ephemeral, and the smallest permanently flowing stream is first order) is the riparian zone. This border of stream-side vegetation produces litter (e.g., leaves, needles, bud and flower scales, seeds and fruits, small wood and bark) most of these enter streams on a seasonal schedule depending upon the relative proportions of deciduous and evergreen species. Other sources of OM are solutions and particles from bank erosion, DOM leachates from riparian litter, exudates, and leachates from periphytic algae and vascular aquatic plants together with their physical fragmentation and moribund tissues.

Physical, Chemical, and Biological Retention Potential

The retention of DOM involves physical flocculation of the OM in solution with divalent cations, such at Ca^{2+}, and biological uptake by resident bacteria and fungi. Chemical reactions between the smaller molecular weight organic compounds may precede the physical complexing with cations. The rate and extent of biological uptake of DOM depends upon factors such as the lability or recalcitrance of the compounds, density and composition of the microbial flora, and water temperature. These mechanisms that convert DOM to FPOM, flocculation and microbial uptake, are quite important ecosystem processes. The conversion of DOM in solution to particles significantly increases the retention of the OM. The difference in the efficiency of retention of OM between soft, stained water streams and hard, clear water streams accounts in part for the greater productivity of the latter. The POM that results from the conversion of DOM is more likely to remain in a given reach of stream or river and enter into trophic pathways.

Retention of POM depends upon channel geomorphology. Large wood debris (LWD), branches and exposed bank roots, coarse sediments, backwaters, side channels, and settling pools are all important retention features. For any given reach of stream or river, a major source of OM is transport from upstream. In addition, OM is retained when bankfull-flow is exceeded and material is deposited on the upper banks or on the floodplain. OM is returned to the channel when water levels recede. Whether these

off-channel areas serve as sources or sinks for OM over an annual cycle depends upon the configuration of the upper banks and floodplains and the patterns of the flood flows. The general fertility of floodplains suggests that they are largely sinks.

Integrative Paradigms in Lotic Ecology

Paradigms, or conceptual models, have continued to be developed, modified, and integrated since the 1980s. The RCC, arguably the most encompassing of these, has guided a large portion of the research on lotic ecosystems in the interim. However, a number of other models have served to elucidate specific components of running-water structure and function or have proposed alternative broad integrating principles.

The RCC

The major goal of the architects of the RCC was to examine the patterns of biological adaptation that overlay the physical setting (template) of stream/river channels in a watershed. The RCC views entire fluvial systems, from headwaters to their mouths, as continuously integrated series of physical gradients together with the linked adjustments in the associated biota. The RCC was founded on many antecedent studies and additional correlates have been incorporated into the general paradigm. Subsequent views and critiques of portions of the RCC also have had significant impact on the present form of the RCC as a general model of lotic ecosystem structure and function. The physical RCC template, and biological communities adapted to it, are viewed as changing in a predictable fashion from stream headwaters to river mouth (**Figs. 5–7**). Major generalizations of the RCC involve seasonal spatial variations in OM supply (e.g., algal/detrital biomass), structure of the invertebrate community, and resource partitioning along drainage networks (**Fig. 8**).

The RCC predicts that recognizable patterns in the structure of biological communities and the input, utilization, and storage of OM will be observable along the continuum. Light limitation inhibits primary production in the headwaters (orders 1–3) due to shading of the channel by riparian vegetation and in the larger rivers (orders greater than 7 or 8) because of light attenuation through the turbid water column that is typical of the lower portions of stream/river networks. The cumulative effect of drainage networks tends to increase nutrient levels in the downstream direction. Overall periphyton and rooted aquatic vascular plant biomass, and insect and fish diversity are all maximized in the mid-sized running waters (orders 4–6). High biotic diversity is

Fig. 5 A headwater stream in the Cascade Mountains of Oregon, USA at winter base flow. The coniferous riparian zone provides partial canopy closure and supplies large woody debris to the channel. Photo by Wilzbach.

Fig. 6 The Firehole River, a mid-sized stream flowing through woodland meadow in Yellowstone National Park, USA. Reduced riparian shading enables abundant growth in in-stream algae. Photo by Wilzbach.

supported in rivers in this size range both because of the variety of habitats and food resources for consumer organisms, and because of overlapping ranges of organisms with evolutionary terrestrial origins (such as the insects) that are dominant in the headwaters with those of marine origins (e.g., annelids and mollusks) that are more prevalent downstream (Fig. 9).

The RCC has been widely utilized as an organizing principle and has been the subject of many studies resulting in various tests of the concept. As would be expected, a degree of unpredictability in the physical template leads to correspondingly less predictability in the overlay of biological communities. This lack of predictability is often a function of the spatial and temporal scales

Fig. 7 The Smith River in coastal northern California, USA. This high order river with a canyon-controlled channel is dependent upon organic matter delivered from the upstream tributary network. Photo by Wilzbach.

of reference employed and it can also be induced by human interference. For example, systems may appear more or less variable over time spans of less than a decade, the time period of observation, but long-term variability, at the scale of centuries or greater, is usually obscured by short-term variations.

Other Paradigms

At least eight paradigms, other than the RCC, continue to guide the development of running-water ecosystem theory (**Table 3**). These include serial discontinuity, hierarchical scales, riparian zone influences, flood pulse, hyporheic dynamics, hydraulic stream ecology, patch dynamics, and network dynamics.

Serial discontinuity

Interruptions in the longitudinal continuum, as proposed by the RCC, are caused by engineered impoundments which serve to reset the general patterns of biotic organization. Above a dam, the system exhibits characteristics of a higher order than the impounded stream. Below a dam, the regulated flows often completely alter the seasonal hydrological patterns of the receiving channel. For example, the normal pattern imposed by the discontinuity resulting from a dam is to decrease the flows during natural high-water periods (reservoir storage phase) and release the water during natural low-flow periods (reservoir release phase). The storage phase retains water to prevent flooding and to provide a later water supply during dry periods. During the release phase, water is delivered for irrigation, drinking, recreation, and, in some cases, to improve fish habitat. In some basins, interruptions in the longitudinal profile of river networks occur in the form of natural lakes or impoundments. Although these may change the sequencing of stream orders, they do not change the annual hydrograph.

Hierarchical scales

The hierarchical scales paradigm addresses a weakness of the RCC. The relative significance of the factors driving the physical, chemical, and biological components of running waters changes with scale. The data on which the RCC is based were all collected at the reach scale and during only several seasons. The hierarchical approach recognizes that ecosystem processes operating at the reach scale and over short time periods do not adequately represent the patterns viewed over greater spatial and temporal scales. Therefore, descriptions of stream/river ecosystem structure and function must be placed in the appropriate context of space and time.

Ecotones

Several paradigms focus on the ecotones that bridge between the stream/river channel and its surroundings and underpinnings. These include the riparian border primarily along small streams, the aquatic terrestrial interface of large rivers with floodplains, and the subsurface region of the sediments beneath running waters (the hyporheic zone).

Riparian zone influences

The riparian zone paradigm attempts to integrate the physical processes that shape the valley floor of streams and rivers with the coupled succession of terrestrial plant communities in the riparian zone along the channel and the role they play in the formation of stream habitat and the production of nutritional resources for organisms that reside in running waters. The ecotone between wetted channel and terrestrial bank vegetation that constitutes the riparian zone is a critical coupling, especially in small streams. The confined or unconstrained nature of the channel system, for example, exert a major influence on the nature of the riparian vegetation that develops along the banks. Definition of the lateral boundaries of the riparian zone, or buffer strip width in the

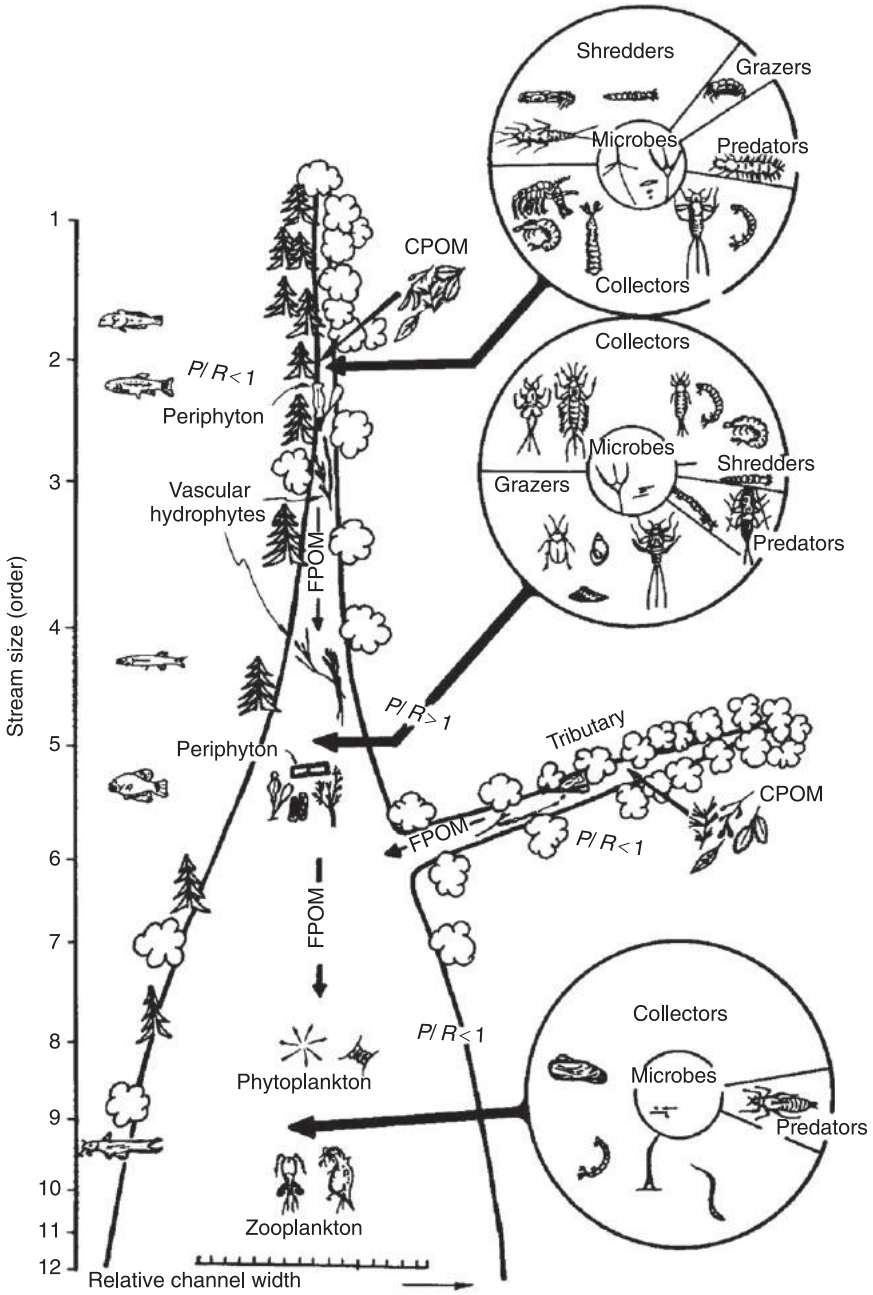

Fig. 8 The "river continuum concept" (RCC). A proposed relationship between stream size (order) and the progressive shift in structural and functional attributes of lotic biotic communities. The heterotrophic headwaters and the large rivers are both characterized by an autotrophic index, or *P*/*R* (ratio of gross primary production to total community respiration) of less than 1 (*P*/*R* = <1). The largely unshaded mid-sized rivers are generally classified as autotrophic with a *P*/*R* = >1. The invertebrate communities of the headwaters are dominated by shredders and collectors, the mid-sized rivers by grazers (= scrapers) and collectors. The large rivers are dominated by FPOM-feeding collectors. Fish community structure grades from invertivores in the headwaters to invertivores and piscivores in the mid-sized rivers to planktivores and bottom-feeding detritivores and invertivores in the largest rivers. From Vannote, R.L., Minshall, G.W., Cummins, K.W., Sedell, J.R., Cushing, C.E., 1980. The river continuum concept. Canadian Journal of Fisheries and Aquatic Sciences 37, 130–137.

parlance of timber managers, is a continuing debate. From the perspective of the stream/river ecosystem per se, the functional roles of the riparian corridor encompass differing areas along the stream bank (**Fig. 10**). Shading of the channel, which along with nutrient levels regulate in-stream primary production, which in turn depends upon the height and foliage density of the vegetation, steepness of the side slopes, and aspect (compass direction) of the channel. The width of the riparian zone that yields litter inputs and large woody debris to the channel can also vary with height and species composition of the stream-side vegetation. Seasonal timing of litter drop and its introduction into the stream produces patterns around which the life cycles of many steam invertebrates have become adapted. This coupling between riparian litter inputs and stream invertebrates is most direct for

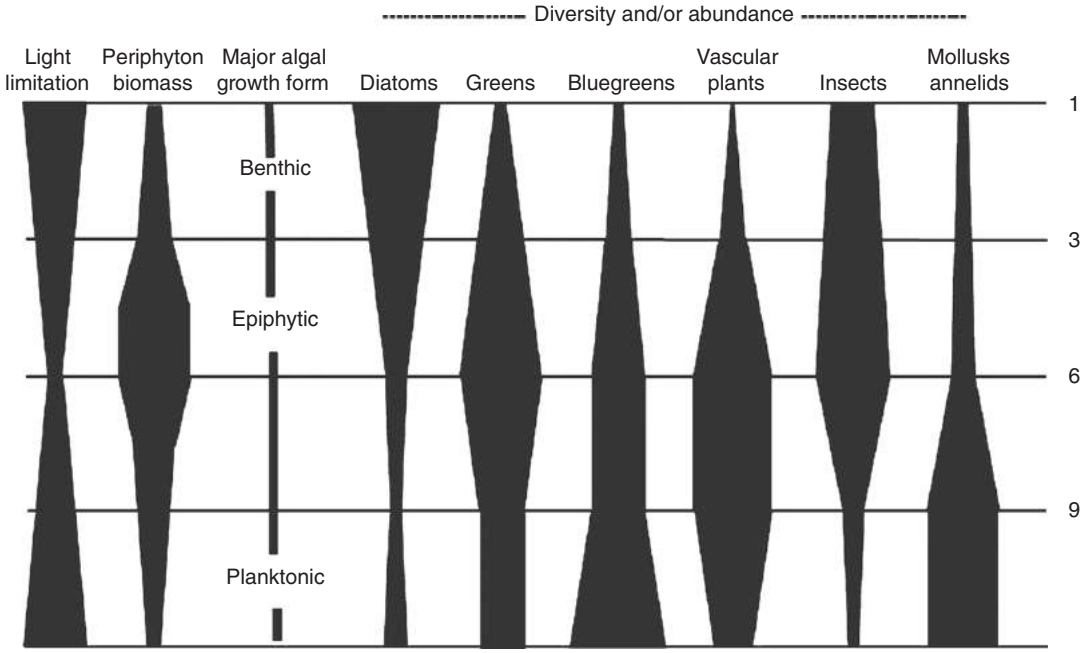

Fig. 9 Patterns in categories of biotic diversity, from small streams to large rivers, compared on a relative scale for each parameter, as predicted by the "river continuum concept." Headings: *RCC*, river continuum concept; *HS*, hierarchical scales; *RZI*, riparian zone influences; *FPC*, flood pulse concept; *HD*, hyporheic dynamics; *HSE*, Hydraulic stream ecology; *PD*, patch dynamics; *ND*, network dynamics. *Table entries*: *a*, most direct influence on stream biota and ecosystem processes; *b*, if channels are braided, ranking moves down in scale to a lower order; *c*, beyond the scale to detect specific (local) differences; *d*, influence too local to detect general, large-scale patterns; *e*, may be of less direct importance in naturally deranged (lake-interrupted) or beaver-influenced stream drainages.

ecoregions and with the species composition of the riparian vegetation. Most deciduous species of riparian trees and shrubs are colonized by aquatic hyphomycete fungi and fed on by shredders much more rapidly than evergreen species such as conifers and rhododendrons and some deciduous species such as oaks (Fig. 12). Roots of riparian vegetation stabilize banks at the edge of the channel and influence the chemistry of subsurface flow into the channel. The width of the riparian zone that encompasses these root functions also varies. Thus, a complete definition of the riparian zone that encompasses all these functions would need to be of sufficient width to accommodate all of them. Just as zones of influence of these riparian functions vary, so do the zones of associated management. For example, if a goal is to manage for the long-term input of large woody debris to the channel from the riparian zone to provide habitat structure for fish and invertebrates, all trees tall enough to reach the channel when they fall and large enough to provide habitat structure should be left in place. However, to accommodate variations in channel and bank morphology and the composition of the riparian vegetation, this management would need to be implemented at the reach scale.

Flood pulse concept

The flood pulse concept addresses the ecotones between rivers and their floodplains. Unlike the lateral riparian influence on stream ecosystem processes where the impact is largely from the landscape to the stream, the flood pulse concept emphasizes the

reciprocal exchange between the major river channel and its floodplain. A consequence of this distinction is that the overwhelming bulk of riverine animal biomass derives directly or indirectly from production on the floodplain and not from downstream transport of OM produced higher in the watershed. Although the importance of this aquatic/terrestrial transition zone, the floodplain ecotones, is widely acknowledged, there are few hard data to indicate whether over annual cycles, or longer periods, the primary movement of nutrients and biomass is onto or off the floodplain, or in balance. The general perception of "fertile floodplains" suggests that the periodically inundated floodplains are sinks relative to the river channel. However, the high productivity of adult fish in many floodplain rivers and the concentration of reproductive activity on the floodplain supports the notion that floodplains are sources and the river is a sink, gradually exporting to the sea. At any rate, the seasonal pulsing of river discharge, the flood pulse, is the major force controlling existence, productivity, and interactions of biota in river–floodplain ecosystems.

For any given storm or series of storms, the movement of material and organisms on to the floodplain follows the rising limbs of the hydrographs, and the return to the river channel follows the falling limbs. Unfortunately, application of the flood pulse concept is restricted because of the wide-scale engineering modifications that have isolated rivers from their floodplains. Natural exceptions to the flood pulse concept are rivers flowing through deeply incised canyons.

Hyporheic dynamics

The hyporheos is the subsurface region beneath and adjacent to stream/river channels that exchanges water with the surface water. This surface water–ground water ecotone is spatially and temporally very dynamic. The conceptual framework of the hyporheic dynamics paradigm has resulted in the incorporation of channel-aquifer dynamics into the general model of the RCC. The hyporheic zone occurs, at least to some extent, beneath and lateral to the active channel from the headwaters to river mouths, except in bedrock channels. Water, solutes, inorganic and organic complexes, and uniquely adapted biota move through interstitial pathways into and out of the sediments. These flow paths are determined by the bedform of the channel. Where the bedform is convex, there is groundwater recharge from the channel into the sediments. These locations where oxygenated water is driven into the sediments are often spawning sites of salmonid fishes. Concave bedforms are sites of groundwater upwelling into the channel. Invertebrates found in the hyporheos include the small early instars of a wide range of taxa and larger forms at times of extremes inflow, either high or low. In addition, there are some microbenthic forms that are specifically adapted to a groundwater existence. The presence of hyporheic invertebrates is determined largely by siltation and the availability of oxygen. If interstitial sediment spaces are filled with fine sediments and/or conditions are anaerobic, the fauna will be excluded.

Hydraulic stream ecology

The hydraulic stream ecology model emphasizes that the local responses of stream organisms to flow conditions can serve as an organizing principle for running waters. Lotic animals are not well-adapted to hydraulic stress and can sustain exposure to such stress for only short periods of time. Common patterns of diurnal and seasonal drift of stream invertebrates along vertical

gradients of sediment and current velocity are a manifestation of this stress response. The model identifies mean water velocity and depth as more critical than characteristics of substrates in determining the distributions of stream animals. The model has yet to adequately incorporate the extensive data that implicates the diurnal light cycle as the major control parameter of invertebrate stream drift.

Patch dynamics

The patch dynamics concept emphasizes the patchy distribution of riverine habitats in space and time, and argues that an ever-shifting mosaic of patches enables a greater number of species to co-occur than would be the case under greater environmental constancy. Environmental conditions are predictable in aggregate, but not within a particular patch, and these aggregate conditions confer some regularity in species composition. In this model, particular patch types can be found at any point along the general longitudinal gradient proposed by the RCC. However, there are clear examples of invertebrate "patches" that at least change in abundance from headwaters along the continuum to large rivers. For example, small headwater streams (orders 1–3) are generally better shaded than higher orders (>3) and sustain less suitable algal periphyton to support scrapers. Further, the dominance of the CPOM–detrital shredder linkage correlates with stream width and the close availability of riparian tree and/or shrub litter, and this generally matches with stream orders 1–3. The extension of the shading of periphyton growth and the riparian CPOM–shredder linkage to larger rivers can occur along braided channels, but these "patches" will always be more abundant in the headwaters than in mid-sized or larger rivers.

Network dynamics

The network dynamics hypothesis, which combines the hierarchical scales and patch dynamics models, is based on the observation that there are abrupt changes that occur at the confluences of tributaries with the receiving channel. Changes in water and sediment flux at these locations result in changes in the morphology of the receiving channel and its floodplain. In this view, the branching nature of river channel network, together with infrequent natural disturbances, such as fire, storms, and floods, are the formative elements of the spatial and temporal organization of the non-uniform distribution of riverine habitats. Further, the tributary junctions are proposed hot spots of biological activity. Some data show increased fish diversity and abundance at these junctions, but the influence on other components of the biota has yet to be investigated. The "network dynamics hypothesis" does not address "patches" represented by braided channels.

Whether hydraulic characteristics, tributary junctions, or other patch phenomena represent local conditions that need to be integrated along river continua to account for whole-profile trends that are clearly apparent, or whether such phenomena are localized specific modifiers that differentially affect stream orders along profiles has yet to be demonstrated clearly.

Conservation and Human Alterations of Streams and Rivers

A great challenge for stream and river ecology in the 21st century will be the restoration of degraded running-water ecosystems while preserving those systems that still remain in good condition. Restoration will dominate in more developed regions where modifications of running waters and their watersheds have been more extensive. In less-developed regions, preservation of many running waters may still be possible, but the distinction between pristine and degraded systems is disappearing rapidly. The historical scientific databases for running waters are generally poor, with largely anecdotal or very incomplete information available. The lotic ecosystem paradigms described above can serve as tools for evaluating present conditions of running waters, surmising their likely antecedent condition, and developing targets and strategies for restoration. Because the majority of degraded streams and rivers have changed beyond our ability to return them to their historical state, it is more logical to use the term rehabilitation. Often the actions will take the form of returning certain organisms or processes to a condition that addresses societal objectives.

In the context of preserving and rehabilitating streams and rivers, it will be important to enlist the best scientific understanding of the structure and function of running-water ecosystems. For example, regulations governing the protection and width of riparian buffer strips, designed to protect stream organisms (usually fish), vary among political boundaries or regulatory authorities, and are wider in some areas, narrower in others. However, managers and environmentalists should not limit their view of riparian buffers as only a matter of vegetative composition and buffer width with the sole aim of providing shading to reduce water temperatures, a source of large woody debris, or stream bank stabilization. This view of riparian buffers ignores the often completely different in-stream trophic role played by the coupled riparian ecosystem. The buffer width required to produce shade, litter, large wood, nutrients, and bank stabilization are often quite different. Thus, the management and rehabilitation of a given reach of running water requires an integrated approach that acknowledges all the riparian functions and places the actions within the context of the larger watershed.

Glossary

Alluvial Deposition of mineral or organic particles by a river. An alluvial river is one in which the channel bed and banks are composed of transported sediment.
Benthic Of, relating to, or occurring at the bottom of a body of water. *Benthos* refers to the community of organisms that live on or in the bottom sediments of a river or other aquatic environment.
Community respiration Metabolism of organic matter by both plants and heterotrophs (bacteria, fungi, and animals).
Detritivore An organism that feeds on and breaks down dead plant or animal matter.
Floodplain Low-lying areas of land bordering a river subject to flooding and formed largely from deposited river sediments.
Geomorphology The study of the physical features of the surface of the earth and the processes which create them.
Hydrology The science that encompasses the occurrence, distribution, movement and properties of the waters of the earth and their relationship with the environment within each phase of the hydrologic cycle.
Invertivore An organism which feeds on invertebrates.
Lotic Of, related to, or living in moving waters.
Point bar Accumulation of deposited sediments along the inner bank of a stream meander.
Primary production Rate of formation of organic matter from inorganic carbon by photosynthesizing organisms in the presence of light.
Riparian zone The land area adjacent to a stream channel influenced by stream-derived moisture.
Water table Upper surface of groundwater below which soil is saturated with water that fills all voids and interstices.

Introduction

Streams and rivers are enormously important ecologically, economically, recreationally, and esthetically. This importance far outweighs their proportional significance on the landscape. Running waters constitute less than 1/1000th of the land surface and of freshwater resources of Earth and contribute only 1/5,000th of annual global freshwater budgets. Streams and rivers are significant agents of erosion and serve a range of human needs, including transportation, waste disposal, recreation, and water

☆*Change History*: February 2018. MA Wilzbach and KW Cummins added an Abstract and a Glossary to define technical terms; added new references and deleted others; introduced small edits in the text of the article and in figure captions; added information on the hyporheic zone, changing patterns in runoff in response to climate change, and impact of altered hydrologic regimes on species diversity and imperilment (in Hydrologic Processes): added discussion of channel units other than pools and riffles and reach types other than pool-riffle, the time frame over which different components of river morphology respond to changes in discharge and sediment supply (in Channel Morphology); added information on forces propelling and resisting current and defined large woody debris (in Physical Factors); and added information on the extent of species imperilment of mollusks (in Adapted Biota).

for drinking, irrigation, hydropower, cooling, and cleaning. At the same time, flooding of streams and rivers pose potential natural hazards to human populations. Irrespective of their direct consequences for people, streams and rivers are rich, complex ecosystems that are diagnostic of the integrity of the watersheds through which they course. Unfortunately, species dependent on flowing waters are in global decline, exhibiting extinction rates four to five times greater than those for terrestrial species.

Streams are generally conceived of as smaller, shallower, and narrower bodies of flowing water than rivers. However, the difference between streams and rivers lacks clear distinction in the literature of the last 100 years. For the purposes of this article, streams refer to channels in drainage networks up to order 5 and rivers as orders 6 and above (see definition of stream order under the section titled "Channel Morphology"). In this article, we discuss the history of stream ecology, followed by a treatment of the physical and chemical setting and biological features of major groups of lotic organisms. In a companion article, we cover ecosystem dynamics and integrating paradigms in stream and river ecology.

History of the Discipline of Stream and River Ecology

The formal published beginning of the study of flowing waters (lotic ecology) dates to the early 20th century in Europe, where initial work focused on the distribution, abundance, and taxonomic composition of lotic organisms. In North America, ecological studies of streams began shortly after. In the 1930s, fishery biology dominated North American stream ecology. Stream and river studies worldwide remained descriptive through the 1950s and this period marked the beginning of a focus by stream ecologists on human impacts. Descriptive studies detailed the taxonomic composition and density of the benthic invertebrate fauna found in reaches of streams and rivers variously affected by human impacts. Beginning in the 1960s and 1970s, research interest shifted to synthetic views of flowing-water ecosystems, with research addressing energy flow and organic matter budgets in small catchments. In 1970, H.B.N. Hynes, pioneer of modern stream ecology, published his landmark book, *The Ecology of Running Waters*, which summarized concepts and literature to that point. With the 1980s came the realization that running-water dynamics demanded an integrated spatial and temporal perspective, and that whole catchments were the basic units of stream/river ecology. For example, holistic organic budget analyses of running-water ecosystems cannot be constructed unless both spatial and temporal scales are applied.

The hallmark of lotic research during the 1980s and 1990s was its interdisciplinary nature. Interactions among stream biologists, hydrologists, geomorphologists, microbiologists, and terrestrial plant ecologists focused attention on physical processes and greater spatial and temporal scales. This perspective of stream ecosystems continues to direct the science in the 21st century, aided immensely by the incorporation of geographic information systems (GIS) analysis and incorporation of concepts from landscape ecology. Emergent areas of study within stream ecology include urban stream ecology, bioassessment, genetic barcoding, food web studies, nutrient cycling, and restoration.

Despite recognition among stream ecologists that the watershed or catchment represents the fundamental unit for the study of streams and rivers, measurements of lotic ecosystem structure and function continue to be commonly made at the reach or microscale level. Impetus has been strong to extend the scope of understanding to the watershed mesoscale and beyond, because ecosystem processes exhibit effects of differing importance at different spatial and temporal scales and these processes interact across scales. Growing concern about impacts of climate change on lotic ecosystems has provided additional motivation to analyze entire basins or all the basins in continental regions. Integration of data-rich studies at the reach level to entire watersheds and the coarse resolution of regional basin analysis relying on satellite imagery remain a challenge for lotic ecologists in the 21st century. The River Continuum Concept and other stream/river conceptual models, coupled with modeling and field experiments conducted at an expanded spatial and temporal scale, continue to aid in the integration of knowledge about lotic ecosystems.

