Abundance Biomass Comparison Method

RM Warwick, Plymouth Marine Laboratory, Plymouth, UK

Introduction

The `abundance biomass comparison' (ABC) method is a means of detecting the effects of anthropogenic perturbations on assemblages of organisms that is underpinned by the *r*- and *K*-selection theory (see *r*-Strategist/*K*-Strategists). Under stable conditions of infrequent disturbance the competitive dominants in the climax community are *K*-selected or conservative species with a large body size and long life span, and are usually of low abundance so that they are not dominant numerically but are dominant in terms of biomass. Frequently disturbed assemblages are kept at an early successional stage and comprise *r*-selected or opportunistic species characterized by small body size, short life span and high abundance. The ABC method exploits the fact that when an assemblage is perturbed the conservative species are less favored in comparison with the opportunists, and the distribution of biomass among species behaves differently from the distribution of numbers of individuals among species.

The Method

The ABC method as originally formulated involves the plotting of separate *k*-dominance curves (see *k*-Dominance Curves) for species abundances and species biomasses on the same graph and comparing the forms of the two curves relative to each other. The species are ranked in order of importance in terms of abundance or biomass on the *x*-axis on a logarithmic scale, with percentage dominance on the *y*-axis on a cumulative scale. Of course the species ordering is unlikely to be the same for abundance and biomass. In undisturbed assemblages a few large species are dominant in terms of biomass but not abundance, resulting in the elevation of the biomass curve relative to the abundance curve throughout its length (**Fig. 1a**). Perturbed assemblages, however, have a few species with very high abundance but small body size so that they do not dominate the biomass and the abundance curve lies above the biomass curve (**Fig. 1c**). Under moderate perturbation the large competitive dominants are eliminated but there is no population explosion of small opportunists, so that the inequality in size between the numerical and biomass dominants is reduced and the biomass and abundance curves are closely coincident and may cross over each other one or more times (**Fig. 1b**).

The contention is that these three conditions (unperturbed, moderately perturbed, or grossly perturbed) should be recognizable without reference control samples in time or space, the two curves acting as an internal control against each other and providing a snapshot of the condition of the assemblage at any one time or place. Of course, confirmatory comparisons with spatial or temporal reference samples are still highly desirable. A prerequisite of the method is adequate sample size or replication because the large biomass dominants are often rare and liable to a higher sampling error than the numerical dominants.

The evaluation of ABC curves involves their visual inspection, and can be cumbersome if many sites, times, or replicates are involved. In such cases it is convenient to reduce each plot to a single summary statistic. If the abundance (A) values are subtracted from the biomass (B) values for each species rank in the ABC curve, the sum of the $B-A$ values across the ranks will be strongly positive in the unperturbed case (**Fig. 1a**), near zero in the case where the curves are closely coincident (**Fig. 1b**), and strongly negative where the curves are transposed (**Fig. 1c**). The summation needs to be standardized to a common scale so that comparisons can be made between samples with differing numbers of species (S), the most widely used form being the W (for Warwick) statistic:

$$W = \sum_{i=1}^{S}(B_i - A_i)/[50(S-1)]$$

For replicated samples, the W statistic also provides an obvious route for hypothesis testing, using standard univariate ANOVA.

Applications

For the most part, ABC curves have been used to indicate pollution or disturbance effects on marine and estuarine macrobenthic assemblages, which are the main target for detection and monitoring programs in these habitats. For example, ABC curves for the

 doi:10.1016/B978-0-444-63768-0.00084-6

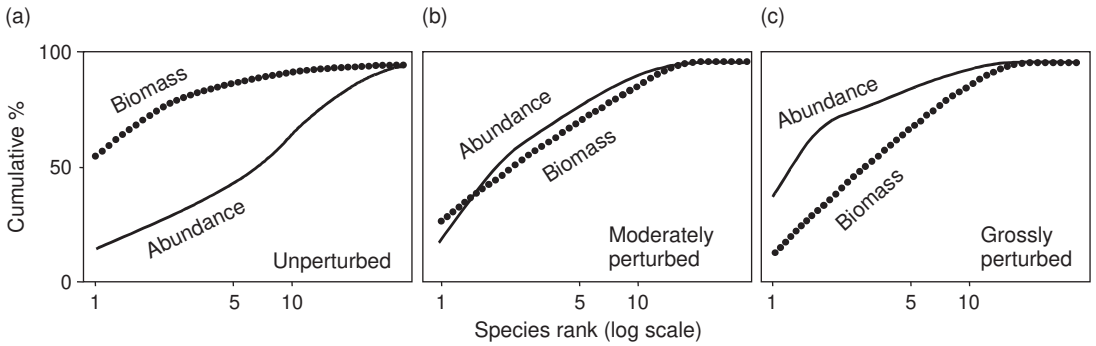

Fig. 1 Hypothetical *k*-dominance curves for species biomass and abundance, showing unperturbed, moderately perturbed, and grossly perturbed conditions.

macrobenthos in Loch Linnhe, Scotland in response to organic pollution between 1963 and 1973 are given in Fig. 2. The time course of pollution from a pulp mill, and changes in species diversity (H'), are shown top left. Moderate pollution started in 1966, and by 1968 species diversity was reduced. Prior to 1968 the ABC curves had the unpolluted configuration. From 1968 to 1970 the ABC plots indicated moderate pollution. In 1970 there was an increase in pollutant loadings and a further reduction in species diversity, reaching a minimum in 1972, and the ABC plots for 1971 and 1972 show the grossly polluted configuration. In 1972 pollution decreased and by 1973 diversity had increased, and the ABC plots again indicated the unpolluted condition. Thus, the ABC plots provide a good snapshot of the pollution status of the benthic community in any one year, without reference to the historical comparative data which would be necessary if a single species diversity measure based on the abundance distribution was used as the only criterion.

Most studies suggest that the ABC curves respond to anthropogenic perturbations but are not affected by long-term natural stresses, since the organisms living in such environments have evolved adaptations to the prevailing ecological conditions. Unperturbed ABC plots may be found, for example, in estuaries where the organisms are subjected to low and fluctuating salinities, provided there are no anthropogenic disturbances. ABC plots indicated that macrobenthic communities near an oil refinery in Trinidad were grossly to moderately stressed, while those close to the Trinidad Pitch Lake (one of the largest natural oil seeps in the world) were not. There is little evidence, however, that the method can distinguish between different types of anthropogenic disturbances. Responses to organic pollution and to physical disturbance caused by demersal trawl fisheries, for example, appear to be similar.

The method has been less well explored with respect to other components of the biota. However, it has been used successfully to indicate environmental impacts on marine phytoplankton, the cryptofauna and mollusks of rocky shores, invertebrates of freshwater streams, and fish assemblages in both marine and freshwater.

Problems and Their Solutions

Very often *k*-dominance curves approach a cumulative frequency of 100% for a large part of their length, and in highly dominated assemblages this may be after the first two or three top-ranked species. Thus, it may be difficult to distinguish between the forms of these curves. The solution to this problem is to transform the y-axis so that the cumulative values are closer to linearity, an appropriate transformation being the modified logistic transformation:

$$y_i' = \log\ [(1 + y_i)/(101 - y_i)]$$

A potentially more serious problem with the cumulative nature of ABC curves is that their form is overdependent on the single most dominant species. The unpredictable presence of large numbers of a species with small biomass, perhaps an influx of the juveniles of one species, may give a false impression of disturbance. With genuine disturbance, one might expect patterns of ABC curves to be unaffected by successive removal of the one or two most dominant species in terms of abundance or biomass, and a solution is the use of partial dominance curves, which compute the dominance of the second-ranked species over the remainder (ignoring the first-ranked species), the same with the third most dominant, etc. Thus, if a_i is the absolute (or percentage) abundance of the ith species, when ranked in decreasing abundance order, the partial dominance curve is a plot of p_i against log i ($i = 1, 2, \ldots, S-1$), where

$$p_1 = 100a_1/\sum_{j=1}^{S} a_j$$

$$p_2 = 100a_2/\sum_{j=2}^{S} a_j, \ldots, p_{S-1} = 100a_{S-1}/(a_{S-1} + a_S)$$

Earlier values can therefore never affect later points on the curve. The partial dominance curves (ABC) for undisturbed macrobenthic communities typically look like Figs. 3g and 3h, with the biomass curve (thin line) above the abundance curve (thick line) throughout its length. The abundance curve is much smoother than the biomass curve, showing a slight and steady decline before the inevitable final rise. Under polluted conditions there is still a change in position of partial dominance curves for abundance and biomass, with the abundance curve now above the biomass curve in places, and the abundance curve becoming much more variable. This implies that pollution effects are not just seen in changes to a few dominant species but are a phenomenon which pervades the

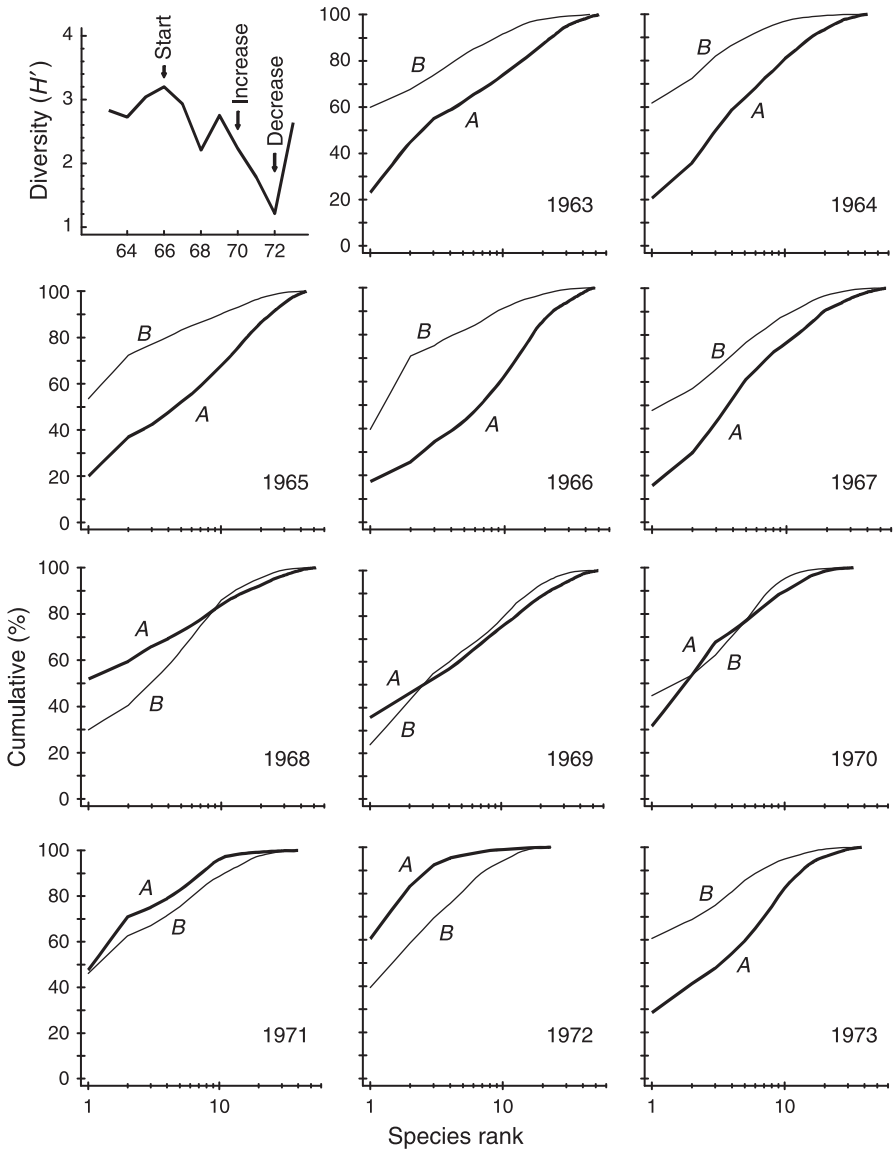

Fig. 2 Loch Linnhe macrofauna: Shannon diversity (H') and ABC plots over the 11 years, 1963 to 1973. Abundance, thick line; biomass, thin line.

complete suite of species in the community. The time series of macrobenthos data from Loch Linnhe (Fig. 3) shows that in the most polluted years, 1971 and 1972, the abundance curve is above the biomass curve for most of its length (and the abundance curve is very atypically erratic), the curves cross over in the moderately polluted years 1968 and 1970 and have an unpolluted configuration prior to the pollution impact in 1966 and 1967. Although these curves are not so smooth, and therefore not so visually appealing, as the original ABC curves, they may provide a useful alternative aid to interpretation and are certainly more robust to random fluctuations in the abundance of a small-sized, numerically dominant species.

In most cases where the presence of large numbers of small-bodied macrobenthic species in unperturbed situations has given a false impression of disturbance, those species have not been polychaetes. Prior to the Amoco Cadiz oil spill off the north coast of France in 1978, small ampeliscid amphipods (Crustacea) were present at the Pierre Noire station in relatively high abundance, and their disappearance after the spill confounded the ABC plots. The erratic presence of large numbers of small amphipods (*Corophium*) or mollusks (*Hydrobia*) also confounded these plots in the Wadden Sea. These small nonpolychaetous species are not indicative of polluted conditions. A taxonomic breakdown of the ABC response has shown that it results from (1) a shift in the proportions of different phyla present in communities, some phyla having larger-bodied species than others, and (2) a shift in the relative distributions of abundance and biomass among species within the Polychaeta but not within any of the other major phyla (Mollusca, Crustacea, Echinodermata). The shift within polychaetes reflects the substitution of larger-bodied by smaller-bodied species, and not a change in the average size of individuals within a species. In most instances the phyletic changes reinforce the trend in species substitutions within the polychaetes, to produce the overall ABC response, but in some cases they may work

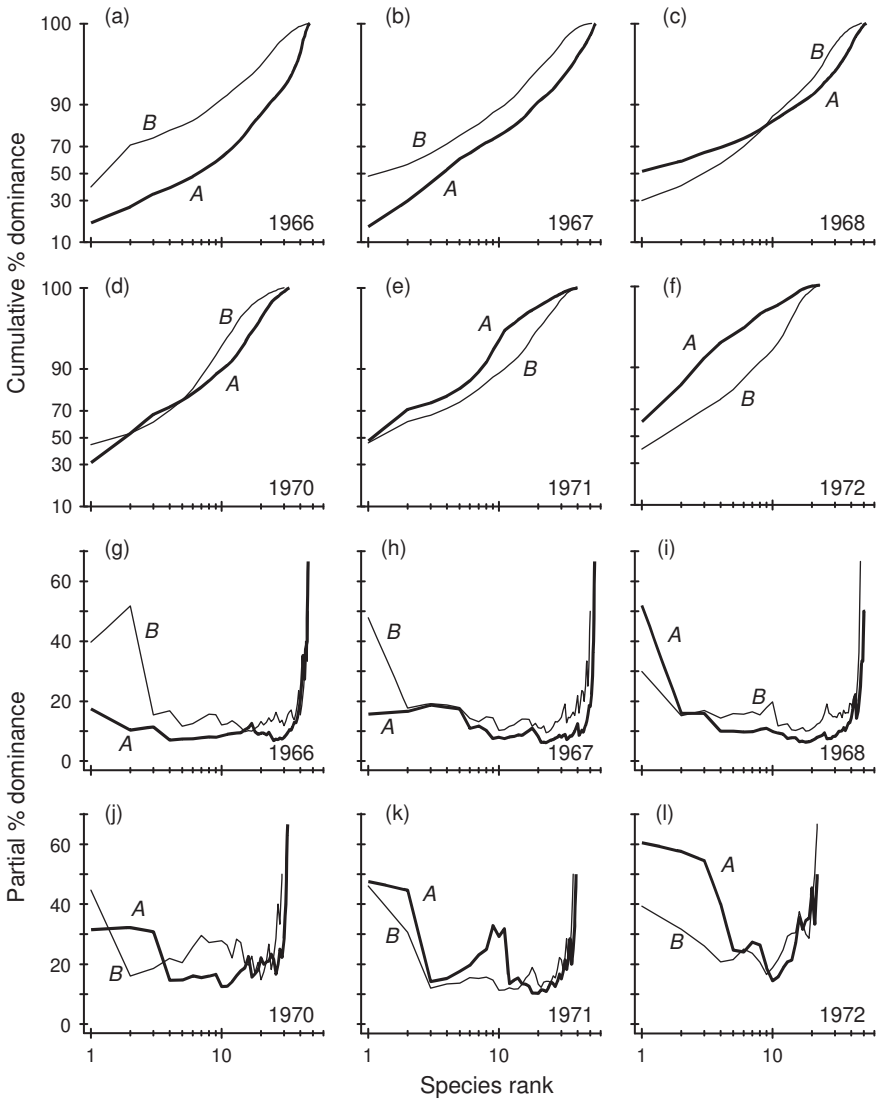

Fig. 3 Loch Linnhe macrofauna in selected years 1966–68 and 1970–72. (a–f) ABC curves (logistic transform). (g–l) Partial dominance curves for abundance (thick line) and biomass (thin line) for the same years.

against each other. Indications of pollution or disturbance for marine macrobenthos detected by this method should therefore be viewed with caution if the species responsible for the perturbed configurations are not polychaetes, and the robustness of the plots should be tested using partial dominance curves.

Finally, a practical rather than a conceptual problem with the method is that it relies on a painstaking and time-consuming (and hence costly) analysis of samples in which all the species must be separated, counted, and weighed. Several groups of marine organisms are taxonomically difficult, for example (in the macrobenthos), several families of polychaetes and amphipods; as much time can be spent in separating a few of these difficult groups into species as the entire remainder of the sample, even in Northern Europe where taxonomic keys for identification are most readily available. Many taxa really require the skills of specialists to separate them into species, and this is especially true in parts of the world where fauna is poorly described. Identification to some higher taxonomic level, for example, family rather than species, is considerably easier and quicker, and the ABC method has proved to be encouragingly robust to analysis at the family level for both macrobenthos and fish; very little information appears to be lost.

Acidification in Aquatic Systems

Morgana Tagliarolo, Ifremer, UMSR LEEISA (CNRS UG Ifremer), Cayenne, France

Glossary

Buffer A compound that limits large changes in pH in a solution. The buffer solution consists in a mixture of weak acid and bases. The buffering ability is defined as the quantity of strong acid or base that must be added to change the pH of 1 L of solution by 1 pH unit.
Chemical equilibrium State of a reversible chemical reaction when the rate of the forward and backward reaction is equal. Consequently, the concentrations of both reactant and product are stables. This equilibrium can be described by a constant (K).
Homeostasis A biological process maintaining a stable condition in an organism even if faced with external changes. An example is the ability of the human body to maintain a relatively constant body temperature independent of external temperatures.
Hypercapnia Disequilibrium in body fluids with an abnormal increase of carbon dioxide and pH drop.
Oligotrophic An environment poor in organic and inorganic nutrients.
Resilient An ecosystem or organism is defined as resilient when it is able to respond and recover from adverse situations.

Introduction

Acidification in an aquatic system is a term describing significant changes to the chemistry of freshwater, marine, and brackish systems, mostly caused by the dissolution of atmospheric carbon dioxide (CO_2). The CO_2 from the atmosphere combines with other dissolved inorganic carbon already present in the water causing several complex chemical changes. The characterization of the physicochemical properties of the carbonate system in natural waters is not straightforward since it can be described by a large number of terms and units. However, pH is the more common parameter employed for describing the acidification phenomena in ecology.

Water pH is an expression of the concentration of hydrogen ions (H^+) on a logarithmic scale, where a neutral pH of 7.00 is represented by pure water at 25°C. Surface waters in the open ocean are slightly alkaline with relatively small pH variability (average values ranging between 7.9 and 8.3). Variability ranges are wider in coastal and freshwater ecosystems where complex biogeochemical dynamics play important roles on the physical and chemical conditions of those waters. In shallow coastal areas pH can vary drastically over daily cycles and small spatial scales (~0.3–0.5 units). In natural freshwater ecosystems pH has an even wider range (between <2 and 12) depending on the region and on the water body characteristics.

Part of atmospheric CO_2 is continuously absorbed by the aquatic systems where it reacts with the water molecules to form weak acids. These acids mostly dissociate into H^+ causing pH reductions. Freshwater and seawater contain a variety of acid–base species able to react with the additional H^+ ions. The predominant ions are carbonate and bicarbonate, but other molecules can also interact. This ability of natural waters to neutralize protons is described by its total alkalinity (Fig. 1). The carbonate chemistry is significantly affected by acidification and the formation of numerous carbonate-containing minerals such as aragonite, calcite, and magnesium calcite is disrupted.

The absorption of CO_2 and the fate of hydrogen ions in water are therefore dependent on various chemical transformations and equilibrium constants. The equilibrium constants are in turn dependent on salinity, temperature, and pressure. For this reason, fresh and seawater are considerably different in the distribution of the carbonic acid fractions. Fresh and brackish water has a lower buffering capacity and thus experiences higher pH fluctuations compared with open ocean waters.

Although the acidification process has mostly been studied in the marine environment, declines in pH can also considerably affect freshwater ecosystems. Marine and freshwater systems may be acidified either from natural or man-made processes, but, while natural processes are slow (geological time frames), anthropogenic activities are accelerating and amplifying these changes.

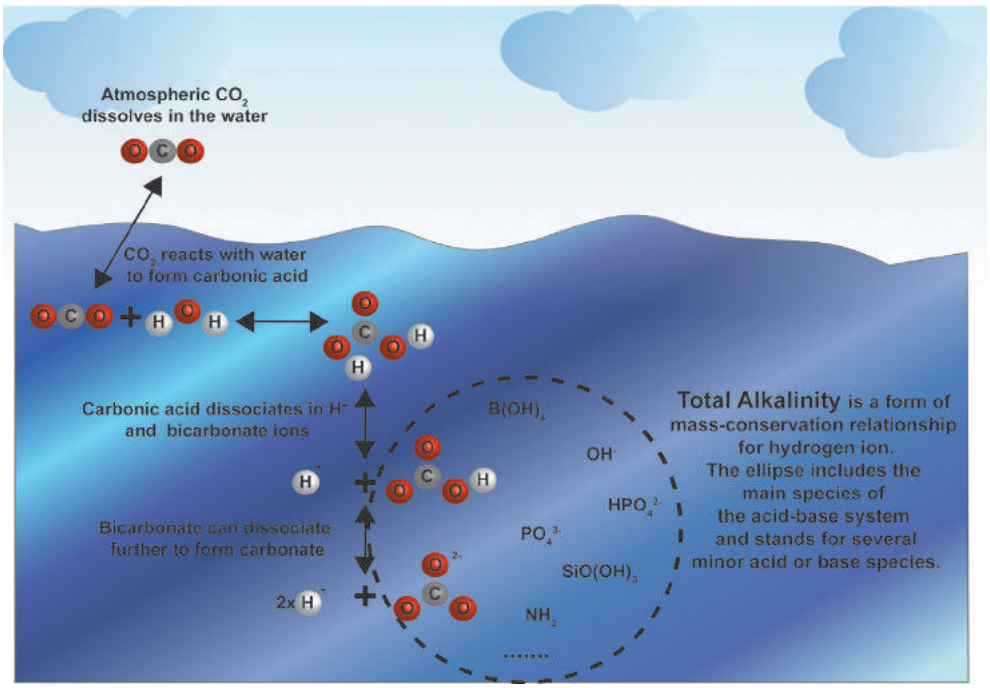

Fig. 1 General scheme on how atmospheric carbon dioxide can interfere with the aquatic chemistry.

The acidification of aquatic systems is mostly a result of the continuous CO_2 release into the atmosphere by fossil fuel combustion (coal, oil, and natural gas), deforestation, and cement production. Since the beginning of the industrial era, the pH of ocean surface water has decreased by 0.1 pH units, corresponding to a 26% increase in acidity. Moreover, pH of internal and coastal areas can also be altered by other anthropogenic inputs such as nitrogen, ammonia, and sulfur. Consequently, freshwater acidification can be a faster and larger phenomenon than ocean acidification involving notable pH drops (up to 2.5) during episodic events.

The anthropogenic CO_2 induced changes in water carbon chemistry have some direct effects on photosynthesis, calcification, and acid–base balance of aquatic organisms. The increased availability of CO_2 can potentially enhance photosynthesis when light and nutrients are available. However, the ability of micro and macro algae to utilize this excess of CO_2 appears to vary widely across taxa. A number of physiological processes can be altered in photosynthetic organisms and the final response is often a compromise between the antagonistic effect of CO_2 on photosynthesis and respiration metabolism. Low pH often causes an increase of the overall energetic costs, which in turn lead to an augmented respiration rate. Therefore, the benefits of an enhanced photosynthetic activity are generally relatively minor relative to the negative effects of acidification on respiration. Moreover, acidification has been shown to promote several metabolic pathways leading to the production and accumulation of toxic compounds in phytoplankton cells.

A decrease in pH and in carbonate ions generally causes a decline in the calcification rates producing calcium carbonate ($CaCO_3$) for shells and skeletons (Fig. 2). Calcifying organisms are extremely diverse and include many taxonomic groups and ecological niches. For instance, calcification is performed by many photosynthetic primary producers, zooplankton, mollusks, and crustaceans. Although the calcification process can be explained by a simple chemical equation, the biological mechanisms are more complex and can vary between species. The calcification process requires an energy investment for the organisms and modifications of the chemistry of the external aquatic environment can cause important perturbations of calcification rates. Although calcifying organisms are mostly negatively impacted by acidification, the growth rate of some species has been reported as insensitive to this stress or positively impacted.

Shell calcification in mollusks is performed in the extrapallial space that is isolated from the surrounding ambient water (Fig. 2). Many species have been shown to produce their own carbonate ions in this space without any interaction with seawater ions. The formation of calcium carbonate structures in this space is thus not directly inhibited by decreasing carbonate ions concentration in the external seawater. The impact of ocean acidification on shell growth is therefore a result of several interlinked physiological processes affecting metabolism and internal body pH. Furthermore, the antagonistic processes of calcification and dissolutions may also represent an important energetic cost for the organisms. For these reasons, marine mollusks have been shown to respond very differently to acidification. In a more acid ocean, on average, shells are expected to be smaller and have a modified mineralogical structure to overcome the energetic costs.

Similarly to mollusks, scleractinian corals do not precipitate their carbonate skeleton directly from seawater, but they produce it in an extracellular medium where the animal can actively manipulate the pH. Cold-water corals are particularly good in regulating

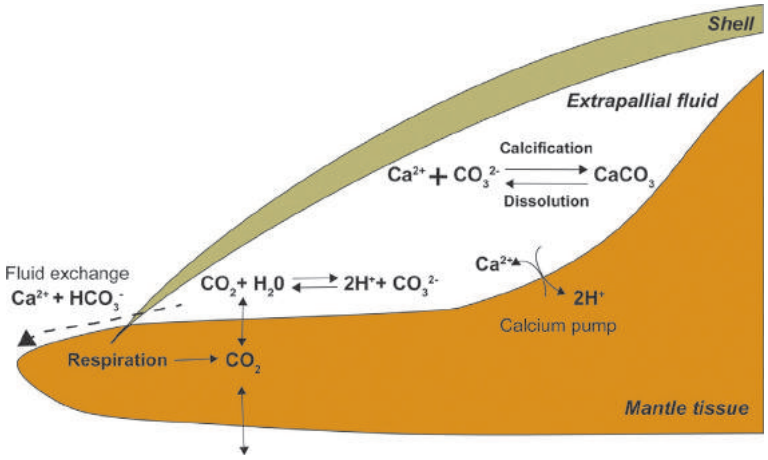

Fig. 2 Cross section of a mollusk shell showing the calcification process in the extrapallial space. Modified from McConnaughey, T.A., Gillikin, D.V. (2008). Carbon isotopes in mollusk shell carbonates. *Geo-Marine Letters* **28**, 287–299. 10.1007/S00367-008-0116-4.

their internal pH and can continue to calcify even in acidic and undersaturated waters. This important adaptive mechanism enables these deep-sea calcifiers to occupy unique niches. In contrast with these highly adapted organisms, other taxa such as the calcitic foraminifera, are not able to control their internal pH and depend entirely on seawater conditions.

The shells of marine organisms are generally made from either calcite or aragonite calcium carbonate. Aragonite is more soluble than calcite and can dissolve easier in undersaturated waters. Changes in water chemistry therefore affect calcifying organisms in different ways depending on their shells compositions. For example, one of the more abundant and important planktonic shelled group living in polar and subpolar waters (pteropods) are expected to be particularly affected by acidification since they are unable to maintain their shell in undersaturated waters with respect to aragonite. On the other hand, arctic bivalves have been shown to be generally resilient to decreasing pH.

Metabolic and biochemical processes within aquatic organisms are influenced by water pH since biological membranes are generally highly permeable to free ions and potentially affected by acid–base distresses. The internal pH of most heterotopic organisms is lower than the surrounding seawater. Active mechanisms of ion transport are constantly working in living cells to maintain pH fluctuations in body fluids within a tolerable range. For this reason, metabolic rates are linked to the homeostasis of the internal pH and to the pH gradient between the body and the external environment. Under acidification conditions some metabolic functions are depressed, oxygen transport efficiency is reduced and acid–base regulation requires higher energetic costs. The effectivity of ion transport systems differs between aquatic organisms depending on their structure and complexity. Some crustacean and echinoderms seem to be able to compensate for acidification by increasing bicarbonate concentration in their body but little is known about the sustainability of this response during long term exposures.

Although there is a general agreement about the effects of increased CO_2 concentrations on the ocean and freshwater chemistry, the magnitude and severity of the potential impact on different organisms and ecosystems is still largely unknown. The large variability in the responses of organisms to acidification is mostly due to the high biotic and abiotic patchiness of natural habitats and the multiple interactions with other existing stresses like temperature changes. This article will give an overview on the different mechanisms and responses of the ocean, coastal, and freshwater habitats and provide some wider concept on the ecological and economic impact of this phenomena.

Ocean Acidification

Oceans play an important role in mitigating atmospheric CO_2 emissions by absorbing around 25%–30% of the CO_2 added to the atmosphere by anthropogenic activities. This process causes a decrease in water's pH, in the concentration of carbonate ions and in the carbonate saturation state. These changes, together with other stressors such as temperature, are significantly affecting marine communities. Numerous research projects have focused on the effect of ocean acidification on marine organisms.

Negative effects have been recorded on most taxonomic groups, and early developmental stages are suspected to be most susceptible. Multigenerational studies on marine copepods showed that fecundity could decrease up to 29% under lower pH scenarios. Moreover, the larval nauplii stage of these taxa exhibit greater sensitivity and mortality rates with increasing CO_2 compared to the other life stages. Higher concentrations of seawater CO_2 have been shown to cause malformations and delays in the larval development of several calcifiers. Sea urchin larvae lose symmetry and their skeleton is highly deformed and corroded with decreased pH (Fig. 3). Beside invertebrates, fish embryos and young larvae are also more sensitive than adults to the effects of ocean acidification. Egg survival, hatching size, and growth rate are generally retarded despite some positive effects that have been

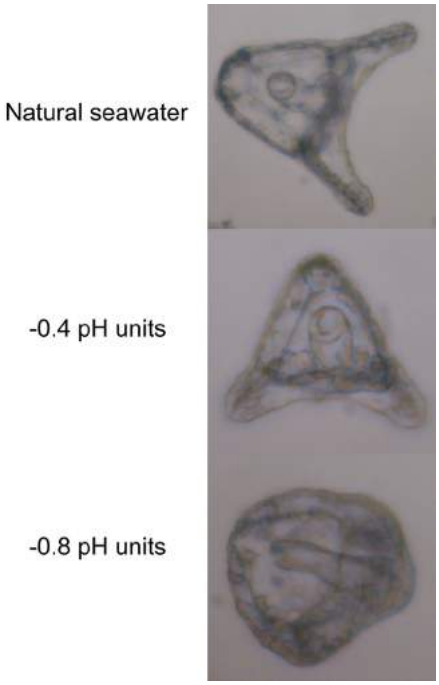

Fig. 3 Sea urchin larvae reared in control and acidified treatments. Lower pH causes asymmetrical and deformed skeletal development.

seen on few species. Even if the growth rate is not affected, other perturbations such as impaired olfactory discrimination and homing ability can still reduce fitness in the natural environment.

The consequences of ocean acidification on the biology of adult marine fish have been extensively studied. Results show a multitude of diverse responses from the death of the individual, to no effect at all. Despite this, most adult fishes can efficiently compensate for a hypercapnic acid–base disturbance, although neurosensory, growth, metabolism, and mitochondrial functions are often disrupted. Therefore, the pH compensation ability does not necessarily mean that the consequences of ocean acidification are reduced. Nonetheless, the mechanisms underneath this process are still largely unknown and predicting species responses remains difficult.

Another unexpected consequence of ocean acidification in the open ocean is the significant decrease in ocean sound absorption. Low frequency range is predicted to change significantly in the near future, mostly due to pH changes. Underwater ambient noise is thus predicted to increase, causing potential problems to human (scientific, commercial, and naval acoustic applications) and natural activities. Disturbance in animal's communication is likely to interfere with the biology and behavior of whales and other marine mammals.

Acidification is also affecting the deep ocean although the responses are delayed by the transport time of water masses between the surface and the deep areas. In those areas, the acidification can happen through a water mass movement or from the decomposition of organic matter "raining" into the deep ocean from the surface. Deep-sea ecosystems have the potential to be significantly affected by pH changes since their inhabitants are adapted to live in extremely stable conditions. The deep-sea is a cold and dark environment where metabolic activities and gas exchanges are generally reduced compared to shallow areas. Historically exceptional changes in oceans bottom pH have been documented to cause significant species extinctions and scientists are concerned that this could happen again in the near future.

The pH of many deep (below 500 m) areas is projected to decrease by 0.2 units by 2100. Carbonate-based organisms such as cold-water corals and sponge reefs are under serious threats. Animals living in the deep ocean are generally characterized by slow growth and limited recovery abilities. Acidification has been shown to negatively affect tissue functioning and membrane pumps of deep glass sponge reefs compromising their feeding efficiency. A similar reduction in feeding rates has been shown in several cold-water corals. The calcification rate of these corals is negatively affected by pH drops in laboratory experiments, but some species have been shown to be more resilient than others. The general idea is that the decrease in pH and aragonite saturation will cause the dissolution of corals skeleton. However, a number of studies suggested that deep-sea corals have some physiological mechanisms to compensate for undersaturation and several natural scleractinian reefs have been found in areas with low aragonite saturation levels.

Acidification in the Coastal Area

Intertidal areas, estuaries, coral reefs, sandy, and rocky shores are just a few examples of how diverse and variable coastal areas are. These ecosystems are submitted to continuous fluctuations due to tides, rivers inputs, waves, currents, and anthropogenic activities. Because of this variability in physical–chemical characteristics, the carbonate systems and pH experience significant fluctuations. The intense variability and the effect of multiple drivers on water pH implies that it is much more difficult to detect acidification trends in these areas compared to the open ocean.

Unlike open ocean areas, coastal ecosystems are often dominated by benthic communities and the metabolic activity of these organisms can drive important diel and seasonal pH oscillations. Coastal communities can support intense metabolic processes, including high primary production, respiration, and calcification rates. All those activities directly influence the water chemical properties such as CO_2 concentration, alkalinity, and pH. For instance, macrophytes growing in shallow coastal zones have the capacity to modify seawater pH and cause diel changes driven by primary productivity. Bivalves have been shown to be capable of raising local pH by 0.3–0.5 units during the daytime. The pH of intertidal rock pools can vary between day and night due to the antagonistic effect of respiration and photosynthesis on the water chemistry.

The presence of all these local biological processes creates a large diversity of pH niches in coastal habitats, offering areas with improved conditions for calcification. For example, calcifiers living close to macrophytes can adapt to acidification by increasing their calcification rates during daytime when CO_2 is drawn down by primary productivity. Despite the fact that this local adaptation can be valuable for adult individuals, it is possible that the pelagic larval stage, typical of many coastal calcifiers, may be critical for the species survival in a more acidic ocean.

Another important phenomena affecting coastal pH is upwelling. Upwelling is a process in which deep, cold, and nutrient rich water upwells from the bottom of the ocean to the surface. This water movement is wind driven and constantly or periodically affects several coastal areas around the word. In upwelling regions, the high concentration in nutrients promotes biological activities, but CO_2 concentrations are generally high and waters are undersaturated with respect to aragonite. The impact of acidification caused by upwelling has been demonstrated in estuarine areas where oyster larvae production was greatly reduced during strong upwelling periods.

Organisms living in coastal areas are generally tolerant to changes in pH due to the high natural variability of their habitats. However, the effect of anthropogenic CO_2 emissions is not yet fully understood for those organisms. Despite their higher tolerance to a variable environment, animals can still be affected by ocean acidification, but in a more subtle way. The physiology and development of intertidal snails are affected under acidified conditions causing a decrease in fitness and survival. Juvenile oysters show a reduction in their energy storage and a weaker shell. The immune response of intertidal mussels is disrupted by higher CO_2 conditions.

One of the more emblematic ecosystem affected by acidification worldwide are coral reefs. There is now abundant evidence that acidification and temperature changes are leading to coral bleaching and mortality. Most shallow water corals depend on an obligate relationship with a photosymbiont microalgae. The algae provides nutrients and energy to the coral facilitating his growth and calcification even in oligotrophic waters. The loss of symbionts in corals is generally called “coral bleaching” due to the impressive color change in coral tissues. When the coral bleaches, it is not dead but it becomes more vulnerable to stress and shows higher mortality rates. One of the more important causes of coral bleaching is thermal stress, but acidification is also known to favor this phenomenon. The symbiotic relationship between coral organisms and photosynthetic symbionts is often disrupted by pH changes since the symbiotic interaction is limited to a very small internal pH range.

The negative impact of acidification on corals is not limited to bleaching, but it also causes significant productivity reductions and higher rates of net dissolution of the calcified tissues. Experiments restoring preindustrial alkalinity conditions in restricted coral reef areas showed that net community calcification is highly affected by ocean chemistry. Coral calcification has been shown to be reduced of about 6%–7% since the beginning of the industrial era. In addition to coral, several other organisms living in these habitats have been shown to be particularly vulnerable to pH changes. Coral reef invertebrate recruitment and abundance are significantly lower in elevated CO_2 areas. These organisms are the key food source of several reef fish and their decline will probably entrain a cascade effect along the food chain.

Acidification in Freshwater Ecosystems

In freshwater ecosystems, the acidification process due to atmospheric CO_2 emissions is often amplified by the effect of other anthropogenic forces such as acid rain and mining drainage. CO_2 concentration in larger lakes tends to be in equilibrium with the atmosphere, but this is generally not the case for lotic systems. Biological activities, rainfalls, and stream order play an important role in regulating pH of freshwater systems. Assuming only an atmospheric CO_2 increase of about 550 μatm, the pH in Great Lakes is estimated to decline at a similar rate compared to the open ocean (about 0.19/0.09 units), but rivers and small lakes are likely to have different responses. Mining activity can cause an even higher impact with pH drops below 4 in certain systems. The release of oxidation products from the soil to the water is called acid mine drainage. This drainage causes important acidifications in hundreds of lakes and rivers situated in proximity to the mining areas.

The effects of acid rain are perhaps more flagrant. Sulfur and nitrogen oxides produced by volcanoes, industries, and other anthropic activities react with atmospheric compounds to create sulfuric and nitric acid. The acids deposit on the ground and drain into lakes and streams. North America and Europe were particularly affected by this phenomenon after the industrial revolution and new developing industrial countries such as China are now subjected to the same issue. Acidic atmospheric deposition can cause pH drops below 5 or even 4 in some freshwater systems. The effects on the aquatic ecosystems are often dramatic and the use of buffering compounds (limestone) has been employed in sensitive areas to limit the damage.

The impact of acidification on freshwater biota has been often underestimated. Only recently, some researchers focused on the effect of acidification at the species/organism level. As documented in marine systems, freshwater macrophytes and phytoplankton can be positively affected by higher CO_2 concentrations, but the response is strongly dependent on nutrient availability in the system. Studies performed on lakes historically affected by acidic atmospheric depositions showed that some freshwater zooplankton taxa are highly adaptable to acidic conditions and can survive and proliferate in a wide pH range. Following an acidification event, community diversity and structure is strongly affected but there is some evidence that ecosystems can recover when lake pH levels rise again above 6.

Another important freshwater community impacted by acidification is the bacterioplankton. Although diversity and richness were found to be generally similar between acidic and more neutral lakes, the community structure was changed. Water chemistry and acid stress have a direct influence on abundances and organization of bacterial assemblages.

In freshwater systems, mollusks, crustaceans, and many aquatic insects play the important role of breaking down the organic material to regenerate nutrients and serve as a food source for several species of fish and birds. Studies performed on several European lakes suggest that pH less than 5 might be critical for insect communities. Very little is known on the effect of pH declines on freshwater mollusks, but they are usually absent from systems with acidity below 5 probably due to an excessively high construction and maintenance cost of their calcareous structures. This is particularly true for freshwater bivalves' shells primarily made up of aragonite, since this type of shell is more soluble than the calcite one of most marine organisms. The decrease in calcium availability in acidified waters has been shown to significantly affect freshwater crustaceans that are particularly sensitive during their rapid post molt calcification of the exoskeleton. In streams, crabs, shrimps, and crayfish disappeared from anthropogenic acidified areas. Species loss among detritivorous insects and crustaceans result in a loss of the litter break down process with important consequences for the entire ecosystem.

The effect of low pH on freshwater invertebrates can be exacerbated by increased metal toxicity. Mercury concentrations are more elevated in crayfish from lower pH lakes compared to less acidified areas. Aluminum appears to be highly absorbed by invertebrates at lower pH. Nonetheless, lead toxicity is often species-specific and little information is available on potential biomagnification along the food chain.

The effect of acidified water on higher trophic levels such as fish and amphibians has received increased interest in the past few years. Under acidified conditions, the growth rate has been shown to decrease in several taxa, mostly due to a higher energetic cost of the acid–base regulation system in the fluids and tissues. The development of pink salmon during its freshwater phase has been shown to be affected by increased CO_2 levels. The growth rate and early embryonic development of this species is impaired by elevated freshwater CO_2 partial pressure. Moreover, the capacity to detect olfactory cues and avoid predators is significantly reduced under projected increases of CO_2. But, this is just an example of how acidification can induce behavioral changes in freshwater fish. Altered dial movement, behavioral changes and modified feeding patterns has been observed in several species suggesting that acidification linked behavioral changes could increase the vulnerability of these organisms to predation and food competition.

Amphibians are experiencing a general decrease in abundance due to several anthropogenic activities, one of the most important being acidification. Common species of frogs have been reported to be gradually decreasing and eventually disappearing from poorly buffered and acidified ponds and lakes. Lower pH and calcium concentration significantly limited frog reproduction and development. In dwarf newts, acidification did not inhibit females from laying eggs but the embryos were exposed to higher mortalities under low pH. A similar response has been seen on toads with up to 100% mortality in eggs maintained at a pH below 5.

All those changes in freshwater ecosystem composition and productivity have direct consequences on the higher consumers such as birds. Acidified streams have been seen to host younger and less site-faithful breeding populations of birds since they provide a lower quality habitat. Furthermore, potentially toxic metals concentration and a decreased availability of calcium, can also negatively affect birds. Piscivorous birds can suffer from strong metal bioconcentration in their prey and a reduction of calcium content in the food could affect bones and egg shells formation.

Ecological Impact

The negative effects of aquatic acidification on single species have received the most attention in recent years. However, the consequences of aquatic acidification are also extremely important at a community and ecosystem level. All organisms are embedded in a complex network of interaction between different species and populations. The impact of acidification on aquatic ecosystems is therefore inextricably linked to the impact of stressors at different tropic levels.