The Physical and Chemical Setting

Stream and river biota evolved in response to and in concert with the physical and chemical setting. Traditionally the domain of hydrologists, geomorphologists, and chemists, the study of processes driving the physical and chemical templates have been embraced by stream ecologists for interpreting patterns in organismic distributions and lotic ecosystem structure and function. From a purely physical perspective, the primary function of rivers is to transfer runoff and move weathering products away from the Earth's land surfaces for delivery to the oceans or terminal water bodies. Despite tremendous variability in the morphology and behavior of rivers, each river reflects the interaction between geomorphic and hydrologic processes. We summarize these processes and their effect on river morphology, and discuss major physical and chemical drivers of river ecosystem dynamics and organismic biology.

Hydrologic Processes

The total amount of the Earth's water does not change. Water is continuously recycled among various storage compartments within the biosphere in a process referred to as the hydrologic cycle (Fig. 1). The cycle involves solar-driven evaporation of moisture from land and evapotranspiration from terrestrial vegetation, cloud formation, and precipitation.

Annual global precipitation averages about 100 cm; the majority of this evaporates and relatively little falls directly into streams. The remainder that falls on land surfaces either infiltrates into the soil or becomes surface runoff. Relative contributions of different

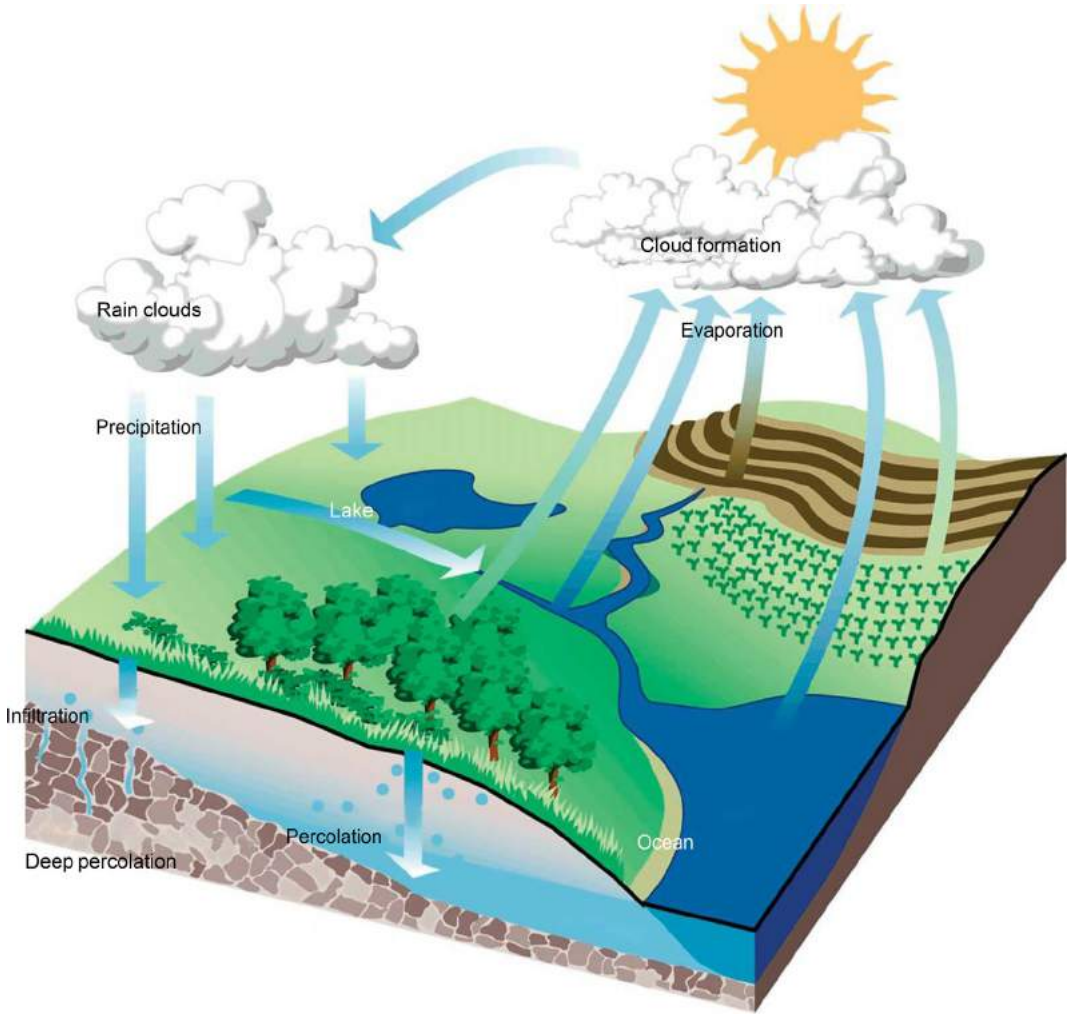

Fig. 1 The hydrologic cycle. From Stream Corridor Restoration: Principles, Processes, and Practices, 10/98, by the Federal Interagency Stream Restoration Working Group (FISRWG).

pathways by which water enters streams and rivers varies with climate, geology, watershed physiography, soils, vegetation, and land use.

Water that infiltrates becomes groundwater, which makes up the largest supply of unfrozen freshwater. Groundwater discharges gradually to stream channels through springs or direct seepage when a channel intersects the groundwater table. The hyporheic zone is the region beneath and alongside a streambed where shallow groundwater mixes with surface water. This zone plays an important role in lotic nutrient dynamics and benthic ecology.

Baseflow describes the proportion of total streamflow contributed from groundwater, and it sustains streamflow during periods of little or no precipitation. Streams can be distinguished on the basis of the balance and timing of stormflow versus baseflow that they receive. Ephemeral streams carry water only during and immediately after a precipitation event, and never intersect the water table. Intermittent streams flow only during certain times of year from springs or from runoff from precipitation, and may flow above or below the water table (Fig. 2). Perennial streams flow continuously during wet and dry periods, and receive both stormflow and groundwater flow. The duration, timing, frequency, magnitude, and predictability of flow greatly affect the composition and life-history attributes of stream communities. A study of 900 rivers published in the American Meteorological Society's Journal of Climate in 2009 concluded that river flows into the oceans have decreased significantly over the last 50 years as a result of changing patterns of precipitation and rising temperatures, and predicted a continuing trend of reduced runoff and greater water scarcity.

Discharge, the most fundamental of hydrological measurements, describes the volume of water passing a channel cross-section per unit time and is computed as the product of the cross-sectional area and the average velocity of water in the cross-section. Any increase in discharge must result in an increase in width, depth, or velocity of a stream channel, or some combination of these. Discharge usually increases in a downstream direction through tributary inputs and groundwater addition, accompanied by

Fig. 2 An intermittent stream at 3.4 km elevation in the Andes Mountains in Chile, bordered by riparian vegetation of herbs and grasses. Intermittent streams are often important in exporting invertebrates and organic detritus to downstream fish-bearing reaches. Photo credit: KW Cummins.

increases in channel width, depth, and velocity. An estimated 35,000 km^3 of water is discharged annually by rivers to the world's oceans, with the Amazon River alone accounting for nearly 15% of the total.

Hydrographs depict changes in discharge over time. The hydrograph of an individual storm event typically displays in succession a steep rising limb from direct runoff, a peak, and a gradually falling recession limb as the stream returns to prestorm conditions (Fig. 3). Variability in the shapes of hydrographs among streams reflects differences in the climatic, geomorphic, and geologic attributes of their watersheds, and differences in the distribution of runoff sources (e.g., subsurface vs. surface, snowmelt vs. rainfall-dominated).

Discharge records of sufficient duration allow prediction of the magnitude, frequency, and periodicity of flood events for a given river and year. Recurrence interval (T, in years) for an individual flood is estimated as

$$T = (n + 1)/m$$

where n is the number of years of record, and m is ranked magnitude of the flood over the period of record, with the largest event scored as $m = 1$. The reciprocal of T is the exceedance probability, which describes the statistical likelihood that a certain discharge will be equaled or exceeded in any given year. Thus, a 1-in-100-year flood has a probability of 1% of occurring in any given year. Recurrence interval information provides important context for interpretation of studies conducted on lotic organisms. Widespread alteration of the timing and magnitude of the natural flow regime of river systems throughout the world has resulted in reduced biotic diversity and loss of sensitive aquatic species.

Geomorphic Processes

Discharge and sediment supply represent the physical energy and matter that move through river systems, and the form and profile of rivers change over time to accommodate the energy and matter delivered to them. Sediments supplied to rivers originate primarily from the physical and chemical weathering of bedrock and soils, transported to rivers largely by direct runoff of rainfall

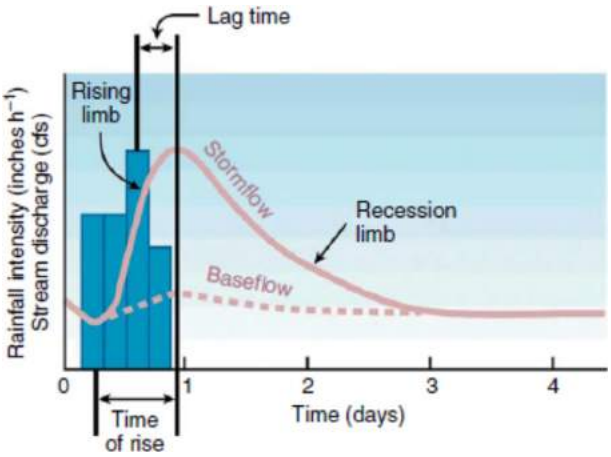

Fig. 3 Stream hydrograph from a rainstorm event. From Stream Corridor Restoration: Principles, Processes, and Practices, 10/98, by the Federal Interagency Stream Restoration Working Group (FISRWG).

and, especially in areas of unstable terrain, sometimes via mass wasting processes. Erosion of alluvial sediments stored within the channel, its banks, and floodplain also contribute to sediment supply.

Within a channel, sediment movement is initiated as a function of drag and lift forces exerted on deposited particles. The greater the shear stress exerted on the streambed, the greater the sediment particle size that can be entrained into the water column. Stream competence and stream capacity refer to the largest particle size moved by a given set of flows and the total amount of sediment that can be transported, respectively. Coarse sediment moves along the stream/river bottom as bedload, and fine sediment moves downstream in the water column as suspended load. As suspended particles absorb and scatter light, high concentrations of suspended sediment reduce light penetration needed for aquatic primary production. Sediment deposition occurs when water velocity falls below the settling velocity for a given particle size, with the largest particle sizes deposited first. Whereas sediments may be temporarily deposited within mid-channel or point bars, longer-term storage occurs on floodplains and elevated alluvial terraces.

Channel Morphology

Within a reach, channel cross-sections reflect the interaction between bed and bank materials and flow, and vary from symmetrical in riffles to asymmetrical in pools as flow meanders. Bankfull discharge occurs every 1.5–2 years on average in unregulated systems. The bankfull cross-sectional area of rivers (i.e., the product of surface width and mean depth) is correlated with streamflow and drainage area.

Channel pattern is described by its sinuosity (amount of curvature) and thread (multiple channel braiding). Sinuosity index is measured as channel length along the thalweg (a line drawn through the deepest points of successive cross-sections along the length of the channel), divided by valley length. Meandering channels have a sinuosity index value exceeding 1.5. Erosion of the channel bank carves the river bends, with the fastest current at the outside of the bend where the bank erodes. The greater the curve, the faster the water flows around the bend, deflecting to the other bank and forming the next curve. This pattern repeats downstream, creating regular swings in the river with a meander wavelength approximately 11 times the channel width.

Riffles are topographic high spots along the channel composed of the coarsest bedload sediments transported by the river, and with a water surface slope that is steeper than the mean stream gradient at low flow (Fig. 4). Riffles are typically spaced every five to seven channel widths in reaches that develop pool-riffle sequences. Pools are topographic depressions with fine sediments and reduced velocity. Reach types other than pool-riffle (e.g., cascades, step-pools, plane-bed) and channel geomorphic units other than pools and riffles (e.g., cascades, runs) have also been identified in stream classification schemes (e.g., Rosgen, 1996).

Change in discharge and sediment supply induce adjustments in river morphology on a time scale that increases with the length scale of morphological attribute. Channel width and depth dimensions adjust on a time step of years or less, and meander wavelength and reach gradient adjusts over hundreds of years or longer. Adjustments in the longitudinal profile of a river to changes in discharge and sediment supply occur over thousands of years. River profiles are generally concave, with declining gradients from headwaters to river mouths. The concavity reflects the adjustment between climate and tectonic setting (land relief and base level) and geology, which control sediment supply and resistance to erosion. Base level describes the limit to which a river cannot erode its channel. For streams emptying into the ocean, this is sea level.

Within a drainage basin, stream channels and their networks grow in size and complexity in a downstream direction as described by stream order (Fig. 5). A first-order stream lacks permanently flowing upstream tributaries and order number increases only where two streams of equal order join. Employing this system, the Mississippi and the Nile Rivers at their mouths are order 10. There are usually three to four times as many streams of order $n-1$ as of order n, each of which is roughly half as long, and drains a little more than one-fifth of the land area. In the United States, nearly half of the approximately 5,200,000 km of total river length are first

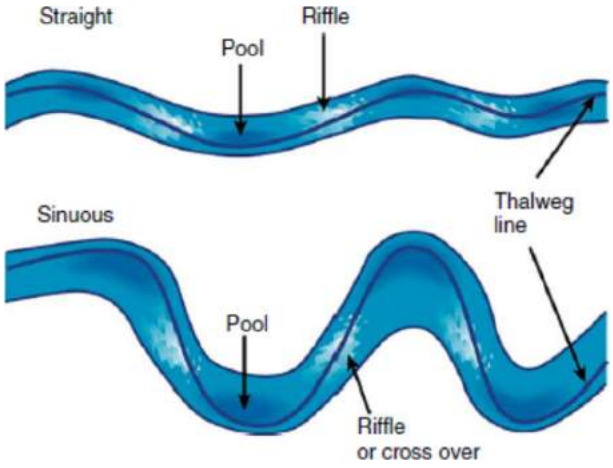

Fig. 4 Riffle and pool sequences in straight and sinuous streams. From Stream Corridor Restoration: Principles, Processes, and Practices, 10/98, by the Federal Interagency Stream Restoration Working Group (FISRWG).

order. As described in the River Continuum Concept, many patterns in biological composition and energy inputs have been found to be correlated with stream order.

Drainage basins, or watersheds, are the total area of land draining water, sediment, and dissolved materials to a common outlet. Watersheds occur at multiple scales, ranging from the largest river basins to first-order watersheds of only a few hectares. Larger watersheds are comprised of smaller watersheds and stream segments in a nested hierarchy. The size and shape of the watershed, and the pattern of the drainage network within the watersheds, exerts a strong influence on the fluxes of energy, matter, and organisms in river systems. Because some energy, matter, and organisms move across and through landscapes independently of drainage basins, a complete perspective of stream ecology requires consideration of landscape ecology.

Physical Factors

Current

Current, the central defining physical feature of running-water systems, refers to the downstream flow of water, propelled by gravity. The forward momentum of water is resisted by friction from the channel bed and banks and viscosity of the water (i.e., resistance to mixing). Velocity, or speed, of the current (m s^{-1}) shapes substrate composition, affects delivery of dissolved oxygen, nutrients, and food and removal of waste materials, and influences the physical forces exerted on organisms in the streambed or water column. Velocity rarely exceeds 3 m s^{-1} in running waters.

Flow in running waters is complex and highly variable in space and time. At a given velocity, flow may be laminar, moving in parallel layers which slide past each other at differing speeds with little mixing, or turbulent, where flow is chaotic and vertically mixed. The dimensionless Reynolds number (*Re*), the ratio of inertial to viscous forces, predicts the occurrence of laminar versus turbulent flow. High inertia promotes turbulence. Viscosity is the resistance of water to deformation, due to coherence of molecules. At $Re < 500$, flow is laminar; at $Re > 2000$ flow is turbulent; intermediate values have transitional flow. Although laminar flow is rare in running waters, microenvironments may contain laminar flow, even within turbulent, high-flow settings. *Re* can be estimated for individual organisms as well as for bulk flow. *Re* increased with the length of an organism. Organisms with high *Re*, such as trout, often exhibit a streamlined body shape to minimize turbulent drag.

In a channel cross-section, a vertical velocity gradient decreases exponentially with depth. Highest velocities are at the water surface where friction is least, and zero at the deepest point of the bottom where friction is the greatest. Mean current velocity is commonly found at 60% of the depth from the surface to the bottom. A boundary layer extends from the streambed to a depth where velocity is no longer reduced by friction and a thin viscous sublayer of laminar flow exists at its base.

Microorganisms and small benthic macroinvertebrates may experience shelter from fluid forces within the narrow sublayer very close to the streambed. However, the sublayer is so thin that most stream organisms must contend with complex, turbulent flow. A variety of morphological and behavioral adaptations in organisms reduce drag and lift forces and risks of downstream displacement. Attributes of macroinvertebrates, for example, can include small size, dorso-ventral flattening to reduce exposure to current, streamlining to reduce current drag, the development of silk, claws, hooks, suckers, and friction pads as holdfasts, and directed movement away from high-velocity areas.

Substrate

For riverine organisms, substrate provides food or a surface where food accumulates, a refuge from flow and predators, a location for carrying out activities such as resting, reproduction, and movement, and material for construction of cases and tubes. Algal growth, invertebrate growth and development, and fish egg incubation largely occur on or within the substrate. Substrate includes both inorganic and organic materials, often in a heterogeneous mixture. Mineral composition of the substrate is determined by parent geology, modified by the current. Organic materials include aquatic plants and terrestrial inputs from the surrounding catchment ranging from minute fragments and leaves to fallen trees (Fig. 6).

Particle sizes of mineral substrates are commonly categorized using the Wentworth scale, in which each size category represents a doubling of the diameter of the next smaller size category (Table 1). Organic substrate particles <1 mm in diameter and >0.45 μm are classified as fine particulate organic matter or PFOM, and often function as food rather than substrate for benthic organisms. Organic materials >1 mm in diameter are referred to as coarse particulate organic matter or CPOM. CPOM serves as substrate or food for litter-feeding invertebrates (Fig. 7). Large woody debris (LWD) is at the upper end of the size range of CPOM, and is used more often as substrate than invertebrate food. Although different definitions are in use, a common definition specifies large woody debris (LWD) as any piece of wood that is greater than, or equal to 10 cm in diameter over a length of 1.5 m or more. Other than particle size, substrate attributes including shape, surface texture, sorting, and stability also influence benthic community structure, but these are less easily quantified. Diversity, biomass, and abundance of benthic invertebrates generally increases with mineral particle size from sand to pebbles and cobble, but decreases for large boulders and bedrock.

Evaluation of the ecological role of substrate is difficult because of its heterogeneity and covariance with velocity and oxygen supply. Mean particle size generally decreases downstream, but this trend may be locally interrupted at tributary junctions. Spatial heterogeneity in substrate at multiple scales is also apparent both vertically and horizontally within the streambed. Substrate embeddedness describes the degree to which larger sediments, such as cobbles, are surrounded or covered by fine sand and silt. Significant embeddedness reduces streambed surface area and organic matter storage, the flow of oxygen and nutrients to incubating fish eggs and aquatic invertebrates, and entrance to and movement within the streambed.

Temperature

Temperature affects all life processes, including those in running waters. Decomposition, primary production, community respiration, and nutrient cycling are temperature dependent. Most stream organisms are ectothermic, and their metabolism, growth rates, life cycles, and overall productivities are temperature dependent. Annual temperature changes often serve as environmental cues for and/or regulate life-history events of invertebrates and fishes, especially emergence or spawning. The temperature regime sets limits to where species can live, and many species are adapted to specific thermal regimes. Increasing water temperature decreases dissolved oxygen solubility at the same time that it increases metabolic demand. Thus preferences of coldwater organisms such as salmonid fishes may have as much to do with temperature effects on oxygen availability as with effects of temperature per se.

Stream temperature is the net result of heat exchange via (1) net solar radiation, modified by cloud cover, day length, sun angle, vegetation, and topographic shading; (2) evaporation and convection; (3) conduction, or heat exchange with the streambed; and (4) advection from upstream water inputs, including groundwater and tributaries. On a diel basis, stream temperature varies less than air temperature because of the high specific heat of water. The greatest daily fluxes occur in summer in temperate regions, with a minimum before dawn. Groundwater inputs, which usually enter the channel at a temperature within 1°C of mean annual air temperature, can greatly affect the flux, as can canopy cover. At the catchment level, daily temperature flux increases with distance from the headwaters, with a maximum in mid-order segments. Thermal stratification is rare except in large rivers and at tributary junctions. Seasonal variations in temperature mirror trends in mean monthly air temperature, with the timing of the summer maximum often lagging the timing of maximum solar radiation. Year-to-year variation in monthly mean temperatures is low, typically less than 2°C. The annual temperature range of temperate streams is generally 0–25°C, and 0–40°C in intermittent desert

Fig. 6 Small headwater stream in old-growth Douglas-fir forest in Oregon (United States), showing large woody debris spanning the channel. This spanner log forms a retention structure for organic detritus and sediment as well as refugia and habitat when the channel is inundated by high flows. Photo credit: MA Wilzbach.

Table 1 Size categories of inorganic substrates in streams and rivers, based on the Wentworth grain size scale

Size category	*Particle diameter (range in mm)*
Boulder	>256
Cobble	
Large	128–256
Small	64–128
Pebble	
Large	32–64
Small	16–32
Gravel	
Coarse	8–16
Medium	4–8
Fine	2–4
Sand	
Very coarse	1–2
Coarse	0.5–1
Medium	0.25–0.5
Fine	0.125–0.25
Very fine	0.063–0.125
Silt	<0.063

Fig. 7 Accumulation of leaf litter in a second-order stream in Oregon (United States) flowing through a second-growth forest with a red alder riparian zone. The litter that is retained at the leading edge of the cobbles provides the major food resource for stream invertebrate shredders and habitat for other invertebrates. Photo credit: KW Cummins.

streams. The lower Amazon River is always within one or two degrees of 29°C. Extremes in temperature occur in hot springs, which can exceed 80°C, and in subarctic and arctic streams that may completely freeze in winter. Surface freezing is usually prevented by snow and ice bridging, but underwater ice may form on streambeds as anchor ice or in the water column as slush or frazil.

Stream ecologists often evaluate temperature effects on stream organisms and ecosystem processes based on degree-day accumulation rather than temperature maxima or minima. Degree-days, which are calculated by summing daily mean temperatures above 0°C, can differ among streams with similar maximum or minimum average daily temperatures. Such differences can affect number of annual generations of aquatic insects and production potential of aquatic organisms.

Water chemistry

Constituents of river water include dissolved gases, dissolved inorganic ions and compounds, particulate inorganic material, particulate organic material, and dissolved organic ions and compounds. Primary dissolved gases are oxygen, carbon dioxide, and nitrogen. Dissolved inorganic ions and compounds include major and minor ion groups and trace elements, which occur in minute quantities, such as copper, zinc, iron, and aluminum. Minor ions such as nitrogen and phosphorus are nutrients essential to plant and animal growth. Major ion groups include cations of calcium, magnesium, sodium, and potassium and the anions bicarbonate, sulfate, and chloride.

Concentrations of dissolved gases and major ions affect pH, which measures hydrogen ion activity. The pH affects many cellular processes of organisms and determines the solubility and biological availability of nutrients and heavy metals. Hardness measures calcium and magnesium concentrations, and is associated with but not identical to alkalinity, which measures the ability of streamwater to absorb hydrogen ions, thus buffering changes in pH. Alkalinity is primarily due to bicarbonate and carbonate ions.

Total dissolved solids, the sum of the concentrations of major cations and anions, is often estimated as specific conductance. Hardness, alkalinity, and ionic concentrations are often positively correlated with stream productivity and taxonomic richness. Particulate inorganic and organic materials together make up the suspended load in lotic systems, and contribute to turbidity.

Carbon dioxide and oxygen are the most biologically important dissolved gases. Diffusion from the atmosphere maintains concentrations of both oxygen (O_2) and carbon dioxide (CO_2) in streams at close to equilibrium. However, CO_2 is more soluble in water than is O_2, which is 30 times less available in water than air. Groundwater and sites of organic matter decomposition are low in O_2 and enriched in CO_2. Photosynthesis and respiration can alter diel concentrations of oxygen and carbon dioxide in productive systems, with O_2 elevated and CO_2 reduced during the day, and the reverse occurring at night. Where production is high relative to diffusion, diel changes in O_2 concentration can be used to estimate photosynthesis and respiration. Because current and turbulence continually renew O_2 supply, O_2 concentrations are usually problematic for stream organisms only in sites severely contaminated with organic pollutants, or in conditions of high temperatures, drought, and dense populations of aquatic plants. Low-oxygen concentrations are better tolerated by stream animals at faster than slower current speeds.

Natural spatial variability in lotic chemistry largely reflects differences in the types of rocks available for weathering and the amount, chemical composition, and distribution of precipitation. For example, total dissolved solids are approximately twice as great in rivers draining sedimentary terrain compared to those draining terrain of igneous and metamorphic rock. Most rivers contain 0.01%–0.02% dissolved minerals, about 1/20–1/40th the salt concentration of the oceans, with an average concentration of 100 mg L^{-1}. Generally $\geq$50% of this is bicarbonate and 10%–30% is chloride and sulfate. River water contains more dissolved solids than does rainwater, because of evaporation, weathering, and anthropogenic inputs. Rainwater, although nearly pure, contains dissolved minerals from dust particles and droplets of ocean spray.

Rainwater is also naturally acidic due to atmospheric carbon dioxide dissolving in water droplets, forming a weak carbonic acid (H_2CO_3). In catchments with erosion-resistant rock, little buffering capacity, or where decaying plant matter is abundant, stream-water can be acidic even in the absence of pollution. Water percolating through the soil enters the stream enriched with CO_2 from plant and microbial respiration, and forms carbonic acid. The carbonic acid dissolves the calcium carbonate in rocks, producing calcium bicarbonate, which is soluble in water and the source of carbon atoms for aquatic photosynthesis. Dissolution of calcium carbonate increases the amount of stream calcium and bicarbonate ions and the latter dissociates to carbonate ions. At equilibrium, bicarbonate and carbonate ions dissociate, forming hydroxyl ions and resulting in weak alkaline waters, with a pH >7. At equilibrium, water resists changes in pH because the addition of hydrogen ions is neutralized by the hydroxyl ions formed by dissociation of bicarbonate and carbonate, and added hydroxyl ions react with bicarbonate to form carbonate and water. Thus the buffering capacity of a stream is largely determined by its calcium bicarbonate content. The pH of most natural running waters ranges between 6.5 and 8.5, with values below 5 or above 9 being harmful to most stream organisms. Industrially derived sulfuric and nitric acids have seriously lowered pH in surface waters of large areas of Europe and North America, resulting in reduced species diversity and density.

The Adapted Biota

Many taxonomic groups inhabit running waters. Key biological attributes, life histories, and distribution patterns of major groupings of organisms that play a central role in energy flux within trophic webs or that are of significant human interest—namely algae, macrophytes, benthic macroinvertebrates, and fishes—are summarized below.

Algae

Algae are the most important primary producers in running-water ecosystems and are drivers of biogeochemical cycling. Because of their sessile nature and short life cycles, algal assemblages are often used to evaluate stream ecosystem health and are particularly precise indicators of ecological change from nutrient contamination and agricultural land use. Algae lack vascular tissue, bear chlorophyll *a* and lack multicellular gametangia. Algal evolution has radiated to include several diverse kingdoms. For example, blue-green algae are classified as bacteria, and dinoflagellate algae as protozoans. Algal taxonomy is based on pigmentation, the chemistry and structure of internal storage products and cell walls, and the number and type of flagella. Divisions of algae common in streams include the Bacillariophyta (diatoms), Chlorophyta (green algae), Cyanophyta or Cyanobacteria (blue-green algae), Chrysophyta (yellow-green algae), and Rhodophyta (red algae). Of these, the diatoms, green algae, and cyanobacteria are most prevalent. Assemblages of benthic algae attached to submerged substrates are dominant members of the periphyton (also referred to as biofilm or aufwuchs), which represents a complex assemblage of algae, detritus, bacteria, fungi, and meiofauna held together in a polysaccharide matrix. Free-floating algae within the water column, the phytoplankton, occur chiefly in slowly moving lowland rivers as sloughed benthic cells or as exports from connected standing waters.