Predator–prey interactions can be extremely important in regulating and structuring populations and communities. Ocean acidification can lead to important indirect changes in the structure, flows, and composition of the food web. Observations from natural CO_2 enriched areas show that communities differ substantially from nearby areas with higher seawater pH. Lower diversity

and higher food web specialization are typically found in acidified areas, suggesting that acidification could induce a dramatic community shift in vulnerable systems.

Phytoplankton constitutes the foundation of aquatic food webs and regulates multiple biogeochemical processes. Acidification has been shown to have a greater impact than seawater warming or reduced nutrient supply on phytoplankton communities. About half of the global functional diversity of marine phytoplankton communities has been estimated to be altered by 2100 and this is mostly caused by ocean acidification. Freshwater phytoplankton communities are also significantly impacted by elevated CO_2 concentration since less diverse populations and smaller cells were collected in altered systems. Tolerance for low pH varied significantly between species and some authors suggested that toxic cyanobacterium strains could be more tolerant and able to proliferate under weak acidification scenarios.

Ocean acidification can also profoundly affect settlement and benthic communities. Although a wide range of species are able to settle and survive under acidified conditions, diversity is generally reduced and few taxa become dominant. This is partly due to the fact that many benthic invertebrates depend on calcified structures that are particularly sensitive to acidification. The negative impacts on the benthic community can have a cascade effect on the trophic chain and several cases of flatfish, sharks, and rays declining have been reported. Regardless of the precise conformation of the local food web, it is likely that bottom-up changes can be important. Moreover, other relatively unexplored problems such as changes in bacteria, pathogens, and parasites could also alter the functioning of the ecosystem.

Assuming that calcified structures can provide protection, function as substrate and give a wide range of other benefit to other organisms, a change in their abundance and distribution can significantly affect local communities. Coral reefs, oysters, mussels, coralline algae, and many other organisms are considered as important ecosystem engineers providing a number of ecosystem services and creating favorable habitats by modifying the environmental physical and biological conditions. Negative impacts on these organisms can cause a cascading effect on competitors and consumers. Depending on species tolerance and adaptability to acidification and climate changes, the effect on the ecosystem can be more or less important and key stone species may be replaced by more resistant ones.

Another important ecosystem alteration related to ocean acidification is the modification of carbon and nutrients biogeochemical dynamics. Variations in nutrient ratios have important effects on phytoplankton and microbial communities and this could lead to a degraded food quality for heterotrophic consumers. Changes in water chemistry could also be directly responsible for modifications in elements availability and organic matter degradation and composition. These changes can directly affect the base of the food webs and consequently the entire ecosystem.

Socioeconomical Impact

Despite the clear negative impact of acidification for the aquatic communities and ecosystem functioning, this phenomenon also has an important economic cost. The loss of economically important species such as fish and mollusks is accompanied by a decrease in aquaculture productivity and the loss of touristic and valuable habitats such as coral reefs. Moreover, any negative effect of aquatic acidification is expected to enhance the already present stressors such as overfishing and global warming.

One of the socioeconomical challenges connected to ocean acidification is the effect that this phenomenon has on seafood. Decreased pH has been shown to decrease appearance and taste of commercially important species like shrimps. Fish and mollusks are predicted to be smaller under the effects of acidification. Some commercially in demand species might decrease causing a shift in marketable goods, such as from fish to jelly fish and algae that are predicted to be more resilient to acidification.

The US oyster industry has been declining since 2005 with an average loss of $111 million per year and one of the causes is the presence of acidified waters in the area. The global economic cost of mollusk loss from ocean acidification has been estimated at about $6 billion annually. In Europe, the annual economic losses due to ocean acidification are estimated to be over $1 billion in 2100. The global value of coral reef based tourism was estimated to be $11.5 billion in 2010 and the industry is in rapid growth. The consequences of coral reefs habitat loss are expected to cost about $49–69 billion by the end of this century.

Economists estimated that the cost of the total impact of ocean acidification is in the same order of magnitude as climate change despite a high level of uncertainty still being present, due to fact that aquatic acidification has only recently begun to receive attention in international discussions. One of the main economic issues, is that ocean acidification is likely to have a greater negative impact on poorer fishing and aquaculture communities such as the small developing island states. These areas are particularly vulnerable to climate change and ocean acidification impacts, and they have fewer possibilities for alternative livelihoods.

For island nations, coral reefs loss can also constitute a substantial socioeconomic collapse. Marine natural touristic attractions such as diving, snorkeling, sightseeing, and recreational fishing will significantly suffer from ocean acidification effects. Moreover, coral reefs offer shoreline protection and support fisheries for a budget estimated at $30 billion a year.

Response Strategies to Aquatic Acidification

Limiting the effects of aquatic acidification is now critical considering the high risks of impact on natural and human systems. An effective response to aquatic acidification is likely to require a large-scale investment plan. Due to a strong connection between

aquatic acidification and the other climate change stressors, regional, national, and global strategies need to consider and manage those issues together.

The primary possible action to mitigate aquatic acidification is to reduce CO_2 emissions since no large-scale system is yet available to remove CO_2 from the atmosphere. Nonetheless, even if all CO_2 emissions were to end now, the CO_2 already released into the atmosphere will continue acidifying the ocean for centuries. It is indeed important to establish some mitigation and adaptation responses.

Ocean and freshwater acidification will not lead to the disappearance of all aquatic organisms. Some species will be able to tolerate the new conditions but ecosystems diversity and abundance are likely to change. The disappearance of economically and culturally important species may lead to extreme social forcing.

The impact of aquatic acidification on juvenile fish, food webs, and coastal habitats are likely to entrain important reductions in fishery resources. Improved managements and reduction of fishing pressure are just some examples on how we can protect and rebuild fish stocks. Other possible actions could involve the development of protection and restoration plans for particularly degraded and important areas.

In aquaculture, the impact of acidification can be limited by selecting more resilient species and employing selective breeding. The entire culture systems could also be monitored and controlled to maintain optimal water conditions for the growth of the selected species. Moreover, monitoring and response plans can be organized to warn and protect aquaculture systems from acidification and other episodic stressor events.

Nevertheless, all these actions to mitigate the effects of acidification require high financial costs and policy commitment and cannot face the extreme scenarios of global CO_2 emissions. It is therefore fundamental to take action in reducing carbon emissions to leave a greater number of effective safeguarding options to protect the marine and freshwater systems and their services to humans.

Constructed Wetlands for Wastewater Treatment[☆]

Jan Vymazal, Czech University of Life Sciences Prague, Praha, Czech Republic

Introduction

Constructed wetland treatment systems are engineered systems that have been designed and constructed to utilize the natural processes involving wetland vegetation, soils, and their associated microbial assemblages to assist in treating wastewater. Constructed wetlands must contain wetland vegetation, the treatment system with no plants are not considered constructed wetlands. They are designed to take an advantage of many of the same processes that occur in natural wetlands, but do so within a more controlled environment. Some of these systems have been designed and operated with the sole purpose of treating wastewater, while others have been implemented with multiple-use objectives in mind, such as using treated wastewater effluent as a water source for the creation and restoration of wetland habitat for wildlife use and environmental enhancement. Synonymous terms to "constructed" include man-made, engineered, and artificial wetlands.

At present, there are many different types of constructed wetlands (Fig. 1). Constructed wetlands (CWs) for wastewater treatment may be classified according to the flow regime into surface flow (SF or free water surface—FWS) and subsurface flow (SSF) systems. The FWS CWs could be further categorized according to the life form of the dominating macrophyte into systems with free floating, floating-leaved, emergent and submerged macrophytes. Within the SSF CWs it is possible to distinguish between systems with horizontal (subsurface) flow (HF or HSSF CWs) and vertical (subsurface) flow (VF or VSSF CWs). As many wastewaters are difficult to treat in a single stage system, hybrid systems that consist of various types of constructed wetlands staged in series have been introduced. In the European sense, hybrid CWs are usually formed by a combination of HF and VF systems. However, any types of CWs could be combined in order to achieve better treatment performance, especially for total nitrogen.

The first experiments aimed at the possibility of wastewater treatment by wetland plants were undertaken by Dr. Seidel in Germany in 1952 at the Max Planck Institute in Plön. However, Seidel's concept to apply macrophytes to sewage treatment was difficult to understand for sewage engineers and therefore, it was no surprise that the first full-scale free water surface (FWS) constructed wetland (CW) were built outside Germany, in the Netherlands, in the late 1960s. However, the first subsurface flow constructed wetland was built in Germany in 1974.

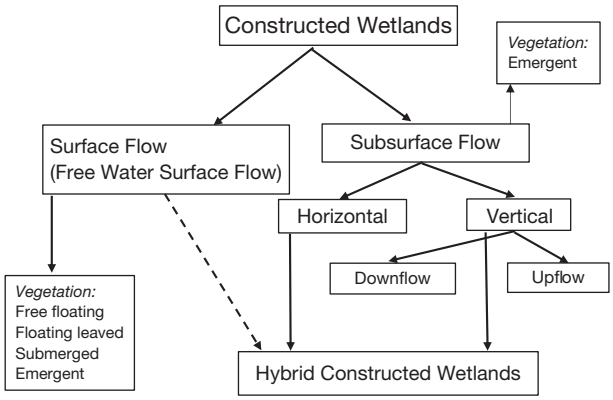

Fig. 1 Constructed wetlands classification.

[☆]*Change History:* April 2018. Vymazal updated the text and figures from the 1st edition, all Tables are new.

Free Water Surface CWs

A typical free water surface constructed wetland consists of a shallow basin constructed of soil or other medium to support the roots of vegetation (when rooting macrophytes are used) and a water control structure that maintains a shallow depth of water (Fig. 2). Flow is directed into a cell along a line comprising the inlet, upstream embankment, and is intended to proceed all portions of the wetland to one or more outlet structures. The shallow water depth, low flow velocity, and presence of the plant stalks and litter regulate water flow and, especially in long, narrow channels, ensure plug-flow conditions. FWS CWs can be classified according to the type of vegetation used (Fig. 2).

FWS CWs function as land-intensive biological treatment systems. Inflow water containing particulate and dissolved pollutants slows and spreads through a large area of shallow water. Particulates, typically measured as total suspended solids, tend to settle and are trapped due to lowered flow velocities and sheltering from wind. Most of the solids are usually filtered and settled within the first few meters beyond the inlet. While settleable organics are rapidly removed in FWS CWs by quiescent conditions, attached and suspended microbial growth is responsible for removal of soluble BOD (Biochemical Oxygen Demand, i.e., organic matter). The major oxygen source for these reactions are algae and cynobacteria growing in the water.

Nitrogen is most effectively removed in FWS systems by nitrification/denitrification. Ammonia is oxidized by nitrifying bacteria in aerobic zones, and nitrate is converted to free nitrogen or nitrous oxide in the anoxic zones near the bottom by denitrifying bacteria. Volatilization is likely as both plankton and periphyton algae grow in FWS CWs and higher pH values during the day may be favorable for ammonia loss. FWS CWs provide sustainable removal of phosphorus, but at relatively slow rates. Phosphorus removal in FWS systems occurs from adsorption, absorption, complexation and precipitation. However, precipitation with Al, Fe and Ca ions—is limited by little contact between water column and the soil. Macrophyte uptake as a removal mechanism in FWS CWs is restricted by the fact that vegetation is not regularly harvested. Also, the amount of N and P sequestered in aboveground biomass is usually quite low as compared to inflow loading (usually $<10\%$). The only exception are CWs with free floating macrophytes where harvesting in necessary for a proper function of the system. FWS CWs have been built to treat various types of wastewater (Table 1) around the world including domestic and municipal wastewater, mine drainage, urban, airport, highway and agricultural drainage, landfill leachate and variety of industrial and agricultural wastewaters.

The system with emergent vegetation is the most commonly used type of FWS CWs with *Phragmites australis* (common reed), *Typha* spp. (cattail), *Scirpus* spp. (bulrush), *Juncus* spp. (rush) and *Eleocharis* spp. (spikerush) being the most frequently used species. In other types of FWS CWs following species are commonly used:

- free floating: *Eichhornia crassipes* (water hyacinth, tropics and subtropics), *Pistia stratiotes* (water lettuce, subtropics and tropics), Lemnaceae (duckweeds, worldwide)
- floating-leaved: *Nuphar lutea* (spatterdock), *Nelumbo nucifera* (Indian lotus)
- submerged: *Ceratophyllum demersum* (coontail), *Najas guadalupensis* (southern waternymph), *Trapa natans* (water chestnut, sometimes classified as free floating), *Myriophyllum heterophyllum* (variable-leaf watermilfoil)
- floating mats: *Phragmites australis*, *Cyperus papyrus* (Papyrus), *Alternanthera philoxeroides* (Alligator weed), *Hydrocotyle umbellata* (Pennywort)

Removal of organics and suspended solids in all FWS CWs is very high while removal of nutrients is only moderate. FWS CWs provide limited contact with soil (if present) so adsorption and precipitation processes are very limited and therefore phosphorus removal mostly proceeds via soil accretion. FWS CWs provide both aerobic and anaerobic zones but neither nitrification or denitrification processes are complete. FWS CWs also provide high removal of enteric bacteria (e.g., fecal coliforms, fecal streptococci, *Clostridium perfringens*), usually in the range between one to two orders of magnitude.

Constructed Wetlands With Subsurface Flow

Horizontal Flow CWs

The most widely used concept of SSF CWs is that with horizontal subsurface flow (HF or HSSF CWs, Fig. 3). The design typically consists of a rectangular bed planted with the macrophytes and lined with an impermeable membrane. Mechanically pretreated wastewater is fed in at the inlet and passes slowly through the filtration medium under the surface of the bed in a more or less horizontal path until it reached the outlet zone where it is collected before discharge via level control arrangement at the outlet. During the passage of wastewater through the reed bed the wastewater makes contact with a network of aerobic, anoxic and anaerobic zones.

HSSF CWs require good mechanical pretreatment with suspended solids being the major target. Excessive suspended solids may cause filtration bed clogging and subsequent surface flow. Small systems for domestic sewage with low flows usually use a three-chamber septic tank. Pretreatment in systems designed for municipal sewage mostly comprise screens and Imhoff tank (sedimentation of particles, both inorganic and organic). When stormwater runoff is also treated (combined sewer system), a grit chamber (removal of inorganic particles) is included. Various types of wastewater may require different types of pretreatment. For example, landfill leachate treatment systems usually include aerated lagoons, systems for the treatment of concentrated wastewaters from agricultural operations commonly include facultative lagoons.

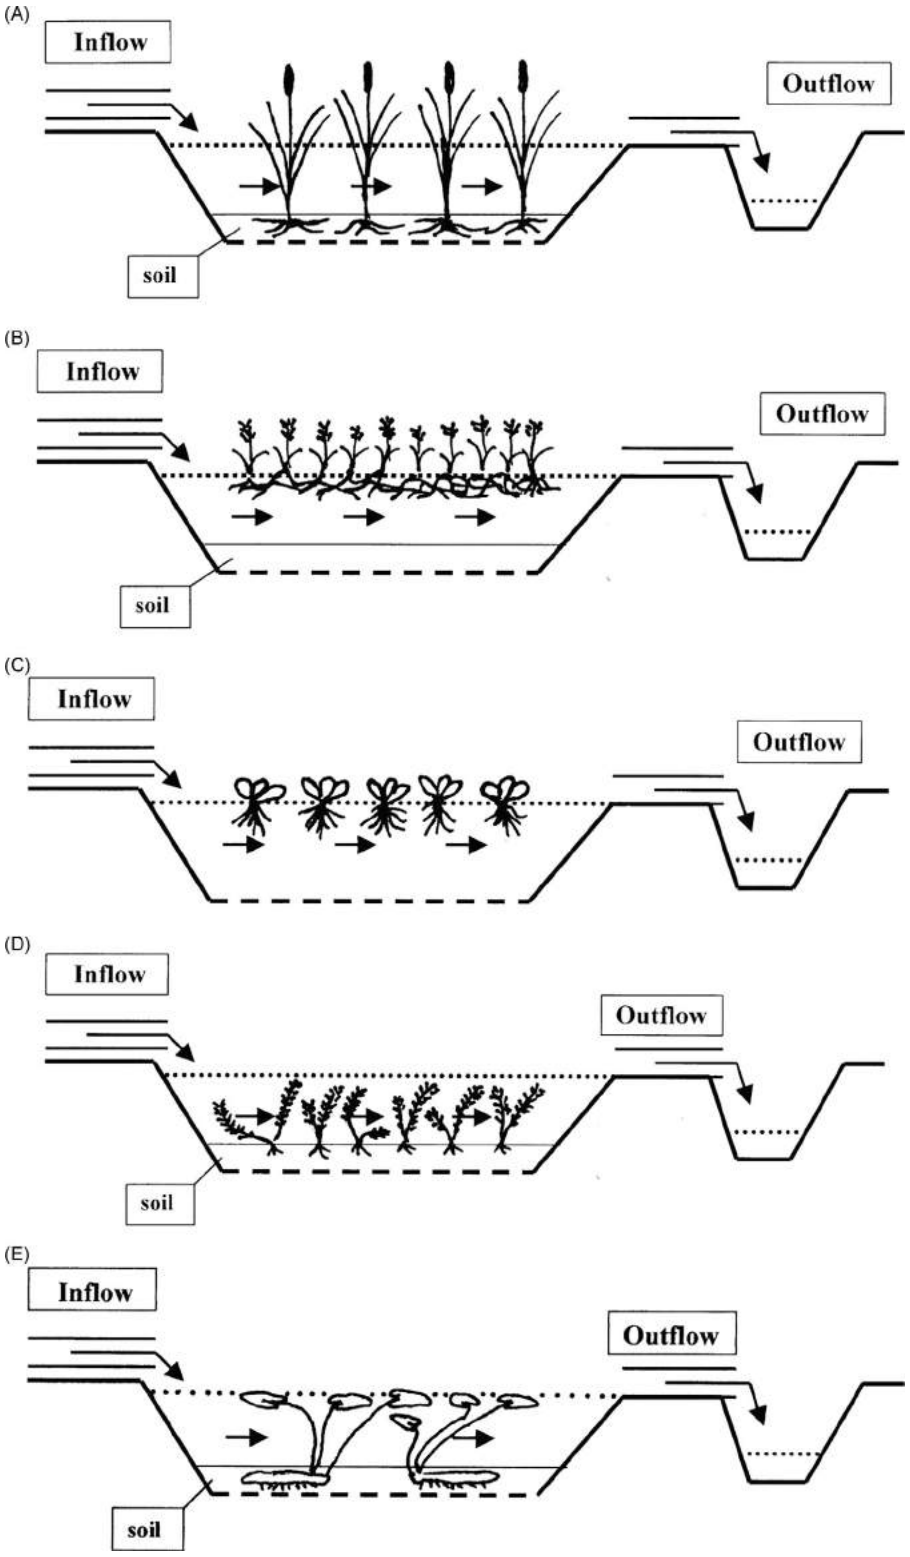

Fig. 2 Free water surface constructed wetlands. (A) With emergent vegetation, (B) with floating mats of emergent vegetation, (C) with free floating vegetation, (D) with submerged vegetation, (E) with floating-leaved vegetation (Vymazal, 2008).

Table 1 Examples of the use of FWS CWs for treatment of various types of wastewater

Vegetation	*Type of wastewater*	*Location*
FF	Municipal	United States, Cameroon, Poland, Thailand, China, Taiwan
FL	Municipal	United States, China
S	Municipal	United States, Sweden, China
	Agricultural runoff	Sweden, United States
	Urban runoff	Canada, United States
E	Municipal	All continents
	Urban stormwater	Australia, United States, United Kingdom
	Agricultural runoff	Australia, New Zealand, United States, Sweden, Denmark, Italy, Korea, Taiwan, China, Norway, Finland, Spain
	Airport runoff	Sweden, Canada
	Feedlot operations	Ireland, Canada, United States
	Mine drainage	United Kingdom, United States, Spain, South Africa, Canada, Australia, Germany, Ireland
	Refinery	United States, China, Hungary
	Pulp and paper	United States, China
	Aquaculture	United States, Taiwan
	Landfill leachate	Sweden, Norway, Canada, Poland, United States
	Food processing	Greece, Kenya, United States, Canada, Thailand, Italy, New Zealand
	Tannery	Turkey
	Woodwaste	Canada
FM	Municipal	United States, China, Turkey, Uganda, Sri Lanka, Colombia, Italy, Taiwan
	Road runoff	Belgium, United States, New Zealand
	Agricultural runoff	China
	Mine drainage	Canada
	Feedlot operations	United States

FF, free floating; *FL*, floating-leaved; *S*, submerged; *E*, emergent; *FM*, floating mats.

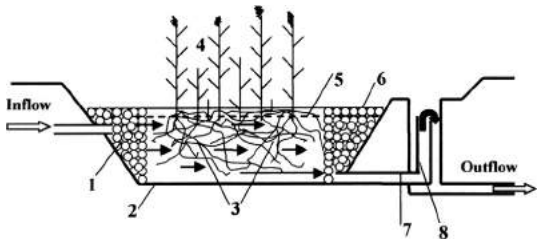

Fig. 3 Constructed wetlands with horizontal subsurface flow. 1—distribution zone filled with large stones, 2—impermeable liner, 3—filtration medium (gravel, crushed rock), 4—vegetation, 5—water level in the bed, 6—collection zone filled with large stones, 7—collection drainage pipe, 8—outlet structure for maintaining of water level in the bed. The arrows indicate only a general flow pattern. From Vymazal, J. (ed.) (2001). *Transformations of nutrients in natural and constructed wetlands*. Leiden, The Netherlands: Backhuys Publishers.

Filtration beds are filled with porous material which allows for good hydraulic conductivity in order to keep the water level below the surface as well as supports growth of macrophytes. The most commonly used filtration materials are washed pea gravel and crushed rock. The fraction size varies among countries but in general, size between 5 and 20 mm is the most common. It is recommended to use only one fraction as various fractions differ in hydraulic conductivity and short circuiting may occur. The inflow distribution and outflow collection zones are filled with large stones (ca. 50–200 mm).

The following equation, first proposed by Kickuth, is widely used for sizing of HSSF systems for domestic sewage treatment:

$$A_h = Q_d(\ln C_{in} - \ln C_{out})/K_{BOD},$$

where A_h = surface flow of bed (m^2), Q_d = average flow ($m^3\ day^{-1}$), C_{in} = influent BOD_5 ($mg\ L^{-1}$), C_{out} = effluent BOD_5 ($mg\ L^{-1}$), K_{BOD} = rate constant ($m\ day^{-1}$).

There were a lot of discussion on the K_{BOD} value. Formerly proposed value of 0.19 m day^{-1} by Kickuth resulted in too small area of the bed (about 2 m^2 per one PE, population equivalent) and consequently lower treatment effect. The field measurements in operational systems indicated that the value of K_{BOD} is usually lower (0.07–0.1 m day^{-1}). The data from 66 Danish HSSF CWs identified *K*-values for total-*N*: 0.033 m day^{-1} and total-*P*: 0.025 m day^{-1}.

The depth of vegetated beds with horizontal subsurface flow was initially based on the requirement that roots and rhizomes of the vegetation should penetrate the full depth of the bed in order to eliminate totally anaerobic zones. As the roots of the most frequently used plant, common reed (*Phragmites australis*) are capable of successful penetration to the depth of about 0.6 m and start to weaken beyond that point, the recommended bed depth was 0.6 m. Although it has been proven that oxygen transported from aboveground organs diffuses only to the thin substrate layer adjacent to the roots and rhizomes the typical depth of filtration bed is usually 0.6–0.8 m.

Constructed wetlands with horizontal subsurface flow are usually sealed in order to prevent uncontrolled water seepage into groundwater. Most of the systems use a plastic liner or membrane such as HDPE, LDPE or PVC 0.5–2 mm thick. Where local subsoil has low hydraulic conductivity (approx. 10^{-8} m s^{-1} or less), it is not necessary to use plastic liners. In order to prevent liner damage by filtration material particles, geotextile is commonly used to cover plastic liner. Also, geotextile could be also used beneath the liner.

The macrophytes growing in constructed wetlands have several properties in relation to the treatment processes that make them an essential component of the design. The most important effects of the macrophytes in HSSF CWs in relation to wastewater treatment processes are the physical effects the plant tissues give rise to such as insulation of the bed surface during the period of cold weather or provision of surface area for attached microorganisms in the filtration bed. The metabolism of the macrophytes (plant uptake, oxygen release from the roots) is of minor importance in HSSF CWs. The macrophytes for HSSF CWs should (a) be tolerant of a relatively high organic load in the wastewater, (b) have high belowground and aboveground biomass, and (c) should grow quickly in order to cover the filtration bed surface soon after planting.

The most frequently used plant around the world is *Phragmites australis*, especially in Europe, Australia, Africa and Asia. In some countries, *Phragmites* is used exclusively; for example, in the United Kingdom, where HSSF CWs are called Reed Bed Treatment Systems. On the other hand, in New Zealand or many areas of the Unites States, *Phragmites* is considered an exotic and invasive species by natural resource agencies and as a result, use of this species has been limited. Other commonly used species are *Phalaris arundinacea* (reed canarygrass), *Glyceria maxima* (sweet mannagrass) or various cattails (*Typha latifolia*, *T. angustifolia*) in Europe, *Cyperus papryrus* (papyrus) in Africa, *Typha domingensis* in South America and *Scirpus* spp. (bulrush) in North America. Weeds (plants that were not intentionally planted) occur mostly within vegetated bed margins and do not have any detrimental impact on treatment performance.

Dissolved oxygen supply is very limited in filtration beds of HSSF CWs and, therefore, anoxic and anaerobic processes usually prevail. Aerobic degradation is restricted to narrow zones adjacent to roots and rhizomes where oxygen leaks to the rhizosphere. Removal of organics (BOD_5, COD) is usually high and exceeds 85% in case of sewage. Suspended solids that are not removed in pretreatment system are effectively removed by filtration and settlement. Most suspended solids are filtered out and settled within the first few meters beyond the inlet zone. Suspended solids are removed in HSSF CWS were effectively, commonly >90%. The accumulation of trapped solids is a major threat for good performance of HSSF systems as the solids may clog the bed. Therefore, the effective pretreatment is necessary for HSSF systems. However, it has been shown that if HSSF CWs are appropriately loaded, that is, <10 g BOD_5 m^{-2} day^{-1}, <20 g COD m^{-2} day^{-1}, <10 g TSS m^{-2} day^{-1}, the partial clogging in the inflow zone occurs only after about 15 years. In addition, partial clogging has no effect on treatment performance of the system.

The major removal mechanism of nitrogen in HSSF constructed wetlands is nitrification/denitrification. Field measurements have shown that the oxygenation of the rhizosphere of HSSF constructed wetlands is insufficient and, therefore, incomplete nitrification (i.e., oxidation of ammonia to nitrate) is the major cause of limited nitrogen removal. In general, nitrification which is performed by strictly aerobic bacteria is mostly restricted to areas adjacent to roots and rhizomes where oxygen leaks to the filtration media. On the other hand prevailing anoxic and anaerobic conditions offer suitable conditions for denitrification but the supply of nitrate is limited as the major portion of nitrogen in sewage is in the form of ammonia. Adsorption and plant uptake play a much less important role in nitrogen removal in HSSF CWs. Volatilization is not effective as there is no free water surface and adsorption is greatly limited by the fact that filtration media (gravel, rock) do not provide suitable sorption sites. Plant harvesting contributes to an overall nitrogen removal only marginally (usually <10% of the inflow load) with N standing aboveground stocks in the range of 20–60 g N m^{-2}. In case of sewage, removal of ammonia and total nitrogen usually does not exceed 50%.

Phosphorus is removed primarily by adsorption and precipitation, however, media used for HSF wetlands (e.g., pea gravel, crushed stones) usually do not contain great quantities of Fe, Al or Ca and therefore, removal of phosphorus is generally low (<40% in sewage). Removal of phosphorus could be enhanced by the use of filtration media with high sorption capacity but the sorption capacity is always saturable and therefore, the media must be replaced after saturation in order to maintain high P removal. Removal via harvesting accounts usually for <5% of the inflow load with the P standing stock in the aboveground biomass in the range of 3–6 g P g m^{-2}. The removal of microbiological pollution is very seldom the primary target for constructed treatment wetlands. However, HSSF CWs are known to act as excellent biofilters through a complex of physical, chemical and biological factors which all participate in the reduction of the number of bacteria of anthropogenic origin.

HSSF CWs are used for many types of wastewater around the world (Table 2). Indeed, the most common use is for municipal and domestic sewage, however industrial and agricultural wastewaters have been successfully treated as well. Besides that, applications for various types of stormwater runoff (e.g., urban, highway, agricultural, golfcourses, nurseries, airports) and landfill leachate have been put in operation.

Table 2 Examples of the use of HF CWs for various types of wastewaters

Wastewater	*Location*
Municipal	Worldwide
Petrochemical	United States, Taiwan, China, Sudan, Oman

Vertical Flow CWs

Constructed wetlands with vertical subsurface flow (VF or VSSF CWs) usually comprise a flat bed of coarse sand or gravel planted with macrophytes (Fig. 4). The most important factors in the design of a VF CWs are: (1) to produce a bed matrix that allows the passage of the wastewater through the bed before the next dose arrives whilst at the same time holding the liquid back long enough to allow the contact with the bacteria growing on the media and achieve the required treatment. (2) To provide sufficient surface area to allow the oxygen transfer to take place and sufficient bacteria to grow. VF CWs were proposed during the 1960s but did not spread as quickly as HSSF CWs, probably because of higher operation and maintenance requirements. However, the increased demand for nitrogen and especially ammonia'nitrogen removal in the 1990s revived this type of constructed wetlands.

All VF systems are dosed intermittently, however, there is no clear recommendation how many batches per day are optimal. It is essential to achieve quick water cover of the surface in order to trap air in the interstices in the bed. In most VF systems the real distributor is the layer of carefully selected sand which first allows flooding of the surface and then gradual seepage down through the depth of the media. The vast majority of the VF systems employ a network of pipes with small holes across the surface area of the bed. The distribution pipes could be insulated by a 0.2 m layer of coarse wood chips or sea shells on the surface of the filter. It is also possible to distribute wastewater from open-ended pipes onto the bed. The area of the immediate vicinity of the discharge should be protected by some paving or tiles to prevent the wash away of the sand or gravel.

The data on maximum HLR vary widely in the literature. However, it seems that VF CWs can operate in the range of 100–1200 mm day^{-1} and usually no clogging problems occur below 800 mm day^{-1} of pretreated wastewater. The organic loading rate should not exceed 25 g COD m^{-2} day^{-1} in order to prevent clogging. The area used for VF CWs varies between 0.9 and 5 m^2 PE^{-1} (PE = population equivalent) but most systems are design with the specific area 2–3 m^2 PE^{-1} stems are usually designed as a single unit, larger systems may have several beds which are fed with wastewater in rotation. Also, some larger systems have two stages of vertical beds in operation.

The size of VF CWs is usually based on the hydraulic loading rate (HLR). The maximum HLR that can be achieved without surface flooding will be affected by many variables but is most strongly related to media size and distribution, rate of biofilm growth and hence the BOD_5/organic mass loading rate and suspended solids loading rate. The Danish guidelines recommend specific area of 3.2 m^2 per person, maximum organic loading of 18.8 g BOD_5 m^2 day^{-1} and hydraulic loading of 47 mm day^{-1}. Filtration medium is sand with a d_{10} between 0.25 and 1.2 mm, a d_{60} between 1 and 4 mm, and uniformity coefficient ($U = d_{60}/d_{10}$) should be <3.5. The contents of clay and silt (particles <0.125 mm) must be <0.5%. Austrian guidelines recommend the specific area of 4 m^2 per person and maximum loading of 20 g COD m^{-2} day^{-1}. The filtration layers should consist of 5–10 cm of gravel (4/8 or 8/16 mm) on top, followed by 50 cm of washed sand (0–4 mm), 5–10 cm transition layer (gravel 4/8 mm) and 20 cm drainage layer at the bottom (gravel 8/16 or 16/32 mm). This set-up guarantees outflow concentrations <90 mg L^{-1} COD, 25 mg L^{-1} BOD_5 and 10 mg L^{-1} $N\text{-}NH_4$ at water temperature > 12°C. In France, the VF systems consist of two beds in series with only 1.2 m^2 per person in the first stage and 0.8 m^2 per person in the second stage. The pretreatment consists only of prescreening, maximum organic load is 100 g COD m^2 day^{-1} and maximum hydraulic loading is 90 cm day^{-1}.

Plants play a very important role in VF CWs. They stabilize surface of the bed, their roots and rhizomes positively affect the hydraulic conductivity of the filter and movement of aboveground stems helps to prevent clogging. The aboveground biomass provides insulation of the bed and belowground organs provide substrate for attached bacteria growth. The oxygen transfer to the rhizosphere is limited but creates microzones where aerobic bacteria can be present. The vast majority of VF CWs is in operation in Europe and the most commonly used plant is *Phragmites australis* (common reed).

VF CWs are very effective in removal of organics, suspended solids and ammonia. The intermittent feeding allows for regular emptying the filtration bed which results in good oxygenation of the bed allowing for nitrification. Therefore, VF CWS are used in

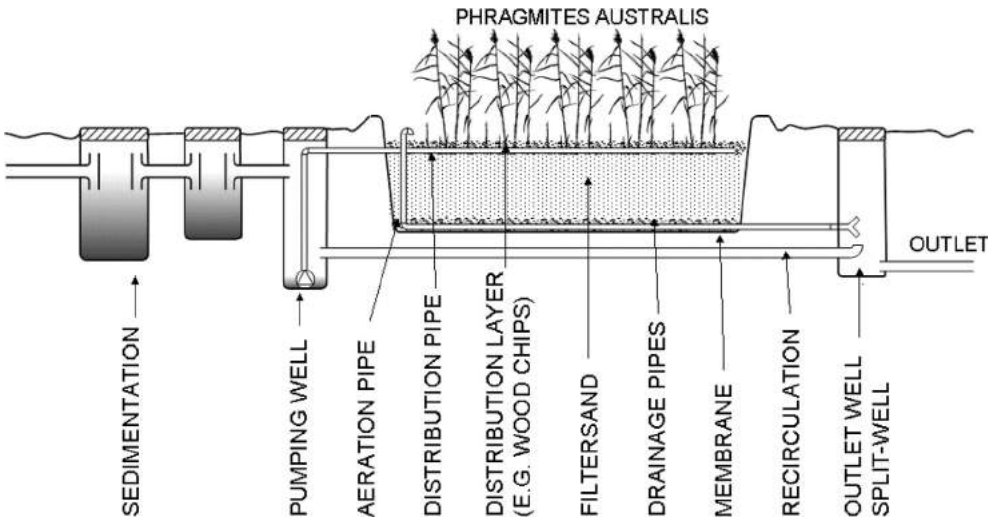

Fig. 4 Layout of a vertical flow constructed wetland system for a single household. Raw sewage is pretreated in a 2 m^3 sedimentation tank. Settled sewage is pulse-loaded onto the surface of the bed by a level-controlled pump. Treated effluent is collected in a system of drainage pipes, and half of the effluent is recirculated back to the pumping well (or to the sedimentation tank). From Brix, H. (2005). The use of vertical flow constructed wetlands for on-site treatment of domestic wastewater: New Danish guidelines. *Ecological Engineering* **25**, 491–500.

Table 3 Examples of the use of VF CWs for various types of wastewater

Wastewater	*Location*
Municipal, domestic	France, Belgium, Austria, Poland, Czech Republic, Italy
Landfill leachate	Norway, New Zealand
Abbatoir	Canada

Textile	United Kingdom, Portugal, Japan
Aquaculture	United States, China, Canada, Vietnam
Winery	Germany
Olive mill	Turkey, Greece
Chemical industry	Portugal
Steel industry	China

case when ammonia is the target of the treatment. On the other hand, due to oxic conditions in the bed, the denitrification is limited and often missing in the system. VF CWs are commonly used for treatment of domestic and municipal sewage but the use for other types of wastewater is common (Table 3).

Hybrid Constructed Wetlands

In hybrid constructed wetlands (CWs), the advantages of various systems can be combined to complement each other. Hybrid constructed wetlands were first introduced by Seidel in Germany as early as in the 1960s. The design consisted of two stages of several parallel vertical flow (VF) beds followed by two or three horizontal flow (HF) beds in series. The VF stages were usually planted with *Phragmites australis*, whereas the HF stages contained a number of other emergent macrophytes, including *Iris*, *Schoenoplectus* (*Scirpus*), *Sparganium*, *Carex*, *Typha* and *Acorus*. The VF beds were loaded with pretreated wastewater for 1–2 days, and were then allowed to dry out for 4–8 days. In this system, nitrification, that is, oxidation of ammonia to nitrate, takes place in the VF stage and denitrification of nitrate, that is, reduction of nitrate do N_2O and N_2, proceeds in the HF stage. The oxidation of ammonia in intermittently loaded VF stage is very high but the concentration of organics in the second stage may not be high enough to support full denitrification. In the early 1980s, several hybrid systems of Seidel's type were built in France and similar system was built in 1987 in the United Kingdom. During the 1990s and the early 2000s, VF–HF systems were built in many countries in Europe, for example, Austria, Slovenia, Norway or Ireland. The VF–HF hybrid constructed wetlands were mostly designed to treat domestic or municipal wastewater where nitrified effluents were required but there were also application for other types of wastewater (Table 4).

Table 4 Examples of hybrid constructed wetlands used for various types of wastewaters

Type of hybrid system	*Location*	*Wastewater*
VF–HF	Belgium, Estonia, Tunisia, Spain, China, Italy, Brazil, France	Sewage
	Italy	Cheese production
	Slovenia	Landfill leachate
	Spain	Winery
HF–VF	Mexico, Poland, France, Italy, Nepal, China, Turkey	Sewage
VF–VF–HF	Poland	Slaughter
	France	Cheese production
	Japan	Milking parlor
VF–VF–HF–VF	Japan	Milking parlor
VF–VF–VF–HF–VF	Japan	Starch production
	Japan	Pig urine
VF–HF–VF	Morocco, Turkey	Sewage
	Bangladesh	Tannery
HF–VF–HF	Poland, New Zealand	Sewage
	Korea	Greenhouse
	Slovenia	Mixed industrial
VFd–VFu	China	Sewage
	China	Aquaculture
FWS in combination with HF and VF	China. Italy, Thailand, Mexico, Taiwan	Sewage
	Italy	Winery
	Taiwan	Aquaculture
	Thailand	Fish industry
	Canada	Landfill leachate
	Kenya	Flower plant

In the late 1990s, also HF–VF constructed wetlands were introduced. This system consisted of a large HF bed placed first and a small VF bed as the second stage. In this system, nitrification takes place in the vertical flow stage at the end of the process sequence. If nitrate removal is needed it is then necessary to recirculate the effluent back to the front end of the system where denitrification can take place in the less aerobic horizontal flow bed using the raw feed as a source of carbon needed for denitrification. The HF–VF CWs has been used exclusively for treatment of sewage so far (Table 4). Besides VF–HF and HF–VF systems other combinations of subsurface flow CWs and also combinations including FWS CWs were used in the 1990s and the early 2000s for treatment of various types of wastewater (Table 4).

Conclusions

Constructed wetlands represent an alternative treatment system to conventional treatment systems such as activated sludge process. All types of constructed wetlands exhibit high treatment efficiency for organics and suspended solids. The removal of these parameters is comparable with conventional systems. Removal of nitrogen depends on the type of constructed wetlands and nitrogen species involved. Ammonia is efficiently removed in vertical flow CWs while nitrate is removed efficiently in HF CWs. However, combination of various types of CWs (usually VF and HF CWs) can enhance removal of total nitrogen and then the efficiency is comparable with conventional systems. Removal of phosphorus is variable depending on the filtration material, however, commonly used materials do not support high phosphorus removal. The advantage of constructed wetlands as compared to conventional treatment systems is low operation and maintenance cost, in some countries also the investment cost is substantially lower than of conventional systems, ability to treat low strength wastewaters and no requirement of continuous feeding and operation.

Dead Zones: Low Oxygen in Coastal Waters

Andrew Altieri, University of Florida, Gainesville, FL, United States

Glossary

Anoxia Absence of dissolved oxygen.
Benthos/benthic The community of organisms in or near the bottom of the ocean.
Dead zone Oxygen-depleted coastal waters that are hypoxic with compromised biological communities.
Eutrophication Excess nutrients in a body of water.
Hypoxia Low dissolved oxygen. The exact threshold is context dependent, but is typically regarded as a concentration < 2.8 mg/L.
Hysteresis The existence of multiple ecological states under a given set of environmental conditions, where thresholds between states differ depending on prior state.
Residence time The average time for the water in a body of water to be renewed.
Stratification Layering of the water column into water masses with different properties.
Suspension feeders Organisms that that feed by filtering food from water.
Water column A section of water extending from the surface to bottom.

Introduction

Oxygen depletion in coastal waters is regarded by many marine biologists and oceanographers as the most pressing water pollution problem in the world because of its severe impacts and accelerating spread worldwide. In extreme cases, this hypoxia creates areas known as "dead zones" that are largely devoid of macrofauna because of mortality and emigration. Concentrations of dissolved oxygen are naturally variable, and this variation can lead to areas with low oxygen concentrations (hypoxia) that are stressful to marine life. However, the duration, severity, and number of ecosystems with hypoxia has increased due to anthropogenic factors including inputs of excess nutrients and organic matter, as well as climate change, and there are now hundreds of coastal ecosystems affected by hypoxia worldwide (Fig. 1).

This article begins by describing and defining dead zones, and then provides background on factors that drive the formation of hypoxic waters including anthropogenic inputs and natural processes. Organismal responses to low oxygen are then presented as a basis for understanding community and ecosystem impacts of hypoxia. The relevance of dead zones to human welfare are provided in the context of ecosystem services, and followed by evidence for the increasing spread of dead zones worldwide. Finally, the article provides background on emerging areas of hypoxia research and possible solutions to address the threat of dead zones.

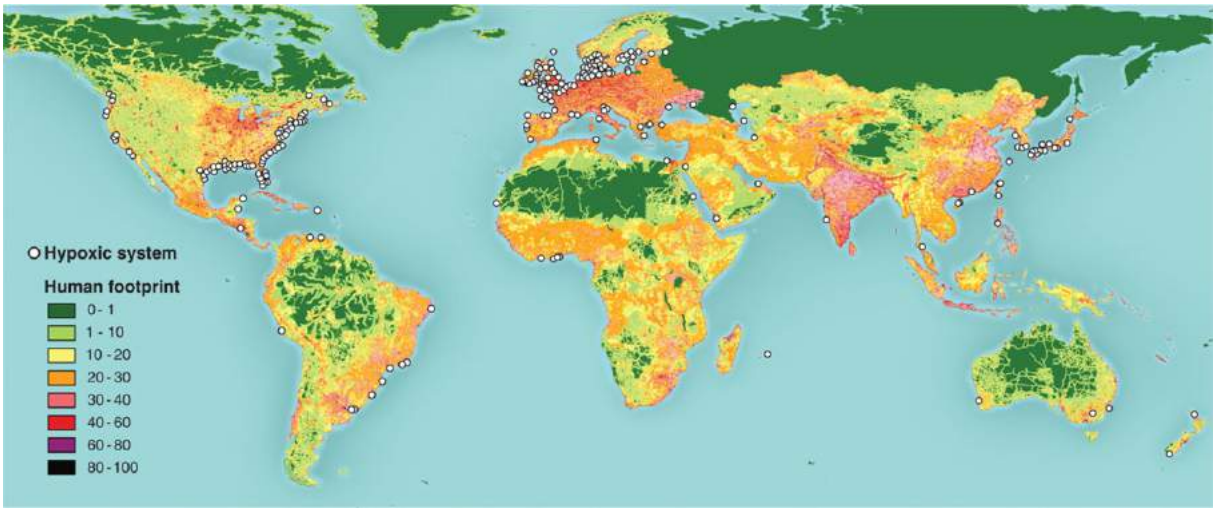

Fig. 1 Global map of hypoxic ecosystems. Dead zones are typically associated with areas of intense human activity (or "human footprint") in the coastal zone. Most known dead zones are located in the temperate regions, but recent research suggests the number of hypoxic ecosystems in the tropics are greatly underestimated. From Diaz, R.J. and Rosenberg, R. (2008). Spreading dead zones and consequences for marine ecosystems. *Science* **321**, 926–929.

 doi:10.1016/B978-0-12-409548-9.10616-5

Dead Zones Defined

The depletion of oxygen in coastal waters, such as estuaries, continental shelf areas, and coastal seas, is now a widespread phenomenon. Low oxygen typically occurs close to the sea floor and in deeper portions of stratified water columns where rates of oxygen consumption are likely to be highest and replenishment lowest. Dead zones can range in size from a small canal or channel to the basin of inland seas such as the Baltic Sea which commonly covers $>60{,}000\ km^2$ (Fig. 2). Dead zones also vary in duration. Some have become permanent features, as found in the Baltic Sea, whereas others occur seasonally, such as the Chesapeake Bay, United States. They can also vary in spatial extent and severity year-to-year based on freshwater inputs and external conditions as in the Gulf of Mexico.

Fish kills, in which dead fish and other marine organisms accumulate on the water's surface and on beaches, are one of the most visible signs of hypoxia. Another conspicuous phenomenon is the "jubilees" in Mobile Bay, United States where hypoxic bottom waters drive fish and crabs into the shallows where they are collected by local residents in a seafood bonanza. However, these events represent just a hint of hypoxia's impacts and prevalence in coastal ecosystems since oxygen measurements require specialized sensors, and the associated biological effects typically occur out of sight below the ocean's surface.

Oxygen depletion is a stress for aerobic organisms that can lead to physiological changes, behaviors responses, and eventually mortality. Hypoxia can, therefore, have a variety of direct and cascading effects on community structure and ecosystem function. In the most extreme cases, hypoxic ecosystems become largely devoid of living macrofauna, hence the name "dead zone." This term originated in the popular press which reported on hypoxic areas that fishers referred to as "dead water" for lack of any finfish or shellfish to catch. In the decades since the term "dead zone" was first coined, it has become more generally applied to any hypoxic ecosystem, and the term is used as such in this article. While there is some disagreement about whether the term "dead zone" is appropriate since microbes and a few other tolerant functional groups can persist in severely hypoxia waters, it does serve as a useful nontechnical shorthand that conveys the seriousness of the phenomenon for the living systems on which humans are so dependent.

Hypoxia in Other Ecosystems

The scope of this article is limited to hypoxia in coastal waters including bays, estuaries, coastal and inland seas, and some shelf systems. However, hypoxia also occurs in other bodies of water with important consequences for the ecology of those systems. For

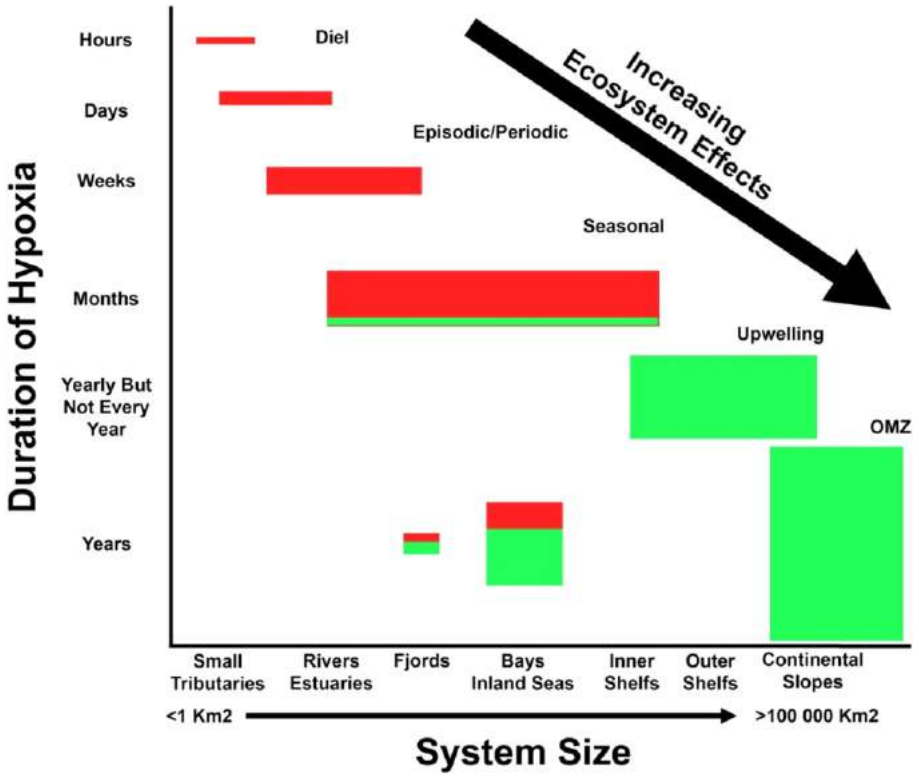

Fig. 2 Schematic representing the general relationship between ecosystem size and duration of hypoxia. The relative contribution of human factors in driving oxygen dynamics is represented in *red*, whereas natural factors are in *green*. This article focuses on those systems in *red*. From Rabalais, N.N., Diaz, R.J., Levin, L.A., Turner, R.E., Gilbert, D. and Zhang, J. (2010). Dynamics and distribution of natural and human-caused hypoxia. *Biogeosciences* **7**, 585–619.

example, freshwater lakes and ponds commonly become hypoxic because of eutrophication and/or seasonal stratification of the water column. There are also large permanently hypoxic areas in deeper ocean basins known as oxygen minimum zones (OMZ) that are a natural phenomenon with diverse adapted communities (Fig. 2). At times, hypoxic waters from the OMZ can be upwelled onto the shelf into shallow coastal waters such as along the western coasts of the United States and South Africa. There are important distinctions between OMZs and dead zones: OMZs are generally considered natural and permanent features (although their expansion appears linked to large-scale climate and oceanographic processes), whereas coastal dead zones can vary in duration and are often associated with eutrophication and other anthropogenic factors.

Quantifying Hypoxia

Hypoxia is generally defined as an oxygen concentration in water that is low relative to either the oxygen saturation at equilibrium with atmospheric concentrations or the metabolic needs of aerobic organisms. As such, dissolved oxygen levels are typically reported as either percent saturation or concentration (mg or mL of oxygen per liter of seawater). Percent saturation is often useful for understanding the drivers of hypoxia because it indicates the severity of oxygen depletion relative to that expected at equilibrium concentrations. Absolute oxygen concentrations (mg/L or mL/L) are more frequently used in studies of biological responses to hypoxia. Saturation and concentration units are not directly interchangeable because temperature, barometric pressure, and salinity affect the saturation of oxygen in water and must be known to derive percent saturation from absolute oxygen concentration.

Concentrations of dissolved oxygen vary continuously, and thresholds of tolerance to hypoxia vary among species. Nevertheless, 2.8 mg/L (equivalent to 2.0 mL/L) has been widely adopted as the oxygen concentration below which a body of water is considered hypoxic. Below that threshold, negative effects of oxygen limitation including mortality are likely to be observed across most taxa. There are proponents for elevating the threshold since fish often show sensitivities to oxygen at the 5–6 mg/L range, and many macrofauna exhibit behavioral changes when oxygen levels drop to the 3–4 mg/L range. For comparison, 100% oxygen saturation in water at 25°C and 1 atm of pressure is 8.2 mg/L.

The oxygen dynamics and ecological effects of oxygen limitation in dead zones are often measured and described in the water column and in the benthos. The benthos in many dead zones is comprised of soft sediments, and the chemical properties (including oxygen concentrations) and biological activity of those sediments are closely linked to properties of the water column. A comprehensive understanding of dead zones, therefore, incorporates characteristics of the sediments, including irrigation by burrowing organisms and the depth of the redox potential discontinuity which indicates the depth within the sediment that transitions from oxic to anoxic layers.

Causes of Dead Zones

Oxygen concentrations decline in dead zones because rates of oxygen depletion outpace rates of oxygen replenishment. This section of the article discusses the origins of low oxygen waters. First, the general processes that deplete oxygen are described with a distinction between natural and anthropogenic factors. Second, the factors that limit oxygen replenishment are outlined. Finally, a discussion is presented as to why some coastal waters are especially susceptible to oxygen depletion.

Oxygen Depletion

Decomposition and respiration

Oxygen consumption by aerobic organisms is the dominant cause of oxygen depletion in coastal dead zones. There are two main processes of biological oxygen consumption that can lead to low oxygen concentrations in coastal waters.

Decomposition by microbes is the primary process of oxygen consumption that leads to the formation of dead zones. As such, factors that increase the amount of organic matter available for decomposition and/or increase rates of microbial activity are ultimately responsible for hypoxia. Many dead zones are linked to phytoplankton blooms. The biomass of plankton that dies and sinks to the bottom fuels aerobic microbial decomposition. Macroalgal blooms can also generate organic matter that fuels hypoxic conditions. Moreover, macroalgae can further increase oxygen stress by smothering the bottom.

Allochthonous organic matter, such as detritus, sediments, and sewage, delivered to coastal waters can bypass the role of algal blooms and lead to microbial oxygen depletion. If oxygen levels drop sufficiently to cause mortality, then the biomass of dead organisms becomes a supplementary source of organic matter that can fuel further decomposition in a localized feedback loop.

A second process of oxygen depletion is respiratory oxygen consumption by primary producers such as phytoplankton and macroalgae. Oxygen consumption by primary producers will outpace their oxygen production in light limited conditions such as those produced by self-shading or at night, leading to temporary or localized oxygen depletion. One of the most conspicuous indicators of oxygen consumption by primary producers is diel cycling in which oxygen concentrations exhibit a saw tooth pattern as a system oscillates between net photosynthetic oxygen production during the day and net respiratory oxygen consumption during the night.

An additional factor leading to oxygen depletion in coastal waters is oxygen consumption by macrofauna. This generally does not lead to large or sustained dead zone formation per se, but can exacerbate the effects of existing low oxygen conditions. For

example, fish that have been shoaled by low oxygen conditions into a semienclosed area can become trapped and rapidly consume remaining oxygen, resulting in a fish kill.

Nutrients

Many studies have identified excess nutrients as the factor most responsible for the formation of dead zones worldwide. As a consequence, hypoxia is viewed as one of the most significantly negative impacts of eutrophication. Since primary productivity by phytoplankton is typically nutrient limited, inputs of nutrients can support the excess phytoplankton biomass responsible for hypoxia. Typically, primary productivity in marine ecosystems is nitrogen limited, and in lower salinity ecosystems is phosphorus limited.

There are several pathways that deliver nutrients and organic matter to coastal waters. Rivers and terrestrial run-off are the dominant sources of nutrients and organic matter for many coastal ecosystems, but atmospheric deposition, upwelled ocean water, and sewage systems play significant roles in some coastal waters. The availability of nitrogen and phosphorus is also be modified within a dead zone by microbial activity and bioturbators in the sediment. The balance between sequestration and release of nutrients from the sediment is dependent on the oxygen concentration, with the potential for feedbacks between oxygen, nutrients, and primary producers.

Inputs of nutrients and organic matter that fuel dead zone formation in coastal waters are often elevated above natural rates by human activity. While there are natural sources such as erosional processes and run-off from terrestrial ecosystems, anthropogenic sources have dramatically increased nutrients above natural background levels and contributed to the prevalence of hypoxia. For example, over the past century there was a 20-fold increase in nitrogen inputs from the Mississippi River that fuels the Gulf of Mexico dead zone. Much of these nutrients and organic matter originate from agricultural sources including excess fertilizer from fields and livestock waste. Additional anthropogenic sources include effluent from sewage treatment plants and household septic systems, urban run-off, paper mills, seafood processing plants, and aquaculture pens. The relative importance of these various sources of nutrients and organic matter is location specific, varying with land-use practices, regulations, and human densities in the watershed.

There are two overall trends that help establish the contribution of human activity to the increase in dead zone prevalence. First, hypoxia is more prevalent near major population centers and watersheds with intensive inputs of nutrients and organic material. Second, there is a temporal trend in which sewage and industrial pollution were dominant drivers of hypoxia through the mid-20th century followed by a shift toward greater run-off/riverine inputs and atmospheric deposition of nutrientsThat coincided with intensification of agricultural practices and an overall increasing rate of nutrient delivery that caused the number of new hypoxic ecosystems to increase at an accelerated rate.

Warming

Temperature has a direct effect on oxygen concentrations since warmer water has a lower capacity for dissolved gasses including oxygen. Temperature also has indirect effects on oxygen depletion since phytoplankton blooms and microbial activity are temperature dependent. This explains why hypoxia is most likely to occur in the summer, when temperature and light levels peak, and why climate change is such a concern for dead zones (as detailed below).

Limited Oxygen Replenishment

Replenishment of oxygen in hypoxic waters occurs through two primary mechanisms: vertical exchange with surface waters that are oxygenated through diffusion and wind mixing, and lateral exchange with the more oxygenated open ocean. Therefore, hypoxia and dead zones typically occur in bodies of water that are isolated by shoreline features and/or stratification.

Stratification and vertical mixing

Hypoxia typically develops at or near the bottom where the organic matter that fuels decomposition accumulates. Stratification of the water column isolates hypoxic bottom waters and prevents surface waters from re-oxygenating the entire water column. Stratification refers to layering of the water column into discrete water masses with different densities due to variation in temperature and/or salinity. Often stratification in dead zones results in two layers: a shallow low-density surface layer that may be well oxygenated from diffusion and wind-mixing of atmospheric oxygen, and a second, deeper, high-density layer where organic matter settles and oxygen is depleted by microbial respiration.

Stratification, and the potential for hypoxia to occur, is strongest when there are processes that establish or reinforce the density difference between surface and bottom waters. Freshwater inputs from rivers and/or rain can create a surface lens of freshwater which is less dense than deeper, saltier water. The sun and warm air can also heat surface waters and contribute to stratification. Processes that promote mixing of surface and bottom waters such as strong winds, tidal currents, and ocean swell can disrupt stratification.

Flushing time and horizontal mixing

Oxygen is more likely to reach a state of severe depletion in bodies of water that are semienclosed. Open ocean waters adjacent to coastal areas are generally well oxygenated due to lower levels of productivity and greater mixing by wind and waves. Limited

exchange with the ocean leads to an increase in the residence time of water (equivalent to a decrease in flushing time), which reduces both import of oxygenated waters and export of organic matter. Headlands and sills limit exchange with the ocean by restricting the width and depth of a bay's opening, respectively. In other instances, a body of water without a restriction at the mouth, such as a fjord, may have limited exchange simply because it is long and/or voluminous relative to the size of the openings through which exchange with the open ocean takes place.

The influence of limited exchange between a bay and the open ocean can be detected in gradients in oxygen concentrations which decline with distance from the open ocean (**Fig. 3**). Depth gradients in oxygen can also be apparent where a pocket of deeper hypoxic water is trapped in the basin formed by a sill.

Shoreline geomorphology is not the only factor that affects the residence time of a body of water. The flushing time of a bay can be tightly linked to freshwater input (higher inputs lead to decreased flushing times), and is therefore dependent on rainfall and water management in the watershed. Tidal amplitude will also determine the volume of water exchanged between a semienclosed body of water and the open ocean, and hypoxia is more likely to occur during or just following neap tides in highly tidal systems.

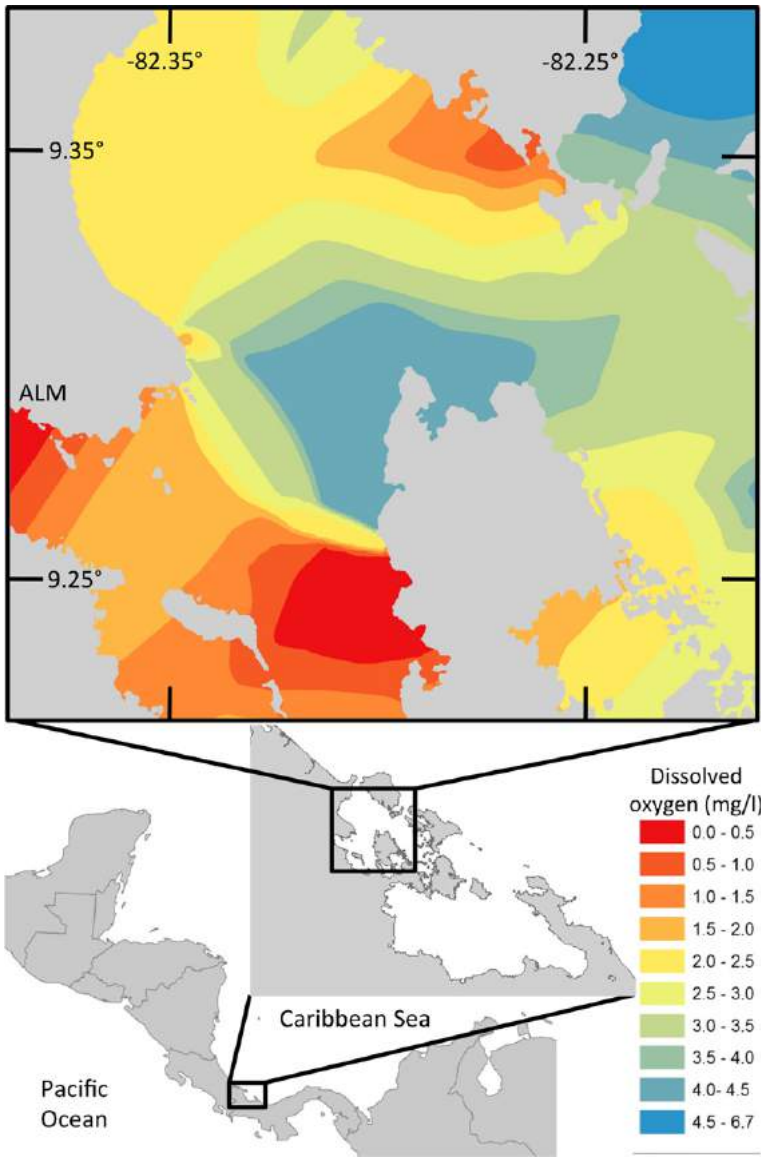

Fig. 3 Map of a dead zone at 10 m depth on the Caribbean coast of Panama in which many corals and reef organisms perished. Typical of many hypoxic ecosystems, there is a gradient in dissolved oxygen. Oxygen concentrations were lowest (*red* and *orange*) inshore, to the lower left, where nutrient inputs are greatest and water circulation is minimal, and highest (*blue* and *green*), to the upper right, where exchange with the open ocean is greatest. There is also a pocket of hypoxic water at the upper center where pollution from the nearby town is retained in an eddy on the lee side of the island. *Gray* represents land, and color represents oxygen concentration according to key at lower right. Modified from Altieri, A.H., Harrison, S.B., Seemann, J., Collin, R., Diaz, R.J. and Knowlton, N. (2017). Tropical dead zones and mass mortalities on coral reefs. *Proceedings of the National Academy of Sciences of the United States of America* **114**, 3660–3665.

In some instances, the effectiveness of exchange with the open ocean for reducing hypoxia is short-circuited when adjacent ocean waters are themselves hypoxic. This can occur, for example, when upwelling brings hypoxic waters onto the shelf and to a bay's entrance as observed in the Saanich Inlet in Canada.

High Risk Ecosystems

Given the factors that deplete oxygen and limit re-oxygenation, there are some characteristics of coastal ecosystems that elevate the risk of oxygen depletion. Nearly all recognized dead zones are in a semienclosed bay, estuary, fjord, inland sea, atoll, or constructed harbor. These bodies of water have some degree of isolation that reduces exchange with the open ocean and the strength of wind, thereby promoting stratification and collection of nutrients and/or organic matter. Moreover, human settlements tend to concentrate on the shoreline of such sheltered bodies of water because of agricultural opportunities and natural harbors, and so agricultural run-off and sewage discharge that fuel microbial activity are often relatively high in those areas. Ecosystems with rivers and terrestrial runoff are at higher risk because they deliver nutrients and organic matter as well as the freshwater that contributes to stratification. Overharvesting of suspension feeders, such as oysters, removes a natural control of phytoplankton that also increases the likelihood that hypoxic conditions will develop. Temperate waters may be especially susceptible to hypoxia because stratification and freshwater inputs can be intensified and synchronized by seasons, and because fertilizer use historically has been higher in temperate ecosystems.

Biological Impacts of Hypoxia

Severe hypoxia that results in dead zone formation can have spectacular effects that galvanize public attention. Failed fisheries and beaches covered with dead animals are among the most dramatic and apparent effects of dead zones. Some estimates put the annual loss of biomass due to dead zones worldwide at over 9 million tons. The term “dead zone” has been earned by events where severe hypoxia rendered thousands of square kilometers of sea bottom largely lifeless. However, it is an oversimplification to view healthy ecosystems and dead zones as dichotomous states since oxygen concentrations can vary continuously. Likewise, there is a range of responses to oxygen depletion from the organism to ecosystem level that must be elucidated to develop a predictive understanding of how dead zones affect natural systems.

Organismal Responses to Hypoxia

Mortality is the most extreme consequence of exposure to hypoxia, and there are range of sublethal responses as well. Many aquatic organisms are able to tolerate a period of exposure to hypoxic or even anoxic conditions by employing strategies that include physiological and behavioral responses. These strategies fall into several broad categories: evading hypoxia, maintaining delivery of oxygen, reducing oxygen demand by conserving energy, and switching to anaerobic metabolism.

Evading hypoxia

Many animals can detect low oxygen and will move toward higher oxygen concentrations. Fish and other highly mobile organisms will flee hypoxic areas. This typically involves moving higher in the water column, into shallows, or toward the open ocean. Less mobile species such as crabs, lobsters, and sea stars will crawl to areas of higher relief and the tops of structures such as rocky outcroppings and coral colonies in an attempt to move above hypoxic bottom waters or reach higher flows with greater oxygen flux. Burrowing species, including worms and shrimp, will crawl out onto the sediment surface for the same reasons.

Maintaining delivery of oxygen

Strategies for maintaining oxygen delivery include increasing water flow over gills and other respiratory structures, and through burrows, by increased ventilation and pumping rates. Some fish are known to air gulp at the surface to attain oxygen. Other fish have the ability to increase the number of red blood cells and to increase the binding capacity of hemoglobin for enhanced oxygen uptake and internal transport. Prolonged exposure to hypoxia can lead to morphological changes such as an increased number of gill lamellae to increase diffusion capacity. Some groups such as sea cucumbers are able to deform their bodies to increase surface area to volume ratios to improve the relative efficiency of oxygen diffusion.

Reducing oxygen demand

Many species will reduce energy use in response to hypoxia to reduce metabolic oxygen demand. This can involve a decrease in overall metabolic rates as well as downregulation of protein synthesis. A hypoxia-induced binding factor can regulate multiple genes involved with this cascade of changes. This response is apparent in reduced activity and movement rates observed across a range of taxa, and changes in the relative abundance of various enzymes involved in metabolic pathways, with the onset of hypoxia.

Anaerobic metabolism

While aerobic metabolism is being downregulated, enzymes involved with anaerobic metabolism can simultaneously be upregulated. Some species tolerate periods of severe hypoxia or even anoxia through anaerobic metabolism. This ability can be so well developed that there are species of clams recognized as facultative anaerobes. However, the shift to anaerobic metabolism comes at a physiological cost since energy reserves will be depleted more rapidly due to the inefficiency of anaerobic metabolism. In addition, the accumulation of anaerobic metabolites can be harmful.

Negative effects of tolerating hypoxia

There are a number of negative physiological consequences of the stopgap measures associated with hypoxia tolerance by aerobic organisms. Reduced growth is a general response to hypoxia that has been observed in a number of taxa including fish, oysters, mussels, worms, and brittle stars. Reduced growth coincides with reduced rates of molting in crustaceans. Reductions in feeding rates, energy stores, and reproduction are also widely observed consequences of hypoxic stress. Fish, shrimp, and crabs exhibit reduced immune responses and increased susceptibility to diseases and bacterial infections when exposed to hypoxic conditions. Primary producers are also negatively affected by hypoxia. For example, hypoxia inhibits respiration and nutrient uptake in seagrass.

While many of the strategies of hypoxia described above are common across multiple taxa, there is tremendous interspecific variation in tolerance to sustained exposure to hypoxia. For example, lethal concentrations of oxygen range from 0 to 8.6 mg/L across phyla. Many species can tolerate hypoxia, but not anoxia, suggesting that survival relies on efficient use of remaining environmental oxygen (rather than an exclusive switch to anaerobic metabolism). It has been suggested that variation in tolerance among species depends on their physiological ability to use that small amount of remaining oxygen. Moreover, species-specific responses to hypoxia are dependent on the concentration, duration, and frequency of oxygen depletion, each of which can independently affect lethality.

Population Responses to Hypoxia

Mass mortality and migration associated with dead zone events have obvious effects on the population size of aquatic organisms, but there are a number of other significant ways in which hypoxia can influence population structure.

Population size structure

Hypoxia affects the size structure of populations in three ways. First, hypoxia commonly reduces individual growth rates—an effect that can be attributed to changes in metabolism and reduced feeding rates. This has broad implications for populations since body size is important for reproductive success, achieving a size refuge from predation, and storing energy for seasons with fewer resources. Even seasonal hypoxia can have a disproportionate effect given that hypoxia is most likely to occur in summer when most of the growth for a given year occurs. Second, hypoxia tolerance is often dependent on body size within a given species and can result in size selective mortality. Some studies with bivalves have found that the largest individuals of a given species are most likely to perish in low oxygen conditions, whereas other studies with crabs and fish have found that only the largest individuals persisted through stressful conditions. Small individuals can benefit from higher surface area to volume ratios for increased diffusion and passive transport of oxygen, whereas larger individuals may have higher energy stores and a better ability to detoxify hydrogen sulfide (which is a toxin that frequently co-occurs with hypoxia). Third, populations may exhibit size-selective migration in response to hypoxia. This phenomenon has been observed in benthic fish where larger individuals were more likely than small fish to flee during the intrusion of lethal hypoxic waters.

Reproduction

Inhibition of reproduction by hypoxia has been observed at all critical life history stages including hormone and gamete production, embryo development, egg survivorship, larval survivorship, larval settlement, and recruit survivorship. Vulnerabilities at any of these stages can lead to failure of population cohorts even when the reproductive adults of the population persist through hypoxic conditions.

Metapopulations

Often a spatially explicit perspective that incorporates a metapopulation framework is necessary to understand a population's response to hypoxia. A given species can be distributed in demographically linked patches across a landscape that exhibits a gradient in dissolved oxygen concentration. In such a case, hypoxia may cause local extinction of some patches, with the potential for later recolonization from remaining patches that survived the event.

Community Responses to Hypoxia

The variation among species in strategies and abilities to tolerate hypoxia has direct effects on community structure as well as indirect effects through modified species interactions.

Biodiversity

Decreasing oxygen concentrations typically lead to declines in biodiversity, as fewer species are able to tolerate increasingly severe physiological stress. Generally, sorting occurs along an oxygen gradient that reflects broader taxonomic differences in hypoxia tolerance: fish and crustaceans are typically the least tolerant, molluscs are intermediately tolerant, and worms and meiofauna are the most tolerant (Fig. 4). There are also shifts among functional groups as oxygen depletion becomes more severe: deposit feeders replace suspension feeders, shallow/surface deposit feeders replace deposit feeders deeper in the sediment, jellies (cnidarians and ctenophores) replace fish, and microbes and meiofauna replace macrofauna. Another commonly observed trend is a shift in biomass from benthic to pelagic species, particularly among harvested species. This latter shift could be explained in part by the tendency for hypoxia to be most severe at near the sea floor, but trends in water clarity and the distribution of primary productivity associated with eutrophication are likely contributing factors to this shift as well.

Predation

Hypoxia can modify predator-prey interactions in a number of ways (Fig. 5). Reductions in feeding rates are associated with the general downshift in activity levels by organisms stressed by hypoxia. Sessile and relatively sedentary species that are able to tolerate hypoxic conditions can benefit from a predation refuge as mobile predators, such as fish and crabs that are typically most sensitive to hypoxia, flee low oxygen conditions. However, when hypoxia subsides, predators can return and take advantage of prey that have remained and died, become moribund, or otherwise been rendered vulnerable as they move from burrows to the sediment surface. In some cases predators closely track the boundary of hypoxic water and will make brief forays into hypoxic waters to take advantage of vulnerable prey. Whether the net effect of hypoxia is to reduce or enhance predation rates depends on factors such as the relative tolerance of predators and prey, the spatial extent and duration of the hypoxic event, and conditions such as tides and winds that can cause movement in the boundary of hypoxic water.

Competition

The effects of hypoxia on competitive interactions have received less attention than the effects of hypoxia on predation. However, there is evidence that hypoxia can lessen competition for space and other resources by removing dominant species through selective mortality or migration. This in turn has been used to explain why diversity can be highest at the edge of a hypoxic area, as predicted by the intermediate disturbance hypothesis. Relaxed competition due to hypoxia also has the potential to increase the success of invasive species. In cases where both predation and competition for food have been analyzed, such as in omnivorous pelagic food webs, predation was found to be consistently a more important determinant of community structure than competition, regardless of oxygen concentration. However, oxygen itself can be a limiting resource, and competition for oxygen can influence community structure as observed in densely settled fouling communities.

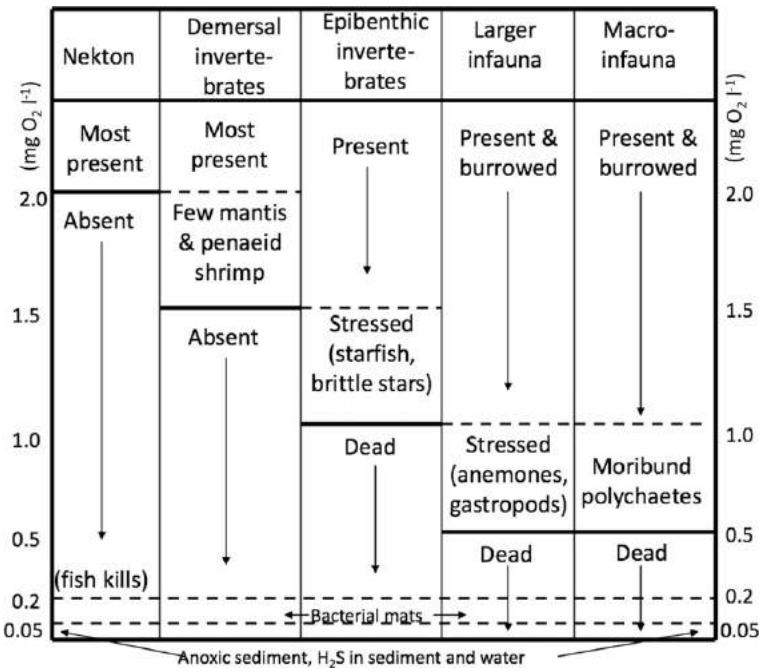

Fig. 4 The behavioral and physiological responses to hypoxia varies across taxonomic groups. As a consequence, functional diversity declines with increasing severity of hypoxia, as indicators of hypoxic stress including moribund inverts, fish kills, and mats of *Beggiatoa* bacteria and other sulfide oxidizing microbes increase. From Rabalais, N.N. and Turner, R.E. (eds.) (2001). *Coastal hypoxia: Consequences for living resources and ecosystems*. Washington, DC: American Geophysical Union.

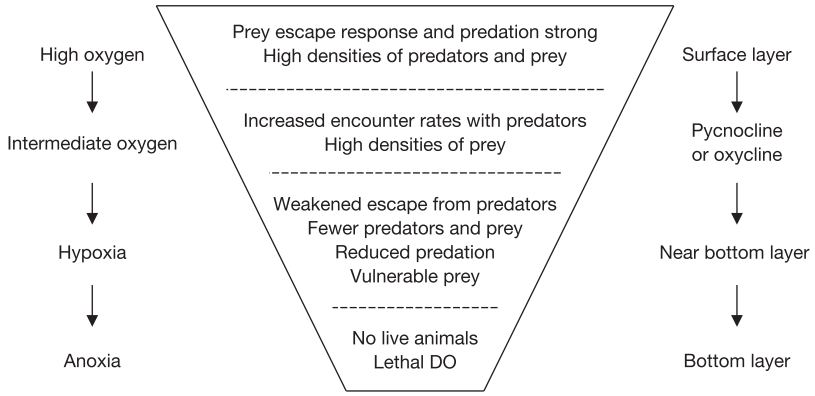

Fig. 5 Hypoxia can have a number of indirect effects on community structure by modifying species interactions such as predation. The exact consequence of hypoxia for predation is dependent on the relative tolerance of predators and prey, their mobility, and the duration and spatial structure of the hypoxic waters. Redrawn from Breitburg, D. (2002). Effects of hypoxia, and the balance between hypoxia and enrichment, on coastal fishes and fisheries. *Estuaries* **25**(4B), 767–781.

Succession

Succession describes the process of community recovery through the gradual accumulation of species and turnover in community composition following hypoxia or other disturbance. Initial recolonization will depend on supply from source populations, and so the size of a dead zone and distance from the edge can determine rates of recolonization. Often the first species to recolonize are not necessarily hypoxia tolerant species, but rather a community of opportunistic species dominated by polychaete worms and bivalves with high dispersal potential and reproductive rates. Since the return time for hypoxic events is often one or a few years whereas succession typically occurs over a longer time period (over a decade in the Black Sea), many periodically hypoxic ecosystems may never reach their natural climax structure. In ecosystems where regularly occurring hypoxia predates scientific surveys, natural or baseline reference conditions may be unknown.

Ecosystem Responses to Hypoxia

Changes in community structure combined with degraded environmental conditions associated with hypoxia can have drastic effects on ecosystem properties and dynamics including habitat provision, trophic function, biogeochemical cycling, and provision of ecosystem services.

Habitat loss

Coastal estuaries and bays are essential habitat for many aquatic species. A dead zone represents an area of critical habitat rendered unavailable or suboptimal. The result is habitat loss and possibly habitat compression in which an impacted population is forced to use only the remaining portion of their potential habitat where there may be higher risks from predation or other stressors such as high temperatures. Even temporary or small hypoxic areas can cut off migration routes or eliminate seasonally important reproductive areas.

Microbial activity

While the term "dead zone" conveys the lack of macrofauna and apparent lifelessness of a severely hypoxic area, the term is a misnomer because life, particularly microbes, can thrive in these areas. As discussed above, it is microbial decomposition of phytoplankton that commonly initiates formation of hypoxic waters. Additional microbial decomposition of fauna that succumb to hypoxia can further deplete oxygen creating a positive feedback loop in the early stages of dead zone formation. Hypoxic conditions and shallowing of the redox potential discontinuity layer in sediments is associated with increased activity of sulfate reducing bacteria that generate hydrogen sulfide. Hydrogen sulfide is toxic to metazoans on its own, and can act synergistically with hypoxia to increase stress and mortality rates. Hydrogen sulfide itself can be reduced by yet other bacteria such as *Beggiatoa*. The presence of this mat forming bacteria is commonly used as a diagnostic of an ecosystems experiencing hypoxia. The proliferation of the microbial communities in dead zones represents a shift in energy flow toward microbial pathways and away from macrofauna and higher trophic levels (**Fig. 6**).

Nutrient dynamics

Nutrient cycling is altered in hypoxic areas because of changes in biogeochemical processes associated with low oxygen conditions. The mortality and emigration of bioturbating organisms also alters the biogeochemistry of the water-sediment interface. Hypoxia leads to increased phosphorous release from sediments to the water column and decreased rates of nitrogen removal through denitrification and anaerobic ammonium oxidation (annamox). This can spark elevated water column productivity, further reinforcing hypoxic conditions through a positive feedback loop. This feedback, combined with

the nonlinear relationship between dissolved oxygen concentration and denitrification rates, explains the hysteresis in which hypoxic conditions often persist after anthropogenic nutrients inputs are reduced below concentrations that initiated oxygen depletion in the ecosystem (Fig. 7).

Ecosystem services

The effects of hypoxia on community structure, biodiversity, and ecosystem functions are detrimental to the output of ecosystem services that provide essential goods and services to humans. The filtration capacity of an ecosystem, which has the potential to mitigate eutrophication by controlling phytoplankton blooms, is reduced when hypoxia causes mortality of bivalves such as mussels and oysters. The coastal tourism industry can also be negatively impacted by hypoxia. For example, the 1976 hypoxic event in the New Jersey Bight in the northwest Atlantic resulted in losses of $16 million (2017 USD) due to impacts on recreational fishing and scuba diving activities.

Fisheries production is an ecosystem service that has been well studied in the context of hypoxia. Dead zones have catastrophic effects on some fisheries, with decreased landings, closed fisheries, recruitment failures, and displaced fishing effort. However, the net effects of hypoxia on fisheries landings are not as clear-cut as once thought. Some harvested species benefit from the predation refuge created by hypoxia, and in other systems fishery outputs have persisted by shifting to species that are more tolerant or found higher in the water column where oxygen levels remain high. When taking a broader spatial perspective across an entire ecosystem, the higher productivity associated with eutrophication beyond the hypoxic area appears on average to offset the loss of fisheries within hypoxic areas.

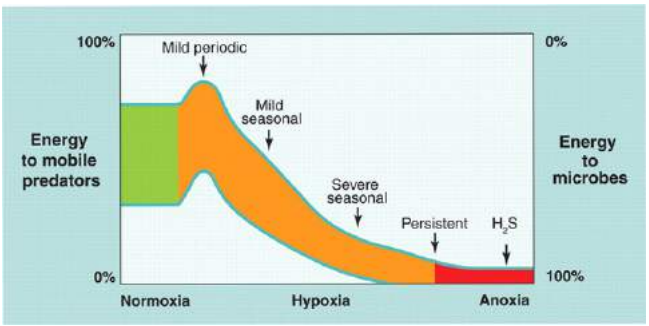

Fig. 6 Food webs shift as hypoxia becomes more severe or longer in duration. Initially there can be an increase in the transfer of energy to higher trophic levels due to predators taking advantage of increased availability of resources as prey die or become vulnerable, move to more vulnerable positions, or die. Eventually microbial pathways come to dominate as macrofauna flee or die. From Diaz, R. J. and Rosenberg, R. (2008). Spreading dead zones and consequences for marine ecosystems. *Science* **321**, 926–929.

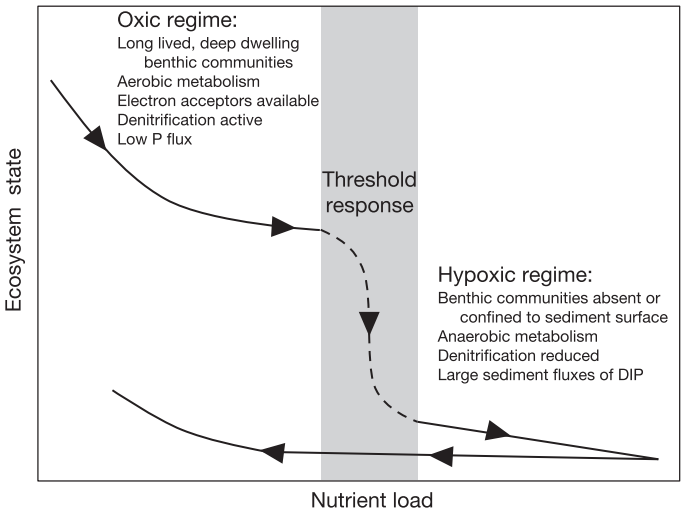

Fig. 7 Hypoxic ecosystem can exhibit nonlinear relationships between nutrient loads and severity of hypoxia. There is also evidence for hysteresis in which reversals in nutrient loading do not necessary result in concomitant reversals of hypoxia. This can result in lags between nutrient abatement and the recovery of physical conditions, community structure, and/or ecosystem function. Redrawn from Conley, D.J. et al. (2009). Ecosystem thresholds with hypoxia. *Hydrobiologia* **629**(1), 21–29.

Climate and Dead Zones

Climate modulates the severity of hypoxia and its biological impacts in a number of ways. Rising temperature is the greatest concern because of its broad impacts on hypoxia and the certainty of future increases (Fig. 8). While climate warming has likely contributed to the increasing prevalence of dead zones, predicting the response of oxygen to climate change requires an understanding of other climate factors including precipitation, cloud cover, and wind, as well as indirect links to sea level rise and land cover, that also affect the establishment of hypoxic conditions.

Effects of Temperature on Hypoxia Formation

Warming can increase the severity of hypoxia in several ways. Increased temperatures directly affect oxygen dynamics because warming reduces the solubility of oxygen in water. Temperature also has several indirect effects on oxygen concentration. Warming increases rates of microbial decomposition of organic matter which depletes oxygen. Increased temperatures also fuel the decomposition process by increasing production of organic matter in the form of phytoplankton. Warming enhances rates of nutrient cycling and therefore nutrient availability for plankton blooms, and earlier onset of spring temperatures due to climate change can extend the summer season of higher productivity.

Effects of Temperature on Organismal Responses to Hypoxia

Higher temperatures increase the susceptibility of organisms to hypoxia. Elevated temperatures lower physiological tolerances to hypoxia such that lethal thresholds may be reached at higher oxygen concentrations and shorter durations of exposure. Warming can also increase metabolic rates which leads to increased oxygen demand and depletion of energy stores that are often limiting in hypoxic conditions. On the landscape scale, low oxygen in deeper, cooler waters can drive mobile organisms into shallow, warmer water that may exceed their thermal tolerances.

Wind, Rain, and Other Climate Variables

There are numerous climate-related variables other than temperature that act on dead zones, primarily by affecting the nutrients and stratification that promote hypoxia. Precipitation can regulate the delivery of nutrients to coastal waters, and can affect the strength and depth of stratification as well as the residence time of estuarine waters. Storms bring pulses of precipitation as well as winds that can disrupt stratification. Sea level rise due to warming temperatures can affect stratification, reduce the ability of wetlands to filter nutrients entering a coastal waterbody, and increase the overall volume of water over a shelf or in a bay that is susceptible to hypoxia. Climate driven changes in large-scale ocean regimes can affect water temperatures and the concentration of oxygen and nutrients, particularly in areas of upwelling. Additional indirect links between climate and hypoxia include cloud cover, which can affect patterns of primary productivity, and changes in land-cover, which can affect nutrient loading in the

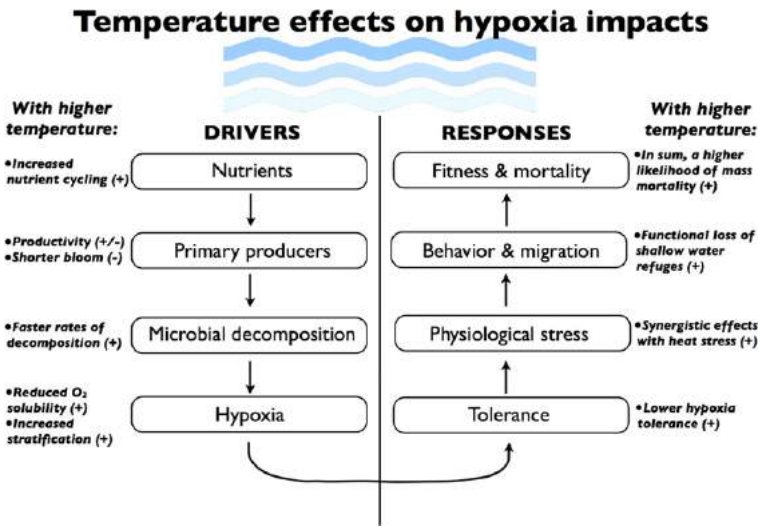

Fig. 8 Warming enhances many of physical drivers of hypoxia and exacerbates a number of negative biological consequences of hypoxia. As a consequence, the prevalence of hypoxia and its negative ecological effects are often associated with summer in temperate regions. Moreover, the warming component of climate change is expected to increase the severity of hypoxia and may have contributed to increase in the number of known dead zones in recent decades. From Altieri, A. H. and Gedan, K. B. (2015). Climate change and dead zones. *Global Change Biology* **21**, 1395–1406.

watershed. The excess carbon dioxide that is triggering climate change also affects water chemistry, and there is growing interest in the interactions between ocean acidification and hypoxic stress.