Diatoms are extremely abundant in freshwater, and typically contribute the majority of species within the periphyton. Generally microscopic, diatoms are brownish-colored single-celled algae constructed of two overlapping siliceous cell walls, or valves, fit together like the halves of a petri dish to form the frustule. Valves are connected to each other by one or more "girdle" bands. Diatoms are largely classified to genus on the basis of unique cell ornamentation, which may include pores (punctae), lines (striae), or ribs (costae). The symmetry of these decorations defines two groups: radially symmetrical centric diatoms and bilaterally symmetrical pennate diatoms. Diatoms may occur individually, in chains, or in colonies, and those with a divided cell wall

(raphe) are able to move. In temperate streams, diatoms commonly exhibit two blooms: in spring prior to shading by deciduous canopies as water temperatures rise and nutrients are plentiful; and in fall following leaf abscission, when nutrients released from decaying green algae and deciduous litter are available. Diatoms constitute a high-quality, rapid-turnover food resource for many stream invertebrates. Representative diatoms common in stream periphyton are shown in Fig. 8.

Green algae can be unicellular or multicellular, occur in a variety of habitats, and are taxonomically distinguished by the number and arrangement of flagella, their method of cell division, and their habitat. Green algal forms may be microscopic or readily visible without a microscope as a thallus (undifferentiated body tissue) or as colonies of filaments. Filamentous forms may be branched or unbranched. Green algae provide attachment sites for diatoms, and are a source of FPOM and photosynthetic oxygen, but are not a major source of food for most herbivorous invertebrates.

Blue-green algae, or cyanobacteria, are prokaryotic organisms of ancient lineage which contain the photosynthetic pigment phycocyanin, used to capture light for photosynthesis. They occur in a variety of habitats and are one of very few groups of organisms that can convert inert atmospheric nitrogen into an organic form. Blue-green algae may be filamentous or nonfilamentous, and only filamentous forms with heterocysts are capable of nitrogen fixation in aerobic settings. Several of the heterocyst-containing filamentous taxa (e.g., *Anabaena*, *Aphanizomenon*, and *Microcystis*) can form dense blooms and produce toxins in warm, nutrient-rich waters. Nitrogen-fixing *Nostoc*, common in small streams, forms a unique commensal association with the chironomid midge *Cricotopus*.

Macrophytes

Macrophytes include vascular flowering plants, mosses and liverworts, some encrusting lichens, and a few large algal forms such as the Charales and the filamentous green alga *Cladophora*. Light and current are among the most important factors limiting the occurrence of macrophytes in running waters. Macrophytes can be categorized into those that are attached to the substrate, those that are rooted into the substrate, and free-floating plants. Attached plants include the mosses and liverworts, certain lichens, and some flowering plants of the tropics. The attached macrophytes are predominantly found in cool, headwater streams. Mosses are unusual in their requirement for free CO_2, rather than bicarbonate, as their carbon source. In shaded, turbulent streams, their contribution to primary production may override that of periphyton. Mosses also support very high densities of macroinvertebrates. Rooted plants include submerged (e.g., Hydrocharitaceae, Ceratophyllaceae, and Halorgidaceae) and emergent (e.g., Potamogetonaceae, Ranunculaceae, and Cruciferae) forms. They usually require slow currents, moderate depth, low turbidity, and fine sediments for rooting. Rooted plants are most common in mid-sized rivers and along the margins of larger rivers where they reduce current velocity, increase sedimentation, and provide substrate for epiphytic microflora. They also provide valuable habitat for some animals. Tough, flexible stems and leaves, attachment by adventitious roots, rhizomes or stolons, and vegetative reproduction are among the adaptations of macrophytes to running water. Free-floating plants (e.g., Lemnaceae and Pontederiaceae) are of minor importance in running waters at temperate latitudes as they depend largely on standing-water conditions. They may accumulate significant biomass in subtropical and tropical settings. Macrophytes in lotic ecosystems contribute to energy flow predominantly through decomposer food chains, as few macroinvertebrates feed on the living plants.

Benthic Macroinvertebrates

Three invertebrate phyla are common in running waters: Annelida (segmented worms), Mollusca (snails, clams, and mussels), and Arthropoda (crustaceans and insects). Both annelids and molluscs are of marine evolutionary origin. While often abundant in fine and coarse sediments in rivers, aquatic annelids are challenging to identify, and information about their distribution in river systems is poorly understood. Molluscs are most abundant and diverse in larger rivers. Arthropoda dominate the headwaters, but are abundant all along drainage networks. Representative taxa are illustrated in Fig. 9.

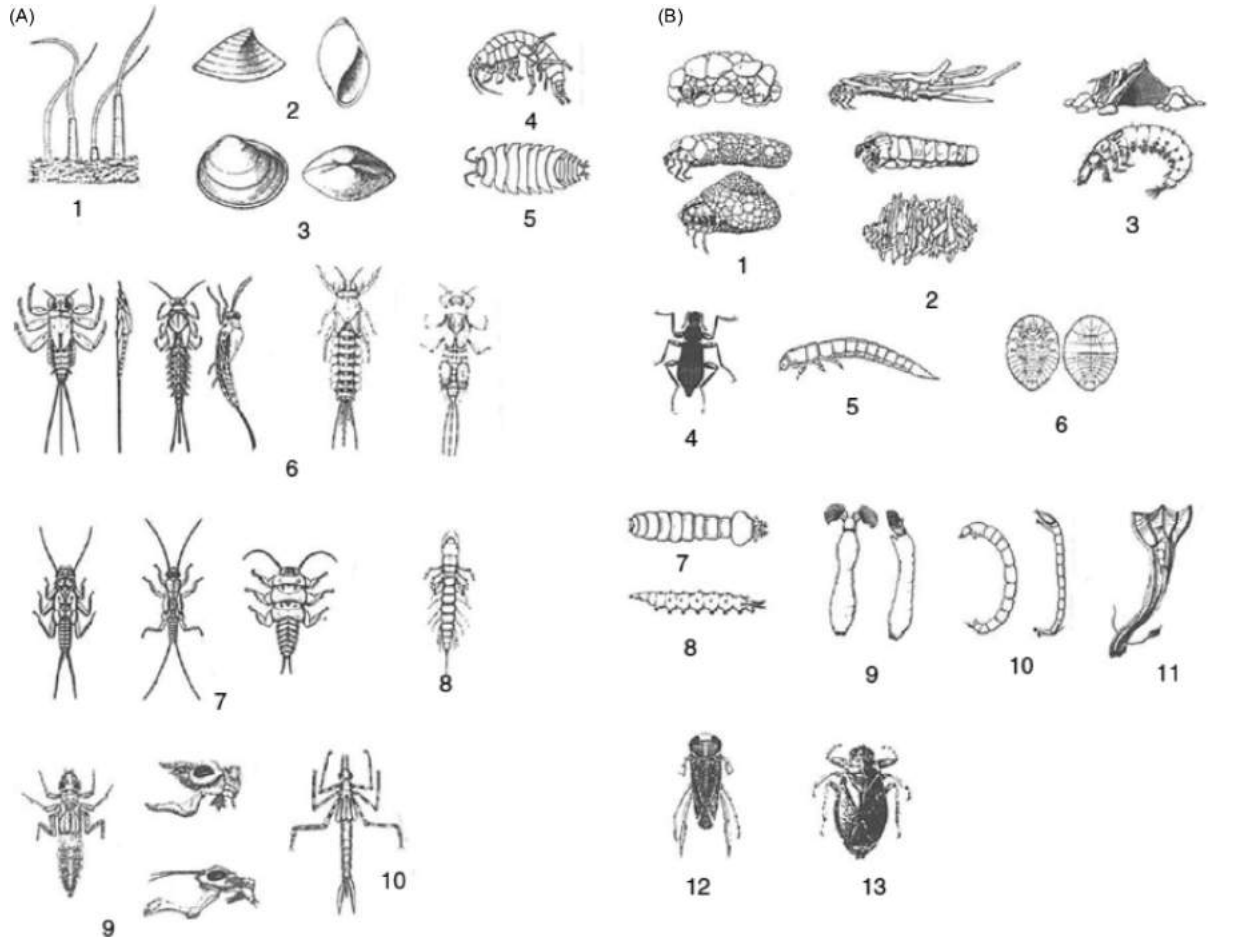

Fig. 9 (A) Examples of lotic benthic invertebrates. 1, Annelida, Oligochaeta (Tubificidae); 2, Mollusca, Gastropoda (*left*, Ancylidae; *right*, Physidae); 3, Mollusca, Bivalvia (Spaeridae: *left*, lateral view*; right*, dorsal view); 4, Crustacea, Amphipoda; 5, Crustacea, Isopoda; 6, Insecta, Ephemeroptera; 7, Insecta, Plecoptera; 8, Insecta, Megaloptera (Sialidae); 9, Insecta, Odonata, Anisoptera (*left*, nymph; *right upper*, lateral view of head with extended labium; 10, Insecta, Odonata, Zygoptera (*right*, nymph; *left lower*, lateral view of head with extended labium). (B) Examples of lotic benthic invertebrates. 1, Insecta, Tricoptera (mineral case bearers); 2, Insecta, Trichoptera (organic case bearers); 3, Insecta, Trichoptera (net spinner, fixed retreat above); 4, Insecta, Coleoptera (Elmidae adult); 5, Insecta, Coleoptera (Elmidae larvae); 6, Insecta, Coleoptera, Psphenidae larvae (*left*, ventral; *right*, dorsal); 7, Insecta, Diptera, Tipulidae; 8, Insecta, Diptera, Athericidae; 9, Insecta, Diptera, Simuliidae (*left*, dorsal; *right*, lateral view); 10, Insecta, Diptera, Chironomidae (*left*, Chironominae; *right*, Tanypodinae); 11, Insecta, Diptera, Chironomidae (filtering tube of *Rheotanytarsusi*); 12, Insecta, Hemiptera, Corixidae; 13, Insecta, Hemiptera, Belastomatidae.

The Oligochaeta are the most abundant and diverse of the freshwater annelids, and are notable for their ability to inhabit low-oxygen environments. Oligochaetes inhabit the sediments, some in tubes, and are almost all gathering-collector detritivores. Their bodies are segmented with two pairs of stout, lateral chetae on each segment. Leeches (Hirudinea), a minor annelid group occurring in small streams to mid-sized rivers, feed as gathering collectors, predators, or ectoparasites.

A calcium requirement for shell formation limits the distribution of gastropod (limpets and snails) and bivalve (clams and mussels) molluscs in streams and rivers. Limpets, such as *Ferrissia* (Ancylidae), frequent small, fast-flowing streams where their hydrodynamic shape and sucker formed by the mantle allow them to move over rocks in the current and scrape loose attached algal food with a rasping radula. Snails, such as *Physa*, are abundant scrapers in river macrophyte beds that use radulae to rasp vascular plant surfaces, removing periphyton and epidermal plant tissue. Clams and mussels are filtering collectors that burrow in the sediments with their incurrent and excurrent siphons exposed, pumping water in to extract dissolved oxygen and FPOM, and out to eliminate wastes. Bivalve mollusks are sensitive to water quality and have been used worldwide as indicators of lotic ecosystem health. Mollusks are one of the most imperiled groups of animals worldwide: of 693 recorded extinctions of animal species since 1500, 42% have been mollusks, almost entirely nonmarine forms. In the United States and Canada, 202 of 300 freshwater unionoid clams are presumed extinct or critically imperiled.

Common Crustacea of running waters include Amphipoda (scuds), Isopoda (aquatic pill bugs), benthic Copepoda (Harpacticoida), and Decapoda (crayfish and freshwater shrimps). Most isopods and amphipods (except *Hyallela*) are detrital shredders feeding on stream-conditioned riparian litter in headwater streams. Although decapod shrimps and crayfish have species found in all sizes of running waters, the former tend to be more abundant in streams, the latter in mid-sized rivers. Decapods are scavengers and facultative shredders of plant litter. These crustaceans have always been of interest because of their large size,

commercial food and bait value, and importance as food for large game fish. The minute harpacticoid copepods are poorly known, but are often found in small streams to large rivers where they feed on fine particulate organic matter.

Aquatic insects (Arthropoda) are the most conspicuous and best-studied invertebrates of running waters. They can be subdivided into the more primitive hemimetabolous orders, in which immature nymphs gradually metamorphose into mature winged adults, and the more evolved holometabolus orders that have larval and pupal stages. Insect growth is accomplished by the nymphs or larvae over weeks to years, while the adults feed little and are short lived (a day to weeks). Thirteen orders of aquatic or semiaquatic (occurring at lotic margins) taxa have been distinguished. The hemimetabolous mayflies (Ephemeroptera), stoneflies (Plecoptera), dragonflies and damselflies (Odonata), and the holometabolous caddisflies (Trichoptera), and dobsonflies and alderflies (Megaloptera) all have aquatic larvae. These signature taxa are represented in almost all unpolluted lotic ecosystems. Mayflies, which are the only insects that molt as winged subadults (subimagos) to sexually mature adults (imagos), are commonly imitated in the sport of flyfishing. All of the odonate and about half of the plecopteran nymphs are predaceous. The dragonflies and damselflies occur in small streams to large rivers, with many species associated with aquatic vascular plants. Nonpredaceous stonefly nymphs feed by shredding conditioned riparian litter. Some of the predaceous Megaloptera are among the largest of the lotic aquatic insects, and they are typical of slow-flowing areas and often associated with submerged woody debris.

Caddisflies are a large aquatic order in which a majority of species construct portable cases made of plant pieces (characteristic of shredders) or mineral particles (characteristic of scrapers) held together with silk extruded from glands in the head. All the cases are lined with silk into which hooks on the hind prolegs are hooked to maintain the larvae in the case. Larvae circulate water through the case by undulating the abdomen to irrigate the gills and integument and to facilitate respiration. Five families of Trichoptera larvae, and all families in the pupal stage, construct nonportable, fixed retreats of organic and mineral material. Most larvae of the five families spin silk nets with which they filter out FPOM food from flowing water. Species of the family Rhyacophilidae are free-ranging without cases and almost exclusively predaceous.

The holometabolous Coleoptera (beetles), Diptera (true flies), Lepidoptera (aquatic moths), and Hymenoptera (aquatic wasps) constitute the largest insect orders and have some aquatic or semiaquatic representatives, as do the spongeflies of the Neuroptera. The beetles are the only aquatic insects with representatives in which both the larvae and adults live in the water. One family of Diptera, the midges (Chironomidae), is usually more abundant and diverse in running waters than all other aquatic insects combined. Chironomid species are found in all lotic habitats and all functional feeding group categories. Difficulty in identifying Chironomid larvae has hampered their use in ecological studies. Very few aquatic moths occur in running waters. Hymenoptera, a large terrestrial order containing many social species, has some parasitic forms in which the females enter the water to oviposit in the immatures of aquatic and semiaquatic orders. The larvae of spongeflies inhabit freshwater sponges where they feed directly on sponge tissue or prey upon other animals.

The hemimetabolous Hemiptera (true bugs), Orthoptera (grasshoppers, etc.), and Collembola (springtails) have aquatic or semiaquatic species. All widely distributed hemipterans are active predators, occupying a full range of slow water and marginal habitats where they capture prey and imbibe their body fluids using piercing mouth parts. Orthoptera and Collembola of running waters are all semiaquatic and function as detritus-gathering collectors. We further describe functional feeding roles in Rivers and Streams: Ecosystem Dynamics and Integrating Paradigms.

Fishes

Fishes, the principal group of vertebrates found in running waters, are of great human interest because of their commercial and recreational value. Approximately 46% (about 15,000 species) of the estimated total number of the world's fishes live in freshwater. Almost all freshwater fish taxa have representatives that occur in running waters, with varying degrees of river dependency and saltwater tolerance. Groups with little or no tolerance for saltwater (e.g., Cyprinidae, Centrarchidae, and Characidae) are classified as primary freshwater fishes; these have dispersed through freshwater routes or evolved in place from distant marine ancestors. Secondary freshwater fishes (e.g., Cichlidae and Poeciliidae) have some tolerance to seawater but are usually restricted to freshwater. Diadromous fishes migrate between freshwater and saltwater. Anadromous fishes, including many salmonids, lampreys, shad, and sturgeon, spend most of their lives in the sea and migrate to freshwater to reproduce. American and European eels are catadromous fishes, which spend most of their lives in freshwater and migrate to the sea to reproduce. Catadromy appears to be more prevalent in the tropics, with anadromy more common at higher latitudes.

Researchers have commonly observed longitudinal gradients of fish assemblages in river systems, resulting in numerous attempts to classify stream zones by the dominant fish species or assemblage found. Because fish faunas vary considerably among geographic and climatic regions, zonation schemes usually have only regional application. Longitudinal gradients arise as the result of species addition and/or replacement, and reflect adaptations to type and volume of habitat and available food along the river continuum. Fishes occupying headwater reaches, typified by salmonids and sculpins, have high metabolic rates and demands for oxygen. Salmonids are active, streamlined fishes with strong powers of locomotion, which maintain position in swift water to feed upon drifting invertebrates. Sculpins, with depressed heads and large pectoral fins, hold close to the streambed and forage for invertebrates among stones on the bottom. Upstream fishes are usually solitary in habit and may exhibit territoriality associated with breeding, food, or spatial resources. Their distribution extends downstream where oxygen and temperatures are suitable, to join deeper-bodied fishes tolerant of warmer temperatures and reduced oxygen. Species richness is usually greatest in the mid-order segments, in association with overall habitat heterogeneity and increased pool development. In high-order reaches, fish assemblages include larger, deep-bodied fishes such as suckers and catfishes feeding on bottom deposits, planktivorous fishes, and fishes that feed on large molluscs.

Rocky Intertidal Zone

PS Petraitis and JAD Fisher, University of Pennsylvania, Philadelphia, PA, USA
S Dudgeon, California State University, Northridge, CA, USA

Introduction

The British ecologist A. J. Southward described the intertidal zone as ``the region of the shore between the highest level washed by the waves and the lowest level uncovered by the tide,'' and thus communities on rocky intertidal shores are primarily defined by the tides and the presence of hard surfaces. The types of organisms, the number of species, and the distribution and abundance of individual species found in a particular rocky intertidal community also depend on the physical aspects of the shore, the supply of resources, food and larvae from overlying water, the biological interactions among the species present, and the regional pool of species. Although rocky intertidal shores cover only a small fraction of the Earth's surface, they contain a large diversity of organisms – ranging from highly productive microalgae to transient vertebrate predators (Fig. 1).

Physical Aspects of the Shore

Tides

Tides are caused by the gravitational effects of the Moon and Sun, which ideally produce a cycle of two high tides and two low tides per day. However, the amplitude and frequency of the tides are altered by the phases of the Moon, the Earth's orbit and declination, latitude, and the configurations of the shoreline and the seafloor. The tidal range tends to be smaller toward the equator and can vary from several meters in high latitudes to less than tens of centimeters near the equator. Configuration of the coast and the ocean basin can cause harmonic resonances and create tides that vary dramatically in amplitude and frequency. In extreme cases, the reinforcing and canceling effects can produce a single high and low tide per day or almost no change over the course of a day.

The timing of low tides can have a profound effect by exposing organisms to extreme conditions. For example, the lowest tides in the Gulf of Maine, USA tend to occur near dusk or dawn, and so organisms are rarely exposed to mid-day sun in the summer but are often exposed to below freezing temperatures on winter mornings. In contrast, the lowest summer tides in southeastern Australia occur mid-day and expose organisms to extraordinarily high temperatures.

Characteristics of the Shore

Any firm stable surface in the intertidal zone has the potential to support the organisms that commonly occur in rocky intertidal communities, and at low tide, intertidal habitats can range from dry rock to filled tide pools. Rock surfaces can vary from very hard to relatively soft rock such as from granite to sandstone and can range from smooth platforms to irregular fields of stone cobbles and boulders. Topography, inclination, color, and texture of the rock affect rate of drying and surface temperature, which can limit the distribution and abundance of species. Man-made surfaces such as rock jetties and wooden pier pilings and biogenic surfaces such as mangrove roots can also support communities that are indistinguishable from the communities found on nearby rocky shores.

Tide pools can be very different than the surrounding shore because of thermal variability, changes in salinity from evaporation and runoff, and changes in pH, nutrients, and oxygen levels caused by algae. Pools often support residents such as sea urchins, snails, and fish that would otherwise be restricted to subtidal areas.

The amount of wave surge affects the types of organisms found on the shore and their distribution. Wave surge and breaking waves tend to expand the extent of the intertidal zone and distribution of species by continually wetting the shore and allowing species to extend farther up the shore. Wave surge can also cause mobile animals to seek refuge and can limit the distribution of slow moving species, and the force of breaking waves can damage and sweep away organisms. Sand and debris such as logs swept up by the waves can scour organisms off the surface. In areas of low wave surge, sedimentation of sand and silt may bury organisms or clog gills and other filter-feeding structures.

Attached Organisms

Unlike terrestrial habitats, which depend largely on local plant material to support resident animal populations, rocky intertidal assemblages are supported not only by algal primary production but also by secondary production from suspension feeders, such as barnacles and mussels, which link the ocean's productivity to the shore.

Fig. 1 Closeup of predatory snails, mussels, barnacles, and brown algae in Maine, USA. Photo by P. S. Petraitis.

Algae

The term `algae' refers to an extraordinarily diverse and heterogeneous group comprising about seven major lineages, or roughly 41% of the kingdom-level branches in the Eukarya domain. Most lineages consist of unicellular microalgae, but the multicellular macroalgae that dominate many rocky shores worldwide occur in only three groups (Rhodophyta, Chlorophyta, and Phaeophyta) (Fig. 2).

Microalgae are ubiquitous and although inconspicuous, they are important members of rocky intertidal communities. For example, diatoms are the primary food source of many grazing gastropods and form biofilms, which facilitate settlement of invertebrate larvae and stabilize meiofaunal assemblages.

Benthic macroalgae (i.e., seaweeds) dominate many rocky shores, especially the low- and mid-intertidal zones of temperate regions, and many exhibit morphologies adaptive for life on wave swept shores. The idealized body plan of a seaweed consists of a holdfast, a stipe, and one or more blades. The holdfast usually attaches the alga either by thin encrusting layers of cells tightly appressed to the rock surface or by a massive, thick proliferation of tissue that often produce mucilaginous `glues' to adhere the tissue to the rock. The stipes are analogous to plant stems and display remarkable material properties that enable seaweeds to withstand the tremendous hydrodynamic forces imposed by breaking waves. The blade is the principal structure for the exchange of gases and nutrients, and the capture of light for photosynthesis. Blades also contain reproductive tissue, either within a vegetative blade, or in sporophylls (i.e., special blades for reproduction). Some larger brown seaweeds, such as fucoids and kelps, have gas-filled floats called pneumatocysts that buoy the blade so that it remains closer to the surface where light intensity is greater.

The diversity and complexity of the life cycles of most seaweeds contributes to their great abundance on rocky shores. The life cycle of most seaweeds consists of an alternation of separate gametophyte and sporophyte generations. The two generations can either look the same (i.e., isomorphic) or different (heteromorphic). In some species, the heteromorphic generations are so different that they were originally described as different species. Heteromorphic life histories are hypothesized to represent an adaptation to grazing pressure, and heteromorphic generations clearly show tradeoffs with respect to competitive ability, resistance to disturbance and longevity associated with upright foliose and flat encrusting morphologies.

Sessile Invertebrates

Adults of many invertebrate species are attached permanently to the rock or other organisms (epibiota). These include members of the phyla Porifera (sponges), Cnidaria (hydroids and sea anemones), Annelida (tube-building polychates), Arthropoda (barnacles), Mollusca (mussels and clams), Bryozoa (moss animals), and Chordata (tunicates). Suspension feeding – either by pumping water through a sieve structure or trapping particles carried on induced or external currents – is a common feature of sessile animals and serves to transfer inputs of energy and nutrients produced in the water column into the intertidal zone via the ingestion of plankton. Additionally, by feeding on locally derived detritus, suspension feeders capture some of the nutrients that are produced by neighboring inhabitants.

Sessile intertidal animals are often physically or chemically defended against predation and display plastic phenotypes in response to changing environmental conditions because they are fixed in place and cannot move to avoid predators. For example, the presence of the predatory gastropod *Acanthina angelica* induces change in the shell shape of its barnacle prey *Chthamalus anisopoma*, and the barnacle forms a curved shell making it more difficult for the predator to attack.

Fig. 2 Extensive brown algal beds in Maine, USA. Photo by P. S. Petraitis.

Mobile Organisms

Mobile invertebrates and vertebrates that are found on rocky intertidal shores are typically divided into two categories based on the amount of time spent between tidemarks. Resident species remain in the intertidal zone throughout most of their life and face a large range of local physical conditions that they mitigate by a variety of behavioral and physiological adaptations. Many residents find shelter during low tides, either between rocks, under algae, or in tide pools, while other species attach to exposed rock surfaces just ahead of the incoming tide. Transient species are those that spend only a small part of their life cycles in the intertidal zone (e.g., as juveniles) or are those that enter and leave the intertidal zone during low or high tide.

Invertebrates

Large, mobile invertebrate consumers are ecologically the most intensively studied guild on rocky shores and include species from Turbellaria (flatworms), Crustacea (e.g., crabs, shrimp, amphipods, and isopods), Annelida (e.g., polychaetes), Gastropoda (e.g., snails, nudibranchs, and chitons), and Echinodermata (sea urchins, brittle stars, and sea stars). Herbivores range from grazers of diatom films to browsers of macroalgae, and predators exploit a variety of methods (crushing, stinging, drilling, and partial consumption) to overcome the defenses of their prey.

Small mobile metazoans (roughly 0.1–1 mm and collectively termed meiofauna) thrive on and among the algae, animals, and the trapped sediments on rocky shores. Meiofauna include consumers from many invertebrate phyla, that – due to their small sizes, extremely high abundances, and high turnover rates – are an important guild of consumers whose effects have largely been neglected in comparison to studies of larger invertebrates.

Vertebrates

Vertebrates tend to be transient species that use the intertidal zone to feed or hide and include fish and marine mammals that enter at high tide and birds and terrestrial mammals that enter at low tide (Fig. 3). For instance, marine iguanas (*Amblyrhynchus cristatus*) of the Galápagos Islands, Ecuador forage extensively on intertidal algae on lava reefs during low tides. The major exceptions are resident intertidal fishes, which are often cryptic and less than 10 cm in length. Resident and transient fishes include hundreds of species from dozens of families, though members of the families Blenniidae, Gobiidae, and Labridae are the most common.

Birds and mammals, characterized by high endothermic metabolic rates and large body sizes, have significant impacts on intertidal communities even at low densities. Birds include locally nesting and migratory species and can remove millions of invertebrates during a season. In addition, birds in some communities provide major inputs of nutrients via guano and prey remains. More than two dozen terrestrial mammals, mostly carnivores, rodents, and artiodactyls, have been reported as consumers or scavengers of rocky intertidal organisms on every continent except Antarctica. Most recorded prey species are mollusks, crabs, or fish. Probably one of the most unusual cases is a population of feral rabbits on a small island off the coast of South Africa that forage on seaweeds in the intertidal zone. Given the mobility of vertebrates, their impact on rocky intertidal shores has been difficult to assess and intertidal activity is often discovered by finding exclusively intertidal animals or algae in the gut contents of otherwise pelagic or terrestrial species.

Little is known about the effects of harvesting by humans in the rocky intertidal zone. Results from a few large-scale studies in Australia, Chile, and South Africa, however, have demonstrated that harvesting has had significant effects on intertidal assemblages.

Zonation

Patterns

Rocky intertidal shores often display a vertical zonation of fauna and flora associated with the strong environmental gradient produced by the rise and fall of the tides. For example, most moderately exposed rocky shores of the northern hemisphere have kelps at the littoral sublittoral interface, followed by rhodophyte algae dominating the low intertidal zone, by fucoid algae, mussels, and barnacles dominating the mid-intertidal zone, and by cyanobacteria, lichens, and a variety of small tufted, encrusting, or filamentous ephemeral seaweeds occurring in the high intertidal zone. While species from many phyla may be found together, often a single species or group is so common; vertical zones are named according to the dominant group (e.g. the intertidal balanoid zone named after barnacles in the family Balanidae).

Combinations of various physical factors acting upon different inhabitants in intertidal zones that vary in their exposure to waves can lead to complex patterns of distribution and abundance along shorelines in a particular region. Nevertheless, some general patterns are evident at a regional scale. Geographically, vertical zonation patterns are most pronounced on temperate rocky shores where species diversity is high and tidal amplitudes tend to be greatest. On rocky shores in the tropics, biotic zones are compressed into narrow vertical bands because of small tidal amplitudes. In polar regions, annual ice scour and low species diversity tend to obscure any conspicuous vertical zonation.