Predicted Effects of Climate Change on Dead Zones

Overall, climate change is expected to increase the severity and prevalence of hypoxia worldwide. Global temperatures are increasing, with over 90% of dead zones expected to experience a $>2^{\circ}C$ increase by the year 2100. As detailed above, warming intensifies the severity of hypoxia in several ways. Increased temperatures can also affect the duration of phytoplankton blooms and overall primary productivity rates, although the net effect of climate on oxygen concentrations through these pathways is not clear. There is also uncertainty regarding the frequency, timing, and intensity of storms and precipitation events which are expected to increase in some areas and decrease in others with climate change. Spatially explicit climate models are needed to forecast oxygen conditions in any given coastal ecosystem.

Global Spread of Dead Zones

The number and severity of dead zones identified worldwide is increasing at an alarming rate, doubling each decade over the past half century. Estimates suggest the increase has been exponential in recent decades, and a recent study identified over a hundred new sites in the Baltic Sea alone. Other work that examined latitudinal trends in numbers of dead zones and research effort suggests that there are hundreds of unidentified dead zones in the tropics.

Where long-term scientific records exist, there is evidence that ecosystems without previous signs of low oxygen, such as the northern Adriatic Sea, have become newly hypoxic in recent decades. In systems where hypoxia was previously observed, dead zones have become larger, such as in the Black Sea, Baltic Sea, and Chesapeake Bay.

Paleo indicators including foraminiferans, glauconite, and biogenic silica from cores collected in dead zones have established that hypoxia can occur naturally, but that significant increases in the number and severity of hypoxic ecosystems have been associated with developments such as the industrialization of agriculture. Much of the research to date has focused on eutrophication as the primary driver of the increased frequency of dead zones. Given the many ways in which climate affects the severity of dead zones, it is also likely that climate change has contributed to this observed increase in the hypoxia problem.

Summary and Outlook

Dead zones are a widespread phenomenon that impacts over 500 coastal ecosystems worldwide. Oxygen depletion is driven by factors including excess nutrients and climate change that are directly tied to human activities. As a consequence, the number of dead zones and their severity has increased exponentially in recent decades. Hypoxia affects the reproduction, behavior, survivorship, and diversity of marine life. The implications of hypoxia for coastal ecosystems are grave. Hypoxia compromises ecosystem functions and services including habitat provision, water filtration, biogeochemical cycling, and fisheries harvests.

This current state of knowledge should motivate efforts to confront the dead zone threat. Encouragingly, there is evidence that human action can reverse hypoxia and dead zones formation. Oxygen conditions have improved in several dozen ecosystems, largely due to reductions in nutrient inputs. Sometimes the efforts are intentional, as along the coast of Sweden where sewage treatment was enhanced, and other times incidental, as in the Black Sea where the collapse of the Soviet Union reduced fertilizer subsidies. Additional research in several areas is needed to build this positive momentum to turn the tide on dead zones, including: an increased number of ecosystems under surveillance, sustained support of long-term monitoring programs, deployment of advanced technology to detect changes in oxygen and associated water quality parameters, scientific networks for enhanced data sharing, and socio-economic data collection to better understand the economic impacts of hypoxia and inform strategies to incentivize sustainable management.

Synthetic studies that integrate across multiple study systems and time scales can establish realistic expectations for both the scope of improvement and the timeline for reaching management goals. Coastal ecosystems are highly variable, and it can take decades to verify sustained improvement of oxygen conditions. Moreover, there is an emerging concern that climate change could nullify some increases in oxygen concentration expected from reductions in eutrophication. System-specific models for predicting the effects of nutrient abatement and climate forecasts on hypoxic conditions are urgently needed to guide management. This will require studying the interactions between hypoxia and other factors such as ocean acidification, toxicity, and temperature in a multiple-stressor framework.

Although dead zones are a worldwide phenomenon, management of eutrophication and organic pollution at the scale of a single watershed can improve oxygen conditions in a given coastal ecosystem. Therefore, dead zones are an environmental problem with a solution at the level of local organizations and local management efforts when supported with robust research. Regional governance, such as the Chesapeake 2000 Agreement and the Convention on the Protection of the Marine Environment of the Baltic Sea, can further support these efforts. Individual communities, organizations, and nations have the potential to confront the global dead zone problem and contribute to our growing understanding of how hypoxia affects coastal ecosystems.

Deep-Sea Ecology

Tracey T Sutton and Rosanna J Milligan, Nova Southeastern University, Fort Lauderdale, FL, United States

Glossary

Benthic Living on the seafloor.

Bioluminescence The production of light by an organism. The light is produced either by symbiotic luminescent bacteria or by chemical reactions within organs called photophores.

Chemosynthesis The synthesis of organic compounds by bacteria or other living organisms using energy derived from reactions involving inorganic chemicals, typically in the absence of sunlight.

Deep scattering layer A layer in the pelagic water column consisting of a variety of marine animals. It was discovered through the use of sonar, as ships found a layer that scattered the sound and was thus sometimes mistaken for the seabed.

Demersal Living close to (but not on) the seafloor.

Epifauna Animals living on the surface of the seafloor, or attached to submerged objects or aquatic animals or plants.

Metazoan Any animal that is multicellular.

Micronekton Small fishes, shrimps, and cephalopods of the open ocean; these animals are mobile enough to maintain position against local currents, but their distributions are generally confined to specific water masses.

Oxygen minimum zones Depths bands within the water column where conditions become hypoxic.

Pelagic Relating to the environment of the open ocean. This environment can further be subdivided by depth: epipelagic (0–200 m), mesopelagic (200–100 m), bathypelagic (1000 m to just above the seafloor), and benthopelagic (within 100 m above the seafloor, but not on the seafloor).

Plankton Organisms that drift or float in the sea or freshwater. Plankton can be divided into two subcategories: phytoplankton (small, single-celled plants) and zooplankton (small animals, eggs, larval stages of larger organisms, gelatinous organisms [jellyfish, tunicates, siphonophores, comb jellies]).

Introduction

The deep sea is typically considered to include all oceanic waters below 200 m depth and is the most ecologically complex cumulative ecosystem on earth, befitting its status as the largest. It contains the vast majority of the planet's metazoan organisms, the widest array of organic production (from photosynthesis to chemosynthesis), the most highly developed spectrum of living light (bioluminescence), and a bewildering array of lifespans (days to centuries) and body sizes (microns to 30 m) among its constituents. It is a fully four-dimensional ecosystem, where vertical and horizontal (distance over ground) animal movements can be tied to the time of day, the time of the year, the time of an organism's life, and/or climatological cycles occurring over decades. The ecology of the deep sea can largely be characterized as the solution to a series of significant challenges: finding enough food in a food-poor environment; finding a mate in an immense, usually dark environment; and, avoiding predators where there may be nowhere to hide. The ecology of the deep sea, despite its rigors, is also driven by its physical stability. It is by far earth's oldest cumulative habitat. Over geological timescales, terrestrial ecosystems are subject to the constant movement of the continents relative to the axis of earth's rotation, resulting in major fluctuations in their climatologies, all while the continents are being uplifted by tectonic activity and weathered by the hydrological cycle. Landmasses are connected and then broken apart, and buried in ice and then bathed in warmth (cyclically). Even the coastal seas have experienced massive shifts in position and volume as sea level rises and falls. The current formation of the Great Barrier Reef, for example, is only 6000–8000 years old. The deep-sea environment, on the other hand, has existed largely as it is now for millennia (save ephemeral habitats based on submarine volcanism). This physical stability at geologic temporal and broad spatial scales has allowed the development of organismal ecologies poorly suited to the relatively rapid-fire pace of terrestrial and coastal ecosystems, but perfectly suited to the harsh-yet-steady conditions in which coastal, "more modern" forms cannot thrive.

At its most basic, the deep sea comprises two major environment types, pelagic (water column) and benthic (seafloor), though the intersection of the two, the benthopelagic realm, has many unique characteristics in and of itself. In many ways these are separate worlds ecologically, with radically different rates of processes (lifespan, turnover, geographic distributions), but they also form a highly connected continuum of life. In this article, we will describe these two main elements, the metazoan (multicellular) life within them, and the ecological processes that drive the diverse array of assemblages that exist in each.

The Deep-Pelagic Realm: Earth's Largest-Volume Habitat

The deep-pelagic zone (waters deeper than 200 m) contains almost 95% of the ocean's volume, and thus about 94% of water on earth (the remaining 1% being ice on the continents, with the water in lakes, rivers, and atmosphere being negligible). A comparison of the spatial scales of pelagic life reveals that the vertical scale of distributions (i.e., depth, measured in meters) is finer by 3–5 orders of magnitude than the horizontal (i.e., geographic, measured in 100's of kilometers) scale. It is not surprising then that the global pelagic

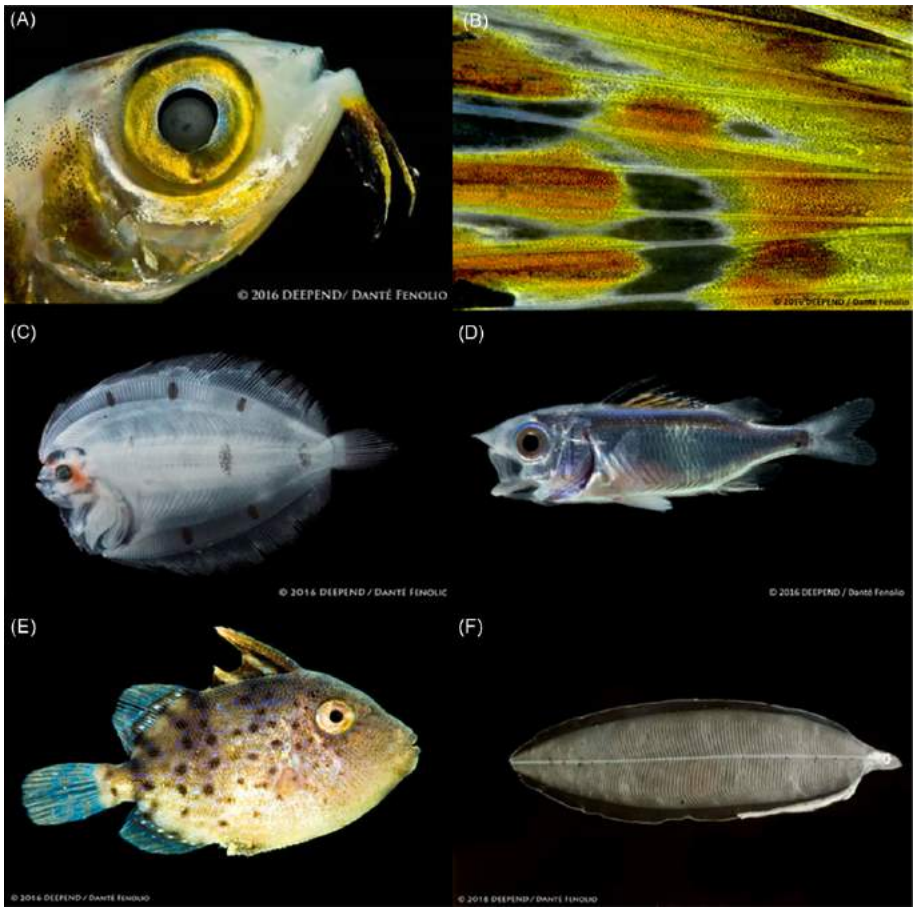

Fig. 1 Representative fishes from the epipelagic zone of the open ocean. (A) Juvenile flyingfish. (B) Close-up of the pectoral fin ("wing") of a flying fish. (C) Larval sole. (D) Juvenile squirrelfish. (E) Juvenile triggerfish. (F) Larval eel ("leptocephalus"). All images courtesy of the DEEPEND research consortium (http://www.deependconsortium.org).

habitat is structured primarily by depth, with each stratum roughly defined by the penetration of sunlight, a covariant of depth, and by the associated biota. Here we will briefly describe each stratum and the life within before considering the ecology of the assemblages.

Epipelagic Biome

The epipelagic biome extends, from the sea surface to 200 m depth and is defined as the stratum in which there is enough sunlight during daytime to support primary production in the form of phytoplankton (drifting, single-celled algae). Although the primary production per unit area is lower in the epipelagic biome than on land, and the epipelagic biome constitutes $<4\%$ of the ocean's volume, its vast surface area accounts for approximately 40% of the plant life on earth. Thus, while the epipelagic zone is not "deep," according to the previous definition of the deep-pelagic zone, it is inexorably tied to the deeper strata by providing energy (organic carbon), as well as providing nighttime habitat for deep-pelagic vertical migrators (see below). The epipelagic biome has greater variability, both physically and biologically, than deeper strata owing to the near-surface circulation patterns established by planetary forcing (e.g., wind stress, earth's rotation) and the much greater effect of seasonality on surface temperature and primary production. Because phytoplankton production occurs in the epipelagic biome, the majority of zooplankton production (small, drifting multicelled animals, the next step up in the food chain) also occurs there. In many ways the base of oceanic food webs resembles an inverted pasture, with plant life (and plant grazers) found near the surface and carnivorous animals found deeper and deeper. The epipelagic biome hosts a specialized fish fauna (Fig. 1), including flyingfishes and their relatives (needlefishes, halfbeaks), flotsam/jetsam-associated fishes (e.g., filefishes, triggerfishes, jacks, dolphinfish), "baitfishes" (e.g., herrings, anchovies), larval/juvenile fishes of astounding variety (e.g., eels, flatfishes, snappers, to name a few) and large, highly migratory fishes (e.g., tunas, billfishes, mako sharks).

Mesopelagic Biome

The mesopelagic biome (also called the "twilight zone") extends from 200 to 1000 m depth and is defined as the stratum of the ocean that receives enough sunlight that the animals within can differentiate night from day, but not enough to support

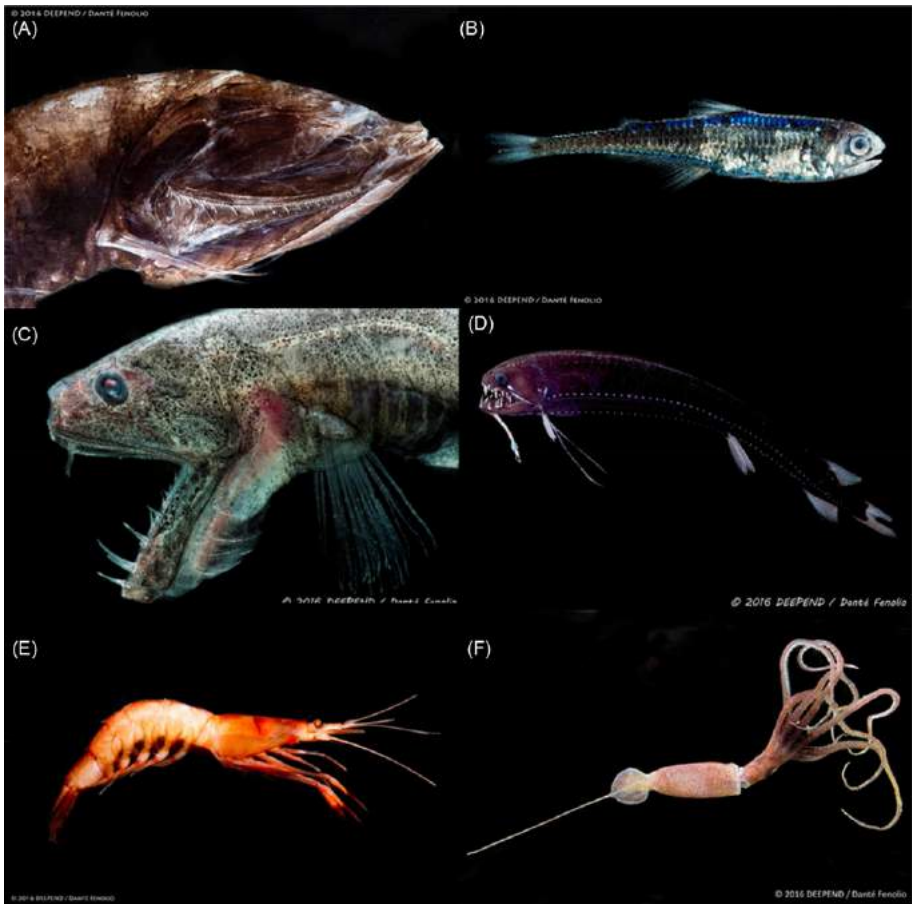

Fig. 2 Representative animals from the mesopelagic zone of the open ocean. (A) Bristlemouth. (B) Lanternfish. (C) Sabretooth. (D) Dragonfish. (E) Decapod shrimp. (F) Squid. All images courtesy of the DEEPEND research consortium (http://www.deependconsortium.org).

photosynthesis (i.e., below 1% surface light level). The highly variable conditions of the epipelagic biome are attenuated at mesopelagic depths and physical conditions become more stable over space and time. During daylight hours the mesopelagic biome hosts an array of specialized fishes from families that are absent or rare in shallow waters (e.g., lanternfishes, bristlemouths, dragonfishes, hatchetfishes), as well as highly adapted shrimps and squid (**Fig. 2**). Bioluminescence is the rule rather than the exception in this environment. Mesopelagic fishes and shrimps are the primary components of the globally ubiquitous "Deep Scattering Layers," detected using hydroacoustics (i.e., scanning sonar) and centered at around 500 m depth during the day and within the top 200 m at night. At night, these organisms vertically migrate into the epipelagic zone to feed on zooplankton, or on organisms feeding on zooplankton. This diel (daily) vertical migration is the largest animal migration on earth. The abundance of fishes in the deep-pelagic realm declines with increasing depth, but due to the enormity of the ecosystem their abundance and biomass is extremely large. Recently, global mesopelagic fish biomass has been estimated at a billion metric tons.

Bathypelagic Biome

The bathypelagic biome (also called the "midnight zone") extends from 1000 m to ~100 m above the seafloor and is defined by the absence of sunlight, and the relative invariance of temperature and salinity. There is some evidence for subdividing the bathypelagic biome at around 2500 m into the "abyssopelagic zone," characterized by dramatic decreases in fish abundance. The bathypelagic realm hosts a unique assortment of highly modified fishes (**Fig. 3**), including the oceanic anglerfishes, whalefishes, tubeshoulders, and gulper eels. Morphological adaptations of typical bathypelagic fishes, relative to mesopelagic taxa, include an increase in relative mouth size, a reduction in relative eye size, loss or reduction in photophores, replacement of reflective/silvery pigmentation with black, brown or red pigment, replacement of dense muscle mass with watery tissues with less metabolic demand, and reduction or loss of swimbladders. Sexual dimorphism is pronounced among many of the primarily bathypelagic fishes, and in some taxa (e.g., anglerfishes, whalefishes) represent the extreme example of dimorphism among all vertebrates. This is considered a form of ecological bet hedging in a food-limited environment, with taxa investing the majority of their species' biomass in females, ostensibly to facilitate greater fecundity.

Benthopelagic Biome

Numerous studies on continental slopes, mid-ocean ridges, and at seamounts have found evidence of a higher abundance and diversity of deep-pelagic organisms at the interface between the pelagic and benthic realms (the benthopelagic biome). In most cases this enhanced abundance and biomass is thought to result primarily from compression of the vertical distributions of pelagic fauna (i.e., the seafloor prevents pelagic fauna from migrating to deeper depths), although there is evidence for active station-keeping over seamounts by some pelagic fauna. Increased abundances of pelagic prey may also promote a larger number of benthopelagic fish predators (e.g., roundnose grenadiers, orange roughy), in addition to the benthic predators that would otherwise be present. Recent studies show that benthopelagic assemblages may represent a vital trophic linkage between the pelagic and demersal faunas, and are important elements of carbon sequestration in the ocean.

The Deep-Benthic Realm: Earth's Largest-Area Habitat

Where the pelagic realm is divided into vertical zones according to solar light levels, the benthic realm is typically categorized according to the topography of the seafloor. Covering over 75% of the Earth's surface, the deep seafloor begins at the continental shelf break (c. 200 m depth; 500 m around Antarctica) at the outer edge of the coastal seas and extends to about c. 11,000 m at the bottom of the Mariana Trench. Across the seafloor, myriad geological and biological features create unique, dynamic ecosystems that support a diverse benthic fauna. In this section we briefly describe each zone and the ecosystems they can contain, before considering the ecology of the fauna.

The Continental Slopes (Bathyal Zone)

The continental slopes extend gradually from the continental shelf break to the continental rise (c. 3000 m depth), with an average gradient of around 4°. Covering only 15% of the Earth's surface, the continental slopes are mostly covered by soft sediments, but are punctuated by a diverse range of geological features, such as seamounts, canyons, hydrothermal vents, cold seeps, and brine

pools. Where the physical and chemical conditions are suitable, cold-water coral reefs, sponge beds or other emergent epifauna (organisms living on the sediment surface) may generate large, complex frameworks that provide a greater diversity of habitats for a range of invertebrate and vertebrate taxa. Among the deep-sea benthic habitats, continental slopes are where the greatest variability in oceanographic conditions occurs, which can strongly affect the distribution of the benthic fauna. For example, oxygen minimum zones can lead to a reduced biodiversity of benthic animals, but an increased abundance of hypoxia-tolerant species. Similarly, varying current speeds may affect the coarseness of the benthic sediments or the deposition of "marine snow" (agglutinated flocs of dead plankton tissue and biological waste) to the seafloor, all of which may affect the abundance and diversity of the fauna living on and in the seabed.

At the upper (shallowest) end of the continental slopes, the fauna generally resembles that found in coastal environments, but as one goes deeper we see progressive shifts in morphology and life-history traits with increasing depth. Demersal fishes, for example, show a general shift towards elongate, eel-like body shapes with increasing depth, which are better suited for conserving energy in a food-poor environment. The systematic form of fishes also changes, with the more "advanced" spiny-rayed taxa (e.g., seabasses, scorpionfishes) giving way to more "basal" taxa (e.g., eels, cusk eels, and cod-like fishes). This trend is mirrored by the cartilaginous fishes, with requiem sharks (e.g., bull, tiger, and lemon sharks) and rays being replaced by basal taxa like catsharks and chimaeras.

The Abyssal Plains (Abyssal Zone)

As the continental slopes become less steep, they give way to the continental rises, and then the abyssal plains, which are vast, flat expanses covering c. 53% of the planet's surface. As we move further from the ocean surface and continental margins, animal biomass declines exponentially, and is reduced to $<1\%$ of the biomass found in coastal seas. Abyssal plains are considered energy-poor, though there is considerable regional variability in energy input depending on surface productivity—some areas can receive relatively large inputs of energy equivalent to 50%–80% of surface primary productivity. Despite their energy limitations, abyssal plains are home to a wide range of benthic organisms that are able to thrive in the high pressures of the abyss. Environmental conditions at abyssal depths are invariant compared to conditions on the upper slope and in coastal waters. There is no solar light, the waters are cold (c. 0.5–3.5°C) and well'oxygenated, and current speeds are generally low. An exception to this can occur below areas where sea-surface kinetic energy is high (e.g., beneath Gulf Stream eddies in the NW Atlantic). This energy can generate high-energy eddies at abyssal depths which cause "benthic storms." It is possible for several storms to occur per year and for those to last for several days at a time, causing broad-scale disturbances to the abyssal fauna in those regions and resuspending fine sediments into the water column. Outside of such regions, slow currents are the norm, however. Soft sediments dominate, but still support a diverse invertebrate infauna (organisms living in the sediment) and epifauna. Predatory and scavenging demersal fishes (particularly rattails; Family Macrouridae) occur in low numbers on the abyssal plains. Like other ecosystems, the distributions and diversity of benthic organisms on abyssal plains are influenced by environmental heterogeneity. At fine-scales, changes in sediment grain size, the occurrence of patches of phytodetritus, epifaunal animals themselves, animal tracks, burrows, and animal waste can all influence the occurrence and distributions of abyssal fauna. At larger scales, the sedimentary plains are interspersed by potentially hundreds of thousands of seamounts and tens of millions of abyssal hills. Abyssal hills are believed to be the most common topographic features on the planet, shed from the far larger Mid-Ocean Ridges as they spread. Similarly, despite the great depths of the abyssal plains, regional differences in overlying surface primary productivity can strongly influence the biomass and composition of abyssal animals.

Trenches (Hadal Zone)

Where tectonic plates collide, subduction zones can form and produce deep trenches in the seafloor. Trenches extend below c. 6000 m depth, and despite their great depths, harbor a unique animal fauna, even at full ocean depth (c. 11,000 m in the Mariana Trench). There are approximately 95 distinct basins deeper than 6000 m worldwide, with 16 recognized trenches. Hadal ecology is still a young and emerging field of research, but recent studies are beginning to shed light on the animals that inhabit these ecosystems and their ecology. Representatives from most marine taxa have been observed in trenches, with gastropods, polychaetes, bivalves and holothurians occurring to 11,000 m, though fishes are also present to c. 8200 m. Due to the relatively isolated nature of trenches, rates of endemism within trenches appear to be high, with different trenches harboring relatively high numbers of unique species.

Hyrdothermal Vents and Cold Seeps

Hydrothermal vents occur where there is volcanic activity and geothermal heating of the seafloor. They are characterized by buoyant plumes of heated water, the temperature of which can vary from slightly above ambient in diffuse flows to over 300°C at intense flows. The precipitation of dissolved minerals when heated water meets cool water can form columnar, chimney-like structures reaching tens of meters into the water column. These habitats are among the most ecologically unique on earth owing to the presence of high-biomass, chemosynthetically supported life. Animals that live in chemosynthetic ecosystems derive their energy from chemicals in seawater rather than from solar light, creating local areas of high animal biomass in an otherwise energy-poor deep ocean. Here chemosynthetic bacteria generate energy from sulphides ejected from volcanic fissures. Large tubeworms (*Riftia*) have evolved a symbiotic relationship with these bacteria and use them to rapidly produce large colonies at vent sites for as

long as the sites exist (~ decades). While hydrothermal vents occur worldwide, their total area is small and thus contribute only a very small fraction of total deep-sea production. Cold seeps are another example of chemosynthetic ecosystems, found in locations where hydrocarbons are expelled at the seafloor at temperatures similar to those of ambient seawater. In these cases, bacteria associated with animals such as mussels may use hydrogen sulphides or methane as their energy source.

Adaptations in the Deep Sea: The Ecological Arms Race

Relative to terrestrial, freshwater, and coastal marine ecosystems, the deep sea is a harsh environment, with organisms likely operating at or near their physiological limits. Extreme pressures, near or total darkness, low temperatures, low food availability, a medium (water) 800 × more dense than air, and in some cases, extreme oxygen limitations all constrain the biology and ecology of the deep sea. Deep-pelagic taxa live in a fully three-dimensional existence with no solid surfaces, whereas benthic and benthopelagic species are adapted to these surfaces, but in the total darkness of the abyss, probably cannot see them. Many of the bizarre-looking characteristics of deep-sea organisms is related to gaining sensory advantages relative to these constraints, and in the same fashion, to defeat the sensory capacities of both prey and predators. As these adaptations are central to the ecology of the deep-sea, we summarize the major adaptations here.

Hiding in the Deep

Many of the diagnostic characteristics of deep-sea organisms involves feeding, both finding prey and avoiding being predated upon. With respect to the latter, the low levels of light in the deep have provided opportunities for camouflage. Animals have adopted three major strategies: appearing to be something they are not (e.g., Müllerian and Batesian mimicry—imitating something inedible or noxious, respectively), being transparent, or blending in with the surrounding environment. Mimicry is largely confined to the surface ocean, where many fish larvae closely resemble inedible objects (especially bird feathers) or stinging gelatinous zooplankton (e.g., siphonophores).

Transparency and "blending in" are common in the deep oceans. Transparency is the extreme case, as it requires polarization of an organism's molecules as well as behavioral modifications to blend in. Transparency is best achieved by the pelagic invertebrates; exemplar organisms include gelatinous zooplankton (**Fig. 4**A), heteropod molluscs, arrow worms (Chaetognatha), certain amphipods, and a variety of decapod shrimps. Transparency is common among larval fishes, with the leptocephali (larvae of eels, bonefishes, tarpons, and halosaurs) being prime examples. No adult fishes are completely transparent, but many species whose body musculature is transparent "hide" their necessarily opaque parts (internal organs, eye retinae, prey in stomachs/intestines) with a silvery membrane invested with multilayered guanine crystals, meant to reflect the ambient water color. As with many cases in the ecological arms race in the deep sea, transparent organisms can be detected by predators equipped with headlight photophores and/or specialized eyes attuned to scattered light (**Fig. 4**B).

There are various ways for organisms to "blend in" with their surroundings. The reflection of a mirrored surface, adopted by many mesopelagic fishes, is an effective way to blend in with the surroundings. For example, hatchetfishes of the genus *Argyropelecus* (**Fig. 4**C) present a near vertical mirror in the water column—when viewed from almost any angle the reflected light is the color and intensity expected (lighter when viewed from below, darker when viewed from above). The bright silver reflection of these organisms when viewed from submersibles or in situ cameras is a function of artificial light introduced from the side, a phenomenon that does not occur in nature.

A "flaw" in the mirrored camouflage technique is that is does not hide an animal when viewed from directly below. To counter this vulnerability, the vast majority of mesopelagic fishes, many shrimps, and even many squids bear bioluminescent photophores (**Fig. 4**E) along their ventral (lower) margins, from which they produce light of the wavelengths and intensity of downwelling sunlight (usually blue). This ventral lighting serves to obfuscate the silhouette of an organism when viewed from directly below. An increasing number of in situ observations have reported that many predatory fishes adopt a vertical, head-up posture in the water column, ostensibly looking for prey outlined against downwelling light. Again as an arms race example, the eyes of many deep-sea predators have yellow lenses, thus allowing differentiation between natural sunlight and organismal bioluminescence.

Lastly, as one goes deeper into the water column (i.e., below 1000 m) animals become black (e.g., gulper eels, anglerfishes), dark brown (bigscales, whalefishes), or red (crustaceans, jellyfishes) (**Fig. 3**), as silvery coloration would serve to "announce" an organism when lit from the side by bioluminescence. Near the deep-sea floor, animals become monochromatically brown, gray, or semi-transparent—the lack of light precludes the need for distinctive coloration, or even hiding for that matter.

Bioluminescence—The Production and Use of Living Light

Bioluminescence is a defining feature of most animals living in the deep-pelagic realm, and even of many living near or on the seafloor. Over 90% of the metazoan species in the mesopelagic zone are bioluminescent. A lesser percentage of bathypelagic organisms are bioluminescent, though nearly all members of deep-sea anglerfishes (Suborder Ceratioidei; **Fig. 3**A–C), the most speciose fish taxon below 1000 m, produce light, as do most gelatinous taxa (especially medusoid cnidarians) and a wide variety of pelagic shrimps. Near the seafloor bioluminescence is greatly reduced among vertebrates and invertebrates alike.

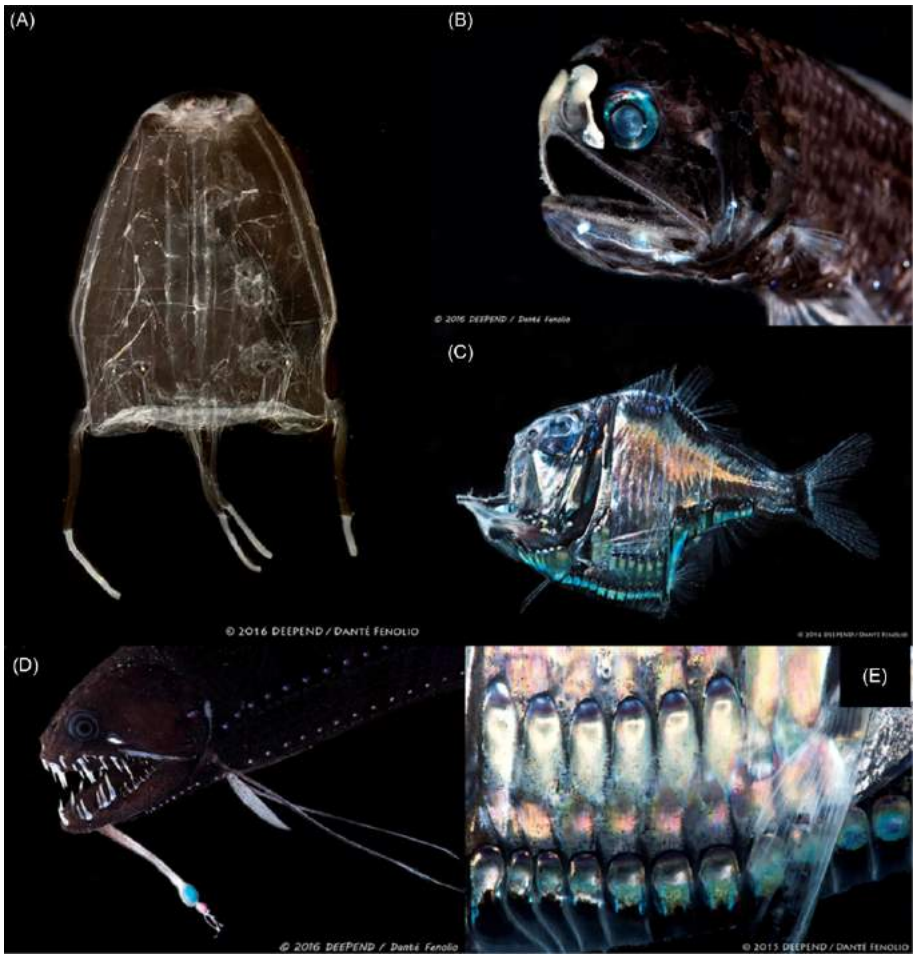

Fig. 4 Adaptations in the deep sea. (A) Transparency (box jelly). (B) Headlight photophores (lanternfish). (C) Mirrored sides (hatchetfish). (D) Chin barbel (dragonfish). (E) Ventral photophores (close-up of hatchetfish in C). All images courtesy of the DEEPEND research consortium (http://www.deependconsortium.org).

Bioluminescence among metazoans is either accomplished using luminescent bacteria cultures bound inside specialized light organs, or by intrinsic light production from photophores. In one case (e.g., female linophrynid anglerfishes), both systems are used. Intrinsic bioluminescence in the deep sea is produced from the same general chemical reactions as that of a firefly—a substrate (luciferin) is exposed to an enzyme (luciferase), which produces an unstable molecule that releases light energy to reachieve stability.

As previously mentioned, bioluminescence can be used to aid in camouflage in the water column, and also as a 'luring' mechanism (e.g., chin barbel of dragonfishes; **Fig. 2**D, **Fig. 4**D), but also has many other uses. Some animals (especially oplophorid shrimps and tubeshoulder fishes) presumably use bioluminescent displays to startle or distract predators, allowing for escape. Certain lanternfishes and dragonfishes use enlarged photophores around the eyes to illuminate prey in the water column. Bioluminescence can also be used to locate potential mates for spawning, as evidenced by the sex-specific photophore patterns of many meso- and bathypelagic fishes. This form of sexual selection and reproductive isolation may be the driver behind the exceptional diversity of the specific taxa that utilize this form of communication, the lanternfishes and dragonfishes.

Vision—Seeing in the Darkness

The importance of vision at mesopelagic and bathyal depths is manifest in the visual adaptations of the fauna. Crustaceans, cephalopods (squids and octopods), and fishes often have huge eyes relative to their body sizes, with vision enhanced by visual pigments tuned to the long, monochromatic wavelengths (470–480; blue-green light) that can penetrate through the epipelagic zone and into the mesopelagic. Fishes also possess multiple-bank retinas to further increase sensitivity and acuity in dim light. Tubular eye structures are common among predatory deep-pelagic fishes (**Fig. 3**D)—this allows binocular vision, which is an adaptive solution to the problem of sizing and ranging in an environment with no reference structures, as humans use when judging distance on land, for example. An additional adaptation among deep-sea fishes is the enlargement of the pupil to allow

light from many directions to pass through the lens onto the retina. Deep-sea crustaceans have compound eyes adapted to low light conditions as well. In many cases the pigment separating the individual ommatidia (single "eyes" of a compound eye) is reduced. This allows greater light sensitivity, but at the expense of image formation, a trade-off that is obviously successful given the large numbers and biomass of shrimps in the deep sea.

Hearing—Listening in the Darkness

Relative to the coastal and surface ocean, the deep sea is a calm and quiet environment, although anthropogenic sounds from sources like shipping, drilling and sonar are increasingly prevalent. Nonetheless, many taxa use this relative quiet to their advantage to offset the inherent visual limitations of the deep sea. All freshwater, coastal marine, and deep-sea fishes use an ear-lateral line system for acoustic sensing. "Ear stones" (otoliths) located within fishes' heads absorb sound, owing to their higher density relative to seawater, and pass this energy to a series of hair cells, which are then transmitted to the brain via nervs. The sensitivity of hearing in deep-sea fishes can be quite impressive, inferred from the observation that the complexity of the hair-cell organization of some deep-demersal fishes is the highest of any vertebrate.

Mechanoreception

The lateral line system (as the name implies) runs down the lateral sides of a fish, and is also most developed in deep-sea fishes relative to coastal forms. The form and complexity varies by taxon, but all possess a series of neuromasts (nerve endings) either exposed to seawater or imbedded in gel-filled cups. This arrangement allows mechanosensing (i.e., detection of mechanical stimuli) of the movement of water around an individual, both due to its own movement as well as movement external to the fish (water circulation and disturbance by other objects). It is not surprising that the highest development of free-standing neuromasts on any fish are found in bathypelagic anglerfishes, befitting a sit-and-wait, luring specialist in an energy-limited environment. Many deep-pelagic fishes also have extremely long fin rays, suspected to serve as extensions of the mechanosensory system (i.e., for vibration detection). Lastly, the elongate form of many fishes (oarfishes, deep-demersal cruisers such as rattails, chimaeras, cusk-eels, morid cods) may be an adaptation to allow greater extension of the lateral line systems.

Olfaction/Chemoreception

Olfaction and chemoreception are believed to be the primary methods by which mobile scavenging animals detect carrion at the seafloor. Baited camera observations (in which a time-lapse camera is used to record the arrival times of different animals reaching a bait package) suggest that this mode of feeding is quite common in the deep sea and is used by a wide range of taxa (e.g., amphipods, fishes, shrimp, sharks, crabs and squat lobsters, among the most prevalent). Chemoreception has also been implicated in the detection of mates, and is the likely method by which small male anglerfishes are able to locate the much larger females in the bathypelagic realm, where the total abundance of fishes is very low. In shallow waters, chemoreception is known to be important in larval settlement of many sessile benthic species, and may be similarly important in the deep sea.

Connecting the morphological characteristics of deep-sea animals with the increasing body of information on organismal biology is one of the most exciting fields of study in deep-sea ecology. As these characteristics are intimately tied to the first survival need in the deep—locating food—we will now discuss the fundamentals of trophic ecology in the deep sea.

Ecological Interactions in the Deep Sea

Feeding

Given that environmental variability in the deep sea is modulated by the overlying mass of water, and that for much of the deep sea (i.e., water column) there is no physical structure about which the fauna can orient, ecological interactions are particularly important as drivers of community structure. Of all interactions, trophic interactions are putatively the most important in a food-limited world. Studies of the trophic ecology of deep-sea organisms have progressed a great deal in the last two decades. Earlier studies focused on analysis of diet, morphological specializations for feeding, and the characterization of feeding guilds. These approaches have been recently expanded using biomarker approaches, revealing new food web pathways and energy sources for deep-sea communities. Recent studies have focused on the connections between the sources of food in epipelagic waters and the deep-sea animals living beneath, and on the vertical connectivity of food webs, both within the water column and between the pelagic and the benthic realms. A number of studies have also attempted to estimate feeding rates and the fluxes of energy between ecosystem components to inform spatially explicit food web modeling.

Feeding in the Pelagic Realm

In the pelagic realm, ecological interactions between species are believed to be particularly important drivers of community structure, since there is far less physical heterogeneity in the environment to drive speciation than is found on the seafloor. Where

benthic organisms can "choose" between sessile and mobile morphologies, or can adapt to different substrate types for instance, pelagic fauna can live their entire lives in the three-dimensional, fluid water column and will never encounter a surface that does not belong to another animal. Feeding strategies among metazoans in the deep-pelagic realm are constrained by a number of factors: there is no solid surface (i.e., seafloor) to accumulate organic matter and support benthic prey; ambush predation is highly reduced because of the relatively structureless environment; there is insufficient particulate organic matter to support filter feeding (a ubiquitous strategy in coastal waters); and herbivory is precluded by the lack of primary production. These constraints result in four predominant feeding modes in the deep-pelagic realm: mucus-trapping of particulate matter, zooplanktivory, micronektivory, and generalist predation. Mucus-trapping is exhibited by a relatively narrow range of gelatinous taxa, particularly appendicularins and salps, and one group of pelagic molluscs (shelled pteropods).

Zooplanktivory is by far the most ubiquitous strategy among metazoans, both in terms of individuals, species, and biomass; the most abundant species (larger zooplankton, fishes, and shrimps) consume zooplankton primarily, as do the larvae of nearly all pelagic teleosts and crustaceans. Within this feeding mode (= "guild"), the most commonly consumed prey taxa are calanoid copepods, the most energy-dense prey per unit weight known. A wide variety of deep-pelagic fishes are specialized to prey on micronekton (small fishes, shrimps, and cephalopods). While some taxa are agile swimmers able to pursue and capture prey (e.g., barracudinas), they majority of species adopt a sit-and-wait predation style, facilitated by long bodies with well-developed lateral lines (e.g., pelagic eels) or luminescent lures suspended on chin barbels (dragonfishes) or modified fin rays (deep-sea anglerfishes). Available data suggest that trophic coupling between micronektivores and their prey is extremely tight, with the former consuming the majority of the annual production of the latter. Generalist feeding, taking a wide variety of any prey that is encountered in the food-poor deep sea, is far less common than originally assumed. The best examples of generalist feeding is found within the bathypelagic zone, and include pelican eels with extremely large but weak jaws, and fangtooths, with massive jaws and fangs.