Causes

It is often stated that the upper limits of organisms are set by physical factors, whereas the lower limits are set by biological interactions but there are many exceptions to this rule. The specific causes of the zonation seen on most rocky shorelines vary with geographic location, but zonation results primarily from behavior of larvae and adults, tolerance to physiological stress, the effects of consumers, and the interplay between production and the presence of neighbors.

Adult movements and larval behavior during settlement from the plankton onto rocky shores have major effects on the distribution of animals. For example, studies of barnacles have shown that vertical zonation of larvae in the water column contributes to corresponding vertical zonations of both larval settlement and adults on the shore, a pattern previously ascribed solely to interspecific competition. For seaweeds, behavior is a relatively unimportant cause of their zonation since adult seaweeds are sessile and settling spores are mostly passively transported.

Marine organisms living higher on the shore are faced with more frequent and extreme physiological challenges than their lower shore counterparts, and the upper limits of intertidal distributions for most species are set by cellular dehydration. Dehydration can occur either from freezing during winter or simply desiccation associated with long emersion times. High temperatures and wind, which accelerate the rate of water loss from tissues, exacerbate the effects of desiccation.

Primary and secondary production by sessile organisms can be limited at higher tidal elevations because nutrients and other resources can be acquired only when immersed. Respiration rates of seaweeds and invertebrates are temperature dependent and thus can be greater when an organism is exposed at low tide. For seaweeds, prolonged exposure to dehydration also reduces photosynthesis.

The reduced productivity associated with increased exposure at higher tidal elevations modifies intra- and interspecific interactions. For instance, competition between seaweeds, which may be intense lower on the shore, is reduced at higher tidal elevations and enables coexistence. Competition among intertidal seaweeds is hierarchical with lower shore species dominating those of the higher shore. Thus, fucoid species of the mid intertidal zone are outcompeted for space in the low zone by foliose red seaweeds that pre-empt space with an encrusting perennial holdfast. There is also a competitive hierarchy among mid intertidal

zone fucoids with those typically occurring lower on the shore competitively dominant to those higher up. This is most apparent on European rocky shores where the diversity of intertidal fucoids is greatest.

Grazing rates tend to be greater lower on the shore, although there are cases of herbivory by insects setting the upper limits of ephemeral green algae. Grazing by sea urchins at the interface with the sub-littoral zone can limit the lower distributions of macroalgae, but there is little evidence for grazing on perennial seaweeds setting the lower limits of those taxa within the intertidal zone. Grazing of perennial seaweeds is most intense at the sporeling stage soon after settlement. Grazing by gastropods and small crustaceans certainly contributes to losses of biomass of established individuals, but does not affect distributions within the intertidal zone. In contrast, the grazing of established ephemeral species both on emergent rock and tidepools is intense during spring and summer in many regions eventually eliminating those algae from their respective habitats. There are also many examples of consumers using seaweeds as habitat as well as food.

Rocky Intertidal Shores as an Important System in Development of Ecology

The rocky intertidal zone has been a stronghold for ecological research, and the success of intertidal experiments stems in part from the fact that intertidal assemblages are often comprised of the few species that are able to survive the environmental variation associated with the cycling of tides. In addition, many resident intertidal species are small, common, and slow moving or fixed in one place. Thus rocky intertidal shores historically appeared as simple, well-defined habitats in which easily observed and manipulated local interactions control the dynamics of the assemblages. Such initial appearances, however, have been deceiving, and variation in recruitment of offspring from the plankton, a characteristic of many marine species, has stimulated an increased appreciation of the role of oceanographic conditions.

Descriptive Studies: Research Prior to 1960

Descriptions of rocky shores and speculation about the causes of vertical zonation go back more than 195 years. Before the 1960s, ecologists had published descriptions of intertidal areas from more than a dozen large geographical regions that spanned much of the globe and included both sides of the North Pacific and North Atlantic; Greenland; the West Indies; South and Central America; the coasts of Africa; the Mediterranean; the Black Sea; Indian Ocean Islands; Singapore; Pacific Islands, Australia, and Tazmania. These early accounts of the rocky intertidal remain a potentially valuable source for comparison to contemporary patterns of species distributions due to local species extinctions and introductions.

The Rise of Experimental Studies: 1960–80

Direct experimental manipulation of intertidal organisms accelerated in the 1960s with the groundbreaking work of J. H. Connell and R. T. Paine. Connell manipulated the presence of two species of barnacles in Scotland by selectively removing individuals from small tiles fashioned from the sandstone rock from the shore. He showed that the lower limit of the high intertidal species *Chthamalus stellatus* was set by competition with the mid zone species *Balanus* (now *Semibalanus*) *balanoides* and that the upper limit of *S. balanoides* was set by physical factors. Paine removed the predatory seastar *Pisaster ochraceus* from an area of the intertidal shore in Washington and showed that *Pisaster* was responsible for controlling mussels, which are successful competitors for space and dominate the intertidal shore in the absence of *Pisaster*. These early investigations provided a framework for the rapid growth of experimental studies that characterized the field in recent decades (Fig. 4).

Fig. 4 Grindstone Neck in Maine, USA with Mount Desert Island in the background. This site was used by Menge and Lubchenco in their groundbreaking work in the 1970s. Photo by P. S. Petraitis.

In general, the observation and experimental manipulations of mobile consumers and their prey has often revealed predation by mobile consumers as an important factor that contributes to the structure of rocky intertidal assemblages. Consumers have been repeatedly shown to be prey species- and prey size-selective, while algal grazing consumers can inadvertently remove newly settled animals and algae as well as their intended prey.

Supply-Side Ecology and External Drivers: 1980–2005

Marine ecologists have known for a long time that success of many intertidal species depend on the supply of propagules (larvae, zygotes, and spores) from the plankton, but it was not until the 1980s that experiments were executed to assess how the supply of propagules influenced the patterns of distribution and abundance of adults in benthic assemblages.

Propagule supply and early post-settlement mortality markedly influence both the strength of interactions among established individuals and overall patterns of distribution and abundance on rocky shores. Abundance of established individuals is often directly proportional to the density of settlement and consequently, and strength of adult interactions depends on variation of settlement. In contrast, if settlement is high enough to consistently saturate the system, then local populations tend to be driven by strong interactions among adults regardless of settlement variation. In some cases, heavy early postsettlement mortality can lead to low densities of adults despite an abundance of settlers, and this has been shown for several seaweeds and many invertebrate species. The causes of variation in propagule supply can be classified into two broad categories – oceanographic transport or regional offshore production. Although invertebrate larvae and some macroalgal spores are motile, their movements are most directly important at small spatial scales near the substrate just prior to settlement. By and large, propagules of benthic species are transported at the mercy of currents and other oceanic transport phenomena. For instance, coastal upwelling results in a net offshore transport of propagules and leads to a reduction in settlement along a shoreline. This commonly occurs with invertebrate species that have long residence times in the plankton. In contrast, seaweeds, which have very short planktonic stages, often dominate intertidal sites within regions characterized by seasonal or permanent upwelling (Fig. 5).

Regional offshore production influences the supply of larvae to a coastal habitat in two ways. First, phytoplankton production in nearby waters offshore affects the abundance of planktotrophic larvae that feed for several weeks in the plankton potentially leading to greater larval supply in areas with greater phytoplankton production. Second and in opposition, increased production in offshore can generate increased resources and habitat for the associated pelagic community that preys upon larvae and thus leads to a reduced larval supply.

Unresolved Problems and Future Directions

Marine ecologists have been remarkably successful in advancing our knowledge of how strong local interactions affect the composition of communities, yet it is not yet clear how the results of small-scale experiments can be scaled up into broad scale generalizations. This is one of the major challenges of rocky intertidal ecology since practical, everyday concerns of management, commercial harvesting, biodiversity, and restoration demand answers on the scale of square kilometers of habitat, not square meters of experimental site. One current approach has been to use teams of researchers undertake identical small-scale experiments over a broad geographical region (e.g., EuroRock in Great Britain and Europe) or over similar oceanographic conditions (e.g., the ongoing studies of rocky shore in upwelling systems on the Pacific Rim by PISCO). Another approach has been the integration of `real time' physical, chemical, biological data from in situ and remote sensors (e.g., satellites that can reveal near shore temperature and primary productivity) with experimental studies on community dynamics.

Fig. 5 The intertidal zone near Antofagasta in northern Chile, a region with upwelling and abundant seaweeds. Photo by P. S. Petraitis.

Neither approach solves the difficulties of working with large mobile consumers such as mammals, whose importance is under appreciated because of the difficulties inherent with studying mammals. Even the rat (*Rattus norvegicus*) – the most widely recorded introduced intertidal mammal with the broadest documented intertidal diet – likely remains underreported as a rocky intertidal consumer from many coastal locations where it is known to be established. It is likely that rocky intertidal organisms supply terrestrial consumers significant amounts of energy, yet there are few data on intertidal–terrestrial linkages and how intertidal shores serve as important subsidies for terrestrial habitats.

It is also unclear if detailed information from one area can be informative about another area. For example, rocky intertidal shores on both sides of the Atlantic Ocean look surprisingly alike with not only the same species of plants and animals present but also similarities in their abundances and distributions. The similarity is so striking that a good marine ecologist, knowing little more than the direction of the prevailing swells, can list the 20 most common species on any 100 m stretch of shoreline. The average beachcomber could not tell if he or she were in Brittany, Ireland, Nova Scotia or Maine. The causes of this similarity are not well understood. Rocky shores in Europe and North America may look similar because of strong biological interactions maintain species in balance or because of historical accident, and these opposing views are endpoints on a continuum but represent one of the major intellectual debates in ecology today.

Finally ecosystems are not static, and rocky intertidal systems, which lie at a land–sea boundary, will be doubly affected by climate change as both oceanic conditions such as storm frequency and surge extent, and terrestrial conditions, such as air temperatures, are altered. Such changes could affect local communities by altering the disturbance dynamics and changing the geographic limits of intertidal species.

Salt Marshes

JB Zedler, CL Bonin, DJ Larkin, and A Varty, University of Wisconsin, Madison, WI, USA

Physiography

Salt marshes are saline (typically at or above seawater, $>34\ g\ l^{-1}$) ecosystems with characteristic geomorphology (sedimentary environments, fine soil texture, and relatively flat topography), herbaceous vegetation, and diverse invertebrates and birds. They occur along shores in estuaries, lagoons, forelands (open areas), and barrier islands in marine environments, and in shallow inland sinks where salts accumulate. They are not found where waves, currents, or streamflow create strong erosive forces. Salt (which stresses most species) severely limits the pool of plant species that can colonize saline sediments, and wetness typically confines the vegetation to herbaceous species, although some species are long-lived `subshrubs'. Given a near-surface water table, most shrubs and trees cannot establish their extensive root systems.

Plants of tidal marshes are usually able to colonize sediment above mean high water during neap tides (MHWN = average higher high-tide level during lower-amplitude neap tides, which alternate with the broader-amplitude spring tides). Sediment stabilization by halophytes initiates salt marsh formation. Plants not only slow water flow and allow sediments to settle out, but also their roots help hold sediments in place. Gradual accretion around plant shoots can further elevate the shoreline, allowing development of a marsh plain and transition to upland. This process can reverse, with tides eroding accumulated sediments. When sedimentation is outweighed by erosion, salt marshes retreat.

The overriding physiochemical influence is salt, which comes from marine waters, from exposed or uplifted marine sediments, or from evaporation of low-salinity water in arid-region sinks. Salt marshes along coasts typically have tidal influence (**Fig. 1**), although many nontidal lagoons have saline shores that support salt marsh vegetation. Salt marshes in inland settings occur in shallow sinks (e.g., around the Great Salt Lake, Utah, USA). The salts that contribute to salinity are primarily those of four cations (sodium, potassium, magnesium, calcium) and three anions (carbonates, sulfates, and chlorides); the relative proportions differ widely among soils of inland salt marshes, but sodium chloride is the predominant salt of seawater.

Tidal regimes differ around the globe, but most tidal marshes experience two daily high tides of slightly different magnitude, while some have the same high and low tides from day to day. Levels alternate weekly as neap and spring amplitudes, with the amplitudes readily predicted given gravitational forces between the Earth, the Moon, and the Sun (astronomic tides). Forces vary in relation to global position and coastal morphology; in southern California, mean astronomic tidal range is 3 m, while in the Bay of Fundy it is 16 m. The influence of seasonal low- and high-pressure systems on water-level oscillations (atmospheric tides) also vary greatly. For example, in Western Australia's Swan River Estuary, atmospheric tides outweigh astronomic tides. In the Gulf of Mexico, astronomic tides are minimal because of limited seawater connection with the Atlantic Ocean. Water levels within the Gulf vary only a few centimeters except during storms and seiches.

In tidal systems, marsh vegetation generally ranges from MHWN to the highest astronomic tide. Depending on tidal amplitude and the slope of the shore, salt marshes can be very narrow or kilometers wide. Strong wave action limits the lower salt marsh boundary, but a sheltered area can extend the lower boundary below MHWN.

Animal diversity is high, especially among the benthic and epibenthic invertebrates and the arthropods in the soil or plant canopies. Species that complete their life cycles within salt marshes either tolerate changing salinity and inundation regimes or avoid them by moving elsewhere or reducing contact. Globally, salt marshes are known to support large populations of migratory birds in addition to resident birds, insects, spiders, snails, crabs, and fin and shellfish. Indeed, foraging is the most visible activity in salt marshes.

Extent

Salt marsh area is not well inventoried. The global extent of pan, brackish, and saline wetlands is approximately 435 000 km^2, or 0.3% of the total surface area and 5% of total wetland area. In USA, the 48 conterminous states have about 1.7 Mha of salt marshes, out of a total of 42 Mha of wetlands.

While broadly distributed, salt marshes are most common in temperate and higher latitudes where the temperature of the warmest month is $>0\ ^{\circ}C$. Closer to the equator, where the mean temperatures of the coldest months are $>20\ ^{\circ}C$, salt marshes are generally replaced by mangroves. Salt marshes sometimes occur inland of mangroves or instead of mangroves where woody plants have been removed.

Habitat Diversity

Habitats within the salt marsh vary with elevation, microtopography, and proximity to land or deeper water. In southern California, the high marsh, marsh plain, and cordgrass (*Spartina foliosa*) habitat tend to follow elevation contours, although

 doi:10.1016/B978-0-444-63768-0.00357-7

Fig. 1 A tidal marsh in San Quintin Bay seen from the air. Image by the Pacific Estuarine Research Lab.

cordgrass is often restricted to low elevations adjacent to bay and channel margins. Other habitats are related to minor variations in topography, which impound fresh or tidal water. For example, back-levee depressions, tidal pools, and salt pans occur where drainage is somewhat impaired. Salt marshes along the Atlantic Coast of USA are very extensive, with *S. alterniflora* creating a monotype except for a narrow transition at the inland boundary where succulent halophytes or salt pans are found.

Tidal creeks provide diverse habitats for plants and animals. Banks are often full of crab burrows, and creek bottoms harbor burrowing invertebrates and fishes. They also serve as conduits for fish, fish larve, phyto- and zooplankton, plant propagules, sediments, and dissolved materials, which move between the salt marsh and subtidal channels.

Adjacent habitats can include small, unvegetated salt pans that dry and develop a salt crust, especially during neap tides. Salt pans occur where salt concentrations exceed tolerance of halophytes. During heavy rains or high tides, water fills the pan, creating temporary habitat for aquatic algae and animals and permanent habitat for the species that survive the dry spells *in situ* as resting stages. More extensive salt pans are sometimes called salt flats. Other nearby habitats usually include mudflats (where inundation levels exceed tolerance of halophytes), brackish marsh (where salinities are low enough for brackish plants to outcompete halophytes), sandy or cobble beaches (where wave force excludes herbaceous vegetation), sand dunes (where soils are too coarse and dry for salt marsh plants), and river channels (where freshwater enters the estuary and is not sufficiently saline).

Salt Marsh Plants

Salt-tolerant plants (halophytes) include herbaceous forbs, graminoids, and dwarf or subshrubs. Many of the forbs are succulent (e.g., *Sarcocornia* and *Salicornia* spp.). Graminoids often dominate Arctic salt marshes, while subshrubs dominate salt marshes in Mediterranean and subtropical climates. Many salt marshes support monotypic stands of cordgrass (*Spartina* spp.) (**Table 1**).

Floristic diversity of salt marshes is low because few species are adapted to saline soil. Members of the family Chenopodiaceae comprise a large proportion of the flora (e.g., species of *Arthrocnemum*, *Atriplex*, *Chenopodium*, *Salicornia*, *Sarcocornia*, and *Suaeda*). In contrast to the flowering plants, salt marsh algae are diverse in both species and functional groups (green macroalgae, cyanobacteria, diatoms, and flagellates).

NaCl is a dual stressor, as it challenges osmotic regulation and sodium is toxic to enzyme systems. Salt marsh halophytes cope with salt by excluding entry into roots, sequestering salts intracellularly (leading to succulence), and excreting salt via glands, usually on leaf surfaces. One succulent, *Batis maritima,* continually drops its older salt-laden leaves, which are then washed away by the tide. I. Mendelssohn has attributed moisture uptake from seawater to the ability of some species to synthesize prolines.

Prolonged inundation reduces the supply of oxygen to soils, causing anoxia and stressing vascular plants. In addition, abundant sulfate in seawater is reduced to sulfide in salt marsh soil, with high sulfide concentrations, which are toxic to roots.

Salt marsh vascular plants withstand brief inundation but do not tolerate prolonged submergence, as occurs when a lagoon mouth closes to tidal flushing and water levels rise after rainfall. Salt marshes in lagoons thus experience irregular episodes of dieback and regeneration in relation to ocean inlet condition.

Regular inundation benefits halophytes by importing nutrients and washing away salts. Salts that accumulate on the soil surface during daytime low tides and salts excreted by halophytes are removed by tidal efflux. Thus, soil salinities are relatively stable where tidal inundation and drainage occur frequently. Inland salt marshes, however, experience infrequent reductions in salinity during rainfall, and soils can become extremely hypersaline (e.g., $>10\%$ salt). In between irregular inundation events, halophytes and resident animals endure hypersaline drought.

Table 1 Representative species of global salt marshes based on a summary by Paul Adam

Arctic Puccinellia phryganodes dominates the lower elevations
Boreal Triglochin maritima and *Salicornia europea* are widespread. Brackish conditions have extensive cover of *Carex* spp.
Temperate
Europe: *Puccinellia maritima* dominated lower elevations historically (but *Spartina anglica* often replaces it). *Juncus maritimus* dominates the upper marsh; *Atriplex portulacoides* is widespread
USA:
Atlantic Coast: *Spartina alterniflora* is extensive across seaward marsh plain; *S. patens* occurs more inland
Gulf of Mexico: *Spartina alterniflora* and *Juncus roemerianus* dominate large areas
Pacific Northwest: *Distichlis spicata* in more saline areas, *Carex lyngbei* in less saline areas
California: *Spartina foliosa* along bays, *Sarcocornia pacifica* inland
Japan: *Zoysia sinica* dominates the mid-marsh
Australasia: *Sarcocornia quinqueflora* dominates the lower marsh, *Juncus kraussii* the upper marsh
South Africa: *Sarcocornia* spp. are abundant in the lower marsh, *Juncus kraussii* in the upper marsh. *Spartina maritima* is sometimes present
Dry coasts vegetation tends toward subshrubs, such as *Sarcocornia*, *Suaeda*, *Limoniastrum*, and *Frankenia* species
Tropical Sporobolus virginicus and *Paspalum vaginatum* form extensive grasslands. *Batis maritima*, *Sesuvium portulacastrum*, and *Cressa cretica* are also found

Salt Marsh Animals

The salt marsh fauna includes a broad taxonomic spectrum of invertebrates, fishes, birds, and mammals, but few amphibians and reptiles. Resident fauna are adapted to the land–sea interface, while transient users benefit from the foraging, nursery, and reproductive support functions.

Salt marsh animals cope with inundation regimes that differ seasonally, monthly, daily, and hourly. Vertebrates accomplish this largely through mobility. For example, fishes exploit marsh surface foraging opportunities during high tides and then retreat to subtidal waters. Birds time their use to take advantage of either low or high tide. Residents, such as the light-footed clapper rail (*Rallus longirostris levipes*), nest during the minimum tidal amplitude. Migrants, such as curlews, move upslope at a high tide and feed during low tide during their seasonal visits. Many invertebrates move away from adverse conditions. Some beetles climb tall plants to escape rising tides. A springtail, *Anurida maritime*, has a circatidal rhythm of 12.4 h that enables it to emerge for feeding shortly after tides ebb and retreat underground prior to the next inundation. For less-mobile fauna, physiological adaptations are essential. Gastropods avoid desiccation during low tides by sealing their shells. Some arthropods avert drowning by trapping air bubbles in their epidermal hairs during high tides.

Another challenge is fluctuating salinities, which salt marsh residents handle with exceptional osmoregulatory ability. The southern California intertidal crab species *Hemigrapsus oregonensis* and *Pachygrapsus crassipes* are able to hypo- and hyperosmoregulate when exposed to salt concentrations ranging from 50% to 150% of seawater (brackish to hypersaline). Tidal marsh fishes also have wide salinity tolerances. Cyprinodontiform tidal marsh fishes can tolerate salinities as high as 80–90 ppt. One species, *Fundulus majalis*, hatched at salinities up to 72–73 ppt. Lower salinity limits for mussels can be as low as $3\ g\ l^{-1}$ and they can tolerate high salinities as well, with mussels able to tolerate losing up to 38% of their water content. Even birds have adaptations for dealing with salt water and saline foods; for example, the Savannah sparrow *(Passerculus sandwichensis beldingi)* has specialized glands that excrete salt through the nares.

Because salt marshes have continuously changing hydrology, small differences in elevation and topography (e.g., shallow, low order tidal creeks) influence foraging activities of fishes and birds by regulating inundation and exposure times, enhancing marsh access for fishes, and increasing edge habitat. Ephemeral pools of just centimeters in depth provide valuable bird habitat, enhance macroinvertebrate abundance and diversity, and support reproductive, nursery, and feeding support functions for fishes.

Ecology

Salt marshes are well studied relative to their limited global area. Knowledge of salt marsh ecology is strongest for vegetation, soil processes, and food webs. Conservation is an emerging issue, given threats of sea-level rise in concert with global warming.

Vegetation and Soils

In Europe, salt marsh ecology developed around floristics and phytosociology. In USA, research on the Atlantic and Gulf Coasts characterized salt marsh ecosystem functioning, especially productivity, microbial activities, outwelling of organic matter, food webs, and support of commercial fisheries, while on the Pacific Coast, studies concern the impacts of invasive species of *Spartina* and effects of extreme events on vegetation dynamics. In Canada, effects of geese damaging vegetation are a research focus. Studies of USA's inland salt marshes have contributed knowledge of waterfowl support functions and halophyte salt tolerance. In South Africa's small estuaries, *Spartina* productivity and shifts of vegetation in response to altered freshwater inflows have been explored.

In Asia, widespread plantings of *S. alterniflora* have been undertaken in order to extend coastal land area, provide forage, and produce grass for human use. In general, salt marshes of Asia, Central America, and South America are poorly known.

Salt marshes develop primarily on fine sediments, but salt marsh plants can grow on sand and sometimes gravel. Older salt marshes have peaty soils, especially in cooler latitudes where decomposition is slow.

Both roots and burrowing invertebrates affect soil structure by creating macropores in soil. Invertebrates also cause bioturbation, a process whereby sediments are re-suspended and potentially eroded away. This activity can be countered by algae and other microorganisms, which form biofilms on the soil surface. Biofilms cement soil particles and reduce erosion; they also add organic matter, and those that contain cyanobacteria fix nitrogen.

Salt marsh soils are often anoxic just below the surface due to high organic matter content and abundant moisture for microorganisms. This is especially so in lower intertidal areas and in impounded marshes. Tidal marsh soils are typically high in sulfur, which forms sulfides that blacken the soil, emit a distinctive rotten-egg smell, and stress many plants. Across intertidal elevation ranges, soil microorganisms, sulfides, and inundation regimes reduce species richness where inundation is most prolonged, often to a single, tolerant species.

Food Webs

Studies of salt marshes have made important advances in food web theory. Early papers focused on primary productivity measurements and attempts to explain differences in rates within and among salt marshes. The energy-subsidy model described *S. alterniflora*'s high productivity at low elevations as a function of increased rates of nutrient delivery and waste removal, due to frequent tidal inundation. It also explained how salt marshes with decreasing tidal energy across Long Island, New York, had a corresponding decrease in *S. alterniflora* productivity. R. E. Turner added the role of climate by relating higher productivity of *S. alterniflora* to warmer latitudes.

In the 1960s, E. Odum's interest in energy flow led several investigators at the University of Georgia to quantify productivity, consumption, and decomposition of various components of Sapelo Island salt marshes. J. Teal's energy-flow diagram depicted Georgia's *S. alterniflora* marsh as exporting organic matter. Although estimated by subtraction rather than measurement, detrital export became a textbook example of how ecosystems channel and dissipate energy.

Later, advances were made in exploring the quantity and fate of detritus derived from salt marsh primary producers. J. Teal's suggestion that substantial organic matter is transported to estuarine waters supported E. Odum's `outwelling hypothesis', that estuarine-derived foods drive coastal food webs and benefit commercial fisheries. A number of ecosystem-scale tests of outwelling ensued, and although outwelling did not prove to be universal, the research demonstrated connectivity between riverine, salt marsh, and open-water ecosystems. Also, the copious detrital organic matter provided by salt marshes was shown to be high in nutritional value once detrital particles were enriched by microorganisms, but microalgae were also shown to be an important food source. Even though their standing crop is low, high turnover rates lead to high primary productivity. In salt marshes with ample light penetration through the vascular plant canopy, microalgae can be as productive as macrophytes, and some species (notably cyanobacteria) are much richer in proteins and lipids. Algae also hold much of the labile nitrogen in salt marshes, widely thought to be the limiting factor for growth of invertebrate grazers.

Food webs are driven by both `bottom-up' or `top-down' processes. Evidence for bottom-up control of trophic interactions comes from experimental addition of nitrogen. Nitrogen has been shown to limit algae, vascular plants, grazers, and predatory invertebrates in nearly every salt marsh field experiment. Recently, however, P. V. Sundareshwar and colleagues showed that phosphorus can limit microbial communities in coastal salt marshes.

Despite widespread evidence for bottom-up effects, there is expanded recognition of the top-down role of consumers in regulating salt marsh food webs. Populations of lesser snow geese have increased due to agricultural grains that are left in the fields after harvest, and large flocks now cause large-scale destruction of vegetation in Arctic salt marshes due to rampant herbivory. In Atlantic salt marshes of southern USA, snail herbivory accompanies drought-induced die-back of *S. alterniflora*.

Ecosystem Services

Several ecosystem services provided by salt marshes are appreciated by society, and some protective measures are in place. The regular rise and fall of water in salt marshes, either daily with tides or seasonally with rainfall, enhances at least six valued functions:

Denitrification improves water quality. The sediments of tidal marshes are well suited to denitrification, which occurs most rapidly at oxic–anoxic interfaces. The first step, nitrification, occurs near soil–water or root–soil interfaces or along pores where oxygen enters the soil at low tide. The second step requires anoxic conditions and proceeds rapidly where moisture is sufficient for bacteria to respire and remove oxygen. In this step, nitrate is reduced to nitrogen gas in a series of microbially mediated steps. The rise and fall of tide waters ensures that oxic and anoxic conditions coexist.

Carbon sequestration slows greenhouse warming. The high net primary productivity of salt marshes creates high potential for carbon storage and the anoxic soils slow decomposition, so carbon can accumulate as peat. Large standing crops of roots, rhizomes, and litter are fractionated by a diversity of invertebrates and microorganisms and incorporated into soil. Rates are potentially highest at

cooler latitudes, where decomposition is slowed by low temperatures. Sea-level rise is also a key factor; as coastal water levels become deeper, decomposition slows. Sedimentation also buries organic matter, making it less likely to decompose. With sea level rising a millimeter or more per year, on average, salt marsh vegetation can build new rooting zones above dead roots and rhizomes of past decades. Along the USA Gulf of Mexico, the ability of salt marshes to keep up with rising sea level is attributed to root and rhizome accumulation, not just sedimentation. If decomposition proceeds anaerobically to states that produce methane, however, not only is carbon storage reversed, but carbon is also released in a form that contributes more to global warming than carbon dioxide.

Fin- and shellfish have commercial value. Tidal marshes are valued for their nursery function, meaning that the young of many fishes, crabs, and shrimp make use of estuarine waters as `rearing grounds'. In the USA, it is estimated that some 60% of commercial species spend at least part of their life cycle in estuaries. Several attributes of salt marshes contribute to the food-web-support function, including high productivity of both algae and vascular plants, detritus production and export to shallow water-feeding areas, refuge from deepwater predators, plant canopy cover as a refuge from predatory birds, warmer temperatures that can accelerate growth, and potential to escape disease-causing organisms and parasites that might have narrower salinity tolerance.

Forage is used to feed livestock. In Europe and Asia, graziers move cattle, horses, sheep, or goats onto the marsh plain during low tides. It is common to see ponies tethered to stakes in *Puccinellia*-dominated salt marshes of UK. The temporary availability (between tides) allows recovery between use and, potentially, high-quality forage and salt for livestock.

Recreational opportunities and esthetics are appreciated by people who live near or visit coastal areas. By virtue of their low-growing vegetation and locations between open water and urban areas, salt marshes attract both wildlife and people. The combination provides high value for birdwatchers, hikers, joggers, and artists. Where there is flat topography above and near the salt marsh, the needs of elderly and disabled visitors can be accommodated along with hikers, school children, and those seeking a refuge from city life. Of particular interest is the ever-changing view, as tides rise and fall along marine coasts, and as water levels change with season in inland systems. Visitor centers have been constructed near many urban salt marshes. Ecotourism then adds economic value to the local municipality as well as the larger region.

Shorelines are anchored by salt marsh vegetation. Recent damages from hurricanes and tsunamis have called attention to the protection that wetland vegetation provides to coastal lands, and especially high-cost real estate. Water flow is slowed by stems and leaves of salt marsh plants, and their roots and rhizomes bind inflowing sediments. Mucilage produced by biofilms (algae, fungi, and bacteria) can then cement particles until new plant growth anchors the substrate. The stems of vascular plants are often coated with biofilms, particularly those of tuft-forming cyanobacteria, such that the total surface area available for sediment-trapping and anchoring is greatly enhanced. Floating mats of green macroalgae *(Ulva, Enteromorpha)* also collect sediments and, when they move to the wrack line and join other debris, add to accretion at the upper marsh plain boundary.

Challenges for Salt Marsh Conservation

Habitat Loss

Estuaries, where rivers meet the sea, are not only suitable for salt marsh development but also ideal places for human habitation. The ocean–river connection is a navigational link, flat land is easy to build upon, the river provides drinking water, the salt marsh and coastal fisheries provide food, outgoing tides facilitate wastewater disposal, and seawater provides an essential preservative and universal seasoning, NaCl. Thus, many cities, such as Venice, Boston, Amsterdam, London, Buenos Aires, Washington, DC, and Los Angeles, were built on or rapidly grew to displace salt marsh ecosystems. Major ports within smaller natural bays, such as San Diego, have displaced nearly all the natural salt marsh, while others, such as San Francisco, sustain large salt marshes despite extensive conversion.

The process of converting salt marsh into nontidal land was historically called reclamation. The practice of building embankments to exclude tidal flows eliminated thousands of hectares of European salt marshes. In the Netherlands, embankments reclaimed substantial land as polders for agriculture. In USA, reclamation reduced salt marsh area by 25% between 1932 and 1954. While the trend is to halt or reverse this practice, estuaries are being dammed in Korea to create tillable fields from mudflats. In Vietnam, Mexico, and other coastal nations, salt marshes are yielding to fish and shrimp impoundments. In such cases, people who use mudflats for fishing and crabbing are displaced by farmers.

Although salt marshes are highly valued, they are increasingly threatened by human population growth. It is estimated that 75% of the global population will live within 60 km of the coast. Thus, coastal ecosystems are particularly at risk.

Eutrophication

Salt marshes are enriched when phosphorus and/or nitrogen flow into waters that ultimately flood the salt marsh. Agricultural fertilizers applied to fields throughout coastal watersheds move downslope into waters that flow toward salt marshes. Because many salt marshes are nitrogen-limited, the effect is to increase the productivity of both algae and vascular plants. Increased nitrogen loading stimulates algal growth, especially of green macroalgae, which form large mats that can smother vascular plants and benthic invertebrates. Indirect degradation occurs when microbial decomposition increases oxygen demand, causing soil hypoxia or anoxia and sulfide toxicity.

I. Valiela's long-term eutrophication experiment in a New England salt marsh indicates that nitrogen addition shifts *S. alterniflora* to *S. patens* and increases competition for light. Such altered competitive relationships are likely widespread, especially where considerable nitrogen is deposited from the air (e.g., from dairy operations in the Netherlands).

Sediment Supply

Both reduced and enhanced sediment supplies can threaten the persistence of salt marsh ecosystems. Sediment supplies are reduced when water is removed from rivers for irrigation, human consumption, and industrial use, or when overbank flooding is prevented by engineering works. Reduced sediment supply from the Mississippi River is one factor contributing to salt marsh loss in Louisiana.

Excessive sediments flow into salt marshes where the catchment has lost vegetative cover as a result of logging, farming, or development. Inflows also occur where mining operations discharge materials directly to streams. Wastes from California's gold rush are still making their way to San Francisco Bay. At a much smaller estuary, the marsh plain of Tijuana Estuary in southern California has elevated 25–35 cm since 1963 due to erosion from rapidly urbanizing canyons in nearby Tijuana, Mexico. The impacts have been losses of microtopographic variation and local species richness.

Global Change

Increases in global mean temperature will have substantial impacts on the world's salt marshes. Sea levels rise when high-elevation glaciers and polar ice caps melt and when seawater warms and expands. The impacts of more rapidly rising sea level depend on rates of sedimentation and uplift. If sediment accretion is equal to sea-level rise, the salt marsh remains in place, but when sea-level rise exceeds sediment accretion, the salt marsh moves inland – unless bluffs or development limits salt marsh migration. As sea level rises relative to the land, salt marsh communities will experience increased inundation, such that plant and animal species should shift upslope. However, not all species will be able to disperse or migrate as rapidly as tidal conditions change. In a few cases, for example, Scandinavia, the coast is still rebounding from the pressure of former glaciers, and land is rising faster than sea level. Salt marsh is then lost at the upper end and slowly gained near the water.

Globally, mean sea level has risen 10–25 cm during the last century. Current models predict an additional 5.6–30 cm rise in sea level by 2040. In areas of rapid shifts in sedimentation or high erosion due to wind and waves, salt marshes are destabilized and threatened with compositional changes and/or loss of marsh area. Salt marshes are also threatened by subsidence; if the land settles faster than sediment or roots and rhizomes can accumulate, vegetated areas convert to open water. USA's largest area of salt marsh loss is along the Louisiana coastal plain, where subsidence, decreased sedimentation, canal dredging, levee construction, and other human disturbances eliminate more than 4300 ha yr^{-1}.

Coastal watersheds that experience increased storminess as a result of climate change will discharge water, sediments, nutrients, and contaminants more erratically than at present, with resulting impacts on salt marshes downstream.

Soil salinity might also rise with higher temperatures, increased evaporation, and increased evapotranspiration. With more rainfall and freshwater flooding, however, soil salinity might decrease. The net effect of warming on salt marsh soil salinity is difficult to predict. Increased storminess could translate into more or stronger dune washover events during high tides, and stronger ocean swells would transport seawater further inland. The toxic effect of salt on upland vegetation, coupled with persistent salt in the soil, would favor halophytes over glycophytes in an increasingly broader wetland–upland transition areas (**Fig. 2**). This prediction is most likely for areas of low annual rainfall, such as Mediterranean-type climates.

Climate change is likely to affect species differently, potentially altering competitive relationships. Photosynthesis, transpiration, nutrient cycling, phenology, and decomposition are influenced by temperature. Salt marshes with a mixture of C3 and C4

Fig. 2 Saltmarsh vegetation from the upland–wetland interface (foreground) to San Quintin Bay, Baja California Peninsula, Mexico. Photo by J. Zedler.

plants might shift toward C4 plants as mean temperature climbs; however, elevated CO_2 might favor C3 species. In subtropical regions, a warming trend and sea-level rise would likely allow mangroves to move northward and displace salt marshes.

Impacts of climate change to plants and animals are difficult to estimate. European ecologists, however, have detailed information on bird use of salt marshes and can predict shifts in invertebrate foods and shorebirds given various scenarios of sea-level rise.

Invasive Species

Plant and animal species are inadvertently moved around the globe when ships take on ballast water in one port and discharge it in another; seeds of alien plants and either live animals or dormant stages are then available to colonize salt marshes. When the USA resumed trade with China, new invaders gained access to San Francisco Bay. Fred Nichols traced the arrival of a small clam, *Potamocorbula amurensis*, to 1876. Now it coats some benthos with thousands of clams/m^2.

Other alien species have been intentionally introduced. In the 1950s, the US Army Corps of Engineers experimentally introduced *S. alterniflora* onto several dredge spoil islands to stabilize the material and provide wildlife habitat. A region-wide invasion of the Pacific Northwestern USA followed several decades of `benign' behavior. Today, the species is dominant along the lower edge of salt marsh shorelines, where it displaces oysters and eliminates shorebird-feeding habitat.

Once a species has taken up residence, it might hybridize with native species and become more aggressive, either as the hybrid or subsequent genetic variants. Such is the case for *S. alterniflora*, which has been widely planted in Europe, China, Great Britain Australia, and New Zealand. In Great Britain, it hybridized with the native *S. maritima* to form *S. townsendii*, which then underwent chromosomal doubling to form *S. anglica*. *S. anglica* can grow at lower elevations than native species and vigorously colonizes mudflats. Dense clones of *S. anglica* reduce habitat for wading birds and displace native salt marsh plants.

Non-native strains of *Phragmites australis* were introduced to the USA 200 years ago, and they have since spread throughout much of North America. Today, the alien strain dominates the less-saline portions of salt marshes in the northeastern USA, where it displaces native plant species, alters soil conditions, and decreases waterfowl use. Disturbances such as ditching or dredging open salt marsh canopies and allow invasion of *P. australis*, while eutrophication, altered hydrologic regimes, and increased sedimentation favor its spread.

Invasive plant species have been linked to reduced diversity, shifts in trophic structure, habitat alteration, and changes in nutrient cycling. Invasive alien animals are equally problematic. In San Francisco Bay wetlands, alien mudsnails outcompete native ones and the Australasian isopod, *Sphaeroma quoyanum*, burrows into and destabilizes creek banks of tidal marshes, causing erosion. Marsh edge losses exceeding 100 cm yr^{-1} have been reported in heavily infested areas. Another invader, the green crab, *Carcinus maenus*, has altered the food web of Bodega Bay, California, by reducing densities of a native crab, two native mussels, and other invertebrates. As the green crab moves north, it will likely reduce food availability for shorebirds.

In the southeastern USA, fur farmers introduced nutria (*Myocastor coypus*) from South America in the 1930s. These rodents feed on roots of salt marsh plants. When fur clothing went out of style, nutria populations expanded and began converting large areas of marsh to mudflat and open water.

Chemical Contamination

Chemical contaminants accumulate in salt marshes that receive surface-water runoff and/or direct discharges of waste materials. Among the most toxic are halogenated hydrocarbons, which include many insecticides, herbicides, and industrial chemicals. When accumulated in the tissues of salt marsh animals a wide range of disorders can result, for example, immunosuppression, reproductive abnormalities, and cancer.

Petroleum hydrocarbons pollute harbors and remnant salt marshes following oil spills, urban runoff, and influxes of industrial effluent and municipal waste. Once they move into anoxic sediments, they can persist for decades, reducing primary production, altering benthic food webs, and accumulating in bird tissues. Polycyclic aromatic hydrocarbons have additional carcinogenic and mutagenic potential for aquatic organisms.

Heavy metals are also toxic to aquatic organisms and can impair feeding, respiration, physiological and neurological function, and reproduction, as well as promote tissue degeneration and increase rates of genetic mutation. Mercury is especially problematic because it is methylated in the anoxic soils of salt marshes and is then able to bioaccumulate in food chains.

Salt marsh plants in urban areas take up, accumulate, and release heavy metals. Judith Weis and others have found lowered benthic diversity and impaired fish behavior in contaminated sites. Fish are slower to catch prey and less able to avoid predators where heavy metals contaminate their habitat.

Research Value

Tidal marshes include an impressive array of environmental conditions within about a meter of elevational range. The compressed environmental gradient invites studies of species $\times$ abiotic factors, and over time, their contributions proceeded from community ecology to ecosystem science and, finally, integration of the two.

Community Ecology

The limited number of vascular plant species has made salt marshes very suitable for both descriptive and manipulative studies. Early researchers attributed plant species distributions to their physiological tolerance for the abiotic environment, without regard to species interactions. J. A. Silander and J. Antonovics used perturbation-response methods to determine that biotic forces also affected species distributions. Others effectively used reciprocal transplanting to examine the relative importance of abiotic conditions and interspecific competition to species distributions. For example, S. Pennings and R. Callaway revealed interspecific interactions among southern California halophytes, and S. Hacker and M. Bertness reported interspecific interactions among New England halophytes. Manipulative transplantation has shown that species distributions respond to abiotic conditions, facilitation, and competition.

The wide latitudinal range of salt marshes allowed study of community structure and function in relation to sea-level variations, for example, James Morris documented and modeled interannual variations in salinity and its effect on *S. alterniflora* growth. Such studies led to predictions of changes in response to global climate change.

Ecosystem Functioning

The monotypic nature of USA Atlantic Coast salt marshes aided early studies of vascular plant productivity and considerable literature developed around the rates of productivity and alternative methods of calculating gross and net productivity – work that transferred to grasslands and other nonwoody vegetation. Nitrogen dynamics were a later focus. The first marine system to have a nitrogen budget was Great Sippewisset Marsh in Massachusetts. The budget quantified nitrogen inputs from groundwater, precipitation, nitrogen fixation, and tidal flow, and nitrogen outputs from tidal exchange, denitrification, and buried sediments.

Integrating Structure and Function

A long controversy over the causes of height variation in *Spartina* spp. has involved USA researchers on both the Atlantic and Pacific Coasts and has linked plant and ecosystem ecology. The most convincing evidence for a genetic (`nature') component is that of D. Seliskar and J. Gallagher, who grew genotypes from Massachusetts, Georgia, and Delaware for 11 years in a common garden and documented persistent phenotypic differences. A series of papers on soil biogeochemistry explained the role of `nurture'. Nitrogen was shown to be a key limiting factor for *S. alterniflora* plant growth because nitrate is quickly reduced to ammonia by bacteria in poorly drained areas away from creeks, where soils have lower soil redox potential. Sulfate-reducing bacteria were also implicated, because they reduce sulfate to sulfide, which impairs the growth of sensitive plant species. Increased soil redox potential and greater pore water turnover in creek-side habitat contributes to taller height forms of *S. alterniflora*. Thus, both genetics and environment influence height forms of *S. alterniflora,* an outcome of both community and ecosystem research.

Restoration

With recognition of lost ecosystem services, interest in restoring salt marshes is growing in Europe and the USA. One way that the British are combating rising sea levels is via `managed retreat', which involves breaching of embankments to restore tidal flushing to lands that were once salt marshes. In the Netherlands, tidal influence is being reinstated to various polders along the southwestern coast to restore natural processes and diverse estuarine biota to former polders.

Fig. 3 Tidal marsh vegetation is typically dominated by salt-tolerant grasses and succulent forbs, easily distinguished in this restored marsh at Tijuana Estuary, near San Diego, California. Photo by J. Zedler.

Some of the earliest salt marsh restoration in USA has been accomplished as mitigation for damages to other sites as required by federal regulatory agencies. In North Carolina, *S. alterniflora* was being replanted in the 1970s, and the practice has expanded widely to mitigate damages due to development.

Some of the most innovative research on wetland restoration has been accomplished in salt marshes by replicating variables in restoration sites; for example, D. Seliskar and J. Gallagher showed that genotypic variation in *S. alterniflora* has implications for nearly every component of the food web (in Delaware), T. Minello and R. Zimmerman showed that channels in replanted salt marshes enhanced fish support (Galveston Bay, Texas), I. Mendelssohn and N. Kuhn showed that dredge spoil addition accelerated *S. alterniflora* recovery in subsiding wetlands (Louisiana), Cornu showed that topographic variation across a tidal floodplain affected salmon use (Oregon), and J. Callaway, G. Sullivan, J. Zedler, and others showed that planting diverse assemblages and incising tidal creeks jumpstarted ecosystem functioning in salt marsh restoration sites (Tijuana Estuary, California) (**Fig. 3**). In Spain, restoration of tidal ponds is being accomplished in replicate excavations that test the effect of size and depth on use by salt marsh animals (Doñana Marshlands).

In conclusion, salt marshes perform highly valued ecosystem services that are lost when habitats are developed and/or degraded. Further innovations will likely take place in both the practice and science of restoration, because salt marshes are highly amenable to experimentation.

Ecosystems: Savanna☆

Lindsay B Hutley, Charles Darwin University, Darwin, NT, Australia
Samantha A Setterfield, The University of Western Australia, Perth, WA, Australia

Introduction

This article examines the ecological features of one of the most important tropical ecosystems, the savannas. Savannas feature the coexistence of both trees and herbaceous plants and are distinct from grasslands (absence of woody plants) and closed forests (tree dominant). Savanna ecosystems occur in over 20 countries, largely in the seasonal tropics. Much of the world's livestock occurs in savanna, underlining their social and economic importance. Approximately 20% of the world's land surface is covered with savanna vegetation, which produces almost 30% of global net primary production. With both tree and herbaceous life-forms, savanna biodiversity is high, often higher than associated dry deciduous forests. Globally, the tenure of savanna lands incorporates pastoral, private use, indigenous, and national parks, with the disparate management aims of grazing, agriculture, mining, tourism, subsistence livelihoods, and conservation. Given their size, savannas affect global carbon, nutrient, and water cycles and with their frequent fires, significantly influence atmospheric chemistry. Savanna ecosystems have existed for approximately 8 million years, although paradoxically, many ecologists regard savannas as an ecologically unstable mixture of trees and grasses. Savanna boundaries are dynamic in space and time and their occurrence and structure are determined by a combination of environmental factors, such as available water, nutrients, the frequency of disturbances (e.g., fire and herbivory) and stochastic weather events. This range of factors results in significant structural variation and providing an overarching and strict definition of what constitutes a savanna has been problematic. This article will provide a commonly used definition, describe savanna distribution and examine factors that influence their structure and function. Understanding the determinants of savanna functioning, resilience and stability are vital ingredients for improved management. Savannas are under increasing development pressure and threats to their long-term sustainability are examined.

Definition and Occurrence

Savanna ecosystems predominantly occur in the seasonal tropics and are a unique mix of coexisting trees, shrubs, and grasses (Fig. 1). Debate surrounds the use and definition of the term savanna, reflecting the range of tree–grass ratios found in these ecosystems. Savanna ecosystems feature a range of structures, from near treeless grasslands to woody dominant open-forest/woodlands of up to 80% woody cover. A widely used, generic definition describes a savanna ecosystem as one consisting of a continuous or near continuous grass dominated understorey, with a discontinuous woody overstorey. Woody components can be a mix of trees and shrubs of evergreen or deciduous phenology, broad or needle leafed. The grass-dominated understory can consist of a mix of species with either annual or perennial habit (often >1 m in height). Ecosystems that fit this definition have ambiguously been termed woodlands, rangelands, grasslands, wooded grasslands, shrublands, open-forests, or parklands.

Savanna formations occur on all continents of the world (Fig. 2), with the largest extent found in the wet–dry tropical regions of Africa, South America, and Australia. Smaller areas occur in Asia, including Sri Lanka, Thailand, Vietnam, and Papua New Guinea.

☆*Change History*: April 2018. Lindsay B. Hutley, Samantha A Setterfield updated (1) minor refinements to text, expression; (2) replacement of Fig. 5 which depicts the non-linear relationship of rainfall with savanna tree basal area for Africa. A more recent study of Lehmann et al 2014 published in the journal Science has now been included as Fig 5. In this new Figure, the same relationship is explored but now for savanna across the 3 major savanna regions of Africa, South America and north Australia. This provides a more comprehensive assessment of drivers of savanna productivity; (3) revised section on Threats to savanna ecosystems that now includes more of a focus on climate change impacts and concepts of differential tree and C4 grass response to CO_2 fertilization, impacts on flammability. Also mentioned is the increase in savanna clearing and land use change, particularly in South America (e.g., the cerrado); and (4) two changes to the recommended reading list.

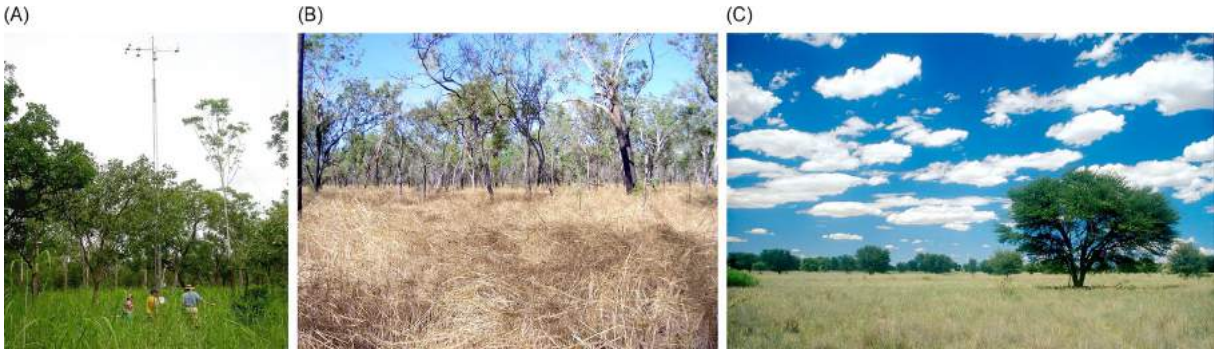

Fig. 1 Savanna ecosystems of the world, featuring the coexistence of a discontinuous woody overstorey with a continuous herbaceous understorey. Plates A and B are of a north Australian savanna site that receives approximately 1100 mm rainfall and is dominated by evergreen trees (*Eucalyptus* sp.) and tall C4 tropical grasses (*Sarga* spp.). Canopy fullness and grass growth are significantly differently in the wet (A) and dry (B) seasons. Tower-mounted instrumentation in Plate A is monitoring ecosystem productivity and water use over wet and dry seasons. Plate C, African savanna of the Kalahari Gemsbok National Park, Botswana. Photo courtesy of Joerg Tews.

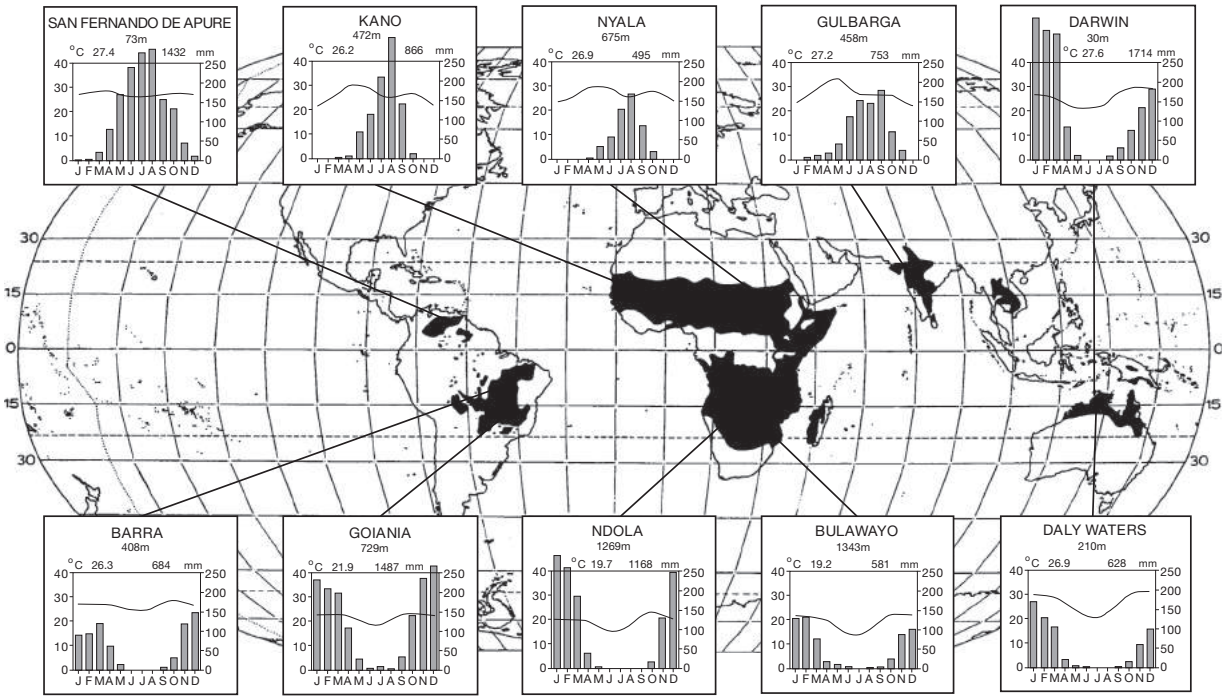

Fig. 2 The distribution of the world's savannas. Temperature and monthly rainfall data for a range of savannas are also given, with highly seasonal rainfall clearly evident.

Savanna also occurs in India, although these tree and grass systems tend to be derived from dry deciduous forest and subhumid deciduous forest due to land use changes and population pressure. Tropical savanna occupies an area of approximately 27.6 Mkm^2. Tree–grass mixtures also occur in temperate regions, in North America (Florida, TX), Mediterranean Europe, and Russia, although these temperate savannas are far smaller in extent at approximately 5 Mkm^2. In total, the savanna biome occupies 1/5th of the global land area and supports a large and growing human population.

The existence of a dry season is a defining feature of savannas; rainfall is seasonal and ranges from 300 to 2000 mm, with a dry season lasting between 2 and 9 months of the year. There can be a single, extended dry season or several shorter dry periods. Interannual variation of rainfall is typically high, as is the commencement and cessation of the wet season and growing season length, making cropping in savanna lands difficult. Indeed, historical rainfall plays an important role in determining the vegetation structure of a savanna. Seasonally available moisture dramatically influences plant productivity, which in turn determines the timing of available resources for savanna animals.

Given their wide biogeographic range, savannas occur on a number of soils types, typically oxisols, ultisols, entisols, and alfisols (using US Soil Taxonomy). In general, these soils are ancient and highly weathered, low in organic matter and cation exchange capacity (CEC). Oxisols occur in tropical savanna regions of South America and central and eastern African savanna and consist of

highly weathered, transported, and deposited material occurring on fluvial terraces. Extensive weathering of primary minerals has occurred and they are dominated by clay minerals such as kaolinite and gibbsite which have low CEC. Also present in the soil are acidic Fe and Al sesquioxides, which limits nutrient availability, especially phosphorus. Savanna soils tend to be sands to sandy loams, deep and well drained but with low soil moisture holding capacity. Entisols that occur in Australian savanna also feature the occurrence of ferruginous gravels, further reducing water and nutrient holding capacity. Bioturbation by earthworms, termites, and to a lesser extent ants are critical in the cycling nutrients through the poor soil systems. Termites essentially act as primary consumers and in savannas that lack a significant herbivore biomass (e.g., Australian and some South American savannas), they have an ecological function similar to that of herbivorous mammals.

Savannas of Australia, Africa, and South America

Tropical savanna is the predominant vegetation type across the northern quarter of Australia where rainfall is above 500 mm per year, an area of ~2 million km^2 (Figs. 1A, B and 2). These savannas are open-woodlands and open-forests, with tree cover declining as rainfall decreases with distance from the northern coast. The overstorey flora is typically dominated by *Eucalyptus*, *Corymbia* species. *Melaleuca and Eucalyptus* assemblages occur in the drier regions of this biome where annual rainfall <1000 mm year^{-1}. The ground layer is dominated by annual and perennial grasses from the *Sorghum*, *Heteropogon*, and *Schizachyrium* genera. A variety of other tall grasses (>1 m height) dominate the ground layer of the monsoonal savannas, which extend from Western Australia to the Cape York Peninsula in Queensland. *Heteropogon contortus* (black speargrass) dominates the tropical savanna understory in eastern Queensland, with *Themeda triandra*, *Aristida*, *Bothriochloa*, and *Chrysopogon bladhii* becoming more dominant as rainfall declines. *Acacia*-dominated savanna communities include extensive areas of brigalow (*A. harpophylla*), lancewood (*A. shirleyi*), and gidgee (*A. cambagei* and *A. georginae*).

The neotropical savannas of South America cover more than 2 million km^2. The Brazilian *cerrado* and the Colombian and Venezuelan *llanos* are a continuous formation, interrupted by narrow gallery forests. The *cerradão* includes a range of vegetation formations from the pure or almost pure grassland of *camp limpo*, to open-woodland with scattered tree cover of *campo cerrado*. These savanna can grade into denser woodland or open-forests, the *cerradão*, where tree cover is greater than 50%. The dominant grasses are *Andropogon*, *Aristida*, *Paspalum*, and *Trachypogon*. The Orinoco *llanos* of are grasslands or with scattered trees typically less than 8 m tall. Common trees include *Byrsonima* spp. *Curatella americana*, *Bowdichia virgioides*, and grasses include *Trachypogon* and *Andropogon*. Hyperseasonally flooded savannas and esteros (savanna wetland) occur in Brazil and Bolivia. Other savanna types, such as savanna parkland and mixed woodland occur through tropical America.