A form of zooplanktivory that has been highlighted during the last decade of research in deep-pelagic, demersal and benthic food webs is consumption of gelatinous zooplankton. In the water column, the "jelly web" can dominate intermediate trophic levels, particularly as depth increases. Gelatinous taxa are then consumed by a number of biomass-dominant deep-pelagic (e.g., deep-sea smelts) and demersal (e.g., slickheads) fishes. Occasional mass accumulations of dead or dying jellyfishes on the seafloor also provide important energy sources for demersal and benthic predators, scavengers, and benthic epi- and infauna. These findings are particularly important because it had long been assumed that jellyfish, with a high water content and low nutritional value, represented a trophic "dead end"; that is, they provided insufficient nutrition to support higher trophic levels, compared to the far more nutritious zooplankton-based foodwebs. However, these new studies suggest that jellyfishes may be an important energy source reaching the deep seafloor.

Feeding in the Benthic Realm

Where trophic specialists are common in the pelagic ocean, generalist feeders appear to be more common across the seafloor. With the exception of herbivory, all feeding types are found in the deep-benthic realm. Suspension feeding occurs when organisms feed on particles in the water column, which may be passively transported to the organism by water currents, or actively captured by moving through the water. Suspension feeding is the preferred mode for most sessile epifaunal animals, including Cnidaria (e.g., corals, anemones and hydroids), sponges, sea lilies and sea squirts, though it is also used by some errant megafauna, particularly brittle stars and sea stars. Suspension feeding is most common on the continental slopes, and at locations where elevated current speeds and particulate organic matter are found (e.g., around some seamount and canyons), but becomes less important with increasing depth.

As depth increases, deposit feeding becomes considerably more common. Where rates of particulate matter deposition are relatively high, subsurface deposit feeding by infaunal organisms tends to be more common, whereas in oligotrophic environments, surface deposit feeding by epifauna is more common. On the abyssal plains, sea cucumbers and sea urchins are common deposit-feeding epifauna that feed by ingesting sediment as they traverse its surface.

Predation is observed at all depths. At the highest trophic levels, ambush predation is exhibited by top predators (lizardfishes, sharks, and skates), and piscivory (fish consumption) predominates. Micronektivory is an important deep-demersal feeding guild, particularly in regions where Deep Scattering Layers intersect bottom topography, such as continental slopes, seamounts, mid-ocean ridges, and canyons. Members of this guild, including commercially important fishes (e.g., orange roughy, grenadiers), may venture a considerable distance above the bottom to utilize this food source. Closer to the seafloor, hyperbenthic predation on crustaceans is a major trophic guild, conducted by sit-and-wait predators (e.g., tripod fishes) and active searchers (e.g., rattails, skates, sharks, cusk-eels, morid cods). Epifaunal browsing is a feeding guild where organisms pick small benthic crustaceans and polychaetes off the seafloor without ingesting sediment (e.g., crabs, squat lobsters, spiny eels). It is interesting that sessile invertebrates (e.g., anemones, sponges, corals) are rarely consumed in the deep sea. Infaunal predation (digging into sediment) is rare in the deep sea, unlike the coastal zone where this strategy is common, and appears to be adopted by a limited fauna (eelpouts, flatfishes, amphipods).

While deep-seafloor trophic dynamics are largely driven by the flux of particulate organic matter from the sea surface, much of this material will have been consumed, egested and reworked by organisms and microbes in the water column and on the seafloor before it is consumed due to the slow sinking rates. Larger food falls sink far faster, and generally arrive at the seafloor quickly to provide a high-quality, energy-rich food source for animals that can detect them and reach them before they are consumed by

other scavengers. Unsurprisingly, scavenging and detritivory are important trophic guilds among benthic animals. The preponderance of these guilds is seen in the speed at which food falls are located and consumed, in some cases minutes to hours, depending on the size of the food fall. The largest whale falls can provide a local source of energy for scavengers for months, and even once the soft tissue has been consumed, the skeleton can provide energy and hard substrate for suspension-feeding organisms for decades. Wood falls and deposits of plant material are also readily consumed by detritivores at the seafloor when it is available. Key organisms in these guilds include sharks, rattails, crabs, hagfishes, cutthroat eels, and amphipods, the latter of which are often the first to arrive. Some fishes (e.g., snailfishes) feed directly on amphipods attracted to food falls, a modified form of hyperbenthic feeding.

Chemoautotrophy

While the majority of food reaching the deep sea can ultimately be traced back to a photosynthetic source, chemosynthesis is known to be a locally important source of energy at the seafloor, though new research suggests that bacterial chemoautotrophy may be a far more widespread source of carbon in the "dark ocean" (i.e., deep-pelagic depths) than previously recognized. Chemosynthesis occurs where bacteria are able to derive energy from chemicals in the water column, rather than using solar light.

Ecosystem Services: The Importance of Understanding the Ecology of the Deep Sea

The Functioning and Services of the Deep Sea

The deep-sea fauna serve vital functional roles in deep-sea ecosystems including carbon sequestration, biomass production, sediment bioturbation and stabilization, organic matter decomposition, and nutrient regeneration. The primary challenges in identifying deep-sea ecosystem services are the many knowledge gaps about the ecology of deep-sea ecosystems and the prevalence of intermediate services relative to final services. Intermediate services include the biologically mediated habitat, nutrient cycling, resilience and resistance, and water circulation and exchange, whereas final services include carbon storage and sequestration, food provision, genetic resources, and waste absorption and detoxification. In many places the bathypelagic and benthos represent important reservoirs of marine biodiversity. Biodiversity is highly correlated to deep-sea ecosystem functioning and increases the resilience of deep-sea ecosystems and their ability to respond to disturbance (see following *Threats* section). The deep sea absorbs ~25% of anthropogenic carbon emissions, a critical service influencing climate. The Gulf of Mexico provides a prime example of waste detoxification services by the deep sea; microbial communities degraded hydrocarbons released by the *Deepwater Horizon* oil spill. The deep sea also provides cultural services in the form of human intrigue and excitement of discovery, which often drives technological advancement (e.g., submersibles, ROVs, landers). This excitement has driven substantial economic investment in the form of physical (ships, sensors, gear) and academic infrastructure. In summary, deep-sea ecosystem services are vital to human well-being.

Threats to the Fauna and Ecology Deep Sea

The deep sea was once considered too large to be disturbed by humans. Decades of declines in deep-sea fisheries landings, along with point-source disasters and growing interest in destructive resource extraction (e.g., deep seafloor mining), has changed this notion. Given that the deep sea is a highly interconnected ecosystem tied to the processes of the surface ocean, such as major circulation patterns and primary production, it is not immune to the effects of climate change. Anticipated ecosystem changes include a more stratified ocean, with implications for the timing and quantity of plankton production, as well as range shifts as warm-water taxa expand their distributions towards the poles, presumably at the expense of polar taxa. A full treatment of climate change as a driver of ecosystem change in the future are beyond the scope of this article, so herein we will describe some of the immediate and ongoing threats to the deep sea.

The largest category of threat to deep-sea ecosystems involves resource extraction, both living and nonliving. As human populations expand exponentially in a Malthusian trajectory, so too does the need for food. As coastal fisheries become increasingly depleted due to overharvesting, fisheries have continued a decades-long trend in fishing deeper. That, combined with the increasing harvesting power of modern vessels with technological advancements (e.g., scanning sonar) and the low recovery potential of many slow-growing deep-sea fishes and habitat-forming benthic invertebrates, makes deep-sea ecosystems particularly vulnerable to trophic cascades, regime shifts, and ultimately ecosystem collapses. Historically, deep-sea fisheries have focused on relatively few species of pelagic and demersal species, with Gadiformes (cods and their allies) comprising the majority. These fisheries have been so intense in some regions (e.g., North Sea) that they have fundamentally altered the very nature of the habitat —trawl tracks have now become the dominant topographic features. Though a few of the world's smaller deep-sea fisheries are considered sustainable, other deep-sea fishes, such as orange roughy and slender armorhead, have been effectively fished to economic extinction. Mesopelagic lanternfishes likely represent the world's largest untapped fisheries resource, and interest in harvesting these fishes is rapidly increasing. If pelagic fisheries follow the same trajectories as other deep-sea fisheries, "sustainable yield" fisheries are unlikely. Fishing will simply remove individuals faster than they can replace themselves. The impact fisheries can have on deep-sea floor can be locally devastating—in the northwest Atlantic, for instance, the effect of bottom trawling below 200 m has an impact at least an order of magnitude higher than all other human activities combined.

Non-living resource extraction also has a profound effect on deep-sea ecosystems, as evidenced by the *Deepwater Horizon* oil spill in the Gulf of Mexico at 1500 m depth. While the full extent of the damage from this event may not be known for some time, the immediate effect on the deep-sea biota have been dramatic—loss of deep-sea corals, reduction in pelagic fish numbers, and mass mortality of marine mammals and seabirds. Once considered "deep," the *Deepwater Horizon* wellhead (Macondo) site now sits shallower than the average depth of deepwater drilling in the Gulf of Mexico. As the risk of accidents increases dramatically with increasing depth of drilling, it is likely that *Deepwater Horizon* will not be the last such deep-sea natural disaster. An emerging field of resource extraction is deep-sea mining, which will alter deep-benthic communities for centuries, perhaps millennia. As of 2013, the International Seabed Authority, the entity regulating deep-seafloor mining, had entered into 11 15-year contracts with several nations to mine a section of the Pacific twice the size of Germany. These activities, plus the ongoing use of the deep sea for waste disposal, call for a new perspective on deep-sea stewardship, one where we move away from a frontier mentality of exploitation and towards an ecosystem health and services management mentality.

Ecosystem Health Indicators—Freshwater Environments

Waterways are akin to the lymphatic system and kidneys of the land in that they drain and process chemicals and material leaving the land. Like lymphatic systems and kidneys, if excessively stressed the health of that system will deteriorate. Anthropogenic stressors of freshwater systems include nutrient enrichment, urbanization, industrial waste, deforestation, water abstraction, flood prevention engineering, sedimentation, dam construction, climate change and invasive species (Foote et al., 2015; Dudgeon, 2014; Cucherousset and Olden, 2011; Woodward et al., 2010; Dewson et al., 2007; Dudgeon et al., 2006). If humans are unwell they will usually see a physician who will assess their "health" with a range of physical, psychological and biochemical indicators. Likewise, good environmental management practices often require that the health of an ecosystem is measured and maintained using multiple indicators (Rapport et al., 2009; Kundzewicz et al., 2007; Steedman, 1994). Though, what is meant by the notion of "healthy ecosystem" and how we measure it is currently far more challenging than for human health. As humans assessing the natural world, we often personify our examinations and in so doing we interpret our observations with a human-lens, this extends to the way we define "ecological health" (Palmer and Febria, 2012; O'Brien et al., 2016; Friberg et al., 2011; Whitfield and Harrison, 2014) In humans, Sartorius (2006) has identified three broad definitions of health:

> The first is that health is the absence of any disease or impairment. The second is that health is a state that allows the individual to adequately cope with all demands of daily life (implying also the absence of disease and impairment). The third definition states that health is a state of balance, an equilibrium that an individual has established within himself and between himself and his social and physical environment.

From these definitions, it is clear that, as humans, we associate health with the absence of stressors, the ability to resist and be resilient to stressors, and that a state of balance is achieved implying that a level of integrity is maintained despite external stressors (persistence). In freshwater ecology, O'Brien et al. (2016) found almost 200 studies directly assessing ecosystem health and over 1000 using the term in a broader context, yet there were vast differences in the way "health" was defined and interpreted. Here we do not attempt to synthesize a new definition of "ecosystem health," but adopt Costanza and Mageau's (1999) definition. This definition not only resembles broad similarity to the concepts many associate with medical health but is also sufficiently generic to apply at all levels of scale. Costanza and Mageau (1999) state that:

A healthy ecosystem is one that is sustainable—that is, it has the ability to maintain its structure (organization) and function (vigor) over time in the face of external stress (resilience).

Structure or organization measures the assembly of a community, it includes species diversity, community composition and food web topology. Whereas function or vigor is a measure of an ecosystems activity; function includes concepts such as the productivity, throughput, cycling and metabolism. The maintenance of structure and function over time in the face of external stress reflects the stability of an ecosystem. Whereby stability is a multifaceted concept that can be divided broadly into resistance (the ability to remain unchanged from stress) and resilience (the capacity and timeliness to return to preperturbation conditions). Given that the term "ecosystem" encompasses both biotic and abiotic factors, in addition to community-level measures (biotic), we also include indicators of habitat (abiotic).

If we are to halt the decline, maintain or restore freshwater ecosystem health then we need to adequately monitor change across all three components of health. Here we introduce each of the common indicator classes (both biotic and abiotic indicators) and discuss their use and interpretation; we do not discuss human-related environmental health indicators (such as those used to assess swimmability). Table 1 categorizes common measures of freshwater ecosystem health as being indicators of organization (structure), vigor (function) or resilience.

Biotic Indicators

Species diversity

Probably one of the oldest and simplest indicators of ecosystem health is species richness. It is usually assumed that a decline in species richness is associated with a decline in health and increasing anthropogenic disturbance. For example, Relyea (2005) showed a 22% reduction in zooplankton diversity in pond mesocosms following overspray of the common pesticide RoundUp^{T} (Glyphosate). However, in many instances species richness is not altered as more tolerant species replace sensitive species. Furthermore, in some situations, small to moderate disturbance can increase species diversity by reducing dominant species and opening new niches—the premise of the intermediate disturbance hypothesis (Townsend et al., 1997b; Resh et al., 1988; Ward and Stanford, 1983). For instance, Death and Zimmermann (2005) found that deforested stream sites had greater macroinvertebrate diversity than sites within the Taranaki native forest park (New Zealand), though the species composition was considerably different. Although anthropogenic disturbance increased species diversity, ecosystem health reduced as ecosystem *structure* was *not maintained* (community composition changed) in the face of *external stress* (deforestation). Thus, species richness can be a misleading indicator of ecosystem health. This has led to the development of indicators that focus on changes in community composition. In rivers, the most common richness based indicator is the number of EPT (Ephemoptera, Plecoptera and Trichoptera)

Table 1 Freshwater ecosystem health indicators and whether they measure structure, function, resilience and/or abiotic components of ecosystems

	Aspect of ecosystem health			
Indicator	*Structure*	*Function*	*Resilience*	*Abiotic*

taxa; species richness is also central to other indicators such as Karr et al.'s (1986) index of biotic integrity and observed/expected ratios, such as AUSRIVAS (Simpson and Norris, 2000).

Community dissimilarity

Rather than using species diversity as an indicator of health, multivariate community distance metrics (e.g., Bray-Curtis similarity Bray and Curtis, 1957), can indicate community dissimilarity from the prestressed state or a natural reference site(s). For example, Cao et al. (1996) showed, using the CY dissimilarity metric (Cao et al., 1997), a clear increase in macroinvertebrate community structure dissimilarity (from a reference site) along a sewage effluent pollution gradient in the Trent River (UK) catchment.

Dissimilarity based metrics usually perform well as metrics of deviation in ecosystem *structure* in the face of *external stress*; however, not all dissimilarity metrics are equal in their sensitivity to change in all situations. Cao and Epifanio (2010) showed that the Bray–Curtis index, CY similarity index and Canberra Metric responded more linearly than Chao's abundance-based Jaccard and Sørenson coefficients, and Morisita index (which showed strong nonlinear changes) to linear changes in stream macroinvertebrate assemblages over a simulated stress gradient. Therefore, before a dissimilarity metric is used, it must be clear that the metric is likely to respond in an ecologically sensible way for a given disturbance and community type. Furthermore, whilst dissimilarity metrics directly measure differences in community structure, they do not provide information on actual species differences that drive community differences.

Algal biomass

Nutrient enrichment, deforestation, water abstraction and increased temperature can all result in increased algal growth (Dodds, 2007) which can alter higher trophic levels through increased risk of hypoxic conditions and changes in food resources (Smith and Schindler, 2009; Bricker et al., 2008; Dodds, 2007). Algal biomass can, therefore, indicate changes in community structure. Algal biomass indicators can usually be classified as either measures of benthic cover or pigment density. Benthic cover measures usually apply to shallow rivers, streams and lake edges, where light penetrates through to gravels, and is often broken down into percent cover of filamentous algae (coarse (thick filaments), slimy (thin filaments), long and short) and algal mats (thick and thin). Algae biomass can also be estimated indirectly via the concentration of pigments as the two are strongly correlated (Hawkins et al., 1982). The most commonly assessed pigment is Chlorophyll a (green/yellow pigment), measured usually with fluorometry or spectrophotometry (Biggs and Kilroy, 2000). Pigment abundance can then be calculated as either a concentration (from pelagic samples) or as an area-density (from benthic samples). As a guideline, Welch et al. (1988) suggests that for periphyton (benthic algae) a chlorophyll *a* density of 100–150 mg m^{-2} and a filamentous algae cover of ~20% may represent a critical level for aesthetic nuisance. Dodds et al. (1998) suggest that oligotrophic streams have an annual mean (and maximum) chlorophyll *a* biomass less than 20 (60) mg m^{-2}, while eutrophic streams experience more than 70 (200) mg m^{-2}. According to the OECD (1982) trophic classification scheme for lakes, oligotrophic lakes have an annual mean (and maximum) chlorophyll *a* biomass of 2.5 (8.0) mg m^{-3} and eutrophic lakes greater than 8.0 (25) mg m^{-3}. Perhaps the biggest issue with algal monitoring is that algae have high spatial and temporal variability, even within a single stream reach. Algae can be very patchy and biomass can change considerably in the order of hours (Biggs and Kilroy, 2000).

Species tolerance indices

Species tolerance indices were one of the first uses of biological information to assess water quality, one component of ecosystem health (Rosenberg and Resh, 1993; Allan, 1984). These include indices such as the Saprobic Index in Europe (Reynoldson and Metcalfe-Smith, 1992), the Biological Monitoring Working Party (BMWP) index in the United Kingdom, the Hilsenhoff Index in the United States (Hilsenhoff, 1987), the SIGNAL (stream invertebrate grade number average level) Index in Australia (Chessman, 2003; Chessman et al., 1997) and the Macroinvertebrate Community Index (MCI) in New Zealand (Boothroyd and Stark, 2000).

The indices are designed to simplify a mix of complex community data to derive a single score as a sum of water quality tolerance scores assigned to each taxon. They are generally specific to a particular type of pollution (most often organic enrichment), a condition that limits or confuses their value as more general ecosystem indicators. In recent years they tend to have been replaced by using observed/expected ratios of species present compared with predictions of community composition for a particular waterbody type (Clarke and Murphy, 2006; Wright et al., 2000).

Body-size indicators

Since Odum (1953), average body size has been predicted to reduce with increasing stress. In lakes, increasing phytoplankton cell-size and decreasing zooplankton body-size are associated with decreasing ecological health. In rivers, diatom cell-size also increase and benthic invertebrate body-size is reduced with increasing stress (Stevenson and Pan, 1999; Townsend et al., 1997a). Havens and Hanazato (1993) reviewed a large number of studies that assess the influence of acidification and pesticide contamination on zooplankton body size in lakes (including surveys, experimental manipulations and mesocosm experiments), primarily from North America and Scandinavia. With a few exceptions, the general pattern is that as acidification and pesticide contamination increase, the macrozooplankton (e.g., large daphnids, predatory cladocerans and copepods) often become extinct and are increasingly replaced by microzooplankton (e.g., rotifers, small cladocerans and crustaceans). It is hypothesized that small bodied zooplankton are more tolerant of chemical stressors because they are r-strategists, have greater species richness (increasing probability of tolerant taxa being present), reduced predation (as *Daphnia* become extinct), fewer molts before maturity, have a lower calcium content and greater tolerance of toxic metals. However, the responses of body-size to multiple chemical stressors is not well understood (Havens and Hanazato, 1993).

Indices of biotic integrity

The index of biotic integrity (IBI) was originally created to assess the condition of riverine fish assemblages in the Illinois River (Karr et al., 1986), and has since become adopted worldwide for both rivers and lakes (Beck and Hatch, 2009; Ruaro and Gubiani, 2013), to assess fish (e.g., Zhu and Chang, 2008; Fayram et al., 2005; Joy and Death, 2004a; Lyons et al., 2000a; Kamdem Toham and Teugels, 1999; Minns et al., 1994), macroinvertebrates (e.g., Lunde and Resh, 2012; Perera et al., 2012; Masese et al., 2009; Raburu et al., 2009; Weigel et al., 2002), macrophytes (e.g.,Beck et al., 2010, 2013), and phytoplankton (e.g., Wu et al., 2012; Maulood et al., 2011; Kane et al., 2009). The term "integrity" refers to a condition that has not been anthropogenically altered. IBIs assess multiple indicators of ecological conditions relative to an un-impacted condition. Ecological metrics are often related to taxonomic richness, functional groups, and community composition. In developing an IBI, the first step is to identify measurable ecological changes over a human disturbance gradient, accounting for natural environmental drivers. The gradient should include sites in pristine condition through to highly disturbed sites. A score is applied to each metric (high scores indicate more similarity with pristine condition), the sum of scores across all chosen metrics yields the IBI score, reflecting the deviation from integrity at reference condition.

Observed/expected ratios

Predictive modeling approaches to the environmental assessment of running waters are particularly appropriate where the focus of monitoring is on overall ecosystem health, not just water quality (Norris and Thoms, 1999; Reynoldson and Metcalfe-Smith, 1992; Reynoldson et al., 1997; Bailey et al., 2004). An important reason for this is that they combine information on a variety of environmental variables and the associated macroinvertebrate or fish assemblages. RIVPACS, developed in the United Kingdom was the first in a suite of similar multivariate approaches (Australia (Hart et al., 2001a), Canada (Reynoldson et al., 2001), USA (Van Sickle et al., 2005), Ireland, New Zealand (Joy and Death, 2000, 2003, 2004b), and Indonesia (Hart et al., 2001b)).

A range of sites are sampled in "reference" or "least impacted" condition for their biological communities. A model is constructed predicting the probability of occurrence of taxa at those sites based on measurements of a suite of environmental variables that are not affected by human activity. A test site is then assessed by evaluating how many of the collected taxa at a site are predicted to be present if there is no anthropogenic disturbance and is expressed as an "observed/expected" ratio. Globally, this is probably the most widely adopted approach for assessing the structural component of ecosystem health, although to the best of our knowledge it has only been applied to running water and not still water habitats.

Ecosystem metabolism

Ecosystem metabolism represents oxygen fluxes in aquatic ecosystems, usually measured in g O_2 m^{-3} s^{-1}, and are one of the most common indicators of ecosystem function. Primary production increases during the day and photosynthesis produces oxygen, but at night those same plants respire dropping oxygen levels. At night the community becomes a net user of oxygen, causing dissolved oxygen (DO) levels to drop. Therefore, to measure ecosystem metabolism, DO, temperature, and depth (and potentially light) need to be monitored continuously for at least one full diurnal cycle. The R package streamMetabolizer (Appling et al., 2016) provides a useful platform to calculate ecosystem metabolism using several alternative calculations.

Ecosystem metabolism is most often broken down into gross primary production (GPP), ecosystem respiration (ER) and net primary production (NPP), such that NPP = GPP – ER. When GPP/ER is <1 then the community is using more energy than it fixes and is reliant on allochthonous inputs (e.g., incoming drift and leaf litter); whereas when GPP/ER is >1 the community uses less energy than it fixes, this either presents itself as increased biomass (usually algal biomass) or increased drift. Ecosystem metabolism can, therefore, impact the food base of an aquatic community. A review by Young et al. (2008) has shown that ecosystem metabolism is responsive to numerous environmental changes, these are summarized in Table 2.

Decomposition rates

Rates of leaf litter decomposition provide another indicator of ecosystem function widely used in rivers (Boyero et al., 2011; Sponseller and Benfield, 2001). Typically, this involves leaving preweighed leaf litter in mesh bags for several weeks at a site and then determining how much biomass is lost over the period. Bags are best secured close to the stream bed to reduce the influence of hydraulic conditions; bags floating in the water column can influence decay rates (Mutch et al., 1983). In many cases, leaf litter decomposition will be size-dependent, so it can be useful having multiple bags with different mesh apertures and different detritus sizes (Boulton and Boon, 1991). A key difficulty with leaf litter decomposition is that it can be difficult comparing between sites if leaf litter composition is not the same, as some leaves and twigs will decompose faster than others. An alternative technique that may circumvent that issue is using cotton strips and popsicle sticks instead of leaf litter (Tank and Winterbourn, 1996; Hildrew et al., 1984; Egglishaw, 1972). Cotton decomposition can be either measured as loss of biomass or loss of tensile strength. Cotton strips and popsicle strips are inexpensive and considerably reduce sample variability. A review by Young et al. (2008) has also shown that decomposition rates are responsive to numerous environmental changes, these are summarized in Table 3.

Secondary production

Secondary production measures the rate of biomass generation for given taxa and can indicate changes in ecosystem function. Common methods for calculating secondary production include the size-frequency method, increment-summation method and the Allen Curve method; each of these methods attempts to quantify any missing biomass from each cohort (Morin et al., 1987; Wildish and Peer, 1981). The methods quantify the eliminated individuals when the population is at equilibrium and thus the

Table 2 The responses of ecosystem metabolism indicators to specific stressors

Environmental change	*GPP*	*ER*	*GPP/ER*
Decreasing forest cover	↑	–	↑
Increasing light	↑	–	↑
Increasing temperature	↑	↑	?
Increasing fine sediment cover	↓	↑	↓
Increasing suspended sediment concentration	↓	–	↓
Reduced hyporheic connectivity	–	↓	↑
Decreasing pH	–	↓	↓
Increasing nutrient concentrations	↑	–	↑
Increasing toxic inputs	↓	↓	?
Increasing flood frequency	↓	↓	↓
Increasing river drying	↑	↑	?
Aquatic plant removal	↓	↓	?

GPP represents gross primary productivity and ER represents ecosystem respiration. Increases are indicated by *upwards arrows*; decreases are indicated *down arrows*. *Dashes* indicate no relationship, and *question marks* show uncertainty.

Table 3 The responses of decomposition rates to specific stressors

Environmental change	*Decomposition rates*
Temperature increases	↑
Increasing distance from headwaters	↓
Water velocity increases	↑
Increasing bed stability	↑
Increasing deposited sediment	↓
Decreasing pH	↓
Increasing conductivity	↑
Nutrient enrichment	↑
Increased heavy metal	↓
Increased insecticide concentration	↓
Riparian deforestation	↑
Increasing river regulation	↑

Increases are indicated by *upwards arrows*; decreases are *indicated down arrows*.

quantum eliminated is equal to the biomass fixed (i.e., the secondary production). Cross et al. (2006) examined the influence of nutrient enrichment in a detritus-based stream in North Carolina, USA. They found that secondary production in the headwaters was 1.2–3.3 times greater when the stream was experimentally enriched, compared with the preceding 15-year baseline.

δ15N of consumers

The elemental composition of organisms is dependent on dietary elemental composition, that is, "you are what you eat." The proportions of nitrogen (N) stable isotopes are dependent on the source and degree of transformation (fractionation). Anderson and Cabana (2006) assessed δ15N in invertebrates and fish from 82 reaches throughout the Saint-Lawrence Lowlands in Québec, Canada. They found that average δ15N values were highly correlated with watershed nitrogen loads ($r^2 = 0.61$), manure-borne nitrogen loads ($r^2 = 0.62$) and fertilizer-borne nitrogen loads ($r^2 = 0.45$). (Clapcott et al., 2010) found that δ15N increased with nitrogen concentration ($r^2 = 0.66$) in 84 New Zealand Streams, but they also found δ15N increased with proportion of catchment deforestation ($r^2 = 0.58$). In addition to indicating catchment activities, nitrogen and carbon isotopes can, through the use of mixing models, allow changes in dietary composition, and consequently overall food web structure and function to be identified before and after a given stressor (Nielsen et al., 2018; Layman et al., 2007; Belgrano et al., 2004). It is, however, advisable that if stable isotopes are used to compare nitrogen loads between catchments then the same species (ideally a primary consumer) should be used to avoid differences in dietary composition and trophic position from influencing the results. Stable isotope analysis is developing as a promising and affordable methodology to detect changes in land use and ecological functioning.

Eco-exergy

The eco-exergy of an organism or system is the chemical work energy including the work energy embodied in genomic information (Jørgensen and Nielson, 2014). Eco-exergy, therefore, represents the exergy of an ecological community since the time before biological evolution started, approximately 4 billion years ago (Jørgensen and Mejer, 1977; Jørgensen and Nielsen, 2014). As

Table 4 An example calculation of Eco-exergy for a hypothetical estuary

Taxa	*Biomass (g dw/L)*	*Weighting factor*	*Individual eco-exergy (MJ/L)*
Algae	100	3.4	340
Plants	50	60	3000
Jellyfish	40	144	5760
Annelids	40	287	11,480
Fish	60	344	20,640
Eco-exergy of community			*41,220*
Structural Exergy			*142.14*

Individual eco-exergy = biomass × weighting factor. The Eco-exergy of the community is the sum of the individual eco-exergies. Structural exergy is the community Eco-exergy divided by the total community biomass. The weighting factors are used to quantify the energy expended in the organization and development of living organisms and account for the chemical work energy per unit of biomass.

ecosystems mature and genomic information increases, eco-exergy is also expected to increase (Silow and Mokry, 2010; Fath et al., 2001; Patten, 1995). Eco-exergy is not directly measured but calculated by multiplying the biomass density of each taxonomic group (usually g/L or g/m^2) by the genetic information content weighting factors and then summing all individual exergies. The genetic information content conversion factors account for the energy expended in the organization and development of living organisms and account for the chemical work energy per unit of biomass. Structural exergy (relative exergy) is the total eco-exergy divided by the total biomass density—this allows comparison between ecosystems. Table 4 shows the calculation of eco-exergy for a hypothetical estuarine community; using the weighting factors from Marques et al. (1997), the eco-exergy is 41,220 MJ/L and Structural Exergy is 142.14.

The Structural Exergy provides a measure of the ability of an ecosystem to utilize available resources. An ecosystem with high Structural Exergy is hypothesized to have greater network complexity and have better niche utilization than an ecosystem with low Structural Exergy. Eco-exergy has been used to indicate on changes in ecosystem health for a variety of stressors (Jørgensen and Nielson, 2014). Ye et al. (2007) provide just one example, whereby they compared the Eco-exergy and Specific Exergy for macrophytes, phytoplankton and zooplankton from bays in Lake Taihu (China) differing in nutrient enrichment. They found a critical threshold in macrophyte exergy when total phosphorus exceeds 0.05 mg/L. There are several more examples in the literature, but depending whether the authors concentrate on exergy, structural exergy, or eco-exergy.

Network metrics

Assessment of both structural and functional aspects of ecosystem health has been notoriously difficult because of the challenges in measuring higher order emergent properties (Friberg et al., 2011; Rapport et al., 2009; Steedman, 1994). Food webs are networks that not only represent ecological community structure but also depict energy or material flows between species and provide the opportunity for more holistic assessment of energy flows and potential trophic cascades. Weighted food webs have quantified stocks and flows, and are often referred to in the literature as Ecological Networks, although technically weighted food webs are a form of Ecological Networks. Network assembly is laborious and requires data on standing biomasses of each taxonomic group, along with estimates of their productivity, consumption (both dietary links and amount of flow), assimilation efficiency, and boundary drift, a brief outline on network construction is presented in Box 1, with more elaborate details on their construction in Fath et al. (2007).

Ecological Network Analysis (ENA) provides an assortment of metrics for food web properties that can potentially serve as indicators of both structural and functional aspects of ecological health (Jørgensen et al., 2010), such as measures of energy flow distribution and efficiency, the dominance and nature of indirect flows, cycling, stability and mutualistic predator-prey interactions (Latham Ii, 2006; Fath and Borrett, 2006; Fath and Patten, 1999). These are all measures of emergent properties that cannot be readily calculated without a complete food web (Latham Ii, 2006; Fath and Borrett, 2006; Fath and Patten, 1999; Ulanowicz, 1997, 2004). The metrics, along with uncertainty analyses (Hines et al., 2018), are readily calculable in the R packages enaR (Borrett and Lau, 2014) and NetIndices (Soetaert and Kones, 2008).

Nutrient cycling

Changes in nutrient cycling can indicate changes in ecosystem function. Nutrient cycling cannot be measured directly but calculated from a quantitative network of nutrient cycling. Nutrient cycling can be calculated using a variety of methods, (Fath and Halnes, 2007; Latham Ii, 2006; Fath and Patten, 1999; Allesina and Ulanowicz, 2004; Vanni, 2002), with Finn's Cycling Index (Finn, 1976) being most common. Nutrient cycling can indicate changes in productivity and consumption, and can influence food web resilience and resistance, though to date has not been well-linked to robustness—which is more dependent on link distribution (Schaeffer et al., 1988; Canning and Death, 2017; Zhao et al., 2017; Mougi and Kondoh, 2016; Saint-Béat et al., 2015).

Relative ascendency

Relative ascendency (RA; Eq. 1) measures both the degree to which energy flows are confined to specialist pathways and the energetic size of a web. Ulanowicz (1997) hypothesized that communities have a propensity for increasing ascendency as they

Box 1 A brief summary on the methods to assemble an ecological network

To assemble an ecological network, first one needs to thoroughly sample the density of all species across all trophic levels within a community. Often the currency of weighted food webs is in terms of nitrogen, carbon or energy, in which case the researcher needs to convert count density estimates into biomass density estimates. The conversion is usually done through a combination of direct biomass measurements, or size estimates followed by conversion through published empirical size-mass relationships. Currency conversion ratios are often drawn from typical literature values (e.g., Brey et al., 2010). As flows between species are not readily quantifiable, flow quantums are estimated by mass-balancing the losses in energy/biomass through production, respiration and excretion. Production can be estimated directly through estimates of growth, such as the size-frequency method (Hamilton, 1969), mass turnover rates (Elwood and Nelson, 1972), observed growth rates (McIntire and Phinney, 1965), or indirectly through models of direct measures of production from the same or similar species (e.g., Brey, 2012; Robertson, 1979). Respiration rates are almost always estimated from chamber experiments that measure oxygen depletion under different scenarios (e.g., Elliott, 1976; Forster, 1981; McIntire and Phinney, 1965), though many species have never been assessed in a respirometer and their respiration is estimated from empirical models of similar species (Gillooly et al., 2001; Clarke and Johnston, 1999; Robinson et al., 1983). Direct measures of excretion rates include measuring fecal biomass or mass turnover rates in experimental conditions (Pandian and Marian, 1986); as with many species, excretion rates have never been estimated and are inferred from similar species. In accordance with thermodynamics, all inputs to a species should balance the outputs, that is, consumption = production + respiration + excretion. If there is data on consumption, though data on another component is missing (e.g., respiration), then the equation above can be used to estimate the missing component (Fath et al., 2007). To ascertain where the energy/biomass for each consumer enters from, the feeding links and dietary proportions need to be estimated. Dietary composition can either measured directly from gut content analysis (at the site or from previous analysis in a similar system) or indirectly from biochemical analysis or functional feeding groups (Hladyz et al., 2011; Fath et al., 2007). Once the flows between all species have been quantified, typically there are discrepancies in the data or from natural patterns that mean the food web is not at steady, that is the network inputs do not balance the outputs. Network analysis often relies on the webs being a steady-state snapshot; therefore, webs are often balanced by adjusting the flows between species and/or system imports and exports—this is usually done manually or by applying a balancing algorithm (e.g., Baird et al., 2009; Allesina and Bondavalli, 2003). Once balanced, the network structure and functioning can then be assessed and validated (Fath et al., 2007). If one wishes to simulate temporal dynamics within a food web then the webs are not balanced to steady-state, rather a differential equation (with predefined directions of control, i.e., bottom up, top down or mixed) is written for each link within a food web (such as a Lotka-Volterra equation or similar) and these are each integrated (solved) across time-steps.

mature in the absence of major disturbance. That is, in ecosystems with stable environments, the probability of prey being lost reduces, thus the need to have species with generalized, highly adaptable diets reduces. Therefore, it becomes advantageous for species to have specialized diets that are more efficient at processing prey and having greater energetic throughput. On the contrary, highly disturbed or immature communities have low ascendency which means species have multiple parallel dietary links and lower energy throughput, yielding greater stability but reduced energy efficiency.

$$RA = \frac{\mathrm{T}\sum_{i=1}^{s}\sum_{j=1}^{s}\frac{t_{ij}}{T}\log\left(\frac{t_{ij}\,T}{T_{(i+)}T_{(+j)}}\right)}{-\sum_{i,j}t_{ij}\,\log\left(\frac{t_{ij}}{T}\right)} \quad (1)$$

Where s is the number of species; t_{ij} is the flow leaving species i and entering another species j; T is the sum of all flows within the network (total system throughput); $T_{(i+)}$ is the sum of all flows leaving species I; and $T_{(+j)}$ is the sum of all flows entering species j.

Zorach and Ulanowicz (2003) found that of 48 weighted food webs assessed, relative ascendency had a central tendency about ~0.4. Ulanowicz (2009) hypothesized that this may represent a window of vitality, whereby healthy ecosystems persist via a balance between stability and efficiency. It is unclear why the webs have a similar relative ascendency, despite different environments; therefore, it may be premature to consider the "window" as goal ecosystem health or to consider an increase or decrease as good or bad. It would, therefore, be prudent to consider any change in relative ascendency (increasing or decreasing) as a change in ecosystem health.

As an example, Miehls et al. (2009) compared the relative ascendency of the Lake Quinte (Canada) carbon flow network before and after a Zebra Mussel invasion. Relative Ascendency increased by 32%, this was driven by an increase in growth and development (total Ascendency), rather than an increase in redundancy, which may reduce stability (Ulanowicz et al., 2009; Saint-Béat et al., 2015).

Indirect effects

Indirect effects occur when a change in one species affects another species via an intermediate species or pathway (Wootton, 1994). Wootton (1998) identified five ways that indirect effects may present themselves in food webs including interspecific competition, trophic cascades, apparent competition, mutual interference, and mutual exploitation. If a web has strong indirect flows, then trophic cascades can permeate further and more intensely, which can severely impact other species and network flows, thereby reducing robustness (Canning and Death, 2017; Saint-Béat et al., 2015; Zhao et al., 2016). To exemplify use, Salas and Borrett (2011) compared the indirect/direct flows (sum of indirect flows/sum of direct flows) before and after the Zebra Mussel invasion at both Lake Oneida and Lake Quinte (Canada) (Miehls et al., 2009). In both lakes, the invasion of Zebra Mussel doubled the

proportion of indirect flows (relative to the direct flows), thereby suggesting that disruptive cascades could travel further and be more destructive post Zebra Mussel invasion.

Post disturbance recovery

Resilience is the ability of an ecosystem to recover from a disturbance. Therefore, assessing the timeliness to recover and ecological distance between endpoints of disturbed ecosystems provides a direct indicator of resilience (Yount and Niemi, 1990). The indicators monitored could include, but are not limited to, any of those discussed in this article, depending on the management objectives. In many instances, particularly where comparable field cases are not available, it is more sensible to model the recovery of disturbance, rather than disturbing a system for assessment sake—especially if the disturbance is not recoverable. As an example, Pool and Olden (2015) found that following large discharge from Alamo Dam in Bill Williams River Basic (USA) fish communities took 8 days to recover to preflood assemblages.

Abiotic Indicators—Physicochemical

Nutrient concentrations

The most common nutrients of concern in freshwater ecosystems are nitrogen and phosphorus. Total nitrogen is composed of both inorganic (including nitrate'nitrogen, nitrite'nitrogen and ammonical'nitrogen) and organic forms, with inorganic forms being readily available for plant/algae uptake. Total phosphorus includes both dissolved reactive phosphorus (DRP) and sediment-bound phosphorus. DRP is the form of phosphorus that is readily usable by plants/algae. When nutrients are the limiting factor, their increase can result in increased algae and macrophyte growth. Given that nitrogen and phosphorus are often the limiting factor for algal growth in many systems, these nutrients are also those for which defined limits of degraded/not degraded are most commonly managed to. For example, the ANZECC (2000) (Australian and New Zealand Guidelines for Fresh and Marine Water Quality) guidelines for South-Australia recommend "trigger thresholds" for total nitrogen and total phosphorus in lowland rivers at 0.5 mg/L and 0.05 mg/L respectively.

Toxic chemicals

Abnormal concentrations in many bioavailable chemicals can be toxic to aquatic life. Toxic effects vary widely depending on the toxin, species and even sex of individuals. For example, van den Heuvel et al. (2012) found that female yellow perch (*Perca flavescens*) in a bitumen contaminated lake in Alberta (Canada) had markedly higher levels of testosterone levels than female yellow perch in the reference lake. The male perch hormones were unaffected by the contamination. The number of potentially toxic chemicals are vast, with the ANZECC guidelines identifying protection criteria for over 350 toxicants relevant to Australian rivers.

Dissolved oxygen (DO)

Not only can dissolved oxygen monitoring be useful for calculating ecosystem metabolism (see Ecosystem metabolism section), but dissolved oxygen concentration can also directly affect biotic communities. If DO drops too low, then fish can become stressed or asphyxiated. By way of example, moderate reductions in fish and invertebrate production occur when dissolved oxygen is <5 mg/L and 50% of New Zealand common bullies (*Gobiomorphus*) will not survive an hour below 3 mg/L (Dean and Richardson, 1999; Franklin, 2013). DO will cycle across the day as instream plants switch from producing oxygen with photosynthesis to using oxygen in respiration during the night. Thus, many fish and invertebrate species are unable to survive at a site, regardless of high oxygen concentrations recorded during the day. If DO saturation gets too high (supersaturated) then fish can suffer from gas bubble disease. This is a condition similar to decompression sickness that SCUBA divers get, whereby air embolisms occur in tissue and vessels (Doulos and Kindschi, 1990; Espmark et al., 2010; Geist et al., 2013; Mesa et al., 2000). When oxygen saturation is high, fish will try to swim deeper as the added water pressure compresses air bubbles (Boyles Law), however if water levels are also low and pools are missing then fish can suffer blistering (Fig. 1) and struggle to maintain buoyancy (Shrimpton et al., 1990). Furthermore, Mesa and Warren (1997) found that when juvenile salmonids were exposed to greater than 130% saturation for 3.5 h their predator avoidance ability was significantly reduced and they had extensive gas embolism blocks of the lateral line and gill filaments. Depending on where embolisms have occurred, they can take between 2 h and 4 days to dissipate (Hans et al., 1999).

Deposited and suspended fine sediment

Sediment is a natural component of aquatic systems, which is transported as suspended and bedload sediment, mostly at times of high river flows and floods (Clapcott et al., 2011). Small particles (<2 mm), such as clay and silt, are generally transported in suspension, whereas larger particles, such as sand and gravel, are usually transported close to the riverbed during high flow events (Death, 2008; Schwendel et al., 2011). Erosion from land use activities greatly enhances sediment supply both during low and high flow events (Lyons et al., 2000b; Scheurer et al., 2009; Fahey and Marden, 2006). Sediment levels during floods are also considerably higher in agricultural catchments than similar catchments with native vegetation (Burcher and Benfield, 2006).

Excessive deposited sediment can smother animals directly (Fig. 2) and/or motivate them to leave. It can also smother and bind with the epilithon on rock surfaces that is the food for many aquatic invertebrates and lower the nutritional quality of this food. It fills in the interstitial spaces between rocks (Fig. 2) where benthic fish and invertebrates reside or seek refuge during flood events. Stream invertebrates and many fish (e.g., eels) can live at least up to a meter under the stream bed if there are suitable interstitial spaces (Stanford and Ward, 1988; Williams and Hynes, 1974; Boulton et al., 1997; McEwan, 2009).

Fig. 1 A rainbow trout (*Oncorhynchus mykiss*) with gas embolism blisters. Image courtesy of David Palmer.