The African savannas occur across a range of soil types within a rainfall range of 200–1800 mm. One of the most extensive savanna areas is the *miombo* which covers about 2.7 million km^2 across central and southern Africa. The *miombo* is characterized by a discontinuous canopy of 10–12 m tall deciduous species of *Brachystegia*, *Isoberlinia*, and *Julbernardia*, with an herbaceous layer of tall grasses including mainly *Andropogon* species. In southern Africa, fine-leaved savannas, dominated by *Acacia* species, occur over fertile soils in low-lying, semiarid (250–650 mm/year) areas. Broadleaved savannas, including *Burkea africana*, *Combretum* spp., *Brachystegia*, occur on weathered, infertile soils. The northern *Sudanian* savannas have scattered deciduous trees, typically *Isoberlinia doka*, over xerophytic grasslands. These are bordered on the north by the drier *Sahelian* savannas and on the south by the wetter *Guinea*-type savannas. The arid and semiarid east African savannas are grasslands (*Aristida* spp., *Brachiara* spp.) with scattered shrubs or trees (including *Acacia*, *Grewia*, *Commiphora*), for example, the Serengeti.

Savannas occur throughout Asia, although many of these are derived from human disturbance. Savanna is fairly extensive in the Indian subcontinent although tree clearing has increased their extent, and many areas have been converted to agriculture. The most significant and widespread savanna type in Southeast Asia is the dry dipterocarp forest, which occurs in Vietnam, Laos, Cambodia, Thailand, Burma, and a small area in India. The region receives 1000–1500 mm rain per year and are dominated by the deciduous *Dipterocarpus* species, which can grow to 20 m, over a dense grass and herb layer including *Imperata cylindrical*, *Apluda mutica*, and *Apluda mutica* (pygmy bamboo).

Adaptive Traits of Savanna Vegetation

Savanna plants display a suite of traits to cope with seasonal drought, low water and nutrient availability, and the impacts of regular fire and herbivory. Adaptive traits which aid in the survival of fire of woody plants include thick insulating bark, high wood moisture content, elevated and well-separated crowns, and significant resprouting capacity. Resprouting can occur via lignotubers and from other underground and stem basal tissues following the death of aerial stems. This enables recovery with minimal developmental costs. Vegetative reproduction from roots, rhizomes, or stolons is dominant in much of the savanna biome. Adaptations to low nutrient availability include root mycorrhizal associations, particularly of ectomychorrhizae. Savanna trees can rapidly translocate sequestered nutrients from the leaves to other tissues (e.g., bark) prior to leaf fall. Woody savanna plants often have thorns that restrict grazing, as well as chemical features, such as tannins making leaves less palatable. Savanna grasses also display morphological features, such as serrated edges and chemical features, including tannins and silica bodies to restrict grazing.

The herbaceous grass layer is dominated by grasses with the C4 photosynthetic pathway. This pathway enables high photosynthetic rates at high temperatures and irradiance and low water availability. Most savanna trees and shrubs have the C3 photosynthetic pathway that has a higher efficiency under low light when compared to the C4 pathway; a characteristic which facilitates

recruitment and establishment under shaded tree canopies. The growth of savanna plants tends to occur mostly during the wet season with senescence or dormancy in the fire prone dry season, a trait that facilitates persistence in unfavorable conditions. Annual herbaceous species persist via a soil seed bank whereas above-ground parts of perennial herbaceous species die during dry periods, with dormant, regenerative buds protected within below-ground rhizomes or by cataphylls. Some annual grass species use hygroscopically active awns and pointed calluses on their seed that enables penetration into the surface soil protecting them from fire. Perennial herbaceous species require wet season rains to produce their first green shoots as carbohydrate storage from the previous wet season is limited. Rainfall stimulates germination of annual herbaceous and grass species and the early wet season is a period of rapid growth. Most herbaceous species flower in the wet season, although in contrast, many woody species flower in the dry season.

Woody species have evolved physiological and morphological mechanisms to either tolerate (evergreen habit) or avoid (deciduous habit) prolonged periods of water stress. Deep-rooting woody plants (usually evergreen) can access water resources throughout the year and provides them with their full photosynthetic capacity when favorable conditions occur. Deciduous species rehydrate stems prior to onset of wet season rains, which is then followed by leaf expansion to maximize photosynthetic activity during the wet season. Deciduousness and evergreeness represent extremes of physiological adaptations to survive the seasonal savanna climate. Evergreen species invest more resources in longer lived leaves, whereas deciduous species tend to support shorter lived leaves with high leaf photosynthetic capacity. Deciduous species need to acquire enough nutrient and photosynthate to ensure persistence and reproduction during the wet season, whereas evergreen species tend to have slower growth rates but persist throughout the seasonal cycle. Evergreeness also allows opportunistic acquisition of resources when soil nutrients are severely limiting and the cost of producing new leaves to respond to change in soil moisture is prohibitive.

Although this section has described broad seasonal growth patterns, it is important to note that the world's savanna plants include a high diversity of species and life-forms, with many distinct phenological patterns. All periods of the climatic cycle is favorable to certain vegetative or flowering phenophases in at least one group of species.

Environmental Factors Determining Savanna Structure

The adaptive traits described above enable individual plant survival in seasonally variable climates, but what environmental factors operate at a landscape or regional scale that determine savanna structure? Evidence suggests that four key environmental factors are responsible; (1) plant available moisture (PAM), (2) plant available nutrients (PAN), (3) fire regime (frequency, severity), and (4) herbivory. Herbivores include vertebrate and invertebrates and consist of both browsers consuming woody biomass and grazers consuming grasses and herbs. The overarching determinants of savanna physiognomy (relative abundance of the tree and grass layer) are climate and soil type (PAM and PAN), which determines the potential growth and survival of trees and grasses at a given site. Growth potential is moderated by disturbance agents, fire, herbivory, and stochastic events (such as cyclones). These factors act in concert to influence both competitive interactions and facilitation of tree and grass growth and determine savanna structure, floristics, and productivity (Fig. 3). The interaction of these factors is poorly understood and their variation in space and time make experimental testing and isolation of any single determinant difficult. Spatial heterogeneity of vegetation due local site histories (determined by antecedent rainfall, fire history, and herbivore numbers) and an inability to quantify these factors exacerbates this difficulty.

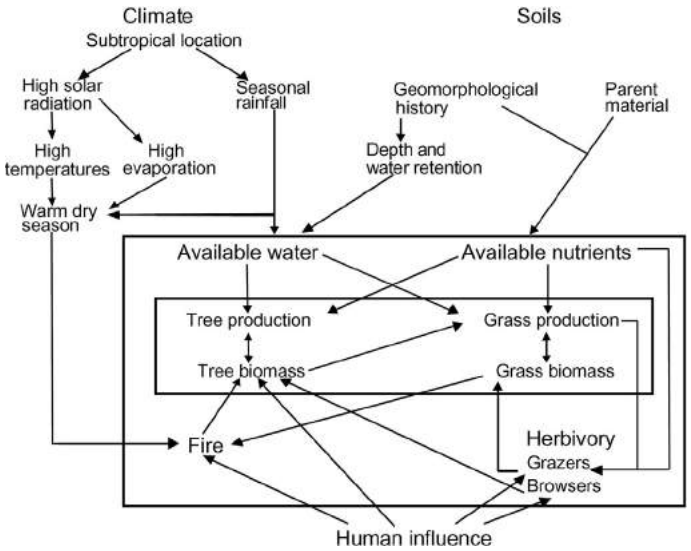

Fig. 3 Interactions between the environmental determinants of savanna structure. The relative tree and grass biomass and productivity is determined by available water, nutrient, and disturbance regime (fire and herbivory). These determinants are in turn characterized by climate and soil type for any given location. Reproduced with permission from House et al. (2003). *Journal of Biogeography* **30**, 1763–1777 (Blackwell Publishing Ltd., Oxford).

Available Moisture and Nutrients

Savannas tend occur in warm climates with an annual drought, with soils typically low in nutrient capital and poor water holding capacity. Trees and grass interactions are dominated by competition for water and nutrients, rather than light or growing space. At a broad, continental scale, PAM is the most significant of the four ecological determinants, with increasing rainfall correlated with increased tree cover and in general, a decreased grass biomass. PAM can be quantified via a range of parameters, from simple measures such as annual rainfall or via water balance parameters (rainfall as a fraction of potential or actual evapotranspiration) or soil characteristics (water release characteristics, soil storage capacity). At fine spatial scales, soil physiochemical properties (PAN) have a more significant influence and the interaction with PAM is often termed the PAM/PAN plane. Nutrient availability is largely a function of soil moisture and dry season nutrient uptake and nitrogen mineralization in particular, is limited by low levels of PAM. Significant plant growth is only possible during periods of high PAM that releases available nutrient via mineralization. Soils of semiarid savanna can have a higher intrinsic fertility when compared to highly, leached soils of mesic sites, but this nutrient capital is only available for uptake during moist periods. Savanna vegetation receiving similar rainfall can exhibit contrasting structure and floristics, simply due to fine-scale changes in soil type. A good example of this interaction comes from the long-term savanna research site of Nylsvley in South Africa; here, nutrient-poor, broad-leafed savanna, dominated by *Burkea africana*, surround patches of nutrient-rich soil that support a very different savanna type, a fine-leafed savanna dominated by *Acacia tortilis*. Both savanna types experience the same climate, but differences in soil parent material result in higher levels of soil available N and P in the fine-leafed patches. Productivity of the fine-leafed savanna is approximately double that of the broad-leafed system and attracts a larger grazing and browsing fauna. Similarly in South American savanna, soil acidity and aluminum levels significantly affect structure and floristics independent of rainfall.

Fire

Fire is an important landscape-scale determinant that impacts all of the world's savanna. Fire is an inevitable consequence of the annual cycle of profuse herbaceous production during the wet season followed by curing of this material in the dry season, when climatic conditions are ideal for burning. Savanna fires are virtually all surface fires, consuming the highly flammable herbaceous layer. Crown fires rarely occur as the fuel loads and dominated by fine fuels (grass and leaf litter) and the foliage of savanna trees and shrubs tend to be of low flammability. Human ignitions largely control fire behavior and extent in savanna, with some fires started by dry lightning strikes. Savanna fires spread rapidly through the surface fuels and high soil temperatures do not persist for longer than a few seconds to minutes. While these fires have a significant impact on above-ground plant parts, there is limited impact on savanna seed banks or above- and below-ground regenerative plant parts.

Fire has a major role in restricting tree establishment and growth, as evident from long-term fire exclusion plots (>25 years) in southern African and north Australian savanna (Fig. 4), which have resulted in a woody thickening. Frequent fire events can reduce tree seedling establishment and the ability of saplings to escape the flame zone via height growth. This limitation on tree establishment enables grass persistence and growth, maintaining the fuel load. The aerial stems of small seedlings and suckers are often killed during fire but the individuals are able to resprout from lignotubers or from other underground and stem basal tissues. Seedlings less than 6 months old have been observed to resprout in some species (e.g., *Eucalyptus miniata*) and frequent fire in the savannas will kill or maintain tree seedlings as a suppressed woody sprout layer until there is a sufficient fire-free period for them to "escape" the fire damage zone. Species can survive for at least 40 years as suppressed sprouts, during which time they develop significant lignotubers which aid in rapid growth during fire-free periods.

Fig. 4 Impacts of overgrazing and fire on savanna structure. Plate A is an overgrazed native grass paddock in semiarid savanna in north Australia (Kidman Springs Station, Victoria Rivers District, NT) at the end of the wet season of 1973. This site would be subjected to wind and water erosion, resulting in further decline in health and productivity of such sites. Exclusion of grazing and fire (Plate B) has resulted in a complete recovery of structure and function, with return of trees and grasses stabilizing soil surfaces, increased water capture, and a recovery in nutrient availability and cycling. Photos courtesy of John Ludwig, CSIRO.

The timing of fires in relation to reproductive phenology can constrain or promote plant reproduction. Studies on the woody species in the Brazilian *cerrado* and mesic Australian savannas have indicated that frequent fire can reduce seed production and sexual recruitment and could cause a shift in species composition, favoring vegetatively reproducing species. However, fire is also important for the sexual regeneration of some species, as burning induces flowering and fruit dehiscence in many *cerrado* species and facilitates pollination in others. Most perennial grass species are generally unaffected by burning and regenerate from basal leaf sheaths protected underground. Some perennial (e.g., *Trachypogon plumosus*) and annual (e.g., *Andropogon brevifolius*) grass species decrease in abundance after a long-term absence of fire.

Prior to human occupation and use of fire in savannas, lightning would have been the dominant source of ignition and it is likely that extensive but infrequent fires would have occurred. In Australia, humans have intentionally used fire for at least 45,000 years and in Africa for potentially 1 million years or more. Large proportions of savanna regions are burnt each year for a variety of reasons; land clearing, livestock management, property protection, conservation management, and cultural purposes. In African savannas, fires burn between 25% and 50% of the arid "Sudan Zone" and 60%–80% of the humid "Guinea Zone" each year. In the high rainfall (>1000 mm annual rainfall), ~50% of *Eucalyptus* dominated open-forest savanna is burnt in northern Australia. With the progression of the dry season, fire intensity increases due to fuel accumulation from curing litterfall and grass senescence, resulting in an increased combustibility of fuels. This and more severe fire weather (i.e., higher temperatures, wind speeds, and lower humidity) result in an increased landscape flammability. Early dry season fires (when fuel accumulation is low and curing incomplete) tend to be low intensity, patchy, and limited in extent whereas fires later in the season are of higher intensity and produce more extensive and homogeneous burning. Impacts on vegetation depend on fire intensity, distribution, and timing (fire regime) in relation to the vegetative and phenological cycles. Determining direct effects of fire on savannas is often difficult due to confounding effects of herbivory. Nevertheless, long-term burning experiments have shown that the higher intensity, late dry-season fires are the most damaging to woody species.

Herbivory

Two common images of savannas are herbivory by large, native ungulates, particularly in Africa and the widespread grazing by domestic herds, particularly cattle. A more neglected group of savanna herbivores are the invertebrates, particularly grasshoppers, caterpillars, ants, and termites. Mammal herbivores are typically categorized as grazers, browsers, or mixed feeders, who can vary their diet depending on food availability. Mammal and insect herbivores impact on savanna structure and function via consumption of biomass, seed predation, trampling of understory, and the pushing over and killing of trees and shrubs. The importance of herbivory as a determinant varies between savanna regions, and appears to largely reflect the abundance of large herbivores present. Large herbivore diversity and abundance are much higher in Africa than in Australia, Asia, or South America. More than 40 large wild herbivore species have been described in African savanna. In contrast, only six species of megapod marsupial have been considered as large herbivorous mammals in the Australian savannas, and only three species of ungulates are regarded as native South American savanna inhabitants. Domestic animals, particularly cattle, buffalos, sheep, and goats, are now the dominant, large herbivores in most savannas.

Large herbivores can lead to changes in species composition, woody vegetation density, and soil structure. For example, grazing pressure in Africa and Australia has led to a decrease in palatable, perennial, grazing-sensitive tussock grasses, and an increase in less palatable perennial and annual grass and forb species. Changes to the soil surface can occur, including loss of crusts (important in nutrient cycling), development of scalds, compaction, increased runoff, soil erosion, and nutrient loss. In parts of Africa, woody vegetation density has sometimes been reduced by large herbivores, for example uprooting of trees by elephants when browsing. Browsers such as giraffes can reduce woody seedling and sapling growth thereby keeping them within a fire-sensitive height for decades. By contrast, in many of the world's savannas the density of woody vegetation has increased at the expense of herbaceous vegetation; one of the major causes has been high rates of herbivory. A decrease in grass biomass following grazing leads to a reduction fuel and thus fire frequency and intensity, enhancing the survival of saplings and adult tress. Fire also affects herbivory as herbivores may favor postfire vegetation regrowth. Clearly, fire and herbivory have an interactive effect on savanna structure and function.

While less spectacular than large browsers and grazers, insects are often the dominant group of herbivores in savannas, especially on infertile soils supporting low mammal biomass. There is a paucity of data describing their abundance or role in these ecosystems. In a broad-leaved, low fertility savanna of southern Africa, a grasshopper biomass of 0.73 kg ha^{-1} can consume almost 100 kg ha^{-1} of plant material and damage an additional 36 kg ha^{-1}. This represents a loss of 16% of above-ground grass production. Grasshoppers and caterpillars can account for up to half the grass herbivory, although the rate and proportion varies substantially between years. Fertile, fine-leaved savannas are able to support a larger mammal biomass and the proportion of herbivory resulting from insect consumption is lower when compared to infertile African sites. The impact of insect herbivores on physiognomy has not been established but they are clearly important herbivores in savannas through their impact on productivity and ecosystem properties.

Conceptual Models of Tree and Grass Coexistence

Interactions between the coexisting life-forms in savanna communities are complex and over the last 40 years, a range of conceptual or theoretical models has been proposed to explain tree and grass mixtures. Contrasting models have all been supported by empirical evidence for particular sites, but no single model has emerged that provides a generic mechanism explaining coexistence. Models can be classified into several categories. Competition-based models feature spatial and temporal separation of resource usage by trees and grasses that minimizes competition and enables the persistence of both life-forms. Alternatively, demographic-based models have been described, where mixtures are maintained by disturbance, resulting in bottlenecks in tree recruitment and/or limitations to tree growth and grasses can persist. Table 1 provides a summary of these models. Root–niche separation models suggest there is a spatial separation of tree and grass root systems, with grasses exploiting upper soil horizons and trees developing deeper root systems. Trees rely on excess moisture (and nutrient) draining from surface horizons to deeper soil layers. Phenological separation models invoke differences in the timing of growth between trees and grasses. Leaf canopy development and growth in many savanna trees occurs prior to the onset of the wet season, often before grasses have germinated or initiated leaf development. As a result, trees can have exclusive access to resources at the beginning of the growing season, with grasses more competitive during the growing season proper. Given their deeper root systems, tree growth persists longer into the dry season, providing an additional period of resource acquisition at a time when grasses may be senescing. This spatial and temporal separation of resource usage is thought to minimize competition, enabling coexistence. Other competition models suggest that trees density becomes self-limiting at a threshold of PAM and PAN and are thus unable to completely exclude grasses. These models assume high rainfall years favor tree growth and recruitment, with poor years favoring grasses and high interannual variability of rainfall maintaining a relatively stable equilibrium of trees and grasses over time.

Alternatively, savannas can be viewed as metastable ecosystems (narrow range of stabile states) with a dynamic structure over time. Demographic-based models suggest that determinants of tree demographics and recruitment processes ultimately set the tree–grass ratio (Table 1). Fire, herbivory, and climatic variability are fundamental drivers of tree recruitment and growth, with high levels of disturbance resulting in demographic bottlenecks that constrain recruitment and/or growth of woody components and grass persistence results. At high rainfall sites, in the absence of disturbance, the ecosystem tends toward forest. High levels of disturbance, particularly fire, can push the ecosystem toward a more open canopy or grassland; this ecosystem trajectory is more likely at low rainfall sites.

There is observational and experimental data to support all of the above models and it is highly likely that savanna structure and function results from the interaction of all processes. In many savannas, root distribution is spatially separated with mature trees exploiting deeper soil horizons as the competitive root–niche separation model predicts. Root partitioning favors tree growth in semiarid systems where rainfall occurs during periods when grass growth is dormant; rainfall can drain to deep layers supporting tree components. By contrast, in semiarid savanna where rainfall and growing seasons coincide, investment in deep root systems could result in tree water stress, as rainfall events tend to be sporadic and small in nature, with little deep drainage. In this case, surface roots are more effective at exploiting moisture and mineralized nutrients following these discrete events. In these savannas, tree and grass competition for water and nutrients would be intense. In mesic savanna sites, root competition between both trees and grass roots in upper soil layers is apparent, contrary to predictions of niche-separation models. Mesic savannas of north Australia (rainfall >1000 mm) are dominated by evergreen *Eucalyptus* tree species and during the wet season these trees compete with high growth-rate C4 grasses for water and nutrients in upper soil layers (0–30 cm). However, by the late dry season, tree root

Table 1 Conceptual models explaining the coexistence of trees and grasses in savanna ecosystems in equilibrium (tree:grass ratio relatively stable at a given site), nonequilibrium (tree:grass ratio variable), or disequilibrium (disturbance agents essential for the maintenance of tree:grass coexistence)

Competition-based mechanisms of coexistence	*Demographic-based mechanisms of coexistence*
Spatial and temporal niche separation of resource usage enables both life-forms to coexist	Climatic variation and disturbance impacts on tree demography Extremes of climate and disturbance influence tree germination and/or establishment and/or transition to mature size classes enabling coexistence
Root–niche separation	Tree and grasses exploit deep and shallow soil horizons
Phenological separation	At low rainfall sites, tree establishment and growth occurs only in above average rainfall periods
Temporal differences in leaf expansion and growth, trees have exclusive access to resources at beginning and end of growing season, grasses competitive during growing season	At high rainfall sites, high fuel production maintains frequent fire to limit tree dominance
Balanced competition	Trees are the superior competitor but become self-limiting for a given rainfall and unable to exclude grasses
Competition–colonization	Rainfall variability results in a tradeoff between tree and grass competition and colonization potential. Higher than mean rainfall favors tree growth, lower than mean favors grasses
Primary determinants PAM, PAN	Primary determinants PAM variability, PAN, fire regime, herbivory
Secondary determinants	Fire regime, herbivory

activity has shifted to subsoil layers (up to 5 m depth) and herbaceous species have either senesced or are physiologically dormant. These root dynamics suggest grasses are essentially drought avoiders but are able to compete with trees during the wet season. This system serves as an example of where both root–niche and phenological separation is occurring.

Tree to tree competition is also significant, as suggested by the strong relationship observed in most savanna regions between annual rainfall and indices of tree abundance, be it tree cover or tree basal area (area occupied by tree stems, Fig. 5). As PAM decreases, tree abundance declines, although there is significant variability at any given rainfall driven by differences in soil type, fire regime, herbivory, and/or land use. Competition models fail to consider impacts of savanna determinants on different demographics of a population, such as recruitment, seedling establishment, and tree sapling growth. Root–niche or phenological separation models largely consider impacts acting on mature individuals, whereas demographic models include impacts of climate variability and disturbance on critical life-history stages (e.g., seedling establishment and accession to fire-tolerant size classes). Demographic models assume that savanna tree dynamics are central to savanna ecosystem functioning and that savanna trees are the superior competitors under most conditions; grass persistence only occurs when determinants act to limit tree abundance. It is clear that competition, both within and between savanna life-forms, occurs and that tree abundance is moderated by climate

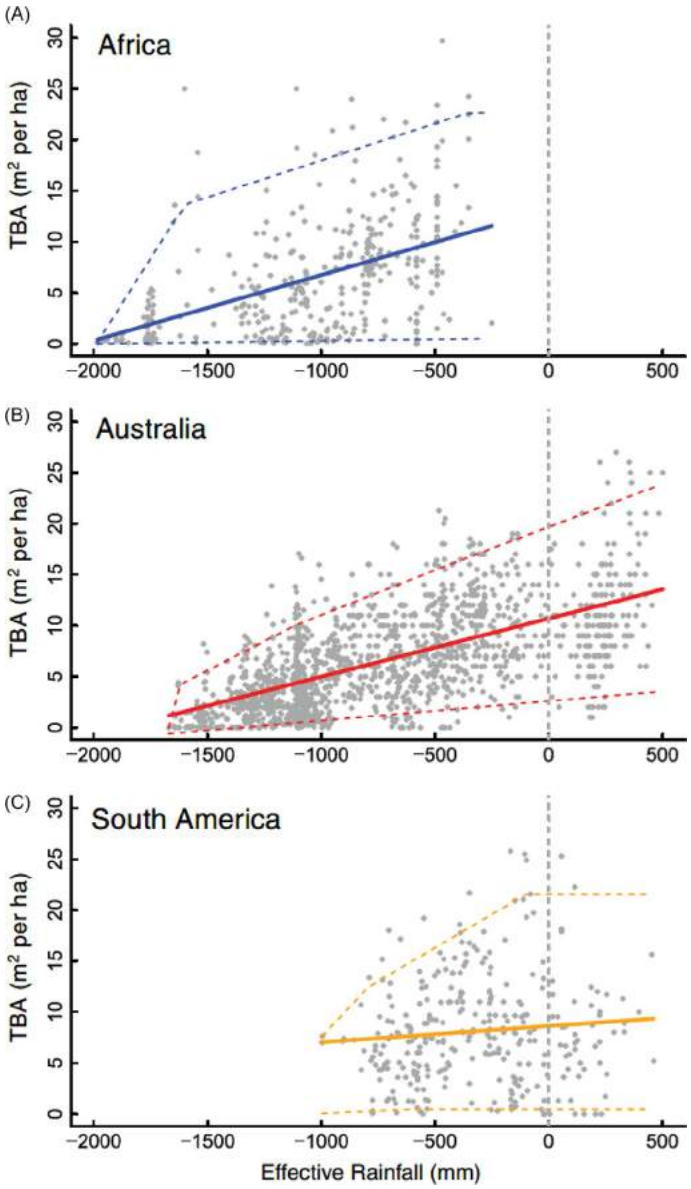

Fig. 5 Relationship between effective rainfall (rainfall–potential evapotranspiration) and tree basal area for African, Australian, and South American savannas. Rainfall sets a maximal climate-determined woody cover with other factors such as available nutrient, fire regime, and herbivory also determining woody cover at any given site. From Lehmann et al. (2014). *Science* **343**, 548–552 (American Association for the Advancement of Science), with permission.

variability and disturbance. A more comprehensive model would integrate both competition and demographic theories to yield a model in which competitive effects are considered for each life-history stage.

The complexity inherent in these models is evident when savanna structure is correlated with any of the environmental determinants. Fig. 5 describes the relationship between tree basal area and effective rainfall, which is calculated as rainfall–potential evapotranspiration, and is a useful surrogate for PAM. Tree basal area data are shown for African, Australian, and South American savanna with a large range of basal are possible at any given effective rainfall, especially for African sites. Rainfall sets an upper limit on tree basal area, with points below this limit determined PAM as well as PAN (soil type) and fire regime playing a significant role. At semiarid savanna sites (<650 mm rainfall), it is likely that rainfall limits tree cover and canopy closure, permitting grass coexistence. At rainfalls >650 mm, tree canopy closure may be possible, with disturbance limiting tree dominance. For African and Australian savanna, the relationship (slope) is similar, with basal area increasing with effective rainfall. This relationship is far weaker for the wetter South American savannas, suggesting other factors such as soil characteristics are playing a more significant role in determining productivity.

Savanna Biomass and Productivity

Global net primary production (NPP), the net production of plant biomass is approximately 67.6 Gt C $year^{-1}$ of which almost 30% occurs in savanna ecosystems (19.9 Gt $year^{-1}$). This production occurs on 18% of the global land surface, demonstrating that savannas are relatively productive ecosystems but subjected to frequent disturbances, such as fire and herbivory that limits biomass accumulation. Mean savanna NPP has been estimated at 7.2 t C ha^{-1} $year^{-1}$ (Table 2), lower than typical values for the other major tropical ecosystem, rainforest, which ranges from 10 to 15 t C ha^{-1}. Savanna NPP and biomass varies by an order of magnitude (Table 2), as would be expected given their geographic range and structural variation. The relative production of trees versus grasses is also highly variable, but in general, NPP of the C4 grass layer is two to three times that of woody NPP. Biomass stored in above- and below-ground pools gives the root:shoot ratio and global biomass data gives a global mean of approximately 2 (Table 2). This reflects the investment in root systems and below-ground storage organs, such as lignotubers, to maintain uptake of moisture and nutrient from sandy, nutrient poor savanna soils and to survive annual drought and disturbance.

Savanna photosynthesis and growth is highly seasonal and interannual variability high. Mesic savanna may receive annual rainfall associated with rainforest ecosystems, yet productivity is significantly lower, due largely to annual drought, poor soils, and impacts of disturbance. Long-term (as opposed to annual) estimates of savanna productivity need to include loss of biomass due to fire and herbivory. Including fire and herbivory impacts in productivity estimates gives the carbon sequestration rate, which represents the net gain (sink) or loss of carbon from the ecosystem to the atmosphere. While wet season productivity can be very high in savannas, much of a wet-season's herbaceous productivity can be lost via fire or grazing. Woody biomass tends to be a less dynamic, longer-term carbon storage pool than the herbaceous components of savanna. Savanna fire results in a significant release of greenhouse gases, including CO_2, CO, methane, nonmethane hydrocarbons, nitrous oxide, particulate matter and aerosols, equivalent to 0.5–4.2 Gt C $year^{-1}$. Fire reduces net savanna sequestration rate by about 50% and protection of savannas from fire and grazing results in an increase in woody biomass which can result in a long term increase in stored soil carbon. Savanna sink strength in mesic Orinoco savannas in South America (~1500 mm annual rainfall) has been measured at 1 t C ha^{-1} $year^{-1}$, with this sink maintained over a 25 year period in plots with fire and grazing excluded. Similarly, the carbon sink strength of north Australian, *Eucalyptus* dominated savannas receiving approximately the same rainfall has also been estimated at approximately 0.5–1 t C ha^{-1} $year^{-1}$, with this sink measured at sites burnt but not grazed. This carbon is likely being stored in woody biomass and soil organic carbon pools, with a small fraction being stored as black carbon (charcoal), a resilient carbon pool. Savanna soil carbon storage is by far the largest terrestrial pool (Table 2) and soil carbon represents a longer-term carbon storage when compared

Table 2 Savanna biomass, soil carbon stocks, and productivity

Parameter	*Mean (sd)*	*Range*
Biomass and soil stocks (t C ha^{-1})		
Aboveground biomass	10.6 (9.0)	1.8–34
Belowground biomass	19.5 (14.9)	4.9–52
Total biomass	33.0 (22.9)	9.4–84
Root:shoot ratio	2.1 (2.0)	0.6–7.6
Soil organic carbon	174.2 (126.0)	18–373
Savanna area (Mkm^{-2})	27.6	
Total carbon pool (Gt C)	326	
Productivity (t C ha^{-1} $year^{-1}$)		
NPP	7.2 (5.1)	1.4–22.8
NEP	0.14	

Data from Grace, J., San, J.J., Meir, P., Miranda, H.S., Montes, R.A. (2006). Productivity and carbon fluxes of tropical savannas. *Journal of Biogeography* **33**, 387–400 (Blackwell Publishing Ltd., Oxford).

to the more dynamic vegetation components. Burning also influences nutrient dynamics via losses due to volatilization (vaporization) of lighter elements such as nitrogen and sulfur. At a global scale, savannas and tropical seasonally dry forests represent a significant source of N_2O to the atmosphere (4.4 Tg N_2O year^{-1}). Shifts to a more frequent fire regime may result in a net loss of nitrogen, significant as savanna are in general nitrogen poor. Many grass species are able to recover quickly after fire, with regrowth attractive to grazing animals, due to the relatively high nutrient content of the foliage.

Threats to Savanna Ecosystems

Savannas are the location of human evolution, and humans are an integral component of these ecosystems. Humans have influenced the determinants of savannas for thousands of years via modification to nutrient availability from fire and clearing for agriculture. Human cultures have used fire as a vegetation management tool and introduced animal husbandry systems, changing grazing, and browsing pressures, modifying tree–grass competitive balances (e.g., Fig. 4). Savannas now face a range of threats, many operating synergistically. A contemporary impact is now being experienced via climate change and its influence on rainfall distribution, temperature increases, climate conditions conducive to fire and increased atmospheric CO_2 concentration. Impacts of climate change will be complex. Elevated atmospheric CO_2 is likely to favor woody growth over grasses given the increased carbon allocation to roots and lignotubers and the higher water and light use efficiencies of the C3 photosynthetic pathway as utilized by woody components when compared to the response of C4 photosynthesis of grasses. Tree:grass balance will be shifted as tree saplings may grow to fire-tolerant sizes faster, limiting the impact of fires that maintain grasses in savanna. However, gains in productivity may be offset by enhanced flammability due to shifts in fire weather from higher temperatures, evaporation rates, and fuel curing. This impact will likely vary in different countries and regions due to the variation in dominance of different phenological strategies. An extended growing season have greater impact on deciduous species (with longer leaf retention) than it would on evergreen species.

Human usage of the savanna biome is increasing, which can lead to degradation of vegetation and soil resources, resulting in nutrient losses and shifts in water balance and availability. Conversion to agricultural production is resulting in the clearing of large areas of the world' savannas. For example, ~50% of the *cerradão* and *llanos* has now been cleared or altered for agricultural crops such as coffee, soybeans, rice, corn, and beans. In addition, an increasing threat is from afforestation, such as growing exotic eucalypt and acacia plantations in Brazil and Nigeria, palm oil in Colombia, and fruit plantations in China. Plantations have replaced large areas of cerrado with few remaining areas of natural vegetation in the eastern cerrado region. Alterations in grazing pressure and fire suppression in managed savannas has also resulted in woody dominance, which ultimately reduces grazing production, severely impacting communities relying on cattle-derived incomes and reducing local biodiversity. This thickening or woody encroachment is being observed in areas subjected to extensive grazing activities in both African and Australian savannas and may be enhanced by increasing atmospheric CO_2 concentration.

Clearing for alternative land uses can result in exotic species invasions, a problem for much of the world's savannas. African savanna, especially in South Africa, are being invaded by woody species, often *Acacia* or *Eucalyptus* species from Australia, introduced for fuel wood or timber production. Reduced herbivory of these species results in high growth rates and water use. The development of thickets reduces deep drainage, groundwater recharge, and streamflow, consequently affecting water supplies. In an attempt to increase the grazing potential of north Australian and South American savanna, fast growing African grasses such as *Andropogon gayanus*, *Melinis minutiflora*, *Panicum maximum*, and *Urochola* spp. have been introduced. They are often more productive than native species resulting in more flammable fuel loads. At infested sites in north Australia, resultant fire intensity is five times that observed from native grass savanna causing major declines in tree cover. This in turn will result in a demographic bottleneck, long-term loss in tree cover and the instigation of a grass–fire cycle.

All of the above examples involve human impacts acting on one or more of the determinants of savanna structure and function. Clearly increased knowledge of their interactions will provide improved understanding of savanna processes and enable better management in a rapidly changing world. Savannas may be ideal ecosystems for agro-forestry applications, rather than traditional cropping systems. Small shifts in fire regime may dramatically increase productivity, thus savanna systems could be used for carbon sequestration and greenhouse gas mitigation schemes, providing alternative livelihoods and aiding in the maintenance of biodiversity.

Steppes and Prairies

JM Briggs, Arizona State University, Tempe, AZ, USA

Steppes and prairies (grasslands) are ecosystems that are dominated by grasses and to help understand grasslands, it is important to know something about grass morphology and growth forms. The remarkable ability of grasses to thrive in so many ecological settings and their resilience to disturbance is largely attributable to their growth form. Grasses are characterized by streamlined reduction and simplicity with tillers being the key adaptive structural element of the plant (Fig. 1). Tillers originate from growing parts (meristems) typically just near, at, or below the surface of the soil. The meristems that produce tillers are generally well protected by their location near or beneath the soil surface. It is the location of the meristem that explains much of the resilience of grasses and thus grasslands to disturbance.

Grass leaves are narrow and generally well-supplied with fibrous supporting tissue that has thick-walled cells. These features, along with a capacity to fold or roll the leaves along the vertical plane, permit the plant to endure periods of water stress without collapse. Another feature of grass leaves is the presence of siliceous deposits and silicified cells (phytoliths). Although silica is present in many plant families, phytoliths are characteristic of grasses. Phytoliths often have distinctive forms within taxonomic groups and since they persist in soil profiles for a very long time, they can be used by paleobotanists to determine shifts in dominance from one grass form to another. Silica also makes grass forage very abrasive and it is now generally accepted that the evolution of abrasion-resistant teeth present in many modern grazing animals was an evolutionary response to tooth-wearing effects of a diet high in grass. This also suggests that the grasses and their megaherbivore grazers are highly coevolved. But recent discovery of grass phytoliths in Late Cretaceous dinosaur coprolites in India suggest that grasses were already substantially differentiated and that abrasive phytoliths were present in many grasses before the explosion of grazers in the Oligocene and Miocene time periods.

Grasses show a very large variation in the way tillers are aggregated as they expand from their origin, but two general forms of grasses are recognized: bunch-forming (caespitose) and sod-forming (rhizomatous). This description captures the major features of the dominant grass species but there are some species and groups that deviate from this general pattern. The most obvious include the woody bamboos (some of which can reach tree size and for the most part are restricted to forest habitats in the tropics and subtropics).

In addition to growth form, grasses can also be roughly divided into two categories based upon their photosynthetic pathways: cool season (C_3) and warm season (C_4). C_4 photosynthesis is a variation on the typical C_3 pathway and is thought to have an advantage in high-light and -temperature environments typical of many grassland regions worldwide. Throughout the world today, tropical, subtropical, arid, semiarid, and mesic grasslands are typically dominated by C_4 grasses while in cooler high-elevation or northern climates, C_3 grasses are more common.

Grasslands

As mentioned above, ecosystems in which grasses and grass-like plants (including sedges and rushes and collectively known as graminoids) dominate the vegetation are termed grasslands. In its narrow sense, `grassland' may be defined as ground covered by vegetation dominated by grasses, with little or no tree cover. UNESCO defines grassland as ``land covered with herbaceous plants with less than 10 percent tree and shrub cover'' and wooded grassland as 10–40% tree and shrub cover. Grassland ecosystems are notable for two characteristics: they have properties that readily allow for agricultural exploitation through the management of domesticated plants or herbivores, and a climate that is quite variable both spatially and temporally. They are found in regions where drought is fairly common but where precipitation is sufficient for their growth. In addition, they can also dominate wetlands in both freshwater and coastal regions. They also occur in sites where more predictable rainfall occurs and soils are shallow or poorly drained, or in areas with topography too steep for woody plants. To put it simply, grasslands usually occupy that area between wetter areas dominated by woody plants and arid desert vegetation.

Grassland biomes occur on every continent except Antarctica. It is estimated that grasslands once covered as much as 25–40% of the Earth's land surface although much of the original extent of native grassland has been plowed and converted to other grass production (corn and wheat) or other row crops such as soybeans. Indeed, grasslands are important from both agronomic and ecological perspectives. Grasslands are the basis of an extensive livestock production industry in North America and elsewhere. In addition, grasslands sequester and retain large amounts of soil carbon and thus, they are an important component of the global carbon cycle.

Indeed, because grasslands store a significant amount of carbon in their soils and they contain relatively high biodiversity, then now play a prominent role in the discussion about biofuel production. Biofuels may offer a mechanism to generate energy that releases less carbon into the atmosphere. Some energy producers recommend intensive agricultural production of corn, or other grasses such as switchgrass or elephant grass for biofuel production. However, agricultural practices have significant energy costs that may reduce the value of these fuel sources. A recent study has suggested, however, that diverse prairie communities on

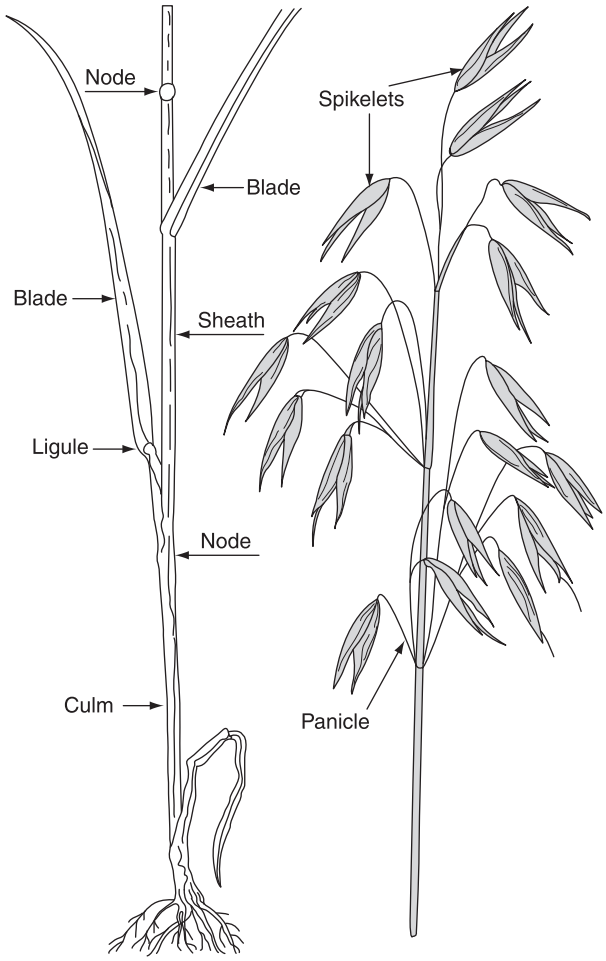

Fig. 1 Common oat, *Avena sativa*, × ½. From Hubbard (1984).

marginal lands are potentially `carbon negative' because they provide significant biomass for fuel and store carbon belowground. Much additional research is needed to assess the sustainability of grasslands for biofuel production, but the prospects are certainly tantalizing to energy producers and conservationists alike.

Grassland Types

It is estimated that prior to the European settlement of North America, the largest continuous grasslands in the United States stretched across the Great Plains from the Rocky Mountains and deserts of the Southwestern states to the Mississippi river. Other extensive grasslands are, or were, found in Europe, South America, Asia, and Africa (**Fig. 2**). Grasslands can be broadly categorized as temperate or tropical. Temperate grasslands have cold winters and warm to hot summers and often have deep fertile soils. Surprisingly, plant growth in temperate grasslands is often nutrient limited because much of the soil nitrogen is stored in forms unavailable for plant uptake. These nutrients, however, are made available to plants when plowing disrupts the structure of the soil. The combination of high soil fertility and relatively gentle topography made grasslands ideal candidates for conversion to crop production and thus have led to the demise of much of the grasslands across the world.

Grasslands in the Midwestern United States that receive the most rainfall (75–90 cm) are the most productive and are termed tallgrass prairies. Historically, these were most abundant in Iowa, Illinois, Minnesota, Missouri, and Kansas. The driest grasslands (25–35 cm of rainfall) and least productive are termed shortgrass prairie or steppe. These grasslands are common in Texas, Colorado, Wyoming, and New Mexico. Grasslands intermediate between these extremes are termed mid- or mixed grass prairies. In tallgrass prairie, the grasses may grow to 3 m tall in wet years. In shortgrass prairie, grasses seldom grow beyond 25 cm in height. In all temperate grasslands, production of root biomass belowground exceeds foliage production aboveground. Worldwide, other names for temperate grasslands include steppes throughout most of Europe and Asia, veld in Africa, *puszta* in Hungary, and the pampas in South America.

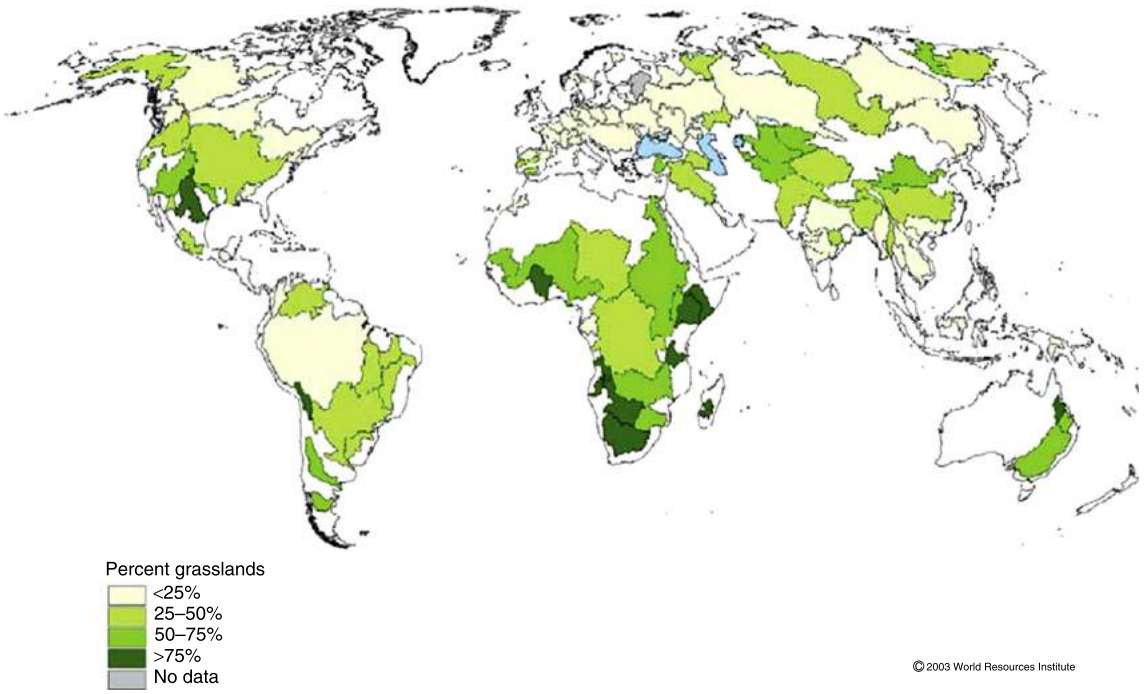

Fig. 2 Map of the grasslands of the world. World Resources Institute – PAGE, 2000. Sources: GLCCD, 1998. Loveland, T.R., Reed, B.C., Brown, J.F., et al., 1998. Sioux Falls, SD: USGS EDC, p. 39.

Tropical grasslands are warm throughout the year but have pronounced wet and dry seasons. Tropical grassland soils are often less fertile than temperate grassland soils, perhaps due to the high amount of rainfall (50–130 cm) that occurs during the wet season and washes (or leaches) nutrients out of the soil. Most tropical grasslands have a greater density of woody shrubs and trees than temperate grasslands. Some tropical grasslands can be more productive than temperate grasslands. However, other tropical grasslands grow on soils that are quite infertile or these grasslands are periodically stressed by seasonal flooding. As a result, their productivity is reduced and may be similar to that of temperate grasslands. As noted for temperate grasslands, root production belowground far exceeds foliage production in all tropical grasslands. Other names for tropical grasslands include velds in Africa, and the compos and llanos in South America.

Although temperate and tropical grasslands encompass the most extensive grass dominated ecosystems, grasses are present in most types of vegetation and regions of the world. Where grasses are locally dominant they may form desert grassland, Mediterranean grassland, subalpine and alpine grasslands (sometimes referred to as meadows or parks), and even coastal grassland. Most grasslands are dominated by perennial (long-lived) plants, but there are some annual grasslands in which the dominant species must reestablish each year by seed. Intensively managed, human-planted, and maintained grasslands (e.g., pastures, lawns) occur worldwide as well.

The Grassland Environment

Grassland climates can be described as wet or dry, hot or cold (typically in the same season), but on average are intermediate between the climates of deserts and forests. The climate of grasslands is best described as one of extremes. Average temperatures and yearly amounts of rainfall may not be much different from desert or forested areas, but dry periods during which the plants suffer from water stress occur in most years in both temperate and tropical grasslands. An excellent example of this comes from North America, where in the area around Washington, DC (dominated by eastern deciduous forest), the annual precipitation is ~102 cm whereas at Lawrence, KS (dominated historically by tallgrass prairie), the annual precipitation is ~100 cm. But the way the rainfall is distributed is notably different. At Lawrence, KS, over 60% of the rainfall occurs in the growing season (April–September), whereas at Washington, DC, the precipitation is uniformly distributed throughout the year. The open nature of grasslands is accompanied by the presence of sustained high wind speeds. Windy conditions increase the evaporation of water from grasslands and this increases water stress in the plants and animals. Another factor that increases water stress is the high input

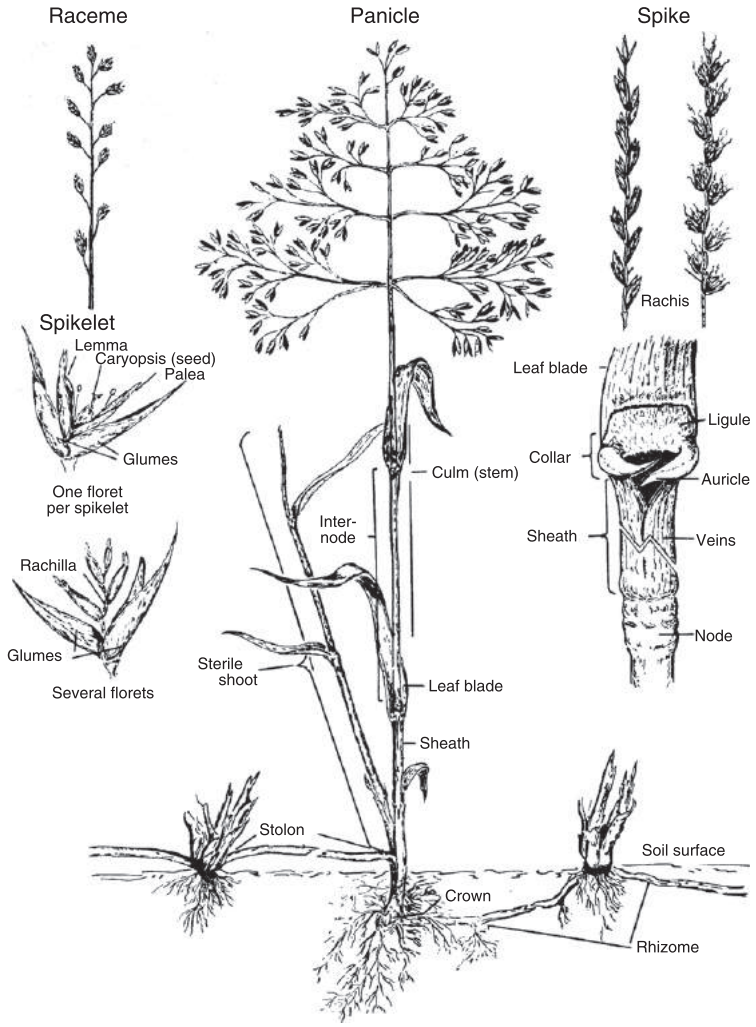

Fig. 3 Structure and architecture of the grass plant. From Ohlenbusch *et al.* (1983).

of solar radiation in these open ecosystems. This leads to the convective uplift of moist air and results in intense summer thunderstorms. Rain falling in these intense storms may not be effectively captured by the soil and the subsequent runoff of this water into streams reduces the moisture available to grassland plants and animals. In addition to periods of water stress within the growing season, consecutive years of extreme drought are more common in grassland than in adjacent forested areas. Such droughts may kill even mature trees, but the grasses and other grassland plants have extensive root systems and belowground buds that help them survive and grow after drought periods (Fig. 3).

Fire in Grasslands

It is generally recognized that climate, fire, and grazing are three primary factors that are responsible for the origin, maintenance, and structure of the most extensive natural grasslands. These factors are not always independent (i.e., grazing reduces standing crop biomass which can be viewed simply as a fuel for fire, and biomass is also highly dependent upon the amount of precipitation). Historically, fires were a frequent occurrence in most large grasslands. Most grasslands are not harmed by fire, many benefit from fire, and some depend on fire for their existence. When grasses are dormant, the moisture content of the senesced foliage is low and this fine-textured fuel ignites easily and burns rapidly. The characteristic high wind speeds and lack of natural fire breaks in grasslands allow fire to cover large areas quickly. Because fire moves rapidly and much of the fuel is above the ground, temperatures peak rapidly and soil heating into the range that is biological damaging ($>60\ ^{\circ}C$) occurs for only a short period of time and only at the surface or maybe a few centimeters into the soil. Thus, the important parts of the grasses (roots and buds) have excellent protection against even the most intense grass fires. Fires have been documented to be started by lightning and set intentionally by humans in both tropical and temperate grasslands. Fires are most common in grasslands with high levels of plant productivity, such as tallgrass prairies, and in these grasslands fire is important for keeping trees and adjacent forests from

Fig. 4 Photograph of a spring fire at the Konza Prairie Biological Field Station. The fire in the background is occurring ~2 weeks after the area in the foreground was burned. Photograph by Alan K. Knapp.

encroaching into grasslands. Many tree species are killed by fire, or if they are not killed, they are damaged severely because their active growing points are aboveground. Grassland plants survive and even thrive after fire because their buds are belowground where they are protected from lethal temperatures (**Fig. 4**).

The response of grassland species to fire mostly depends upon the production potential of the grassland. In the more highly productive grasslands (e.g., tallgrass prairie), fire in the dormant season (usually right before the growing season) results in an increase in growth of the grasses and thus greater plant production or total biomass. This occurs because the buildup of dead biomass (detritus) from previous years inhibits growth; fire removes this layer. However, in drier grasslands, or even in years in productive grasslands when the precipitation is low, the burning of this dead plant material may cause the soil to become excessively dry due to high evaporation losses. As a result, plants become water-stressed and growth is reduced after fire, thus resulting in lower productivity. It is only with long-term data that the true impact of fires on grasslands can be determined (**Fig. 5**).

So what are the mechanism(s) behind the increase in production in mesic grasslands after a fire? One of the most common misconceptions is that fire in grasslands increases productivity by increasing (releasing) the amount of nitrogen (N), a key limiting nutrient in terrestrial ecosystems. Actually, soil N decreases with burning. However, as mentioned above, the primary mechanism by which fire increases production in tallgrass prairie is through the removal of the accumulation of detritus produced in previous years. Standing dead biomass has been reported to accumulate to levels of up to 1000 g m^{-2} in tallgrass prairie and a steady state is achieved *c.* 3–5 years after a fire. The specific effects of this blanket of dead biomass on production are numerous and manifest on individual through the ecosystem levels. This detritus may accumulate to >30 cm deep, and this nonphotosynthetic biomass shades the soil surface and emerging shoots. This reduction in light available to shoots in sites without fire occurs for up to 2 months and because soil moisture is usually high in the spring, loss of energy at this time is especially critical for primary production. In concert with reductions in light available to the grasses, the early spring temperature environment is much different between burned and unburned sites, with burned sites having a higher temperature favoring the dominant C_4 grasses. All of these factors result in less production in unburned tallgrass compared to annually burned prairie (**Fig. 5**). Other evidence that fire does not increase N availability in mesic grasslands comes from N fertilization experiments. Within tallgrass prairie, in annually burned sites, N fertilizer had a strong impact on production, but in sites that have not been burned for several years, additional N did not enhance production and sites with intermediate fire histories had intermediate responses to N fertilization. The results of many studies suggest that one generality regarding grasses and fire is that grasses tolerate fire extremely well and in most cases reach their maximum production in the immediate post-fire years. One qualification to this statement is that the beneficial effect of fire is not uniform across all precipitation gradients. In addition, the growth form type of the dominant grass is also very important. Highly productive grasslands on the high end of precipitation gradients show moderate to high positive response to burning whereas more arid grasslands and some bunchgrass grasslands show reduced productivity in the first few years after fire.

Most grasslands have an active growing season as well as a dormant season. Although fire can occur year-round in many grasslands, fire is most likely to occur during the dormant season and it is most rare in the middle of the growing season during normal (non drought) years. Given the fact that so many aspects of a grassland change during the yearly cycle, it seems fair to expect that a fire in different seasons would have dramatically different impacts. However, in spite of the many studies that have examined the impact of fires at different times of the year, there does not seem to be a general consensus on fire seasonality. Rather, it is probably best to say that grasslands seem somewhat sensitive to `season of burn'. In one long-term study, it was found that the dominant grass in the tallgrass prairie (*Andropogon gerardii*) increased with burning in autumn, winter, or spring (dormant season), whereas burning in summer (growing season) resulted in an increase in many of the subdominant grasses with a reduction in *A. gerardii*.

Research indicates that community structure and ecosystem functioning in grasslands are impacted strongly by fire frequency. Plant species composition, in particular, differs dramatically between annually burned and less frequently burned sites in mesic grasslands. In tallgrass prairie, annually burned sites are dominated strongly by C_4 perennial grasses. Although C_4 grasses retain

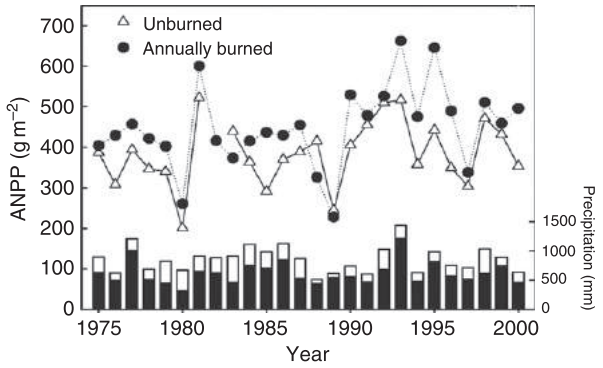

Fig. 5 Long-term record (26 years) of aboveground net primary production (ANPP) at Konza Prairie Biological Field Station from unburned sites (clear triangles) and annually burned sites (solid circles). The growing season precipitation (April–September; solid bars) and annual precipitation (clear bars) is also shown.

dominance at infrequently burned sites, C_3 grasses, forbs, and woody species are considerably more abundant resulting in greater diversity and heterogeneity in unburned prairie. In fact, the flora on annually burned sites is a nested subset of that found on less frequently burned areas. Thus, the differences reflect shifts in dominance between frequently and infrequently burned sites, rather than difference in composition *per se*. Again as with response of production to fire, there appears to be a gradient of response in community structure to grassland fires. In more northern prairies of North America, burning has not been shown to strongly affect community structure. However, these northern grasslands are dominated by C_3 grasses, which tend to decrease with burning, unlike the C_4 grasses that dominate prairies in warmer climates. Thus, the role of competition and fire in structuring grassland plant communities may increase along a latitudinal gradient throughout the Great Plains.