Direct impacts of excessive suspended sediment on fish include: mechanical abrasion to the body of the fish and more significantly its gill structures, death, reductions in growth rate, lowered resistance to disease, prevention of successful egg and larval development, and impediments to migration. Indirect impacts include displacing macroinvertebrate communities that provide food, and reducing visual clarity so finding prey is more difficult (Scheurer et al., 2009; Fudge et al., 2008; Herbst et al., 2012; Sternecker and Geist, 2010; Kemp et al., 2011; Collins et al., 2011).

In rivers, deposited sediment is most often measured using a bathoscope to estimate percentage cover or by using a corer to estimate fine deposited sediment concentration. In lakes, deposited sediment is usually measured using a grab-sampler or depth corer. In both rivers and lakes, suspended sediment (and clarity/turbidity) is often measured using a Secchi disk (visible depth measured), a clarity tube, or by measuring spectrophotometric absorbencies (Wren et al., 2000).

Temperature

Water temperature can affect both community composition and dissolved oxygen saturation. As most freshwater organisms are ectotherms, their productivity rates will vary with temperature. As an example, water temperature can drastically impact the success of salmonid spawning. Low temperatures (below approximately 6°C) slow egg growth dramatically and may take twice as long to develop, thus increasing their chance of being killed. On the flip side, high temperatures not only reduce a waters capacity to hold oxygen but will also increase the growth and oxygen demand of other taxa which can, in turn, cause the eggs to suffer from hypoxia. High temperatures also increase the rate at which toxins are assimilated and fatal thresholds may be reached faster. In salmonids, maximal egg survival and development has been found to occur between 8°C and 10°C, with no embryos hatching above 16°C. An upper limit of 12°C is recommended for the success of healthy spawning (Jonsson and Jonsson, 2009; Ojanguren and Brana, 2003). Ojanguren and Brana (2003) showed that embryo size at hatching decreased with increasing temperature. Whilst temperature allows embryos to mature faster, this could result in lower yolk conversion efficiency and consequently smaller body size at hatch (Kamler, 1992). Individuals incubated at low temperatures were larger because they benefited from greater yolk resorption and would consequently be larger at the onset of exogenous feeding (Ojanguren and Brana, 2003). Larger body size is key for survival and competitive ability; therefore, embryos that developed at lower temperatures would have considerable competitive advantage (Elliott, 1989; Cutts et al., 1999; Johnsson et al., 1999; Einum and Fleming, 2000).

River flow metrics

High, moderate and low river flow and frequency contribute to different aspects of ecosystem function. For example, floods are important for the natural alteration of a river's channel, adjacent vegetation, meander, clearing interstitial spaces, scouring periphyton and the repositioning of pool/riffle/run sequences. Baseflows are also essential for providing refuge during periods of no rainfall.

Flow metrics are usually derived from continuous flow gauging data (usually measured as discharge or velocity) and often attempt to quantify the magnitude and frequency of key ecological events. For example, a common statistic is the number of times within a year that flow peaks above a defined multiple of the median flow. When interpreting changes in hydrological regimes, it is important to also consider climatic changes, such as the Inter-Decadal Pacific Oscillation, as climate can cause significant interannual variability that may not be registered by short term flow monitoring. These fluctuations can cause rivers in some years to experience low flows with little variability and high flows with high variability in other years. This results in drastic changes in community composition with species who have interannual life histories being most affected (Biggs et al., 2005, 2008).

Physical habitat

The influence of geomorphological structure in determining river ecosystem structure and function often forms the underlying framework for many hypotheses in stream ecology such as the river continuum concept (Vannote et al., 1980), network dynamics

Fig. 2 New Zealand Freshwater Crayfish (*Paranephrops planifrons*) (top) and New Zealand Banded Kokopu (*Galaxias fasciatus*) (middle) smothered in fine sediment. Bottom–stream substrate with interstitial spaces partly clogged with deposited sediment.

hypothesis (Benda et al., 2004) and the riverine ecosystem synthesis (Thorp, 2008; Thorp et al., 2006). Geomorphological structure includes meanders; sinuosity; the area of pools, riffles and runs; gravel composition; riparian vegetation; and stream bed movement. The size of meanders, pools, riffles and runs can be measured directly (usually using aerial photography) or acoustic doppler profilers. Gravel composition is measured directly, often by estimating proportions of stones in each Krumbein Phi class. The area, width, length, nature and species composition of riparian vegetation is often measured directly or from aerial photography. Stream bed movement is often measured by using tracer stones of different size classes and measuring their movement over a defined period. A river with rounded stones can indicate more mobile river bed than one with angular stones too. Metrics that quantify

physical habitat change often include some or all of these parameters. Some metrics are species-specific and only measure (or place more weighting on) parameters relevant to the species being managed. Species specific habitat metrics form the basis of many physical habitat models, such as PHABSIM. In Japan, DHABSIM (Diversity Habitat Simulation) is used to calculate the Eco-Environmental Diversity (EED) Index, which attempts to quantify the diversity of habitat within a defined home-range area. It was found that EED was positively correlated with fish species richness (Sekine, 2017).

Here we have introduced numerous indicator groups of freshwater ecosystem health. No single indicator exists to measure the entirety of ecosystem health, rather each have been developed to measure a particular aspect of ecosystem health. It is often unpragmatic to measure health using indicators from all groups; typically, managers would select measures based on environmental objectives and impacts. If one were to gauge ecosystem health in its entirety, then numerous metrics that indicate on ecosystem structure, function and stability (Table 1) would be required.

Equilibrium Concept in Phytoplankton Communities

Background

In various fields of science `equilibrium' refers to a balance between opposing forces: positive and negative values in an equation, reactants and products in a chemical reaction, production and respiration in an ecosystem, and supply and demand in a market. An equilibrium will be stable or unstable, steady state or dynamic, depending on both the stability of the interacting forces and the control and retro-control mechanisms of the interactions. Since forces are spatially and temporally defined, equilibrium is also spatially and temporally defined, or scale dependent.

The concept of equilibrium was introduced in those fields that are now known as community and ecosystem ecology in the late nineteenth/early twentieth centuries by Stephen A. Forbes and F. E. Clements. These authors had defined ecological communities as organisms interacting with each other (i.e., predator–prey, competitor–competitor, etc.), and had described community evolution toward an ordered stage or condition, which was formalized by Clements through the climax concept. A climax was defined as a community equilibrium stage that is persistent, self-sustaining, and at which further `change' is limited if at all possible. It has a mass balance component that is described by the thermodynamic equilibrium between gross production and respiration at the ecosystem level, and a food web stability component, which is described by the interacting population equilibrium between gains and losses of individuals at the community level. Stable or dynamic equilibrium conditions correspond to the assumption of perfect fitness equivalence among coexisting species in a certain time interval.

Numerical (or biomass) abundance and taxonomic composition are two major components of every guild and community, which, taking into account average individual body size and metabolic rates, give information on the overall energy and matter flow and on its apportionment among species. However, since the early definitions of climax and community persistency, community ecology has mainly used the term equilibrium to refer to a situation characterized by little variability in species composition over time or by the indefinite coexistence of a single species in a mixture.

Focusing on primary producers in terrestrial ecosystems, where producers are large and long-living trees, the temporal scale of the equilibrium conditions can be measured in terms of hundreds of years: the primary succession established on the Lake Michigan sand dunes spans over 11 000 years. In contrast, in aquatic and deep-water ecosystems, where producers are microscopic phytoplankton species, dynamic equilibrium conditions can be described on temporal scales of days, weeks, or months.

Phytoplankton are phototrophs, able to reproduce and build up populations utilizing sources of CO_2, inorganic nitrogen, sulfur and phosphorous compounds, and a number of other elements (Na, K, Mg, Ca, Si, Fe, Mn, B, Cl, Cu, Zn, Mo, Co, and V), most of which are required in small concentrations and not all of which are known to be required by all groups. In addition, several phytoplankton species are known to require vitamins, namely, thiamine, the cobalamines, and biotin.

When light is available, the processes of absorbing light and nutrients to build up biomass and reproduce are carried out at a very high rate by the small phytoplankton cells, measuring between 0.5 μm and *c*. 200 μm as linear dimension. In oligotrophic conditions, ranging from atoll lagoons to coastal marine and open ocean environments, phytoplankton biomass has an average turnover rate of 1.4–2.0 d^{-1}; in eutrophic conditions phytoplankton biomass has a much higher turnover rate, up to 10 times per day in shallow, enclosed, brackish ecosystems (e.g., Mediterranean lagoon ecosystems – such as Lake Alimini Grande, Puglia, Italy).

The high turnover rate of phytoplankton cells has different implications for the equilibrium concept of phytoplankton communities depending on whether it is applied to numerical and biomass abundance or to species interaction and community taxonomic composition. As regards numerical and/or biomass densities, a high turnover rate confers high resilience on phytoplankton communities with respect to spatial and temporal variation of those forces determining phytoplankton production, respiration, and predatory loss. Spatial and temporal patterns of numerical and/or biomass densities in phytoplankton communities are commonly observed at the ecosystem level in lake, lagoon, and marine ecosystems as a result of the equilibrium between phytoplankton requirements and both abiotic and biotic conditions. As regards taxonomic richness and species composition, a well-known tradeoff occurs between turnover rates and population stability, which also holds for phytoplankton communities. The dynamics of phytoplankton populations and the coexistence of a number of species on a limited amount of inorganic and organic resources distributed in a relatively isotropic and unstructured environment has challenged phytoplankton community ecologists over the last 50 years, representing a classic paradox of ecology: that is, the plankton paradox.

The dichotomy between (1) the balance between phytoplankton (numbers and biomass) and limiting factors and (2) the apparent lack of competitive equilibria among species has long been the subject of debate on the equilibrium concept in phytoplankton communities. The critical aspect of phytoplankton communities, which is difficult to explain in the context of the

equilibrium concept, is their taxonomic richness, the number of species being much higher than the number of factors limiting phytoplankton numerical and biomass densities.

Numerical and Biomass Equilibrium in Phytoplankton Guilds (Patterns and Limiting Factors)

Common patterns of numerical and/or biomass phytoplankton variations in space and time reveal the balance between nutrient and light availability and phytoplankton requirements and losses. Numerical and biomass equilibrium in phytoplankton communities is achieved (and can be observed at different scales) as a result of the phytoplankton's high potential resilience, enabling local communities to attenuate unbalanced conditions, and to adapt to fluctuations of limiting factors, which occur on a range of scales from hours to centuries, as well as from meters to hundred of kilometres.

Large-scale patterns of phytoplankton numerical and biomass variation have received much attention. However, evidence from coastal marine ecosystems shows that phytoplankton species manage to balance environmental conditions even while settling along the water column, resulting in deterministic phytoplankton size structures which are perturbed when storm events disrupt water column stability, determining mixing conditions. Since scales are measures of how organisms perceive their environment, and what is small and fast for an organism may be large and slow for another one, variance cascading of ecological processes, from large and slow to small and fast, is a point that deserves the utmost attention.

Large-Scale Patterns of Phytoplankton Numerical and Biomass Variation

Phytoplankton biomass in relatively large bodies of water, for example, coastal marine ecosystems and large and/or deep lakes, shows highly auto-correlated spatial and temporal patterns (Fig. 1), revealing a balance between nutrient and light availability and phytoplankton biomass; descriptions of spatial and temporal patterns and manipulative enrichment experiments have shown that when light conditions allow phytoplankton growth, natural waters are an environment of striking nutrient deficiency, so that competition is likely to be extremely severe. Therefore, a dynamic equilibrium characterizes the auto-correlated phytoplankton biomass patterns, where nutrient and light availability, phytoplankton absorption and reproduction, and zooplankton grazing represent the contrasting forces whose balance varies predictably in space and time at certain spatial and temporal scales.

As regards space, in large aquatic ecosystems (i.e., lakes and sea), three main spatial scales can be detected: one, up to roughly 1 km, which is dominated by horizontal turbulent diffusion; the second, between 1 and 5 km, at which the effect of turbulent diffusion is overridden by growth, grazing, and vertical mixing; the third, at scales larger than 5 km and up to 100 km, at which phytoplankton distribution is controlled mainly by advection, eddies, and upwelling. Diffusion processes imply turbulent diffusion caused by a wide range of movements in three dimensions, whereas advective processes are related to large-scale horizontal and vertical movements of water (and the suspended organisms).

Spatial patterns can be detected as chlorophyll density variation by means of satellite images. Strong auto-correlated spatial patterns occur along transects from the coastline to open waters (Figs. 1a (Adriatic Sea–Mediterranean Sea) and 1b (Lake Michigan – North America), across fronts and up-welling zones, even at the largest spatial scale of the oceanic transects (e.g., the Atlantic transect, Fig. 2), across coast-open sea gradients, eddies, and temperature gradients. In large and deep lakes of North America, 60%–80% of the phytoplankton spatial variation can be accounted for in terms of depth and light, temperature, nutrients and zooplankton density.

As regards time, seasonal variation dominates temporal patterns of phytoplankton densities, particularly in large and deep lakes and marine ecosystems. In temperate lakes, phytoplankton density has two main pulses of increase, in early spring and late summer (Fig. 1c). Early spring pulses are generally dominated by diatoms, which benefit from the availability of silicates, while late summer pulses are generally dominated by dynoflagellates. Larger-scale patterns, following nutrient enrichment from the catchment area of the waters, are also commonly observed in lakes and relatively enclosed seas.

Both temporal and spatial patterns of numerical and biomass densities in phytoplankton communities are related to directional and predictable variations of light limitation, nutrient limitation, and zooplankton grazing. Light and nutrient limitations have independent effects on phytoplankton communities but they also have a synergic effect mediated by water column stability. These relationships will be described in the following sections.

Body size of phytoplankton cells has a deterministic influence on light and nutrient limitations as perceived by phytoplankton cells and on the risk of predation. Light absorption (A) for a spherical cell is directly proportional to pigment-specific absorption cross section (a^*; m^2 mg pigment^{-1}), intracellular pigment concentration (c_i), and cell volume (V):

$$A = a^* c_i V \quad [1]$$

Nutrient requirement U depends on cell mass (BS):

$$U = b\mathrm{BS}^{0.75} \quad [2]$$

where b represents the nutrient uptake of a unitary cell mass. Nutrient uptake per unit of cell mass or volume (V) depends, in turn, on nutrient diffusion toward the cell surface:

$$U/V = 3D\Delta C r^{-2} \quad [3]$$

where r is the cell radius, D is the substrate diffusion coefficient, and ΔC the nutrient concentration gradient from the cell surface to the bulk media. As a consequence of the body size dependency of light absorption, nutrient uptake, and diffusion, the three

phytoplankton size fractions (i.e., pico-phytoplankton (cell diameter <2 μm), nano-phytoplankton (cell diameter between 2 and 20 μm), and micro-phytoplankton (cell diameter >20 μm)), together with the phytoplankton size spectra, show deterministic spatial patterns which are relevant to understanding phytoplankton community organization, although they are not treated specifically in this section.

Light Limitation of Phytoplankton Biomass

Light is a major resource potentially limiting phytoplankton communities. Absorption of light in water is approximately logarithmic:

$$I_z = I_0 e^{-kz} \quad [4]$$

where I_0 is the incident light intensity, z is the water depth, I_z is the light intensity at depth z, and k is the light extinction coefficient. The light extinction coefficient is affected by both solutes and suspended particles, including phytoplankton cells. Even in pure

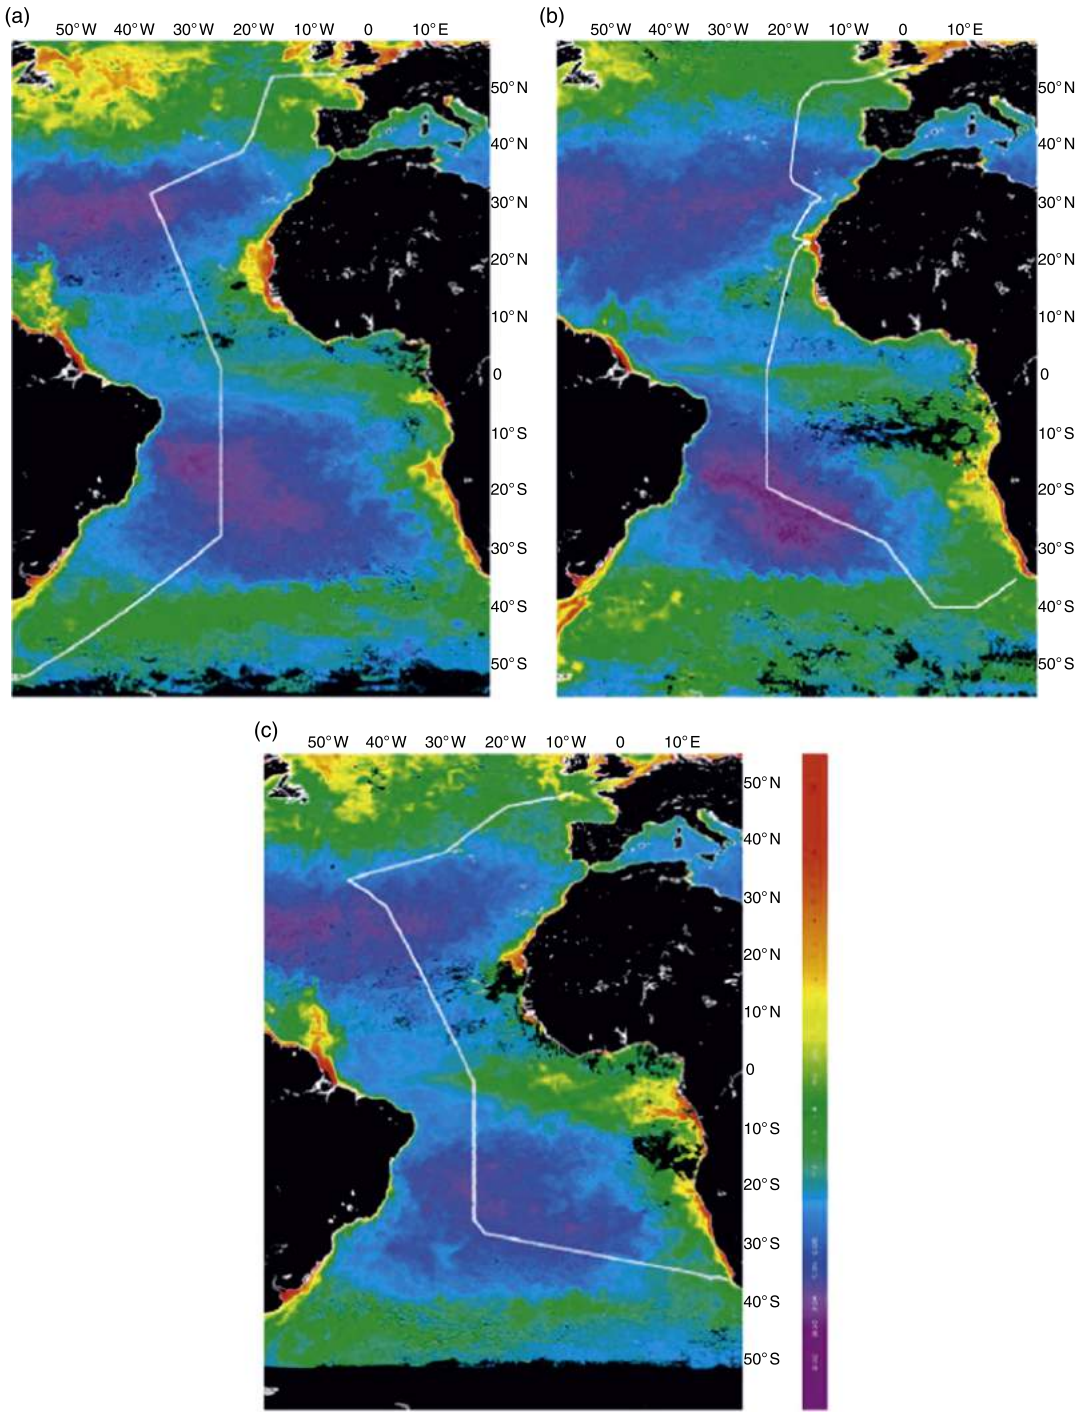

Fig. 2 Composite chlorophyll *a* images of the Atlantic Ocean (551° N–551° S by 601° W–201° E) for the months of (a) May 2004 (AMT14), (b) October 2004 (AMT15), and (c) June 2005 (AMT16). The tracks of each cruise are shown as a white line and are the same on each cruise between the Equator and 201S along the 251W meridian. Reproduced from Robinson, C., Poulton, A.J., Holligan, P.M., et al., 2006. The Atlantic Meridional Transect (AMT) programme: A contextual view 1995–2005. Deep-Sea Research II 53, 1485–1515, with permission from Elsevier.

(distilled) water, only about one half of incident visible light energy remains at a depth of 10 m and only 1% at 130 m. The thickness of the layer which benefits from more than 1% of the incident light (i.e., the euphotic zone) is very restricted in most oceans and lake ecosystems and only in very shallow and clear waters does the euphotic zone reach the bottom. Although many phytoplankton species are adapted to photosynthesizing at relatively low light intensities, the attenuation of light along the water column ultimately limits primary production.

Phytoplankton biomass growth rates are a saturating function of incident irradiance:

$$dB/dt = B_i[\mu_i I_0/(I_0 + K_i) - m_i] \quad [5]$$

where B_i is the biomass of species i, I_0 is the incident irradiance, μ_i is the maximum growth rate per unit biomass, K_i the half-saturation constant of a Monod-type function, and m_i is the phytoplankton biomass loss as a result of respiration, grazing, sedimentation, and washout.

Residence within the euphotic zone is essential for autotrophic organisms. However, since most phytoplankton species, with the major exception of Cianophyceae, cannot regulate their buoyancy and sink in the water column at a speed depending on their size, shape and appendices, as well as on the difference between the density of the cell and that of the water, their permanence in the euphotic zone is closely related to water column stability and mixing depth. Turbulent water movement influences the light to which phytoplankton are exposed. If the mixing depth (d_m) significantly exceeds the euphotic depth (d_e), then the phytoplankton is alternately carried into and out of the illuminated layers; primary production and phytoplankton biomass are strongly limited under these conditions. If $d_e > d_m$, phytoplankton can survive outside the mixing layer, provided they have some means of regulating their vertical position within the euphotic layer. The predominance of flagellates in deep, transparent tropical seas and in the metalimnia of stratificated lakes is made possible largely by their motility. Extensive vertical mixing in lakes and seas generally favors the dominance of diatoms. Apart from the morphological adaptation which enables diatoms to achieve suspension in turbulent eddies, they are adapted physiologically to contend with fluctuating irradiance conditions. Average photic conditions (related to the interaction between spatial and temporal fluctuation in water movements) and the suspension adaptations of phytoplankton strongly affect the rate of biological production, and account for the scarce winter development of phytoplankton at high latitudes.

Nutrient Limitation of Phytoplankton Biomass

Coast-open sea (or open lake) spatial patterns and manipulative enrichment experiments have shown that phytoplankton can become limited by the availability of nutrients when light and temperature are adequate and loss rates are not excessive. Phosphorus (P) and nitrogen (N), which are required in the largest amounts, are the two most common limiting nutrients. Ecological stoichiometry describes the relative requirements of phytoplankton groups with respect to the different nutrients entering the cell's anabolism. As a general average for marine phytoplankton, the uptake ratio of C, N, P, and S is 106:16:1:0.8, respectively. Therefore, the balance between the requirement and the availability of limiting nutrients, whose spatial and temporal variations determine the observed patterns of biomass density, depends on lateral nutrient inputs, on deep water nutrient inputs, and on nutrient turnover rates within the water column. Silicates, for example, strongly limit diatom growth, mainly because of their low turnover rates within the euphotic layer; diatoms are limited at silicate concentrations of below 1.4 mg l^{-1} – which are rapidly reached during the spring blooms. On the other hand, P has a much faster turnover rate than N in the euphotic zone, partly due to inorganic excretion by zooplankton grazers, allowing phytoplankton growth even at very low P concentrations. Since almost all nutrients have sedimentary biogeochemical cycles and terrestrial origins, the coast-open sea(lake) patterns arise from the progressive dilution of terrestrial inputs in aquatic ecosystems.

Taxonomic Composition and Richness Equilibria in Phytoplankton Communities

The equilibrium concept in phytoplankton communities refers to the steady state of a set of phytoplankton populations which are coexisting and hence `sampled together'. This means that while growth and loss processes occur simultaneously in the populations of a guild, it is possible that the result of these processes is the persistence of composition over time.

Persistence can be measured on the timescale of significant environmental variability as well as the turnover and generation times of individual species. In phytoplankton communities, where generation times are measured in hours and days, a few weeks of similar densities and community composition can be considered indicative of equilibrium or steady-state persistence. Cases of steady-state persistence are: the co-dominance of five species (*Planktothrix agardhii*, *Limnothrix redekei*, *Dictytosphaerium* sp., *Cyclotella meneghiniana*, and *Cryptomonas erosa*) over nine unperturbed weeks in El Porcal Lake (a gravel pit in Central Spain); the dominance of a number of species in 31 fluctuating sites of a wetland (La Safor, Mediterranean Spanish coast); and the persistence of some nondominant species (*Peridinium willei* and *Planktonema lauterbornii*) over more than 3 weeks in the water column mixing period in Las Madres Lake (Central Spain).

The observation of persistence within phytoplankton communities is also related to the spatial and temporal scale of the observer. From a practical point of view, it is a rule for researchers to sample at least weekly. This is because the time generation of microalgae is from 0.3 to 3 days, so a week is a representative timescale of population response. From a statistical point of view, a similar assemblage must be found in at least three successive samplings in order for it to be considered stable. Therefore, the minimum timescale commonly utilized to evaluate persistency may cover more than 50 generations of the smallest species.

The equilibrium concept in phytoplankton communities is supported by evidence of nutrient and resource limitation, of interspecific competitive coexistence and of trait-specific competitiveness ability among phytoplankton species. The high resilience of phytoplankton communities also supports the achievement of equilibrium conditions among species pairs or species groups on a

given time and spatial scale. The relatively small number of dominant species in phytoplankton communities supports this simplification.

However, the equilibrium concept in phytoplankton communities is not supported by the large number of coexisting species in a medium which can be considered relatively isotropic and unstructured; nor is it supported by the well-known tradeoff between population growth rate and stability. These considerations, which were first raised by Hutchinson, led to the famous `paradox of the plankton' and disequilibrium or nonequilibrium theories.

Therefore, the two branches of theories (i.e., equilibrium vs. nonequilibrium) address two different aspects of phytoplankton community structure: the relationship between pairs or small groups of species on the one hand, and the organization of phytoplankton communities as a whole, on the other hand.

Equilibrium Theories

The original description of persistent or steady-state phytoplankton communities was focused on dynamic features of temporal changes in phytoplankton and was based on resource-partitioning concepts, and more specifically on competition. The Tilman extension of the Volterra equilibrium model to primary producers represented the basis of equilibrium theory in phytoplankton communities.

To explain the `plankton paradox', equilibrium theories propose that several species of phytoplankton can coexist in true competitive equilibrium if they are collectively restricted from further growth by different nutrients. The relative abundance of the coexisting species can thus be controlled by the ratio of limiting resources. The hypothesis assumes that (1) several nutrients are in relatively short supply; (2) growth of each species is restricted by a single nutrient or a unique combination of several nutrients, according to the Liebig's law principle that the growth of each population occurs at the rate permitted by the most limiting factor; and (3) different species have different uptake capacities for the various nutrients. Equilibrium approaches to the phytoplankton paradox are deduced theoretically and verified in chemostat experiments. Equilibrium conditions between species pairs on two limiting resources can be described in terms of the competitive ability of each species with respect to each resource, as described by the resource requirement at equilibrium:

$$R^* = DK_i/(r_i - D) \qquad [6]$$

where R^* is the equilibrium extracellular resource density, r_i is the maximum growth rate, K_i is the resource concentration at which growth is half of the maximum growth rate and D is the dilution rate, taking account of resource concentrations at the start and resource inputs; the result of the equilibrium can be also derived graphically (**Fig. 3**).

Laboratory competition experiments have supported the relevance of resource competition as a process that determines the species composition of phytoplankton communities. Under chemostat-type steady-state conditions phytoplankton species limited by different resources can coexist in equilibrium; and the relative abundance of coexisting species is controlled by the ratio of limiting resources. Tilman has shown this with 76 competition experiments between the two species of freshwater algae *Asterionella formosa* and *Cyclolella meneghiana* under a wide range of Si:P ratios.

As results of these experiments *Asterionella formosa* was observed to be competitively dominant when both species were phosphate limited; *Cyclolella meneghiana* was dominant when both species were silicate limited; and both species stably coexisted when each species was growth rate limited by a different resource. Extension of this approach from a two-species system to multispecies experiments has supported the equilibrium theories; however, they are able to explain only a small proportion of the diversity and species richness of natural phytoplankton.

The Plankton Paradox, or 'Supersaturated' Communities

The remarkable diversity of phytoplankton communities in aquatic ecosystems is recognized as a 'paradox', because many more species with similar requirements (to be satisfied from the surrounding environment, apparently isotropic or unstructured) co-occur than is expected in a competitive equilibrium. The high level of richness of phytoplankton communities in the same water body has been called by G. E. Hutchinson the `plankton paradox' and the resulting communities are defined as `supersaturated'.

The plankton paradox was based on the assumption that: (1) phytoplankton guilds are assembled on the basis of differential growth rates among species, determined by the availability of inorganic nutrients; (2) species interact through competition for mineral nutrients, and (3) pelagic habitats are closed homogeneous systems. However, pelagic habitats are open systems, intraspecific competition is generally stronger than interspecific competition, and nutrients (as well as some other limiting factors) vary in time and space at different scales.

Therefore, in general terms, competitive equilibrium is never expected when a virtually complete competitive replacement of one species by another occurs in a time (t_c) of the same order as the time (t_e) taken for a significant seasonal change in the environment which reverses the competitive ability of the interacting species. Thus, ideally there are classes of cases:

1. $t_c \ll t_e$, competitive exclusion at equilibrium complete before the environment changes significantly;
2. $t_c \cong t_e$, no equilibrium achieved; and
3. $t_c \gg t_e$, competitive exclusion occurring in a changing environment to the full range of which individual competitors would have to be adapted to live alone.

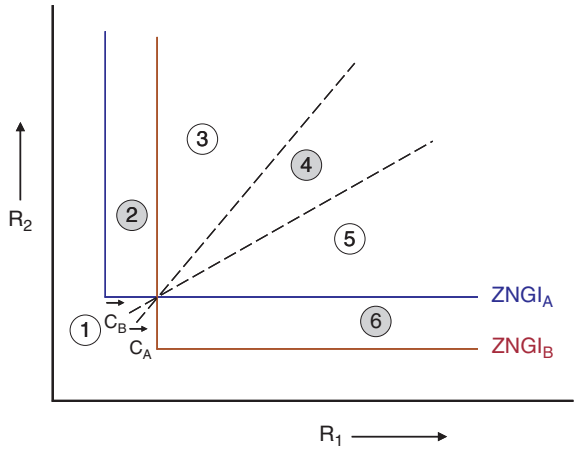

Fig. 3 Potential coexistence of two species for two limiting resources. ZNGI*i* (*i*=A and B) curve represents the amounts of the two resources which must be available for the species *i* to maintain an equilibrium population. Dashed lines are consumption vectors (CA and CB) of the species A and B, which represent the total consumption rates of resources by the species at equilibrium. ZNGI's curves cross at a two-species equilibrium point. ZNGI's curves and consumption vectors define six regions. Habitats which have resources points within the region 4 will have both species coexisting, while species A will dominate in habitat 2 and 3, and species B will dominate in habitat 5 and 6. Reproduced from Tilman, David; *Resource Competition and Community Structure*. © 1982 Princeton University Press. Reprinted by permission of Princeton University Press.

Case 2 gives rise to a number of nonequilibrium theories concerning phytoplankton communities. A nonequilibrium model assumes that fluctuations or disturbances occur with sufficient frequency to disrupt the course of competitive exclusion, but not so frequently as to force species to adapt to the overall variability. High biodiversity is attained when fluctuations or disturbances keep the competing populations far from equilibrium, thus allowing more species to coexist.

Two types of fluctuation can be distinguished.

1. Fluctuations caused by internal nonequilibrium dynamics generated by competitive interactions.
2. Fluctuations caused by external factors, such as oscillation in light and nutrient supply due to the seasonal cycle or less predictable factors such as changes in weather and hydraulic conditions. Moreover, spatial heterogeneity is an important reason to expect coexistence of species. Even in seemingly homogeneous environments, such as the open ocean, meso-scale vortices and fronts generate barriers preventing complete mixing and competitive exclusion.

Nonequilibrium Theories

Fluctuations determined by internal feedback factors

It is usually thought that in the absence of any externally imposed environmental fluctuation, phytoplankton communities will approach competitive exclusion and ecological equilibrium. However, phytoplankton continue to fluctuate erratically even when the environment is completely constant and uniform. This is because the high turnover rates and feedbacks in the phytoplankton system itself generate complex dynamics preventing the system from coming to equilibrium, the resulting community being referred to as 'supersaturated'.

It has been shown that competition for limiting resources leads to chaotic dynamics if multiple species compete for at least three resources. Theoretical models have shown that these dynamics depend crucially on the relationship between the resource requirements and the resource consumption characteristics of the species. Competition generates: (1) stable coexistence, if species consume most of the resources for which they have high requirements; (2) oscillations and chaos, if species consume most of the resources for which they have intermediate requirements; and (3) competitive exclusion, with a winner that depends on the initial conditions, if species consume most of the resources for which they have low requirements.

Fluctuations determined by external factors

Environmental disturbances that occur so frequently as to preclude competitive exclusion in phytoplankton species lead to a nonequilibrium, promoting coexistence and enhancing diversity. General analytic models show that resource supply in a situation of nonequilibrium can allow coexistence of species competing for the same fluctuating limiting resources. Theoretical results showing that resource fluctuations allow coexistence have been confirmed experimentally for phytoplankton competing for key nutrients (phosphorous and ammonia) and light. The coexistence-promoting mechanism believed to operate in variable environments is the creation of temporal niche opportunities that allows competitors to utilize the scarce resources at different times.

The coexistence of two or more species under variable resource supply conditions is possible when species exhibit a gleaner-opportunist tradeoff that entails a tradeoff between a low minimum resource requirement and a high maximum growth rate. A

gleaner species grows better at low resource levels as a result of a low minimum resource requirement. An opportunistic species is one that can take advantage of high resource levels.

Environmental fluctuations such as a pulsed nutrient supply can increase phytoplankton species diversity, facilitating coexistence. In equilibrium theory, the gleaner or `affinity specialist' is able to exclude the other competitors if the system tends toward the equilibrium resource level of the minimum R^* value. Fluctuations in resource levels can prevent this. If nutrients are sinusoidally fluctuating, then a species with a high growth rate, able to take higher advantage of high resources levels (i.e., opportunistic or velocity specialist), might coexist with a slower-growing but more efficient (gleaner) population. These results can be generalized to a wide class of growth functions and to pulsed variability of nutrient supply simulating periodic upwelling events.

Light fluctuations may also have an effect on the outcome of competition between phytoplankton species, leading to nonequilibrium coexistence. Light is never homogeneously distributed, even in a well-mixed water column; the light intensity at the surface always exceeds the light intensities at the bottom and a spatial gradient in light distribution with depth, coupled with diffusion of algal cells through the water column, may allow coexistence of many species of phytoplankton as well as their vertical segregation. Temporal variability in light supply can also have significant effects on the outcome of competition between phytoplankton species when species exhibit the gleaner-opportunist tradeoff. Rapid light fluctuations can reverse competitive dominance from a gleaner to an opportunist; slow light fluctuations can change the identity of the dominant competitor and also lead to the stable coexistence of competitors. Coexistence is easiest between species that are highly differentiated along the gleaner-opportunistic tradeoff.

Summary

The concept of 'equilibrium', as a balance between contrasting forces, may resemble to be not appropriate to describe structure and dynamics of phytoplankton communities, where species show extremely high population growth rates and high temporal and spatial variability. However, the small body size of phytoplankton individuals, which strongly affects individual energetics and population potential to growth, actually enable populations to adapt rapidly to varying environmental conditions, increasing population resilience and facilitating the achievement of equilibrium conditions. In fact, in terms of biomass, phytoplankton communities emphasize patterns of equilibrium with the environmental limiting factors both in space and in time. Most of the debate on the occurrence of some kind of equilibrium in phytoplankton communities deals with the taxonomic composition and richness of phytoplankton communities, being synthesized by the `plankton paradox' concept. Hutchinson introduced the term `plankton paradox' to describe the coexistence of so many phytoplankton species under limiting and relatively isotropic conditions, suggesting that whenever rates of competitive exclusion and of environmental changes are very close, a `dynamic equilibrium' with supersaturated communities can be observed. The `plankton paradox' is still unsolved; however, factors determining competitive abilities of phytoplankton species, potentially leading to `stable equilibrium conditions', as well as factors contributing to the maintenance of supersaturated communities under `dynamic equilibrium' conditions, have been emphasized. They include the intrinsic variability of phytoplankton populations and the occurrence of external factors of disturbance contributing to increase the patchiness in the apparently isotropic and unstructured water column.

The Failure of Present Estuarine Management From Ignoring Ecohydrology

Throughout the world, estuaries and coastal waters have experienced environmental degradation. Present proposed remedial measures based on engineering and technological fix have been unable to restore the ecological processes of a healthy, robust estuary and, as such, will not reinstate the full beneficial functions of the estuary ecosystem. The successful management of estuaries and coastal waters requires ecological engineering, that is, an ecohydrology-based, basin-wide, approach. Ecohydrology is the science that relates hydrological processes to the biological dynamics of ecosystems at various spatial and temporal scales. The ecohydrology concept was developed in the framework of UNESCO's International Hydrological Programme (IHP). It hypothesized and empirically confirmed in a number of demonstration sites that the ecological services of rivers and lakes can be restored by using hydrology to regulate biota dynamics and vice versa. The synergic integration at the basin scale of various ecohydrological measures based on ecological needs provides the scientific background for twinning ecosystem variables in order to enhance the carrying capacity and the resilience of ecosystems while promoting positive socioeconomic feedbacks.

Implementing the ecohydrology approach necessitates getting away from present management practices based on regulation focused on the geography (e.g., individual municipalities or counties) or on individual, specific activities (e.g., farming and fisheries, water resources, urbanization, shipping) without integrating among localities and users so as to consider the ecosystem. Without this change in thinking and management concept, estuaries and coastal waters will continue to degrade, whatever integrated coastal management plans are implemented because these ignore the basic ecology fact that the land, the river, the estuary, and the coastal waters are connected by being in the same ecosystem.

Can science-based management save estuaries and coastal waters? About environmental management the main thing that can be reliably managed is the human behavior and practices. The main thing that ecological engineers can do is to highlight the role of ecohydrology in offering a robust, science-based way to quantify both the present human impact on the degradation of estuarine and coastal ecosystems and the likelihood of success of various remediation measures in improving the health of these ecosystems. Remediation measures include changing human behavior and practices in using the land and water resources. These measures also include boosting the ecosystem robustness by manipulating the ecosystems so as to reinforce the beneficial ecological feedbacks in these ecosystems. The eventual success of these measures relies on adopting an ecohydrological approach.

Estuaries and coastal areas are traditionally among the most highly impacted waters. For centuries human populations have settled and have benefited from the services provided from these highly productive ecosystems. During the last century, the human population worldwide has increased by a factor of about 10 in coastal areas of many developing countries and probably a factor of 4 for most developed countries, as a result of natural population growth and migration. As a result the carrying capacity of coastal ecosystems is exceeded and this has commonly led to a serious environmental degradation of estuaries and coastal waters worldwide. This is best demonstrated for the megacities and harbors in the Asia Pacific region where the best of engineering practices have failed to provide a healthy environment to 100 million people. In most sub-Saharan African countries, migration to the coast is still increasing the coastal population yearly at typically 5%–8% because coastal areas provide free access to food (fisheries) and timber (mangrove trees) and hope for jobs in harbors and coastal cities.

In view of this ever-increasing human impact on coastal ecosystems, corrective or preventive measures based on an ecohydrological approach should be considered instead of just engineering measures as has been the general approach so far. This does require changing the legislation that is a quagmire for the management of estuarine and coastal waters. The successful implementation of an ecohydrology approach to managing estuaries and coastal waters must be based on a sound scientific knowledge of the ecosystems functions and dynamics.

The ecohydrological approach has been tested successfully in various locations and systems (salt marsh estuary, mangrove estuary, and coral reefs) around the world, particularly in the Guadiana Estuary in temperate Portugal and Darwin Harbor and the Great Barrier Reef in tropical Australia. The health of these ecosystems was demonstrated to depend on the connectivity between estuarine and coastal waters, on the links between physical and biological processes, on the drainage basin hydrology, and on the disturbance caused by human activities. It was possible at these sites to quantify the human impact on the ecosystem health, and the impact of remedial activities.

Major observed impacts in estuarine and coastal ecosystems are the increasing eutrophication risk, toxic algal bloom events, muddiness and siltation of estuaries and coastal erosion, and also modifications in biodiversity resulting in the loss of traditional ecosystem services (e.g., coastal fisheries) and having negative socioeconomic impacts (e.g., the loss of income and employment for coastal communities). The degradation is most dramatic for coastal coral reefs located within the estuary and in its coastal waters (Fig. 1). Coral reefs possess the highest diversity of any marine and most terrestrial ecosystems and they greatly benefit humanity by building islands and atolls, by protecting shorelines from coastal erosion, and supporting fisheries and diving-related tourism. Coastal reefs are being destroyed at an accelerating and unsustainable rate worldwide (e.g., up to 50% in the last 15 years

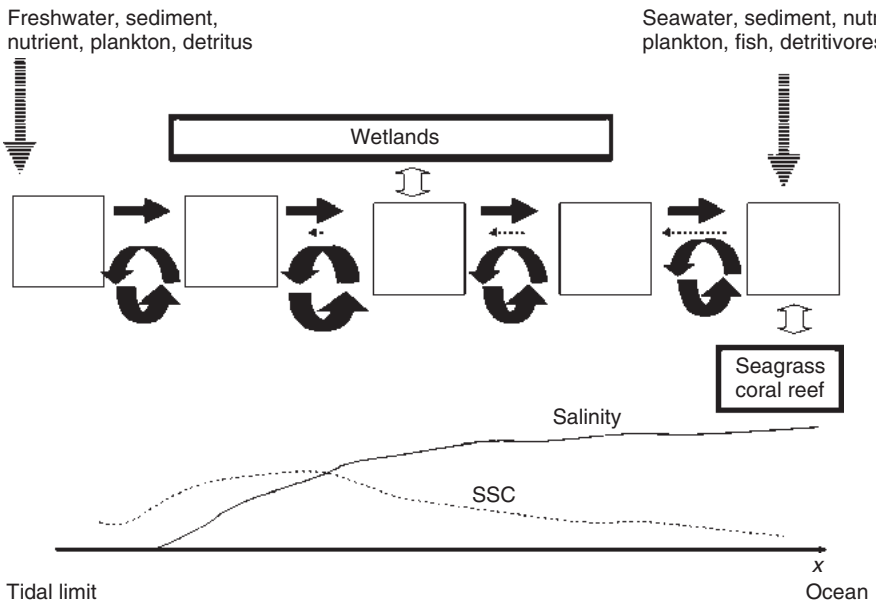

Fig. 1 The physical submodel schematizes the estuary as a series of cells connected to each other by advection driven by both the river discharge (straight thick arrows) and the salinity-induced currents (broken thin arrows) and by tidal mixing (curved arrows). The open boundary conditions are located at the tidal limit where a riverine flux of water and waterborne particles is imposed, and at the mouth where an oceanic flux is also imposed. The estuary also exchanges water and waterborne particles with the wetlands (perimarine wetlands, mangroves, and salt marshes) and the seagrass and the coral reefs. The suspended solid concentration (SSC) commonly has its largest value in the turbidity maximum zone. The salinity increases in the estuary toward the mouth.

in some Asian countries) by human activities that can be devastating (e.g., mining for limestone, fishing with explosives and cyanide, infilling for urbanization) or threatening but possibly manageable (e.g., increased runoff of mud, nutrients, and pesticides from adjacent river catchments, overfishing, and global warming). The present coral reef strategy principle relies on drawing a line around coral reefs and protecting the corals inside that line. It is politically convenient and it ignores the fact that the land and the reef are ecologically connected through the rivers. It thus invariably fails worldwide wherever the reefs are impacted by runoff that is modified in quantity and quality by human activities on land.