At a mesic grassland (Konza Prairie Biological Station), a clear picture of fire effects on plant community structure has emerged from the long-term (>20 years) empirical and experimental research done at the site. In the absence of large herbivores, the system is strongly driven by bottom-up forces associated with light, soil resource availability, and differential ability to compete under low-resource conditions. Although light availability increases with burning, the abundance of other critical limiting resources, N and water, declines as fire frequency increases. This is especially true in upland areas (with shallow soils) where production is likely limited by water. These changes in resource availability favor the growth and dominance of a small number of perennial C_4 grasses and forbs. As dominance by these competitive species increases, general declines in plant species diversity and community heterogeneity occur.

Impact of Fire on Consumers

Direct effects

Most grassland animals are not harmed by fire, particularly if fires occur during the dormant season. Those animals living belowground are well protected, and most grassland birds and mammals are mobile enough to avoid direct contact with fire. For example, there were few differences in the kinds and abundances of ground-dwelling beetles in frequently and infrequently burned Kansas tallgrass prairie. Insects that live in and on the stems and leaves of the plants are the ones that are most affected by fire. Fire has been shown to reduce directly the abundance of caterpillars which means fewer butterflies, which are important pollinators, in frequently burned prairies. Fortunately, most natural fires are patchy in that many unburned areas remain throughout a larger burned area. These patches serve as refugia for many insect populations. Given that these animals have short generation times these refugia often allow insect populations to recover quickly following a fire.

Indirect effects

Given the distinct effects of fire frequency on plant community structure and dynamics within and among burning treatments, it seems plausible that consumers that depend on the primary producers for food and habitat structure will be indirectly affected because fire alters food availability and habitat structure. Given that fire usually homogenizes grassland plant communities, one would predict that this would hold true for consumers. However, there does not appear to be tight linkages between changes in vegetation composition and structure animal populations. Indeed, work in an Oklahoma prairie shows that more grassland birds occur in areas with patchy burns than in areas that are uniformly burned or not burned. Much more work on how fire affects habitat heterogeneity and grassland consumers communities is needed.

Grazing in Grasslands

Grazing is a form of herbivory in which most of the leaves or other plant parts (small roots and root hairs) are consumed by herbivores. Grazing, both above- and belowground, is an important process in all grasslands. The long association of grazers and

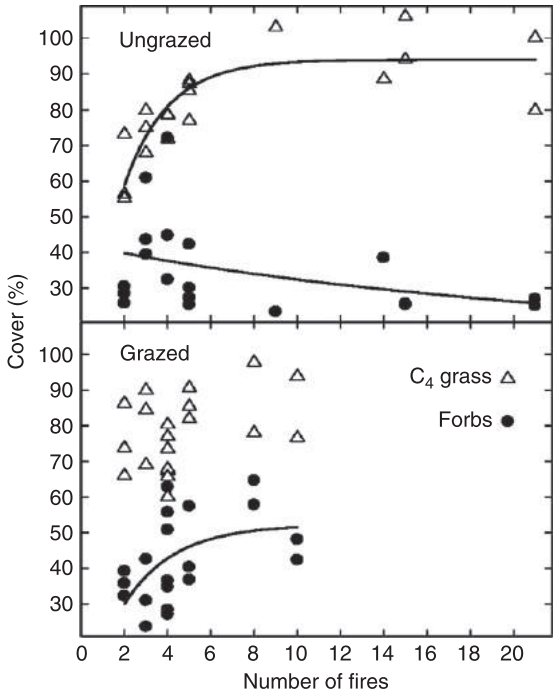

Fig. 6 Aboveground biomass removal by large ungulates modulates plant community responses to fire in mesic grasslands. In ungrazed prairie (top), cover of dominant C_4 grasses increased with increasing fire frequency, while cover of forbs decreased, resulting in a loss of diversity. However, in prairie grazed by bison (bottom), the cover of forbs was positively correlated with fire frequency and the cover of grasses was unaffected, resulting in high diversity in spite of frequent fires. From Collins, S.L., Knapp, A.K., Briggs, J.M., Blair, J.M., Steinauer, E.M., 1998. Modulation of diversity by grazing and mowing in native tallgrass prairie. Science 280 (5364), 745–747.

grasslands has prompted the hypothesis that grasses and their megaherbivore grazers are a highly coevolved system, but, as mentioned above, there is some more recent evidence that this might not be the case. However, there is no disagreement that large grazers have been a factor in grassland ecology since their origin. The herbivory actions of many other smaller organisms including small mammals and insects may be equally important. There is no doubt that the impact of native grazers in grasslands can be extensive and work on the East African Serengeti plains estimated that 15% to >90% of the annual aboveground net primary productivity can be consumed by ungulates. However, data from small mammal exclosures suggest that small mammals can also impact grasslands as when small mammals were excluded from plots in Kenya; biomass was 40–50% higher than in adjacent plots where small mammals occurred.

Due to the ability of grasses to cope with high rates of herbivory, many former natural grasslands are now being managed for the production of domestic livestock, primarily cattle in North and South America and Africa, as well as sheep in Europe, New Zealand, and other parts of the world. Grasslands present a vast and readily exploited resource for domestic grazers. However, like many resources, grasslands can be overexploited (discussed in more detail below).

Grazing systems can be roughly divided into two main types – commercial and traditional – with the traditional type often mainly aimed at subsistence. Commercial grazing of natural grasslands is very often at a large scale and commonly involves a single species, usually beef cattle or sheep for wool production. Some of the largest areas of extensive commercial grazing developed in the nineteenth century on land which had not previously been heavily grazed by ruminants; these grazing industries were mainly developed in the Americas and Australia, and to a much less degree in southern and eastern Africa. Traditional livestock production systems vary according to climate and the overall farming systems of the area. They also use a wider range of livestock, including buffaloes, asses, goats, yaks, and camels. In traditional farming systems, livestock are often mainly kept for subsistence and savings, and are frequently multipurpose, providing meat, milk, and manure as fuel.

Grazing aboveground by large herbivores alters grasslands in several ways. Grazers remove fuel and may lessen the frequency and intensity of fires. Most large grazers such as cattle or bison primarily consume the grasses; thus the less abundant forb species (broad-leafed, herbaceous plants) may increase in abundance and new species may invade the space that is made available. Thus, fire reduces heterogeneity in mesic grassland (a few species dominate) while grazers increase heterogeneity regardless of fire frequency. In other words, grazing decouples the impact of fire in productive grasslands (Fig. 6). As a result; grazing increases plant species diversity in mesic grasslands. In xeric grasslands, on the other hand, grazing may lower species diversity, particularly by altering the availability of suitable microsites for forb species. These effects are strongly dependent on grazing intensity. Overgrazing may rapidly degrade grasslands to systems dominated by weedy and non-native plant species.

Grazers may also accelerate the conversion of plant nutrients from forms that are unavailable for plant uptake to forms that can be readily used. Essential plant nutrients, such as nitrogen, are bound for long periods of time in unavailable (organic) forms in

plant foliage, stems, and roots. These plant parts are slowly decomposed by microbes and the nutrients they contain are only gradually released in available (inorganic) forms. This decomposition process may take more than a year or two. Grazers consume these plant parts and excrete a portion of the nutrients they contain in plant-available forms. This happens very quickly compared to the slow decomposition process, and nutrients are excreted in high concentrations in small patches. Thus, grazers may increase the availability of potentially limiting nutrients to plants as well as alter the spatial distribution of these resources.

Some grasses and grassland plants can compensate for aboveground tissue lost to grazers by growing faster after grazing has occurred. Thus, even though 50% of the grass foliage may be consumed by bison or wildebeest, when compared to ungrazed plants at the end of the season, the grazed grasses may be only slightly smaller, the same size, or even larger than ungrazed plants. This latter phenomenon, called `overcompensation' is controversial, yet the ability of grasses to compensate partially or fully for foliage lost to grazers is well established. Compensation occurs for several reasons, including an increase in light available to growing shoots in grazed areas, greater nutrient availability to regrowing plants, and increased soil water availability. The latter occurs after grazing because the large root system of the grasses is able to supply abundant water to a relatively small amount of regrowing leaf tissue.

As with fire, the impact of grazing on grasslands depends upon where in the precipitation gradient the grassland occurs (usually more mesic grasslands can recover more quickly than arid grasslands) as well as the growth form – cespitose (bunch-forming grasses) versus rhizomatous grasses. But another key factor is the evolutionary history of the grassland. In general, grasslands with a long evolutionary history of grazers, as in Africa, are very resilient to grazing whereas grasslands with a short evolutionary history such as desert grasslands in North America can easily be damaged by even light grazing.

Threats to Grasslands and Restoration of Grasslands

Grassland environments are key agricultural areas worldwide. In North America and elsewhere, grasslands are considered to be endangered ecosystems. For example, in US Great Plains up to 99% of native grassland ecosystems in some states have been plowed and converted to agricultural use or lost due to urbanization. Similar but less dramatic losses of mixed and shortgrass prairies have occurred in other areas. While the loss of native grasslands due to agricultural conversion is still occurring in some places, dramatic increases in woody shrub and tree species threatens many remaining tracts of grasslands. Indeed, across the world, the last remaining native grasslands are being threatened by an increase in the abundance of native woody species from expansion of woody plant cover originating from both within the ecosystem and from adjacent ecosystems. Increased cover and abundance of woody species in grasslands and savannas have been observed worldwide with well-known examples from Australia, Africa, and South America. In North America, this phenomenon has been documented in mesic tallgrass prairies of the eastern Great Plains, subtropical grasslands and savannas of Texas, desert grasslands of the Southwest, and the upper Great Basin. Purported drivers of the increase in woody plant abundance are numerous and include changes in climate, atmospheric CO_2 concentration, nitrogen deposition, grazing pressure, and changes in disturbance regimes such as the frequency and intensity of fire. Although the drivers vary, the consequences for grassland ecosystems are strikingly consistent. In many areas, the expansion of woody species increases net primary production and carbon storage, but reduces biodiversity. The full impact of shrub encroachment on grassland environments remains to be seen.

Another threat to native grasslands is the increase of non-native grass species. For example, in California, it is estimated that an area of approximately 7 000 000 ha (about 25% of the area of California) has been converted to grassland dominated by non-native annuals primarily of Mediterranean origin. Conversion to non-native annual vegetation was so fast, so extensive, and so complete that the original extent and species composition of native perennial grasslands is unknown. In addition, across the western US, invasive exotic grasses are now dominant in many areas and these species have a significant impact on natural disturbance regimes. For example, the propensity for annual grasses to carry and survive fires is now a major element in the arid and semiarid areas in western North America. In the Mojave and Sonoran deserts of the American Southwest, in particular, fires are now much more common than they were historically, which may reduce the abundance of many native cactus and shrub species in these areas. This annual-grass-fire syndrome is also present in native grasslands of Australia and managers there and in North America are using growing season fire to try to reduce the number of annual plants that set seed and thus reduce the populations of exotics, usually with very mixed results.

Conservation and Restoration

Because grasslands have tremendous economic value as grazing lands and also serve as critical habitat for many plant and animal species, efforts to conserve the remaining grasslands and restore grasslands on agricultural land are underway in many states and around the world. The most obvious conservation practice is the protection and management of existing grasslands. This includes both private and public lands. Probably the largest private holder of grasslands in the world is The Nature Conservancy. The Nature Conservancy is a global organization that works in all 50 states in the United States of America, and in 27 countries, including Canada, Mexico, Australia, and countries throughout the Asia-Pacific region, the Caribbean, and the Latin America.

However, as mentioned numerous times, the factors that led to the establishment of grasslands and, in particular, the organic-rich soils derived from the dominant biota have facilitated the agricultural exploitation of grasslands. Consequently, many

grasslands that were historically persistent have been converted to cropland. Thus, restoration of grasslands is also a very important conservation practice. Grassland restoration is the process of recreating grassland (including plant and animal communities, and ecosystem processes) where one existed but now is gone. Grassland restoration can include planting a new grassland where one had been broken and farmed, or it can include improving a degraded grassland (e.g., one that was never plowed but lost many plant and animal species due to prior land management practices). Restoration practices of existing grasslands may include reintroducing fires into grasslands following extended periods of fire suppression. On areas that have been moderately to heavily grazed (but not completely overgrazed), reducing the intensity of grazing may be required. In addition, mowing is also a cost-effective method of restoring grasslands. Mowing can be effective on sites that have been invaded by brush and forest, but the grasses are still present.

In areas where the grasses are completely absent (agriculture fields) or in a very degraded state, reseeding of grasses is usually necessary. There are proven techniques, complete with specialized equipment (seed drills) for restoration of grasslands, and, for the most part, it is fairly easy to get the dominant grasses established in an area. Indeed, some of the earliest examples of restoration ecology come from efforts to restore native tallgrass prairie in North America. As a result, the market for restoration of grasslands (at least in North America) has developed to the point that obtaining enough grass seed (sometimes even local native seed) is not a problem. A bigger challenge, however, in restored grasslands is increasing establishment of the nongrass species which are so critical for biodiversity. Seeds may be more difficult to obtain (especially for rarer plants), and then getting the forbs to survive and reproduce in many grassland restoration projects has been challenging. Further research is needed regarding what management techniques are important to their establishment and growth in these restored areas.

In addition to the prairie flora that is at risk, grassland animals (particularly birds and butterflies) suffer when grassland quality declines. In North America, grassland birds were historically found in vast numbers across the prairies of the western Great Plains. Today, the birds of these and other grasslands around the world have shown steeper, more consistent, and more geographically widespread declines than any other group. These losses are a direct result of the declining quantity and quality of habitat due to human activities like conversion of native prairie to agriculture, urban development, and suppression of naturally occurring fire.

Swamps

C Trettin, USDA, Forest Service, Charleston, SC, USA

Introduction

Swamp is a general term that is defined as ``spongy land, low ground filled with water, soft wet ground" (Webster, 1983), hence its association with a wide variety of terrestrial ecosystems. Typically, a swamp is considered a forested wetland. A wetland is a type of terrestrial ecosystem that has a hydrologic regime where the soil is saturated near the surface during the growing season; the soil has hydric properties, expressing characteristics of anaerobic conditions; and the dominant vegetation is hydrophytic with adaptations for living in the wet soils. In the case of a swamp, the forest species are adapted to the wet soil conditions. Without geographic context, there is little functional information conveyed by the term swamp other than the prevalence of wetland conditions and dense forest vegetation (**Fig. 1**).

The following discussion is designed to convey the common hydrologic settings, soil conditions, and vegetative communities that occur within the common usage of the term swamp. References focusing on swamp forests should be consulted for specific geographic regions.

General Properties of a Swamp

Hydrology

The hydrologic setting controls the form and function of the wetland because of the dependence on excess water to mediate biological and geochemical reactions. There are four general settings that may be used to characterize the swamp hydrology (**Fig. 2**). The riverine or floodplain setting is the most commonly associated hydrogeomorphic setting for swamps. It is characterized by periodic flooding from the river or stream, and it may also receive runoff from adjoining uplands. The periodicity, and flood depth and duration are the key factors that affect the type of forest communities present in the swamp. Depressional wetlands occur where there are surface depressions which receive water from the surrounding uplands, directly from precipitation, and in certain instances, they may also intersect a shallow water table. Lacustrine and estuarine fringe wetlands receive their water primarily from an open-water body; runoff from adjoining uplands and precipitation also contribute to the water balance. The common hydrologic attribute of swamps in each of those settings is the presence of water above the soil surface, but the period of inundation varies widely. While it is common for swamps to have flooded conditions for periods ranging from days to months on an annual basis, it is not uncommon for there to be multiyear intervals between flood events. The factors that affect the flooding regime include timing and amount of precipitation, groundwater level, land use in the watershed contributing to the swamp, and evapotranspiration.

Soils

Swamp soils cover the full range of texture classes and degrees of organic matter accumulation (**Fig. 3**). The wet mineral soils are characteristic of riverine and depressional settings. The histic mineral soils have a moderately thick accumulation of surface organic matter (<40 cm) reflecting prolonged periods of saturation and little scouring action if located in a floodplain, hence they may be found in any of the four hydrologic settings. The histosols or peat soils have a thick layer (>40 cm) of organic matter accumulation, representing the long periods of saturation on an annual basis. These soils typically occur in depressional settings and are not common in floodplains due to the periodic scouring that occurs during flood events.

In: McFee WW and Kelly JM (eds.) *Carbon Forms and Functions in Forest Soils*, pp. 437–461. Madison, WI: Soil Science Society of America.

Vegetation

The term swamp generally implies a forested wetland. However, due to the wide range of physical settings (see the previous two sections) and geographic locations ranging from the boreal to the tropical climatic zones on each continent, there are no consistent characteristics or attributes beyond the occurrence of hydrophytic vegetation. Accordingly, swamps may be dominated by either conifers or angiosperms, but a common situation would be a mixture of species and communities reflecting relatively minor differences in a microsite. For example, while a floodplain forest may be broadly characterized as a bottomland hardwood swamp, it contains a mosaic of vegetative communities which reflect small differences in hydrology and soils.

Ecological Functions

The ecological functions of swamps are significant, because of their prevalence and the wide range of conditions that they occupy. The following overview highlights some of the major ecosystem functions that are provided from swamp wetlands; specifics for a particular type of swamp are available from the regional references.

Hydrology

Hydrologic functions that are mediated by swamp wetlands depend on the hydrogeomorphic setting. Riverine swamps provide temporary storage for floodwaters, thereby reducing the peak flow to downstream areas. This function is physically based, with little interaction with the type of forest vegetation. However, changes in land use, especially conversion to agriculture, in the floodplain, may reduce the water storage potential, resulting in enhanced downstream conveyance of flow. The flood storage function also serves to sustain stream flow, as the waters slowly drain from the area. Swamps occurring in a depressional setting may be a source of groundwater recharge, where accumulated surface water slowly infiltrates through the subsurface sediments. In estuarine and lacustrine settings, swamps occurring at the land–water margin are important for the stability of the shoreline.

Water quality

The effects of a swamp on water quality depend on the hydrogeomorphic setting. The riverine swamp affects water quality in two primary ways – by physical and biogeochemical reactions. Sediment removal is an important function of the riverine swamps; this is a process where sediment in the floodwaters settles out onto the floodplain surface. The deposited sediment provides nutrients to the swamp vegetation and it represents the removal of a contaminant from the floodwater. Floodplains with dense understory vegetation can be more effective than open forest settings in filtering sediment from the floodwaters.

The floodplain and riparian zone swamps may also remove chemical constituents from the water, particularly nitrogen and phosphorus. As a result of the anaerobic soil conditions, nitrate nitrogen, which is a common pollutant in surface and shallow-subsurface runoff, can be converted to nitrogen gas, thereby removing it from the water. The removal of phosphorus compounds typically involves reactions associated with the sediments.

Habitat

Swamps are important for the diversity of habitat conditions that they provide. At the large scale, swamps comprise part of the mosaic of land types, yielding wet, vegetative conditions among uplands. At smaller scales, within a swamp, there are a multitude of habitat conditions that are largely dictated by elevation relative to the mean high water level.

Terrestrial

The terrestrial habitats provided by swamps are diverse due to variations in vegetative composition and structure, which are largely regulated by the hydrologic conditions of the site. The habitat also changes through the development of the forest. In early successional stages, the vegetation is typically a dense combination of shrubs and trees; then, as the trees gain dominance, the shrub layers die back yielding a less dense understory. Correspondingly, the habitat conditions for amphibians, birds, reptiles, and mammals change as the stand evolves. The swamp forests are particularly important habitat for birds, especially migratory song birds.

Aquatic

Swamps also provide important aquatic habitat for fish, birds, and amphibians. Organic matter produced in the swamp is an important energy source for aquatic organisms, including those living in water bodies within the swamp and also larger receiving bodies such as lakes, rivers, and oceans. In floodplains, the floating debris and logs provide physical structures that are an important component of the aquatic habitat.

Restoration

In many areas, swamps have been converted into agricultural use, through the use of drainage systems and clearing of the forest vegetation. The merits of restoring the converted wetlands back to swamp forests include the reestablishment of flood water storage, in the case of floodplains, and the development of wildlife habitat. The restoration of swamp forests is complicated by the myriad of soil and hydrologic conditions that one may encounter, and the effects of past management practices which necessitate the restoration may also exacerbate the situation. However, with proper consideration of the hydrologic setting and matching species to the soil and water regimes, functional restoration is feasible. The typical sequence of restoring swamp forests is to reestablish the wetland hydrology by blocking drainage ditches, and planting appropriate tree and understory species.

Ecosystem Services and Values

Swamps provide both direct and indirect values to society. Direct values include raw materials, such as timber and food stocks. Indirect values include floodwater storage, water supply, water quality, recreation, esthetics, wildlife diversity, and biodiversity. The valuation will depend on inherent characteristics of the resource that are largely constrained by the biogeographic zone and location within a watershed, societal norms, and economic conditions.

Temperate Forest

WS Currie and KM Bergen, University of Michigan, Ann Arbor, MI, USA

Introduction

The temperate forest biome is characterized by a distinct seasonality that includes a long growing season together with a cold winter season in which much of the vegetation may be dormant. The strong seasonality drives physiological events to occur at regular annual intervals for plant species. These include bud break, flowering, and foliar and shoot extension. As the growing season ends, marked by dropping temperatures and shortening photoperiod (day length), trees and shrubs undergo seasonal physiological changes that include the senescence and abscission of foliage (although in evergreen species some foliage is also retained) and the setting of buds for the next growing season. Because of the cold winters, the dominant woody vegetation is characterized by freeze-hardy species. During the winter season, the air temperature drops below freezing and soils are frozen or cold and wet, impeding decomposition of plant litter and promoting the accumulation of an organic layer on the soil surface.

The temperate forest is distributed over portions of five regions of the globe: North America, South America, Europe, Asia, and Australia–New Zealand (**Fig. 1**). Within this biome, distinct biogeographic units are recognized, particularly the mixed-deciduous temperate forest (the largest in terms of area), the mixed-evergreen temperate forest (sometimes called subtropical evergreen), and the temperate rainforest. Major taxa include pines (*Pinus* spp.), maples (*Acer* spp.), beeches (*Fagus* spp., *Nothofagus* spp.), and oaks (*Quercus* spp.) in the mixed-deciduous and mixed-evergreen temperate forests; spruces (*Picea* spp.), Douglas-fir (*Pseudotsuga menziesii*), and redwoods (*Sequoia sempervirens*, *Sequoiadendron giganteum*) in the Northern Hemisphere temperate rainforests; and southern beeches (*Nothofagus* spp.) and eucalyptus (*Eucalyptus* spp.) in Southern Hemisphere temperate rainforests.

Within a continent, forests in the temperate biome grade into subdivisions based on latitude, elevation, and large-scale patterns of precipitation. In North America, for example, the predominant natural vegetation in the eastern United States and the southern reaches of eastern Canada is mixed-deciduous temperate forest. This forest grades to the south through broad-leaved-coniferous mixtures to the mixed-evergreen forest along the Atlantic coastal plain (**Fig. 2**). Temperate rainforests in North America are found in the coastal Pacific Northwest where marine climates together with orographic lifting produce high rainfall. In South America temperate forests are found in Chile and parts of Patagonia. In Europe, within the temperate forest biome the mixed-deciduous forests dominate in the western continent, Great Britain, southern Eastern Europe, and southern European Russia. In Near-East Asia, the temperate forest occurs in Turkey and Iran and a narrow band is found in Central Asia as a transition between the boreal forest to the north and steppe to the south. The temperate forests in East Asia occur predominantly in northern and central China, but also over most of Japan, Korea, and of the southern tip of Siberia. Temperate forests, including rainforests, are also found in parts of New Zealand, the southeast coast of Australia, and Tasmania.

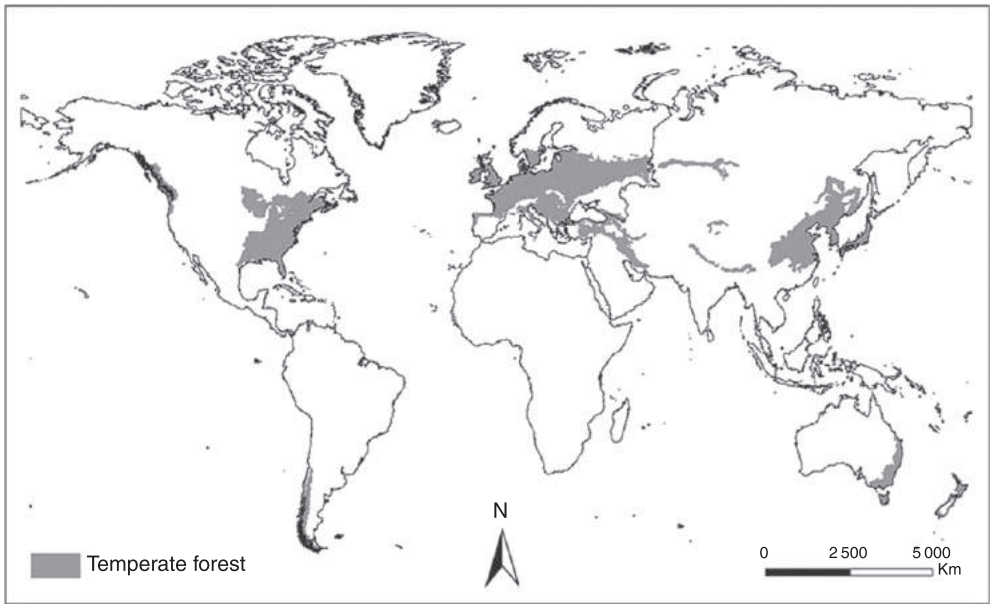

Fig. 1 The distribution of temperate forests of the world. Map data: Olson, D.M., Dinerstein, E., Wikramanayake, E.D., et al., 2001. Terrestrial ecoregions of the world: A new map of life on earth. BioScience 51, 933–938. Map prepared by the Environmental Spatial Analysis Laboratory, University of Michigan, USA, 2006.

Fig. 2 The edge of a mixed coniferous–deciduous forest in southeastern Maine, USA. Photo by W. S. Currie.

Temperate forests are distinguished from boreal forests by having a 4–6-month (140–200 days) frost-free growing season with on average at least 4 months at 10 °C or above and mean annual temperatures from 5 °C to 20 °C. At higher latitudes, the temperate forest transitions to the boreal forest, a biome of evergreen cold-tolerant forests with much shorter growing seasons. The latter are also found in middle latitudes as montane forests at high elevations and are often closer, floristically and functionally, to boreal than to temperate forests.

The occurrence of frost (at 0 °C or colder) differentiates the extratropical (including temperate) from tropical regions. Moisture also distinguishes temperate regions from drier forested regions, such as chaparral and wetter forested regions such as tropical rainforests. In temperate regions, precipitation exceeds potential evaporation and water is available at approximately 50–200 cm yr^{-1}. Precipitation in most temperate regions is fairly evenly distributed throughout the year in contrast to the tropics where there are typically pronounced wet and dry seasons.

Physiography, Climate, and the Temperate Forest Biome

Climatic and Physiographic Controls on the Distribution of Temperate Forests

The geographic distributions of the different vegetation biomes of the world are dependent on the physical environment and climate in the form of light, temperature, and moisture. In middle latitudes (30°–60° N and S), these controls result in a temperate forest biome within each hemisphere that is discontinuous, separated by the oceans and the tropics, and by moisture and physiographic barriers. The present-day distribution of temperate forests derives not only from present climatic controls but also from paleoclimates and past connections among the continents. Climates during the Pleistocene (*c.* 1.8 million to 10 000 years ago) set the stage for the present-day distribution. During glacial maxima, ice sheets covered large parts of Europe and North and South America as well as isolated areas in East Asia. In North and South America, plants migrated to unglaciated refugia and re-migrated, as glaciers receded, to their present-day distributions. Evidence suggests that many genera of forest trees that remain in North America and unglaciated East Asia were extirpated from Europe because the east–west running Alpine range blocked migrations to refugia during Pleistocene glaciations. Similarly important were continental connections between North America (the Nearctic), East Asia, and Europe (the Palearctic) at different points in geologic history. As a result, floristic differences are relatively small across the Holarctic, which spans from the west coast of North America to the east coast of Asia and includes the majority of the world's temperate forests.