Intensive agriculture practices, urban sewage, and manure from pig farms and cattle feedlots provide quantities of nutrients that reach the estuary by runoff or as groundwater and can cause eutrophication to a level dependent on the robustness of the estuary. The riparian vegetation upstream and the vegetation in salt marshes and/or mangrove swamps downstream play a bottom-up role as buffers that retain nutrients and reduce the load remaining in the estuary. Also, filter-feeders and grazers (e.g., fish and bivalves) can exert a top-down control on primary producers' biomass (**Fig. 2**) and improve water quality. Indeed, bivalve suspension feeders have also been suggested as a means to control algal blooms, in both the marine and freshwater regions of the estuary. However, bivalve excretion increases the pool of nutrients available for other primary producers as the macroalgae like *Ulva* sp. or the colony-forming *Phaeocystis* sp.

Studies also provide evidence that changes in the river discharge impact on the structure of estuarine plankton, fish, and bivalves communities. In fact, the response to low-flow periods has been recognized as one of the most important factors in structuring biota, both in the estuary and coastal waters. During low-flow periods, a decrease in the concentrations of those nutrients reaching the sea may occur, especially in dammed rivers, since the silicates (Si) trapped in the dam is not reintroduced downstream in the system, as may occur with N and P (as consequence of the use of fertilizers in agriculture). In such situation, Si can be limiting to the growth of diatoms, and may contribute to the occurrence of toxic algal blooms. The reduction of low flows by dams and irrigation is thus a threat to the health of estuarine ecosystem.

Dams reduce river flows. These high river discharges are ecologically important because they 'feed' the coastal waters with sediments and nutrients, ensuring the adequate nutrients Si:N:P ratios and promoting coastal waters productivity There is increasing evidence that coastal fisheries landings are related to the high river flows discharge and not climate factors, as has been demonstrated for South Portugal, the East Mediterranean coast, the Black Sea, and the Gulf of Carpentaria. For instance in the Guadiana Estuary and coastal waters following high-discharge periods, catches are dominated by planktivorous fish like the anchovy (*Engraulis encrasicolus*) and the sardine (*Sardina pilchardus*). This is because high river discharges promote primary and bacterial production from increased nutrient loading and organic matter loading. They also increase larval and juvenile survival because higher turbidity associated with greater sediment loads reduces predation. They facilitate the retention of early life-history stages and increase the survival. They provide an environmental clue (salinity gradients) for shrimps and fish to migrate towards the estuary where tidal wetlands (salt marshes and mangroves) are used as a nursery for the larvae and juveniles. In areas where the continental shelf is narrow, the effects of freshwater runoff can reach the upper continental slope, especially during upwelling events, increasing larval physiological

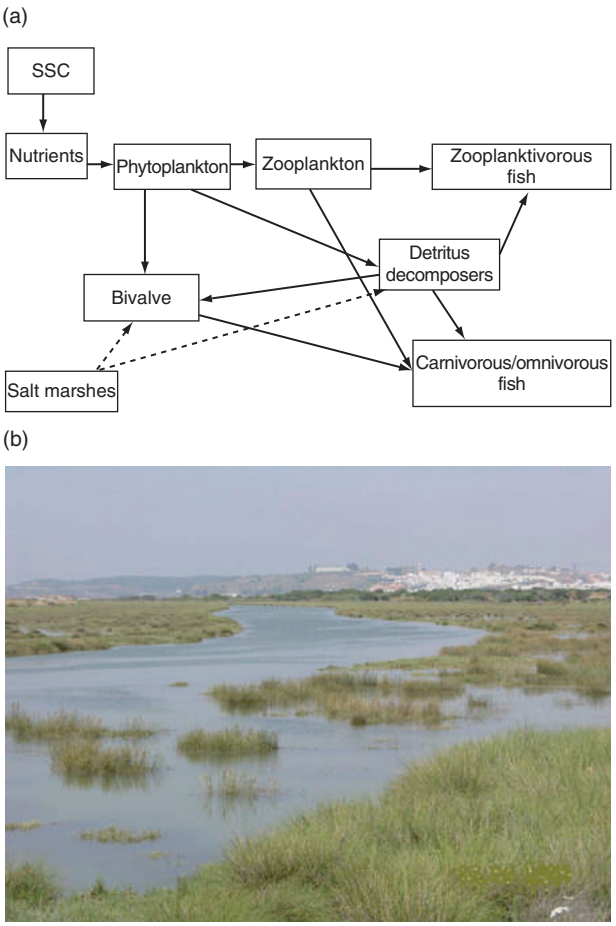

Fig. 2 (a) The biological submodel for the Guadiana Estuary, Portugal. The salt marsh is modeled as a source of detritus and juvenile bivalves (broken arrows). At death all organisms become detritus (not shown). SSC, suspended solid concentration. (b) Photograph of Guadiana Estuary salt marshes and encroaching urbanization in the background.

condition and consequently decreasing larval mortality. These larvae can find abundant food in winter because during this rainy period the freshwater discharge is usually high, promoting salinity stratification and the development of a shallow surface mixed layer where phytoplankton that can bloom long before the spring phytoplankton blooms occur.

These examples show that the regulation of estuarine and coastal biota processes is highly dependent on the river discharge. This offers politicians and water resources managers the option to try to improve estuarine ecosystem health on a case to case basis by modifying mostly one variable.

The estuarine ecosystem modeler is faced with complex processes and feedback processes between the physics and the biology, which in practice cannot be fully quantified because the data are inadequate. For this reason, models should only be used as tools that help to explain the reality, steer field researchers towards studying key processes that most control estuarine health, and help quantify the impact of human activities on the health of estuarine ecosystems. Models should not be seen as able to replace reality and the need for field observations. Governments often want to cut budgets for field research and instead promote the cheaper option of modeling. Estuarine ecosystem models are simply unable to provide reliable answers without field studies.

Estuarine ecohydrology models are based on the knowledge and quantification of physical and biological processes controlling the ecosystem. They can quantify the likely effectiveness of ecohydrology solutions for eutrophication by two opposite ecological approaches, namely top-down control on vegetation by herbivores, or bottom-up control of nutrients loads. They can also quantify the likely effectiveness of dealing with eutrophication by regulating the river flow, for example, allowing freshets. The control of nutrient input into the system can be obtained by creating or restoring wetlands, which will act as buffers and trap nutrients. These wetlands, when located near the coast, also protect the coast from erosion, thus protecting inland infrastructures and coastal populations. The cumulative effect of wetland creation and controlling the riverine nutrient loads through changes in land-use practices invariably lead to an efficient decrease in nutrients in the estuary, often larger than the sum of the two impacts individually. For each of these solutions and for each case, models should be used before field implementation of the remediation activities to assess likely improvements in the health of the ecosystems and to compare these with observations, so as to be able to separate human from climate effects.

A top-down approach can be considered and modeled for control of eutrophication, that requires the knowledge about the ecological food web in the area: who eats who, when, and how much. The quantification of these processes and relations is basic to the selection of the most effective grazer species. In some cases manipulation of the food web could be necessary, for example, (1) controlling the density of the predator species; (2) allowing the herbivore species – that will control the vegetation growth – to become more abundant, and (3) introducing bivalves to filter the water and reduce the risk of toxic algae blooms. Such is the case in San Francisco Bay where eutrophication is inhibited because half of the water is filtered daily by bivalves that were accidentally introduced.

Toxic algal blooms are frequent in nutrient-enriched estuaries and, in particular, in dammed estuaries, and estuaries with reduced flushing and very long residence times. For instance, Tokyo Bay in Japan and the Pearl River estuary in China have respectively about 100 and 200 days of toxic algae blooms every year in various areas. Bivalves have been successfully tested to control phytoplankton blooms and reduce eutrophication and toxic algal blooms. Another way to control algal blooms is to generate freshets (i.e., freshwater discharge pulses). During freshets, with the duration of typically few days, the amount of nutrients available for phytoplankton growth increases, causing a decrease in competitive exclusion mechanisms and the consequent increase in phytoplankton diversity. In turn this promotes the growth and the diversity of zooplanktonic species. Consequently, more zooplankton species may play a regulatory role by controlling phytoplankton density and 'avoiding' the phytoplankton growth of just few species, therefore reducing the risk of toxic algal blooms.

The use of freshets to control algal blooms requires a profound knowledge of the system on a case to case basis, in order to determine the timing, the magnitude, and the duration of the freshet. A poor timing of freshets could negatively impact species that use the estuaries and its tidal wetlands as a nursery ground, if the freshet interferes with the natural recruitment of these species, for instance by flushing out the eggs and larvae.

Estuarine ecohydrology models have been developed and verified for few ecosystems, recently for the Guadiana Estuary in Portugal and Darwin Harbor and the Great Barrier Reef in Australia in a program supported by UNESCO-ROSTE, NOAA, AIMS, and the University of Algarve/CCMAR. The explicit aim was to offer science-based solutions to management. The ecohydrology models due to its holistic approach is a tool that aims to facilitate an interaction between scientists, economists, the public, and decision-makers to promote the ecologically sustainable development of an estuary and its coastal waters.

An Estuarine Ecohydrology Model

This model is based on the dominant ecohydrological processes in tidal estuaries. The model is best suited to estuaries that are fairly well mixed vertically. In practice this constraint is adequate for many applications because critical conditions in estuaries commonly arise during low-flow conditions brought upon by dams and water extraction. These conditions are exacerbated by excess nutrients from, typically, sewage discharge, effluent from feedlots, and fertilizers from farming. Thus the physical submodel, sketched in **Fig. 1**, views the estuary as a series of connecting cells that exchange water by advection as result of the river runoff and the saltwater inflow, and by tidal mixing. The upstream cell receives freshwater, sediment, nutrient, and freshwater plankton. The downstream cell receives seawater and marine sediment, nutrients, and plankton. Cells can also exchange water and particulates with fringing wetlands both in the fresh and the saline region of the estuary. The physical processes and the open boundary conditions control the salinity distribution and the suspended solid concentration (SSC; both are sketched in **Fig. 1**). An estuarine turbidity maximum (ETM) commonly prevails. The salinity and SSC distribution vary both spatially and temporally.

This physical submodel model is linked to an ecological submodel that is adapted to local conditions and is based on the results of field studies. This submodel is also a simplification of the processes in estuaries, focusing on the dominant processes in terms of mass transfer. The resulting ecological submodel for the Guadiana Estuary is shown in **Fig. 2** and that for Darwin Harbor in **Fig. 3**. **Fig. 2** and **3** show the minimum level of complexity of the model that is necessary to capture the ecology of these estuaries. There are important features that are found in both temperate and tropical estuaries, namely (1) the importance in turbid waters with a very long residence time of the suspended solid in releasing for biological productivity particulate nutrients, (2) the dominance of the microbial loop especially near the ETM zone, (3) the role of detritivores and bivalves, and (4) the role of wetlands as a source of detritus as well as mainly a nursery ground. These tidal wetlands are made up of mangroves in the tropics and salt marshes in the temperate climates. A key commonality also is the importance of river floods, even short-lived ones, in attracting coastal fish to migrate up-estuary by kinesis or taxis by swimming following environmental clues, primarily salinity gradients.

The model has been successfully verified against field data for these two estuaries.

Estuarine Ecohydrology Applications

For the Guadiana Estuary the model is particularly useful in quantifying the importance of short freshets in enhancing plankton and fish diversity (**Fig. 4**). It is also useful in quantifying the importance of tidal wetlands (salt marshes) in reducing eutrophi-

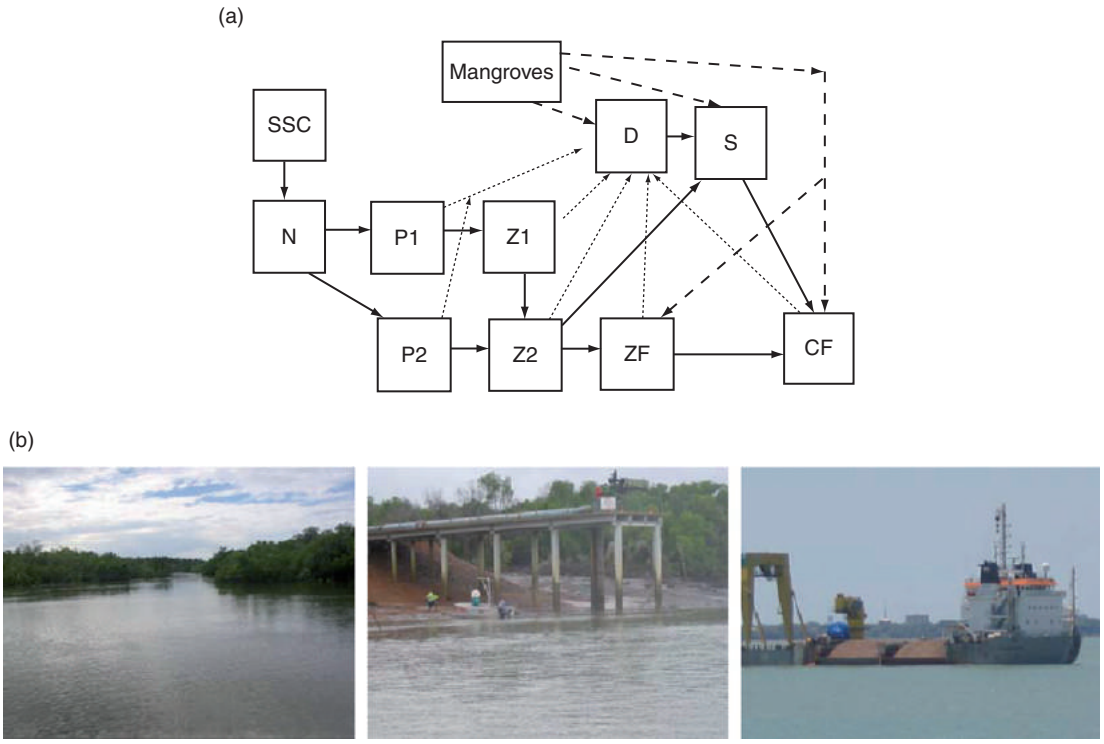

Fig. 3 (a) The ecology submodel for tropical Darwin Harbour, Australia. SSC, suspended solid concentration; N, nutrients; P, phytoplankton (two dominant species with different turnover rates); Z, zooplankton (two dominant species with different preys and turnover rates); D, detritus; S, detritivores; ZF, zooplanktivorous fish; CF, carnivorous fish. The mangrove swamp is modeled as a source of detritus as well as a source of young detritivores and fish (thick broken arrows). At death all organisms become detritus (thin broken arrows). (b) Photographs in Darwin Harbour of pristine mangroves in traditional Aboriginal land on the west bank (left), aquaculture industries encroaching in mangroves in the southern region (middle), urbanization and port development on the east bank removing all natural habitats (right).

cation (Fig. 5). This demonstrates clearly two management strategies that can be used to alleviate eutrophication and promote biodiversity and estuary robustness, that is, create freshets from the dam and creating or restoring tidal wetlands. The ecology submodel also highlights the key role of bivalves in filtering the water, suggesting another strategy of manipulating bivalves to reduce eutrophication.

Similarly for Darwin Harbor the model is useful to assess to what degree the estuarine ecosystem health may degrade – and what level of human disturbances in the drainage area is admissible to maintain a reasonable ecosystem health – as a result of future human activities in the catchment, particularly the urbanization of Darwin, the impact on the estuarine health of nutrient enrichment from sewage discharges, and the destruction of tidal wetlands (mangroves) for shipping and industry.

Coral Reef Ecohydrology Model

The sustainable development of coastal waters and coral reefs is dependent on development policies for land and water resources. To quantify this dependency, it is necessary to understand the key biological and oceanographic processes governing the health of these coastal ecosystems. These processes are then incorporated in a coral reef ecohydrological model that can predict reef health. The immediate use and role of this model is to help answer two key questions for managers. These two key questions are as follows: (1) to what extent do changes in quality and quantity of terrestrial runoff lead to reef degradation by generating phase shifts – the process by which areas formerly dominated by corals are overgrown by algae; and (2) is the reef capable of sustaining or rebuilding its biodiversity by self-seeding if remediation measures are implemented on land and in rivers to moderate the human impact?

The estuarine ecohydrology model has been modified and applied to coastal coral reefs that are subject to human impacts from (1) land runoff resulting in an increase in suspended sediment, increased water turbidity, and increased nutrient concentration, and (2) from global warming resulting in increased bleaching events in summer. The coral reef physical submodel (Fig. 6) is more complex than that of estuaries because it considers also river floods and tropical cyclones that both negatively affect coral reefs, and the oceanographic connectivity between reefs that enable self-seeding as well as the connectivity, that is, the exchange of coral planulae between reefs. The biological submodel (Fig. 7) is based on the competition for hard substrate space between the algae

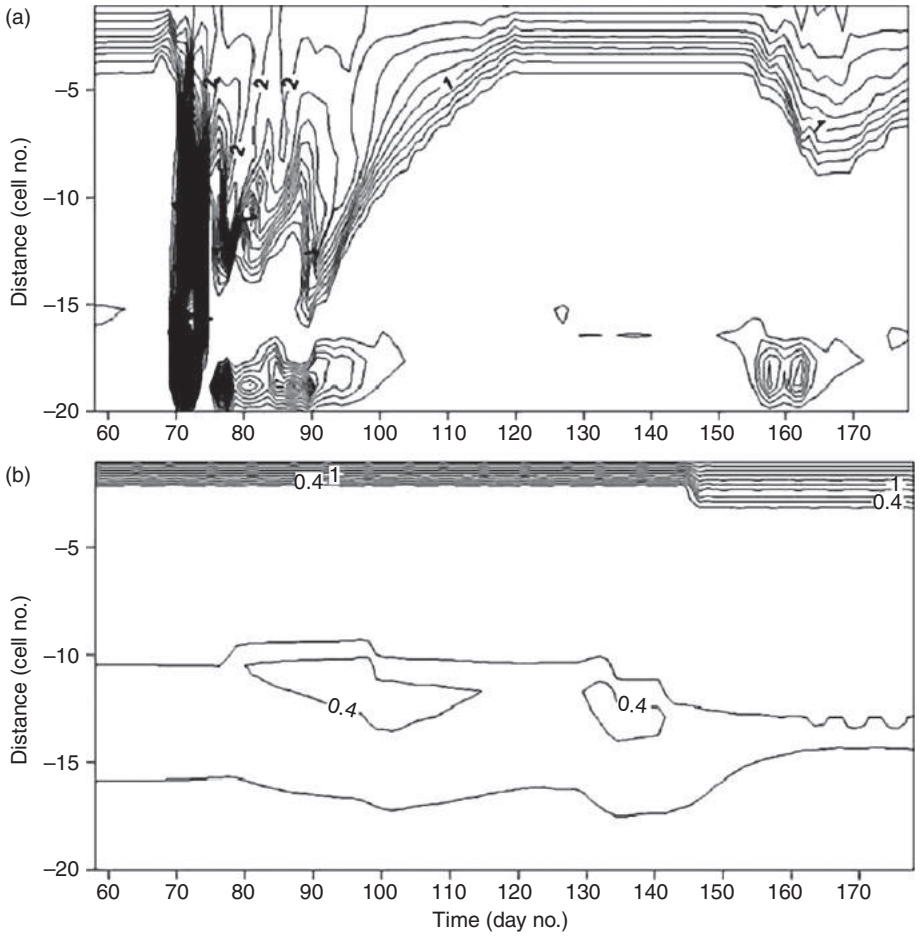

Fig. 4 Predictions of the along-channel distribution (cell 20, river mouth; cell 1, tidal limit = 60 km) of zooplanktivorous fish biomass in the Guadiana Estuary, Portugal, in 2004, (a) without and (b) with the Alqueva dam. The dam construction was completed in 2003 and in 2004 the dam suppressed all freshets. The 'without dam' calculation assumes natural river hydrographs that were calculated from rainfall data. The 'with dam' calculation uses the observed river runoff as the open boundary condition at the tidal limit. To convert biomass to concentration for fish $2.8 \approx 2.87\ g\ cm^{-2}$.

and the coral. The coral is preyed upon by crown-of-thorns starfish, whose population dynamics is also modeled. Algae are preyed upon by herbivorous fish that in turn is preyed upon by carnivorous fish that is harvested by people. Suspended sediment concentration (turbidity) and nutrients modulate all these processes. Additionally the success of recruitment of juvenile coral decreases with increasing algal cover on the hard substrate. Global warming results in an increased mortality of adult corals.

Coral Reef Ecohydrology Applications

This model was developed for the Great Barrier Reef and successfully verified against an extensive data set. It has also been applied to reefs in Micronesia (Guam, Palau, and Pohnpei).

The people of Micronesia have centuries, as opposed to decades in the Great Barrier Reef, of experience in dealing with coral reefs upon which their livelihood depends. They have traditional management policies that highlight the need to manage human activities that affect coral reef ecosystems. In many islands, the people have direct ownership of coral reefs and the fisheries they support. For Micronesia, the model highlighted the beneficial role of mangroves, and this has resulted in a legislative protection of mangroves in at least one state (Palau). For Guam, Palau, and Pohnpei, the study demonstrated the need for integrating land-use and coral reef management. In islands where some form of traditional leadership still exists, this model has measurably helped in improving local environmental planning because these traditional leaders take into account the long-term, multigenerational impacts of activities in the development of environmental policies. Thus ecohydrology and ecological engineering are accepted and becoming a powerful tool in such islands.

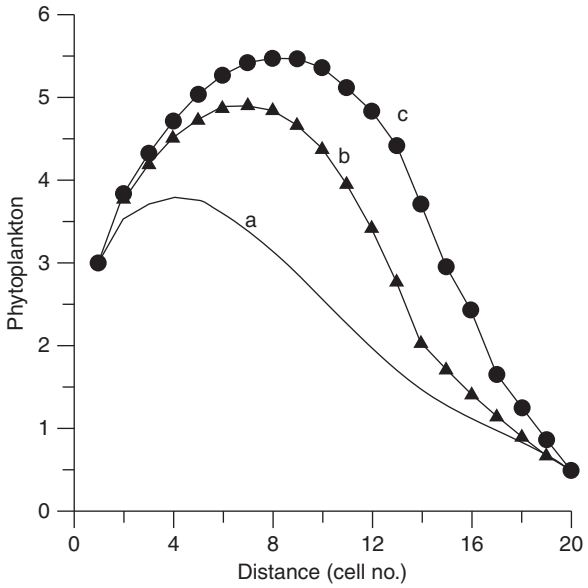

Fig. 5 Predictions of the along-channel distribution (cell 20 = river mouth; cell 1 = tidal limit = 60 km) of phytoplankton biomass for (a) low-flow conditions (2 $m^3 s^{-1}$) in summer in the Guadiana Estuary, Portugal, for (b) a hypothetical doubling of the riverine nutrient inflow as a result of planned irrigation farming using Alqueva dam water, and (c) with in addition the removal of the salt marshes. To convert biomass to chlorophyll *a* concentration 3.5 $\approx$ 7.8 $\mu g\ l^{-1}$.

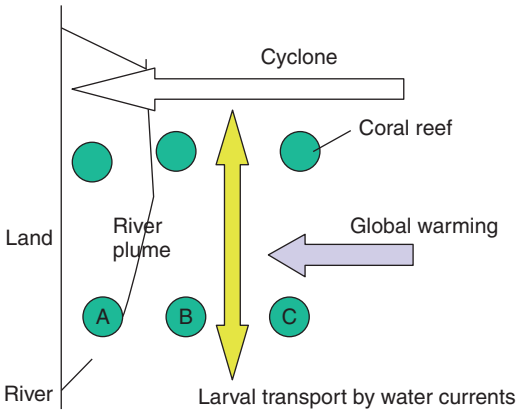

Fig. 6 Sketch of the dominant physical processes in the coral reef ecohydrology model. A, B, and C represent coral reefs with increasing distance from the coast.

For the Great Barrier Reef of Australia, the model suggests that land use has contributed to the degradation of the health of the Great Barrier Reef and to an increased frequency and intensity of crown-of-thorns starfish infestations. The model also predicts that the health of the Great Barrier Reef will significantly worsen by the year 2050 as a result of global warming. The model demonstrates to managers and politicians that it is worth improving land-use practices to recover the health of the Great Barrier Reef ecosystem. Indeed the model suggests that much-improved land-use practices will enable some regions of the Great Barrier Reef to recover, even with global warming. However, in the longer-term the situation is more gloomy, because the model suggests that if global warming proceeds unchecked only biological adaptation can prevent a collapse of the Great Barrier Reef health by the year 2100.

This ecohydrology model can be used to quantify the effectiveness of remedial measures on land. In theory thus ecological engineers can offer to economists and politicians the hard science data on ecosystem health that are needed to develop management policies that integrate socioeconomics and ecosystem health, as a first step towards planning an ecologically sustainable development. In practice however for the Great Barrier Reef and most corals reefs worldwide outside of a few islands in Micronesia, ecological engineering may have little impact because of two phenomena. Firstly there is the 'tragedy of the commons' where few

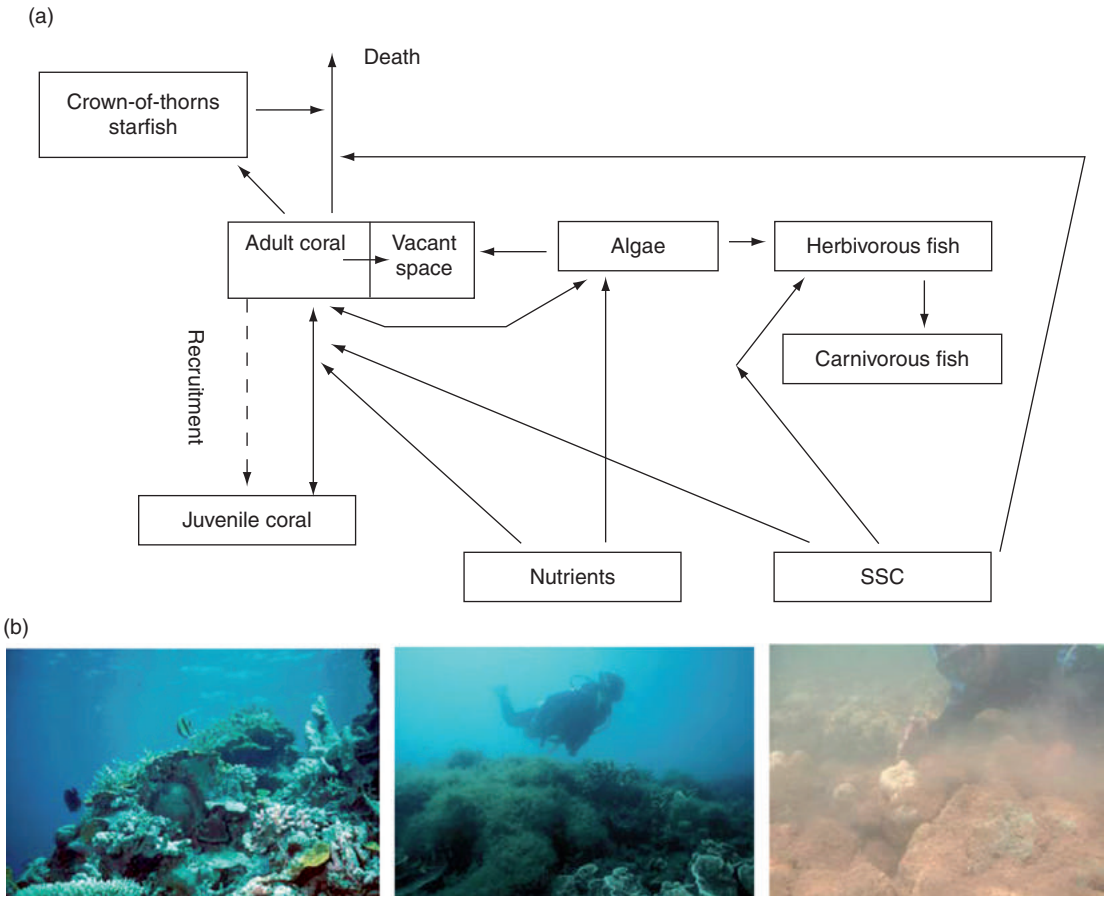

Fig. 7 (a) Sketch of the dominant biological processes in the coral reef ecohydrology model where SSC indicates the suspended sediment concentration that is a measure of turbidity. (b) Underwater photographs of a healthy coral reef (left), a coral reef overgrown by algae – this is a stable ecological state as long as poor water quality prevails (middle), a coral reef smothered and killed by mud from eroded soil from the adjoining river catchment (right).

take any responsibility but everyone has ownership – this is the same problem which has resulted in the collapse of fisheries worldwide. Secondly there is uncertainty in the science of cause and effects of reef degradation – some of that uncertainty is inherent to science, much is purposely manufactured – and this uncertainty helps politicians and decision-makers to justify ignoring the problem and implement no remedial measures.

Conclusions

Estuarine and coastal habitats are increasingly degraded worldwide. Ecohydrology demonstrates unambiguously that the land, the river, the estuary, and coastal waters are components of the same ecosystem. They are connected through a number of physical and biological processes that determine environmental health. Traditionally, the estuarine management strategy relies on technology and engineering fixes and it neglects ecohydrology principles; these strategies invariably fail to maintain ecosystem health and the ecological services that these ecosystems provide. Coastal coral reef management strategies worldwide also neglect ecohydrology science and also invariably fail. Ecohydrology science offers a number of solutions, including top-down and bottom-up ecological manipulation as well as the use of created or restored wetlands to help restore the health of estuarine and coastal waters. Combined with some technological fixes, such as the creation of freshets and smarter land-use, ecohydrology science offers an ecologically sustainable management strategy for estuaries and coral refs. Worldwide the implementation of this science-based strategy will most likely stall, and estuaries and coastal waters will continue to degrade, until a political solution is found to the quagmire (i.e., the present estuarine and coastal management framework) which basically ignores ecosystem ecology.

Estuarine and coastal areas suffer an increasing pressure from anthropogenic activities. Modifications of physical and chemical parameters affect biodiversity and hamper the traditional uses and services by local populations. Estuarine and coastal management relied, traditionally, on technology and engineering fixes, neglecting the ecological equilibrium of the systems.

Alternatively, ecohydrology science, based on the interplay between hydrology and ecology, offers a number of sustainable and long-lasting solutions to increase the robustness and to restore the health of estuarine and coastal waters. Estuarine ecohydrology models aiming to facilitate the interaction between scientists, economists, the public, and decision-makers have been developed and verified for a few ecosystems, recently for the Guadiana Estuary in Portugal and Darwin Harbor and the Great Barrier Reef in Australia, under a scientific program supported by UNESCO-ROSTE, NOAA, AIMS, and the University of Algarve/CCMAR.

The Estuarine Quality Paradox Concept☆

Michael Elliott, University of Hull, Hull, United Kingdom
Victor Quintino, University of Aveiro, Aveiro, Portugal

Introduction

Estuaries are naturally stressed, highly variable ecosystems and at the same time they are exposed to high degrees of anthropogenic stress (Elliott and Whitfield 2011). In marine and estuarine areas those stressful conditions are manifest as a suite of symptoms which relate to the structure and functioning of biological communities (Pearson and Rosenberg, 1978; Gray and Elliott, 2009). This article describes the similarity between the features of organisms and assemblages in both estuaries and anthropogenically-stressed areas and hence it emphasizes the difficulty of distinguishing natural from human-induced stress in estuaries - this concept was named the *Estuarine Quality Paradox* by Elliott and Quintino (2007). The features of coping with stress, whether natural or anthropogenic, relate to both areas. The analysis of such estuarine features requires extensive data relating to the structure and functioning of the ecological communities and their response to natural and anthropogenic perturbations (Quintino *et al.*, 2006).

Estuaries are regarded as stressed ecosystems because of their highly variable salinities which are also, by definition, usually lower than the adjacent coastal areas (Elliott and McLusky, 2002; McLusky and Elliott, 2007; Elliott and Whitfield, 2011). The other physico-chemical elements such as hydrographic patterns (current speed and direction, density stratification, riverine and tidal inputs, etc.), temperature, nutrient levels, pH, etc. are also more variable than in corresponding coastal and marine sites and so this variability will also contribute to stress on the biota if they are not able to withstand it (Whitfield *et al.*, 2012). Although the estuarine fauna and flora has freshwater elements, such as tubificid oligochaetes, which are of course able to tolerate very low salinities but are stressed by any salinity greater than 0.5, most estuarine biota are marine-derivatives in which the assumption is that therefore they will be stressed in salinities below 30 (McLusky and Elliott, 2004). Hence typical estuarine species, that is, those such as certain nereid polychaetes which occur mainly in estuaries, do not appear be stressed by variable salinity and indeed appear to thrive because of it.

Salinity is the predominant environmental master factor in estuaries in which the balance between the river flow and marine ingression, especially in tidal systems, creates the salinity gradient (Smyth and Elliott, 2016). Salinity then has a large physiological effect on marine organisms which may encounter estuarine conditions (Smyth *et al.*, 2014). This in turn produces a set of ecological patterns and gradients called the Remane curve and ecotones where systems merge (Whitfield *et al.*, 2012; Basset *et al.*, 2013b). This article aims to consider these features in the estuarine biota but places more emphasis on the macrobenthic invertebrates given their often sessile nature and an inability to move rapidly if the conditions are unsuitable. However, it emphasizes that the patterns also are shown in other organisms, such as opportunistic macroalgae and fish.

Anthropogenically and Naturally Stressed Areas

Environmental impact assessments in the coastal and estuarine environments have by necessity focused on the faunal and floral community structure, and especially the analysis of soft sediment benthic infaunal communities, given its sessile nature (McLusky and Elliott, 2004; Gray and Elliott, 2009). This large body of information has led to conceptual models against which change is measured. This is typified by the Pearson-Rosenberg paradigm (Pearson and Rosenberg, 1978), an extensively-used conceptual model and similar to the Rhoads-Germano model cited in North America (Rhoads and Germano, 1982). It has long formed the basis of approaches and indices used to detect and explain anthropogenic stress, especially that for various forms of organic enrichment. The latter includes many causes of environmental damage such as pulp and paper mill waste discharge, urban sewage effluent discharge, the later stages of oil pollution on beaches and the seafloor, and the disposal of organic dredged sediments (Gray and Elliott, 2009).

The Pearson-Rosenberg model and others shows the well-accepted features of anthropogenically-stressed benthic infaunal communities, which are well known (**Table 1**) (Elliott and Quintino, 2007; Gray and Elliott, 2009). They are characterized by small organisms, high abundances of few species, low diversity and low individual biomass organisms with the potential to produce high biomasses. In addition, they have a high turnover and biological productivity (as shown by an increase in the production to average biomass ratio, P/B) and a dominance by oligochaetes and oligochaetiform polychaetes. This is summarized in ecological terms by the increase in r-strategists and the replacement of k-strategists, that is, the dominance of fast breeding, poor competitors over the long-lived, good competitors in ecological terms. Furthermore, given the inputs of organic matter (from sewage, etc.) and/or fine sediment, which also accumulates organic matter, in areas of low hydrodynamic energy such as estuaries, there is dominance by detritus and deposit feeding organisms in which food rather than space is the limiting factor (McLusky and Elliott, 2004). The assemblage is tolerant of adverse environmental conditions such as low oxygen and low and variable salinity,

 doi:10.1016/B978-0-12-409548-9.11054-1

Table 1 Conceptual basis and assumptions inherent in macrobenthic impact studies

(A) Natural state
(1) A natural macrobenthic assemblage either tends towards or is in an equilibrium state;
(2) Under nonimpacted conditions, there are well-defined relationships (which therefore may be modeled) between faunal and environmental (abiotic) variables;
(3) In approaching the normal equilibrium state, the biomass becomes dominated by a few species characterized by low abundance but large individual size and weight;
(4) Numerical dominance is of species with moderately small individuals, this produces among the species a more even distribution of abundance than biomass;
(5) The species are predominantly K-selected strategists;
(B) Moderate pollution
(6) With moderate pollution (stress), the larger (biomass) dominants are eliminated, thus producing a greater similarity in evenness in terms of abundance and biomass;
(7) Also, with moderate pollution, diversity may increase temporarily through the influx of transition species;
(C) Severe pollution
(8) Under severe pollution or disturbance, communities become numerically dominated by a few species with very small individuals;
(9) Those small individuals are often of opportunist, pollution-tolerant species which have r-selected strategies;
(10) Under severe pollution, any large species that remain will contribute proportionally more to the total biomass relative to their abundance than will the numerical dominants;
(11) Thus, under severe pollution, the biomass may be more evenly distributed among species than is abundance;
(12) However, under severe pollution, species with large individuals may be so rare as to be not taken with normal sampling;
(13) The change in assemblage structure with increasing disturbance is predictable, follows the conceptual models and is amenable to modeling and significance testing;
(D) Recovery
(14) Opportunists are inherently poor competitors and may thus be out-competed by transition species and K-strategists if conditions improve;

McManus and Pauly (1990) also consider that under normal conditions:
(1) The biomass-dominants will approach a state of equilibrium with available resources;
(2) The smaller species are out of equilibrium with available resources;
(3) The abundances of the smaller species are subject to more stochastically controlled variation than the larger species.

especially where many polluting discharges have a freshwater component. However, it is especially of note that these characteristics have been seen in many stressed ecosystems not only those found in the marine and estuarine environment (Odum, 1969, 1985) (**Table 2**).

The estuarine stress response has been observed in the macroflora (especially seaweeds) as well as the macrofaunal benthic community (e.g., Wilkinson *et al.*, 2007) and it relates to individual (physiological) stress (Smyth and Elliott, 2016). Polluted estuarine areas, especially those influenced by organic discharges, sewage run-off and industrial effluent which are noted for high levels of nutrients, become dominated by opportunistic green algae, occasionally forming large mats which then adversely affect the estuarine functioning such as the ability of wading birds to feed on the infaunal prey. Large concentrations of ephemeral green filamentous algae naturally occur in transitional waters bodies which usually have large nutrient inputs from riverine and anthropogenic sources and, depending on the relative riverine and tidal influences, retain these nutrients (Wilkinson *et al.*, 1995). Estuaries naturally show the transition from a highly diverse marine flora, with many red and brown macroalgae as well as green macroalgae in the outer regions, to an upper estuarine algal flora dominated by the Chlorophyceae. Under high organic and nutrient loading the features produce macroalgal mats, with the latter often displacing seagrass beds (de Jonge and Elliott, 2002).

Not only is such an estuarine stress detected at the community level but also at the physiological level of biological organization (Smyth and Elliott, 2016; Solan and Whiteley, 2016). Methods such as Scope-for-Growth (SFG) have long been used to good effect as an indication of anthropogenic stress in marine and estuarine areas (e.g., Widdows and Johnson, 1988; Mazik *et al.*, 2013). However, Navarro (1988) and Guerin and Stickle (1992) both indicate the way in which salinity stress, through natural freshwater inputs, reduces energetic budgets. Therefore, as SFG shows reduced physiological fitness due to salinity stress, it is difficult to use the technique for detecting and separating anthropogenic stress from natural stress.

Methods for detecting anthropogenic stress include those centred on the primary community structural variables (abundance, species richness, and biomass) and derived community structural variables (such as diversity indices, abundance (A/S) and biomass (B/A) ratios, evenness indices) (see Quintino *et al.*, 2006; McLusky and Elliott, 2004; Gray and Elliott, 2009; Borja *et al.*, 2011; Ducrotoy *et al.*, 2011 for references and details). They also include functional analyses such as those involving feeding guilds (as in the Infaunal Trophic Index, ITI, by Word, 1990) and their responses to elevated organic levels (as in the AZTI Marine Biotic Index, AMBI, by Borja *et al.*, 2000 and the Benthic Quality Index, BQI, by Rosenberg *et al.*, 2004, among others). For example, detritus and deposit-feeding dominance is reflected in any assessment of trophic analysis. There are many numerical and graphical methods which aim to detect and illustrate stress in benthic communities (e.g., see the 27 families of methods in Gray and Elliott, 2009, with references). For example: Species-Abundance-Biomass curves (Pearson & Rosenberg, 1978), Abundance-Biomass-Comparison curves (Warwick, 1986), the AMBI and diversity indices, etc. (e.g., Borja *et al.*, 2007; Rosenberg *et al.*, 2004). Despite this, these methods detect naturally as well as anthropogenically-stressed areas. Given that all impact assessments are required to

Table 2 Trends expected in stressed ecosystems: the estuarine features as applied to topics summarized by Odum (1985)

Feature	*Odum (1985)*	*Estuarine feature*	
Energetics	1. Community respiration increases	Yes, in general:	Higher respiration in larger populations of small organisms and organic rich sediments; possibly with osmoregulatory stress caused by salinity change
	2. P/R (production/respiration) becomes unbalanced	Unknown	Possibly due to higher respiration caused by salinity stress
	3. P/B and R/B (maintenance: biomass structure) increase	Yes, in general:	Higher P/B in smaller and shorter-lived organisms, for example, dominance by oligochaetes and small polychaetes; high turnover organisms
	4. Importance of auxiliary energy increases	Depends on meaning:	Increase in allochthonous energy input as well as relatively high autochothonous production
	5. Exported or unused primary production increases	Depends on meaning:	Export of material to adjacent sea areas but also import from catchment
Nutrient cycling	6. Nutrient turnover increases	Yes, but:	Because of physical characteristics - high nutrient inputs and use
	7. Horizontal transport increases and vertical cycling of nutrients decreases (cycling index decreases)	Partly the case:	Both horizontal and vertical cycling is high, depending on flushing characteristics and residence time; importance of material movement from pelagic to benthic system
	8. Nutrient loss increases	Yes, but:	because of the physical characteristics—high nutrient loss through flushing and export through predators
Community structure	9. Proportion of r-strategists increases	Yes:	High abundances of few, short-lived stress-tolerant species
	10. Size of organisms decreases	Yes:	High abundances of small organisms dominate in benthos; low megafaunal populations
	11. Lifespans of organisms decreases	Yes, in general:	On average, benthic and planktonic community composed of short-lived organisms; planktonic organisms adapted to prevent flushing of populations
	12. Food chains shorten because of reduced energy flow at higher trophic levels and/or greater sensitivity of predators to stress	Not necessarily:	Food chains can be very short (macrophytes-herbivorous ducks) but also very long because of the opportunistic nature of many predators; while marine predators (stenohaline marine fishes) may be reduced there are many other fish and bird predators
	13. Species diversity decreases and dominance increases; if original diversity is low, the reverse may occur; at the ecosystem level, redundancy of parallel processes theoretically declines	Yes (first part); unknown (second part):	Classic estuarine community in all components of few species; exacerbated with distance landward in the estuary; competition between species may be less than competition within species
General system-level trends	14. Ecosystem becomes more open (i.e., input and output environments become more important as internal cycling is reduced)	Not necessarily so;	Internal cycling is important even though nutrients and organic matter are delivered from external sources
	15. Autogenic successional trends reverse (succession reverts to earlier stages)	Unknown:	
	16. Efficiency of resource use decreases	Not necessarily so:	While there may be an excess of organic resources, leading to export, much is used within the system to support high predator populations
	17. Parasitism and other negative interactions increase, and mutualism and other positive interactions decrease	Not shown:	
	18. Functional properties (e.g., community metabolism) are more robust (homeostatic-resistant to stressors) than are species composition and other structural properties	Yes:	Ability of the system to withstand stressor-effects without adverse impacts

Box 1 The Estuarine Quality Paradox (modified and expanded from Elliott and Quintino, 2007)

This states that the dominant estuarine faunal and floral community is adapted to and reflects high spatial and temporal variability in naturally highly stressed areas such as estuaries and other transitional water bodies. Despite this, the community has ecological features very similar to those found in anthropogenically-stressed areas thus making it difficult to detect anthropogenically-induced stress in estuaries. Furthermore, as estuaries are naturally organically-rich areas then the biota has similarities to anthropogenically-organic rich areas such as due to urban and industrial organic effluents. Stress therefore becomes a subsidy which benefits those organisms able to tolerate the conditions. Because of this, there is the danger that any impact assessment methods which are based on those features and used to plan environmental improvements are inherently flawed.

detect or predict anthropogenic change against a background of natural variability, the so-called signal-to-noise ratio, then this becomes particularly difficult in highly variable estuaries.

As suggested above, the natural (non-anthropogenic) characteristics of estuaries, and many other transitional waters are highly influenced by freshwater inputs leading to a reduction in salinity, high organic production and organic inputs in the estuary and from the adjoining catchment and wetlands (the allochthonous and autochthonous production). This produces a low diversity of all components but often high abundances of those species which can tolerate the variable and (assumed to be) environmentally stressful conditions (e.g., McLusky and Elliott, 2004, 2007). The features of anthropogenic stress coincide with those for natural stress (**Tables 1** and **2**) (from Elliott and Quintino, 2007). This makes it particularly difficult to determine the effects of human activities in estuaries and other highly variable but organically-enriched transitional waters: that is, the estuarine benthic communities have many of the same characteristics as areas suffering from human-induced stress. This is the so-called "*Estuarine Quality Paradox*." This is especially the case in the mid to upper estuarine regions which receive organic matter from natural autochthonous and allochthonous sources and where the Freshwater-Seawater Interface is highly variable in space and time and thus has naturally stressful conditions (Day *et al.*, 2012).

In ecological theory terms, in having the characteristics described above, it is questioned whether the estuarine community is a climax one or whether it is just held as a subclimax level, that is, whether it has reached a final, stable assemblage or is attempting to attain such a final state. The estuarine fauna and flora do not show recovery to maintain a full k-strategist complement, and large individuals (both fauna and flora) are not present, hence there is a naturally lower Biomass/Abundance ratio and higher Abundance/Species Richness ratio, and the trophic system is dominated by organic/detritus-responsive invertebrates and nutrient-reflective algae. This then suggests that the variable state is paradoxically stable.

The Estuarine Quality Paradox

These features, in particular the difficulty of separating natural and anthropogenic stress in estuaries, produced the concept of the "Estuarine Quality Paradox." Since being introduced in the paper by Elliott and Quintino (2007) and mentioned in Dauvin (2007), this concept has been cited and used on many occasions (e.g., Dauvin and Ruellet, 2009). It is defined in Box 1.

There are many systems globally which aim the assess changes to the natural status because of human activities and pressures (Borja *et al.*, 2016). The Estuarine Quality Paradox has repercussions for the implementation of all environmental management systems which all rely on an ability to detect a change in estuarine flora and fauna from a defined reference condition. These systems include the European Union Water Framework Directive (Borja *et al.*, 2000, 2007, 2010b; Apitz *et al.*, 2006; Breine *et al.*, 2007; Coates *et al.*, 2007; Hering *et al.*, 2010), the National Land and Water Resources Audit in Australia (Heap *et al.*, 2001), the Clean Water Act in the US (USEPA, 2002) and the 1998 Water Act in South Africa (Adams *et al.*, 2002). In some of these quality assessments, which require environmental managers to determine a pass–fail criterion for good status, it is suggested that the Estuarine Quality Paradox will make it more difficult to determine that criterion and hence make any boundaries more uncertain (see Alvarez *et al.*, 2013; Basset *et al.*, 2013a).

In turn, the conclusion that a usual estuarine condition is similar to a stressed and polluted condition has repercussions for indications of what constitutes health and the criteria showing poor health, for example, see Tett *et al.* (2013). Hence the presence of symptoms such as opportunistic species should not necessarily be taken as a sign of anthropogenic stress. Similarly, this affects the ability to determine when recovery is taking place and whether this is also against the background of variability (Verdonschot *et al.*, 2013; Elliott *et al.*, 2007; Borja *et al.*, 2010a, 2011a,b; Duarte *et al.*, 2015).

As this paradox has now been accepted, as indicated by a large number of citations, by relying on the presumption that estuaries are stressed areas then there is the need to break out of this circle. This requires science and environmental management either to fully quantify and explain the natural variability and stress and subtract this from measures of the anthropogenic stress or alternatively by having an alternate set of methods which can detect anthropogenic stress against a background of natural stress. This may involve relying not on the structure of the system (the features at one time such as species richness or diversity) but to consider whether an estuary is still functioning as an estuary. Hence, we recommend that assessments should use functional symptoms as well as structural ones (see also de Jonge *et al.*, 2006; Hooper *et al.*, 2005). This agrees with Odum (1985), who

suggested that functional properties may be more robust than structural ones (de Jonge *et al.*, 2006). However, this contrasts with management recommendations and procedures such as the EU Water Framework Directive, which relies heavily on structural features such as taxonomic richness, diversity and abundance. Because of this, we may need different methods for the open coast than for the estuaries.

Estuarine Resilience, Environmental Homeostasis and the Stress-Subsidy Continuum

With regard to organismal physiological response and stress tolerance, Margalef (1981) emphasized that stress leads to organisms implementing homeostasis as a stress-reduction or stress-avoidance mechanism (see also Costanza *et al.*, 1992). Odum (1985) then regarded stress as a detrimental or disorganizing influence and McLusky and Elliott (2004) considered that with regard to polluting effects, stress reduces the fitness-for-survival. Individual organisms have an ability, termed homeostasis, to adapt to and withstand changes in environmental conditions that may be outside their optimal ranges. This is expanded here to the term *environmental homeostasis* to emphasize the ability of each level of biological organization, be it at the individual, population, community or ecosystem level, to withstand/tolerate/adjust/adapt to stressors. Thus, environmental homeostasis here is taken to be the ability of the estuarine organisms to achieve a stable state by compensating for the estuarine environmental physico-chemical variability; this may also be regarded as ecological robustness in which the resistance of the ecosystem to change and the resilience of the ecosystem to recover from change become emergent properties (Borja *et al.*, 2010a; Duarte *et al.*, 2015; Tett *et al.*, 2013). Hence it is concluded here that homeostasis can operate at any level of biological organization: individual (physiological) homeostasis, population homeostasis, community homeostasis and ecosystem homeostasis. It is hypothesized that in estuaries, the high natural variability and environmental homeostasis may increase resistance and resilience and an ability to withstand stress, both natural and anthropogenic. Therefore, the background of high estuarine variability (i.e., noise) increases the difficulty of detecting anthropogenic perturbation signals.

Given the above and using Odum's (1985) framework of symptoms in naturally-stressed areas, in estuaries salinity decrease is not a stress but a subsidy (Costanza *et al.*, 1992). Whitfield *et al.* (2012) show the dominant effect of salinity, through the so-called Remane diagram, and Basset *et al.* (2013b) show the effects of such environmental variables which create estuaries as the sites of multiple ecotones, each spreading across the range of environmental tolerances of organisms (Smyth and Elliott, 2016; Solan and Whiteley, 2016). If an estuary had high levels of natural stress, irrespective of anthropogenic stress, then there would be severe adverse consequences whereas there are not and therefore the system copes with that stress. Hence instead of considering estuaries as naturally stressed areas, they should be considered as areas with a subsidy rather than a stress, that is, as a perturbation with a positive effect on the system (Costanza *et al.*, 1992). The positive effect being the ability of estuarine organisms to tolerate the adverse and variable environmental conditions by capitalizing on the lack of inter-specific competition which leads to high population densities. Hence the natural estuarine system is maintained by providing a benefit for those species adapted to the inherently variable conditions. Therefore, those estuarine environmental managers who require to detect change need to determine whether natural stress is occurring, in particular whether salinity decrease is a stress or, for a brackish community, the stress would be in not experiencing a decrease in salinity. Thus reduced and highly varying salinity may only be a stress for a marine-dominated or marine-derived estuarine community. In essence, if a species is typically estuarine then the conditions are a subsidy, generating benefits whereas if a species in not adapted to estuarine conditions then these are a stressor.

Because of the many quality assessments linked to the EU Water Framework Directive (Borja *et al.*, 2010b; Hering *et al.*, 2010), there are numerous studies which define and quantify the way in which the estuaries respond to human activities. As shown by Elliott and Whitfield (2011), the estuarine functioning, such as the ability to support high predator populations of fishes and overwintering birds, does not rely on a high biodiversity per se. The biodiversity-ecosystem functioning (BEF) debate, that is, that a high diversity is required for successful functioning and vice versa, seems to be well developed and agreed for terrestrial, freshwater and microbial systems (e.g., Strong *et al.*, 2015; Loreau *et al.*, 2002, and papers therein), but little considered for estuarine and other transitional waters. Estuaries and other transitional waters thus become an anomaly in this in that they function successfully precisely because they have a low biodiversity. Therefore, analyses of ecosystem structure (which often rely on diversity measures of various types) related to human impacts are not sufficient and so ecosystem function has to be given more importance. This then has to be incorporated into the conceptual models, such as by Costanza and Mageau (1999), which aim to assess estuarine ecosystem vigor (based on function) together with organization (i.e., structure).

Concluding Comments

The acceptance of the Estuarine Quality Paradox depends on two primary concepts related to what constitutes stress and the ability to detect stress/show stress. Stress can be regarded as a perturbation with a negative effect on an area and thus resulting from a pressure which will reduce the ability to survive (and function) of a level of biological organization (cell, individual, population, community or ecosystem). In relation to human activities, a pressure is regarded as the mechanism of change in the natural status of a system which in turn adversely impacts the human system and welfare (Elliott *et al.*, 2017). As the stress can be caused by

natural or anthropogenic factors, managers therefore need to determine the presence and cause of that stress and separate the various influences. If, however, an area has such a high degree of natural variability that it is difficult detecting such a change (i.e., a low signal to noise ratio), then this makes it more difficult to detect anthropogenic change. Therefore, following the logic described here regarding natural estuarine variability stress as a subsidy then signs of that subsidy (natural estuarine biological characteristics) need to be separated from the assessment of stress per se (anthropogenic estuarine biological characteristics).

The Estuarine Quality Paradox provides an example of the subsidy-stress gradient (or more correctly a continuum) (Rapport *et al.*, 1985). Hence whereas in open marine systems it is easier to detect an anthropogenically-affected area along that continuum, this is more of a challenge in estuaries. The currently-used assessment methods indicate that detecting this difference between natural and anthropogenic stressors is difficult unless the anthropogenic stressor action is severe, such as adjacent to a sewage outfall, fish cage or oil spill area. Hence, we have to question whether we are using methods based on a false paradigm and how we can break out of this difficulty. For example, the continued use of ecological structural elements instead of a combination of structure and functioning is unlikely to indicate whether an estuarine area is anthropogenically-affected.

Secondly, as indicated here, we have to reassess whether we regard transitional waters (including estuaries) as naturally environmentally-stressed areas and we conclude that natural environmental variability only constitutes stress for those organisms not able to tolerate it. Thirdly, we have to further assess estuaries within the framework of the biodiversity-ecosystem functioning debate and consider that, in such transitional habitats, successful ecosystem functioning does not require a high biodiversity. Finally, there is the need to test the hypothesis that environmentally-variable areas can better withstand, absorb or mitigate anthropogenic perturbations (environmental homeostasis) which again makes more difficult the detection of anthropogenic signals against background (natural) environmental noise.

Eutrophication

Daniel A Lemley and Janine B Adams, Nelson Mandela University, Port Elizabeth, South Africa

Definition

Concern over eutrophication is a relatively recent development in the scientific literature, with the earliest recollection dating back to the 1950s. Furthermore, a working definition of what this phenomenon entails was only provided in the mid-1990s, where Nixon (1995) described it as "*an increase in the rate of supply of organic matter to an ecosystem.*" This was a crucial step as it recognized eutrophication as a process rather than confusing it with cause or consequence (i.e., a trophic state). Despite this, however, the definition leaves considerable room for interpretation, particularly from a management standpoint. With this in mind, subsequent reworkings of what constitutes eutrophication were required to meet both scientific and legal requirements. As a result, eutrophication has been defined as "*the enrichment of water by nutrients causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms present in the water and to the quality of the water concerned*" (OSPAR, 2003). The key feature of this definition is founded in the prerequisite for deleterious consequences to occur as an explicit response to anthropogenic nutrient loading for it to be considered eutrophication. This is an important distinction to make, as symptoms generally associated with eutrophication can also occur in pristine ecosystems, with little or no human impacts, due to natural features such as increased water temperature and residence times (Human et al., 2018).

Coastal Eutrophication

The "*coastal eutrophication problem*" was initially brought to light in an important study by Cloern (2001), where three evolving conceptual models were put forward, encompassing the early, contemporary and future vision for addressing this issue. The early model (Phase I), with its foundations in the field of limnology, was based on a signal–response relationship, whereby phytoplankton biomass was assumed to respond proportionately to changes in nutrient loading with subsequent increases in decomposition/organic matter loading and oxygen depletion. However, the difference in the responses of freshwater and coastal-estuarine environments to nutrient enrichment necessitated the inclusion of three fundamental advancements into a more robust contemporary conceptual model (Phase II). These included the recognition of (1) a suite of direct and indirect responses to anthropogenic nutrient enrichment, (2) interacting system-specific features that act as a filter to modulate these responses (i.e., each coastal system has varying sensitivity to nutrient enrichment), and (3) the potential for successful reversal of direct/indirect responses through implementation of appropriate management actions. Despite being an advancement, Cloern (2001) acknowledged the "*narrow and limited*" nature of this contemporary model as it lacks a broad ecosystem-perspective that compensates for the complex interactions that exist between nutrient enrichment and other stressors (e.g., toxic contaminants, freshwater manipulation and climate change). As such, the final model (Phase III) suggests an intersystem comparative approach aimed at garnering a mechanistic understanding of eutrophication, with the ultimate objective of producing a set of tools that can support effective management of these ecosystems.

Anthropogenic manipulation of freshwater affects the physical and biogeochemical balance of estuaries by altering the input, transport, and assimilation of water (i.e., quantity and quality), inorganic nutrients, dissolved and particulate organic matter, toxic metals and organopollutants. The ecological significance of altering the quantity and quality of freshwater inputs into estuaries include the risk of mouth closure, resistance to scouring events, accelerated rates of sedimentation, a shift to or loss of marine-dominated systems, restructuring of food webs and an increased incidence of eutrophication (Paerl et al., 2014; Cloern et al., 2016). With a particular emphasis on eutrophication, the natural progression of symptoms generally entails an initial surge in microalgal, macroalgal and/or epiphyte biomass related to anthropogenic nutrient loading (i.e., "primary symptoms"), followed by more severe and developed impacts such as a loss of submerged aquatic vegetation, oxygen depletion, proliferations of harmful algal blooms (HAB), imbalanced food webs, reduced biodiversity, altered biogeochemical cycling, fish-kills and the formation of "dead zones" (i.e., "secondary symptoms") (Bricker et al., 2003; Conley et al., 2009; Ferreira et al., 2011).

Estuarine and coastal habitats are important for ecological sustainability, water quality and nutrient cycling, as well as recreation, making their susceptibility to climate change and eutrophication a multidisciplinary, modern problem. Embedded in the definition

of eutrophication, the intensification of anthropogenic nutrient loading—particularly nitrogen (N) and phosphorus (P)—to aquatic ecosystems is regarded as a key culprit responsible for facilitating eutrophic conditions. Management usually aims to mitigate those factors which might exacerbate or disrupt these processes, such as controlling nutrient input or maintaining hydrological integrity. However, whilst P reductions have served as the core focus of management interventions aimed at preventing eutrophic symptoms globally, particularly in freshwater ecosystems, the recent proliferation of non-N_2 fixing HAB taxa suggests that elevated N loads are equally important to address, that is, the "N problem" (Paerl and Scott, 2010). By only controlling P inputs to freshwaters the uptake of N by algae is reduced, thus facilitating increased transport of N to downstream coastal waters (i.e., generally N-limited environments), potentially resulting in exacerbated eutrophic symptoms (Conley et al., 2009; Glibert, 2017). As such, it is imperative that nutrient reduction strategies, aimed at thwarting estuarine eutrophication, consider both N and P. However, because nutrients alone are not an obligatory indicator of eutrophication (i.e., manifesting itself in various forms), this phenomenon has proven to be a far subtler issue than originally anticipated. Therefore, frameworks and accompanying methodologies should adopt a multimetric and adaptive approach, incorporating both pressure and response variables, to obtain robust assessments of eutrophic condition in coastal environments.

Coastal Eutrophication: "Where, What, When"

The "*Where*"

The extent of eutrophication is widespread globally due to the synergistic relationship between ever-increasing human populations and the concomitant increase in anthropogenic nutrient loading to aquatic ecosystems. As such, coastal eutrophication issues have been documented worldwide, including the United States (US), Europe, Australasia, Latin America, Asia and Africa (Selman et al., 2008). For example, Bricker et al. (2008) indicated that 65% of estuaries in the US exhibit moderate to high eutrophication problems. Similarly, a study by Andersen et al. (2011) classified 93% of the assessment units (i.e., coastal and open water areas) within the Baltic Sea—one of the largest brackish-water basins in the world—as being "affected by eutrophication". Recent technological advances related to the identification and reporting of eutrophic conditions has contributed to the steadily increasing awareness of eutrophication. However, in regions such as Asia, Latin America, Africa and the Caribbean, a lack of explicit and systematic monitoring of coastal eutrophication, means that the true global extent and prevalence of this phenomenon is almost certainly underrepresented by the 415 affected areas identified by Selman et al. (2008). Socio-economic and political landscapes further compound the likelihood of eutrophication in these regions, where accelerated population growth coupled with rapid economic development (e.g., China) or, alternatively, limited resources (e.g., Africa) increase the amount of nutrients entering coastal waters. This is evidenced by studies in China (Strokal et al., 2014), Africa (Yasin et al., 2010) and South America (van der Struijk and Kroeze, 2010) where model results indicated a significant increase in total nutrient export by rivers for the period 1970–2000.

The "What and When"

Over recent decades the frequency, magnitude and extent of HABs have increased globally in estuarine and coastal waters (Anderson et al., 2002; Glibert et al., 2008; Glibert, 2017). Embedded in the definition of eutrophication, anthropogenic nutrient loading (N and P) is the key culprit responsible for the increased incidence of HABs. The primary concerns arising from such HAB events is founded in the array of possible consequences, including direct toxic effects on higher trophic levels (e.g., shellfish poisoning and bioaccumulation), bottom-water oxygen depletion related to bloom decay processes (i.e., decomposition and microbial respiration), mechanical interference and suffocation of faunal communities (e.g., mucilage production), and habitat destruction through shading of submerged aquatic vegetation. Such impacts can have severe social (e.g., esthetic degradation and loss of subsistence resources), economic (e.g., loss of tourism and collapse of fisheries) and human health implications. Broadly speaking, Dinophyceae are the most common HAB-forming phytoplankton group in coastal waters. Perhaps one of the most relevant HAB species from a eutrophication perspective is the high-biomass, potentially toxic dinoflagellate *Prorocentrum minimum*, due to its pan-global distribution and known association with regions of high dissolved inorganic and organic N and P river exports (Glibert et al., 2008). Other dinoflagellate HAB species indicative of eutrophic conditions include: *Akashiwo sanguinea*, *Alexandrium catenella*, *A. minutum*, *A. tamarense*, *Gymnodinium catenatum*, *Heterocapsa rotundata*, *H. triquetra*, *Karenia brevis*, *K. mikimotoi*, *Karlodinium veneficum*, *Lingulodinium polyedrum* and *Pyrodinium bahamense* var. *compressum* (Burkholder et al., 2008 and references therein; Lemley et al., 2018). Additionally, the incidence of coastal HABs species belonging to other phytoplankton classes are also on the rise globally, such as Raphidophyceae (e.g., *Heterosigma akashiwo*, *Chattonella* spp.), Prymnesiophyceae (e.g., *Prymnesium parvum*, *Phaeocystis* spp.), Bacillariophyceae (e.g., *Pseudo-nitzschia* spp.) and Cyanophyceae (e.g., *Microcystis aeruginosa*).

Macroalgal proliferations are another common symptom of eutrophication, with the incidence of bloom conditions increasing globally in response to increased nutrient availability. At a glance, macroalgal blooms have similar consequences to those imposed by HABs (e.g., oxygen depletion, loss of submerged vegetation). However, the ability of macroalgal blooms to persist in the absence of a natural disturbance (e.g., flushing event, high turbulence) (Valiela et al., 1997) facilitates an additional suite of possible impacts, including the production of foul odors, clogging of waterways, and drastic restructuring of trophic pathways (i.e., collapse of microalgal and grazer communities). All three macroalgal clades (Chlorophyta, Rhodophyta and Phaeophyceae) possess bloom-forming species, yet the most commonly occurring macroalgal blooms are composed of Chlorophyta species, known as "green

tides." Blooms of species belonging to the genera *Ulva* and *Cladophora* are particularly widespread examples of this phenomenon, and have been documented in North America, Europe, South America, Africa, Asia and Australia (Teichberg et al., 2010; Thornber et al., 2017).

An important distinction to make regarding the interpretation of these two acute symptoms of eutrophication (i.e., HABs and macroalgal proliferations) is that both can occur under natural, oligotrophic conditions. Therefore, to be considered a symptom of eutrophication, it is essential that such events are (1) related to increased anthropogenic nutrient loading, (2) persistent (i.e., not stochastic) and recurrent (i.e., seasonal), and (3) induce deleterious consequences on the environment (e.g., oxygen depletion, loss of ecosystem structure and function). For example, with regards to the latter, a study by Diaz and Rosenberg (2008) reported that eutrophication-induced hypoxia (i.e., episodic, periodic, seasonal or persistent) is responsible for approximately half of the 400-plus known dead zones globally. Some of the potential consequences of dead zones include mass mortalities of benthic fauna, reduction in demersal fish predators, release of poisonous microbially generated hydrogen sulfide under anoxic conditions, and ultimately a loss of nursery and recruitment areas. This is of concern, as such occurrences are an indication that a system has reached a critical point of eutrophication where ecosystem resilience is severely impaired, or even lost.

Eutrophication Assessment Methods

Numerous mandates have been formulated globally to protect coastal ecosystems from continued degradation arising from human-related impacts. The United States (US) and European Union (EU) are at the forefront of designing and implementing such legislation aimed at addressing these issues. In the US, the Clean Water Act (PL 92-500, 1972), together with the Coastal Zone Management Act (PL 92-583, 1972) and Harmful Algal Bloom and Hypoxia Research and Control Act (PL 105-383, reauthorized in 2004), provides the core impetus for the development and application of eutrophication assessment efforts, such as the Assessment of Estuarine Trophic Status (ASSETS) and Environmental Protection Agency National Coastal Assessment (EPA NCA) methodologies. In the EU, the assessment of eutrophication in marine and coastal waters is encompassed under umbrella regulations including the Water Framework Directive (WFD; 2000/60/EC), Marine Strategy Framework Directive (MSFD; 2008/56/EC), Nitrates Directive (ND; 1991/676/EC) and Urban Wastewater Treatment Directive (UWWTD; 1991/271/EC). The MSFD was an important development in the EU, as it explicitly includes eutrophication as 1 of the 11 holistic quality descriptors that together enable the assessment of environmental status of marine waters. Like the US, a variety of assessment methodologies have been designed to fulfill the requirements of these directives. Some examples of these include the Trophic Index (TRIX), Transitional Water Quality Index (TWQI), Oslo Paris Convention for Protection of North Sea Comprehensive Procedure (OSPAR COMPP), French Research Institute for Exploration of the Sea (IFREMER), and Helsinki Convention Eutrophication Assessment Tool (HEAT).

Other countries that have implemented preventative legislative actions, include South Africa (National Water Act of 1998), Australia (Oceans Policy of 1998), China (Law on Prevention and Control of Water Pollution of 1984) and Canada (Oceans Act of 1997). However, the overarching objective of these policies is to promote sustainable development whilst protecting and/or restoring coastal ecosystems. As such, eutrophication is not explicitly incorporated as a prerequisite component which needs to be addressed; thus, resulting in a lack of regionally specific eutrophication assessment methodologies. This is generally overcome by either adopting existing methodologies (e.g., China; Xiao et al., 2007) or developing an assessment method outside the bounds of a specific legislative framework (e.g., South Africa; Lemley et al., 2015). In the case of the latter, this is a crucial step toward providing a baseline from which the eutrophic condition of coastal waters can be monitored—particularly in regions where such assessment frameworks are lacking.

Eutrophication assessment methodologies serve as the basis for routine monitoring and establishment of ecological objectives worldwide. As such, it is imperative that the process involved with the formulation, implementation and interpretation of these methodologies are continuously improved to ensure results that are useful for management. A common thread that exists between eutrophication assessment methods is the integration of biological (micro- and macroalgae, marine angiosperms, zooplankton, macroinvertebrates and fishes) and physico-chemical (nutrients and dissolved oxygen) indicators that provide information at a desired level of confidence. Furthermore, selected indicators should reflect a gradient in responses that correspond with the level of human-induced impacts (i.e., nutrient loads). Many assessment frameworks utilize similar indicators, yet discrepancies arise due to differences in (1) temporal and spatial scales of analysis, (2) the characteristics included in indicator metrics (e.g., concentration, frequency, spatial coverage), (3) the statistical measures used to assess each indicator parameter (e.g., percentile, mean, absence/presence), (4) the determination of reference conditions and (5) the manner in which multiple lines of evidence are combined into a final status rating (Devlin et al., 2011; Ferreira et al., 2011).

As such, the application of different frameworks to the same coastal water body can culminate in confounding assessment ratings. For example, a study by McLaughlin et al. (2014) assessed the eutrophic condition of estuaries in the Southern California Bight (US) using multiple assessment frameworks (i.e., ASSETS, IFREMER and UK-WFD), and highlighted the varying applicability of specific indicators and threshold values on an individual estuary level. Similar observations have been made in Europe, where Garmendia et al. (2012) indicated the suppressed relevance of benthos and macroalgae indicators in Spanish estuaries where hydromorphological conditions are not conducive to the development of these communities. These overall sentiments were echoed in a comparative study by Devlin et al. (2011), where five assessment methodologies (i.e., UK-WFD, OSPAR COMPP, TRIX, ASSETS and EPA NCA) were applied to two estuaries in the United Kingdom. Whilst the various approaches indicated similar overall ratings, the authors suggested (1) sufficient timeframes of analysis (i.e., annual data), (2) use of frequency, spatial extent and duration in

indicator metrics, (3) inclusion of "secondary symptoms" as indicators, and (4) a multicategory rating scale to ensure a more representative assessment (i.e., Phase II approach sensu, Cloern, 2001).

Management Insights From Selected Case Studies

The implementation of proactive integrated coastal management, including both regulatory and cooperative approaches, provides the foundation for successful rehabilitation of eutrophic systems. The Tampa Bay Estuary, US provides a good example of where such an approach has been successfully adopted (Lewis III et al., 1998; Greening and Janicki, 2006). In summary, the Tampa Bay Estuary began exhibiting eutrophic conditions by the late 1970s (i.e., phytoplankton/macroalgae blooms and seagrass losses of ~50%) due to accelerated human settlement and associated nutrient loading. The restoration of seagrass habitat became the key management goal, with ensuing targets and actions for nutrient load (particularly N) and chlorophyll-*a* (related to light availability) reductions adopted to achieve this. Management actions taken to reduce N loads, and subsequently chlorophyll-*a* levels, included the requirement for advanced wastewater treatment of discharges from municipal plants, stormwater regulations and upgrades, implementation of agricultural best management practices, and habitat restoration projects. The responses to these actions included significant reductions in N loads and chlorophyll-*a* concentrations, increased light availability, and a recovery of seagrass coverage by approximately 25%. The continued reversal of eutrophic conditions in the system is largely a result of the multientity (i.e., Tampa Bay Estuary Program), integrated catchment management process that facilitates and coordinates these efforts. This case study demonstrates an effective and cooperative approach, following a logical sequence of (1) identifying the problem, (2) setting system-specific quantitative management goals, (3) establishing the environmental requirements necessary to achieve these goals, (4) implementing pertinent management actions and plans, and (5) continuous monitoring to assess progress toward meeting established goals.

The Blackwater Estuary in Ireland provides a EU example of where management actions, driven by national regulations (e.g., Good Agricultural Practice for Protection of Waters S.I. No. 101 of 2009) and European Directives (i.e., WFD, MSFD, ND and UWWTD), have proved successful in improving deteriorating water quality and biological trends (Ní Longphuirt et al., 2015). Recent improvements in farming practices, due to fertilizer reduction measures, have culminated in significant reductions in nutrient loads to coastal waters. Continuous monitoring of the Blackwater Estuary has taken place to assess the efficacy of implemented measures in achieving water quality improvements. Over a 20-year monitoring period, results indicated a decrease in N (17%) and P (20%) river loads, together with downstream estuarine reductions in P concentrations and chlorophyll-*a*. An interesting observation emanating from this case study was the decoupling between N load reductions and downstream response times, that is, N concentrations increased over time in the estuary. This paradoxical occurrence in the estuary was attributed to internal nutrient pools of N released via sediment remineralization (i.e., "legacy nutrients") and the suppressed N assimilation by primary producers (i.e., lower chlorophyll-*a*). As such, this example highlights the importance of considering the response times of system-specific processes and the implications of imbalanced nutrient reductions when assessing the effectiveness of eutrophication mitigation measures.

Finally, a study by Iho et al. (2015) compared trends in water protection and water policies in the Chesapeake Bay and Baltic Sea. These two coastal systems share similar characteristics, being large bodies of shallow and brackish waters that have been intensively managed throughout the past 40 years due to the increased incidence of eutrophic conditions. Despite successful reductions in point source (PS) nutrient loads and region-specific success stories, management measures have largely been unable to achieve desired water quality targets in both. At the forefront of the difficulties encountered from a policy and program implementation perspective is the multitude of stakeholders and political jurisdictions involved in coordinating the protection of Chesapeake Bay (US EPA and six states) and the Baltic Sea (EU and nine littoral countries), each with their own environmental laws and policies. Each of these systems are managed under a specific overarching regulatory framework, which set clear objectives for protection. For example, the Clean Water Act (CWA) makes provisions for a Total Maximum Daily Load (TMDL) to Chesapeake Bay, while the Helsinki Convention—facilitated by the Helsinki Commission (HELCOM)—aims to restore good ecological condition in the Baltic Sea using the Baltic Sea Action Plan (BSAP). In the case of Chesapeake Bay, the primary reason for shortfalls in achieving the desired water quality improvements is largely due to significant and unregulated discharges from nonpoint sources (NPS). Whilst the CWA has successfully enforced PS control via a permitting process (i.e., compliance with water-quality-based effluent limits), the same federal regulations do not apply to NPS, instead shifting responsibility to the states thus culminating in a mosaic of state and local initiatives which adopt a voluntary compliance strategy toward NPS control (i.e., nonbinding). A similar scenario exists in the Baltic Sea, where HELCOM have provided country- and pollution-specific (N and P) recommendations for pollution abatement through the BSAP; however, these limits are nonbinding as there are no means of enforcement due to the multinational political climate. Therefore, a key obstacle hindering the successful reversal of eutrophication in the Baltic Sea is founded in the difficulty of integrating the various EU directives into the national legislation of HELCOM contracting parties. Ultimately, this study highlighted that an "ideal policy," in terms of efficiently controlling pollutants, is achieved when (1) mitigation costs are equal across dischargers, and (2) mitigation costs equal the benefits obtained from improving environmental health (Iho et al., 2015). However, because the benefits of such actions are often unknown and financial/institutional constraints are commonplace globally, it is necessary for policies to be cost-effective and to adopt innovative ways (e.g., performance-based instruments) of enticing a positive attitude toward managing eutrophication.

Freshwater Aquaculture

James H Tidwell and Leigh A Bright, Kentucky State University, Frankfort, KY, United States

Introduction

Aquaculture is the culture of aquatic plants and animals under controlled or semicontrolled conditions. In its simplest terms, aquaculture is underwater agriculture. While long ago man transitioned to agriculture for its land sourced foods, in the area of aquatic foods, mankind has largely remained at the hunter and gatherer stage until recent years. Aquaculture is now the world's fastest growing food producing sector. Aquaculture possesses inherent characteristics which allow it to be one of the most efficient and low environmental impact methods of producing high quality protein for the human population.

History

Most agree that aquaculture began in China 5000–7000 years ago. It is believed that early efforts involved the common carp (*Cyprinus carpio*) and evolved from catching wild fish, holding those fish in baskets until market, and then feeding them to grow them to larger sizes. Carp culture was spread from China to various parts of Southeast Asia by Chinese immigrants. The Romans reportedly introduced carp culture into Europe. Egyptian hieroglyphics appear to show pond culture and tilapia (*Oreochromis niloticus*) are identifiable in the paintings (Stickney and Treece, 2012).

In what is now the United States, native Hawaiians have been growing fish in ponds for over 700 years. They allow seawater and the juvenile fish to enter the ponds with the rising tide, and then block off the openings before the tide recedes. The trapped juveniles are then allowed to grow to harvest size. Trout were among the early fishes to be cultured in Europe (as early as the 14th century). Initially the European brown trout (*Salmo trutta*) though the rainbow trout (*Oncorhynchus mykiss*) later became more popular. The British introduced trout to some of their colonies in Asia and Africa. In the 1800s, interest in recreational fishing and the need for supplemental stocking led to the development of private and public hatcheries in Europe and North America. It was not until the mid-twentieth century that the art of aquaculture developed into what exists today as a complex multidisciplinary science (Stickney and Treece, 2012).

Importance and Current Status

Fish is a vital component of the human food supply and man's most important source of high quality animal protein. (As used here, the general term "fish" includes fish, mollusks, and crustaceans consumed by humans). It is estimated that in 213 fish provided more than 3.1 billion people world-wide with at least 20% of their average per capita animal protein intake (FAO, 2016). It is a particularly important protein source in regions where high-quality protein from terrestrial livestock is relatively scarce. For example, in 2013 fish supplied only 11.7% of animal protein consumed in developed countries, but 20% of animal protein in developing countries (FAO, 2016).

Consumption of food fish from all sources is increasing, having risen from 40 MMT in 1970 to 146 MMT in 2014 (FAO, 2016). Global per capita fish consumption has increased over the past four decades, rising from 9.0 kg/person in 1961 to an estimated

20 kg/person in 2014 (FAO, 2016). Based on projected increases in consumption rates alone (assuming no increase in the human population) it is estimated that the demand for seafood will increase by more than 10 million tonnes per year by 2020 (Diana, 2009). While increases in per capita consumption account for a portion of the increase in total demand, it is human population growth that is the main driving force for this steadily increasing demand for food fish.

In 2014, the total world supply of fish from all sources was about 167 MMT (FAO, 2016). Capture fisheries primarily from the ocean, produced about 93 MMT of which about 21 MMT was destined for nonfood uses, primarily as fish meal in animal feeds. The other 87% of total fishery production was for human food (FAO, 2016).

Fish is the only important human food source where a large portion is still gathered from the wild and we once thought that the oceans, which cover ¾ of the earth's surface, contained an unlimited source of seafood. However, while demand for fish as food increases >10 million tons each year, sustainable harvests of wild fish are not able to expand significantly. For marine capture fisheries, FAO reports that in 2013 only 10% of the stock groups were under exploited while 58% were fully exploited (FAO, 2016). Global marine capture fisheries production has been at best stagnant for over 25 years. Global marine capture fisheries increased only 10% between 1992 and 2014 (FAO, 2016). The maximum yield fisheries to be captured from the world's oceans have likely been reached. In fact, by some estimates, current ocean harvests may already be *greater* than levels considered sustainable (Coll et al., 2008).

Status of Aquaculture

As we look to the future we see the demand for food fish increases each year while the supply from wild harvest is not expected to increase. So where do we get our fish in the future? The only other source for food fish is aquaculture and global aquaculture growth has been extraordinary. In the 1970s aquaculture contributed less than 4% of total seafood production but by 2014 contributed more than 50%. Aquaculture has now passed capture fisheries as the leading source of food fish for the human population and that proportion will continue to increase each year from here forward.

These projections only bolster the case that a prudent development of aquaculture is essential. In 2008, total aquaculture production of food fish was 53 million tonnes (FAO, 2008). It is anticipated that to keep pace with demand, aquaculture production of food fish will need to increase to 102 million tonnes (>90% increase) by 2025 (FAO, 2016).

Centers of Production

So where is aquaculture production occurring? Currently, Asia dominates the industry. In 2009, Asia accounted for 89% of world aquaculture production by quantity and 79% by value (FAO, 2008). China alone produces more than 60% of the world's aquaculture by volume (FAO, 2016). Of the top ten countries in aquaculture production in 2014, only two (Chile and Norway) were not in the Asian region and they account for approximately 3% of world production. However, there are rapid increases in production occurring in some countries outside of Asia.

Differences From Terrestrial Agriculture

Terrestrial animal agriculture relies on only a few species. In cattle, milk and meat production both utilize one species. In pigs, all commercial production is based on one species. In poultry, we have hundreds of varieties of chickens but they are all actually one species, and then we also have the turkey. These animals are *all* warm-blooded and differ at only the genus or class level. However, in aquaculture we raise over 400 species (Duarte et al., 2009), all are cold blooded, and many differ at class or even phylum level.

Even more than terrestrial farm animals, aquatic animals are captives of their environment. All terrestrial livestock are homeotherms (warm-blooded). That means they are able to regulate their body temperatures to stay within the narrow range needed for proper function. However, aquacultured animals are primarily poikilothermic (cold-blooded), so their body temperature is basically the temperature of their environment.

Terrestrial animals live in a relatively high oxygen gaseous environment (>21% by weight) and use lungs for gas exchange. Aquatic animals have evolved diverse structures to utilize the oxygen which is dissolved in the water. However, oxygen is much scarcer in water (0.00001% by weight) making an adequate oxygen supply a bigger consideration for the aquatic animal. Also, to complicate matters even more, the effects of temperature on the fish and the availability of oxygen in the water operate in conflict. As water temperatures increases, the metabolism of the animal (and its oxygen demand) *increases*. However, as temperature increases the solubility of oxygen in the water *decreases*, meaning less is available just when the animal needs it most. Nature played a cruel joke on the aquaculturist (Timmons et al., 2002).

Differences in Freshwater and Marine

For terrestrial animals air is pretty much air but for aquatic animals freshwater and saltwater represent very different environments and physiological challenges. Virtually all aquatic animals have to work against their external environment to maintain their internal environment. Most fish require an internal osmotic concentration of 250–500 m Osmol/kg. However, freshwater is <0.1 m Osmol/kg and seawater is approximately 1000 m Osmol/kg (Evans and Claiborne, 2008). That means that in marine fish, water is constantly trying to leave the fish and in freshwater species, water is constantly trying to move into the fish. Some species, known as euryhaline species, have mechanisms which allow them to adapt to a range of salinities. Others are known as stenohaline are strictly confined to one environment or the other.

Classifications of Culture Species

One way of classifying fish is based on tier optimal water temperature. Fish are often characterized as coldwater, coolwater or warmwater species. Some descriptions add a fourth category of tropical species. The characteristics, requirements, and especially tolerances of the fish within these groups are largely controlled by enzyme functions and efficiencies. Many enzymes only operate within a limited temperature band, which in the case of a poikilothermic animal means that the animal itself also operates efficiently within a narrow temperature band (Somero and Hochachka, 1971), so it is important that the culture system provide that proper temperature.

Finfish and invertebrates whose thermal optimum for growth is below 20°C are classified as coldwater species. Important aquaculture species within this group include the Atlantic salmon (*Salmo salar*), the rainbow trout (*Oncorhynchus mykiss*), and the Pacific oyster (*Crassostrea gigas*). Their optimum temperature for growth is about 10°C–16°C. They require relatively high oxygen levels (>5 mg/L) and tolerate only low levels of ammonia (<0.0125 mg/L un-ionized).

Species whose optimum temperature is around 20°C are considered coolwater species. Currently there are fewer commercially important aquaculture species in this category. The striped bass (*Morone saxatilis*) and yellow perch (*Perca flavescens*) and European perch (*Perca flaviatilis*) are examples.

Many important aquaculture species are considered warmwater species, with an optimum temperature around 30°C. Among crustaceans, they would include the Pacific white shrimp (*Litopenaeus vannamei*), the tiger shrimp (*Penaeus mondon*), and the freshwater prawn (*Macrobrachium rosenbergii*). Among mollusks are the American oyster (*Crassostrea virginica*), Northern quahog (*Mercenaria mercenaria*), and blue mussel (*Mytilus edulis*). Among finfish we would include the common carp (*Cyprinus carpio*), channel catfish (*Ictalurus punctatus*), and sea bass (*Dicentrachus labrax*). Compared to coldwater species, warmwater species in general tend to have a greater tolerance for lower dissolved oxygen (DO) levels and a greater tolerance for ammonia concentrations.

As stated earlier some classifications add a fourth category. Tropical species would be those whose optimum temperature would be >30°C. You may also add a characteristic of having a minimal lethal temperature of ≤10°C–15°C. Examples would be tilapia, with an optimum temperature of 29°C–31°C (Popma and Masser, 1999). They also tend to be very tolerant of low oxygen concentrations and high concentrations of nitrogenous waste products.

Ecological Services Provided by Culture Systems

Aquatic animals are very much "captives" of their environment. In aquaculture, we do not so much manage the animals as much as we manage their environment. That is also largely the function of the different aquaculture systems—to manage the animals' environment. Not only must the environment be maintained to support life but in the case of aquaculture, it needs to be maintained in such a way as to support maximum growth rate, with maximum efficiency, and a minimum of waste. A few environmental variables are fundamental and a discussion of the ways that aquaculture systems control them is the unifying theme of this chapter, how the specific system being examined provides the cultured animal with the, (1) proper temperature for growth, (2) sufficient oxygen to breathe, (3) removes the inevitable waste products and in some cases, (4) provides some or all of the animals' food needs.

Types of Production Systems

There is a vast range of intensities of production in freshwater aquaculture systems. For reservoir ranching systems, there may be 10 kg of animals in a hectare (10 kg/ha) while in an intensive recirculating system we may be have 10 kg of animals in *one square meter* (or 100,000 kg/ha). Within this continuum of increasing intensity we have three major categories or classifications for aquaculture production systems. These groupings are primarily based on the amount of control or intervention the aquaculturist provides in terms of the three basic functions or ecosystem services, each system must provide (proper temperature, adequate oxygen, and waste removal). However, the demarcations between these systems are not always clear and distinct. There are even hybrids among and between these categories

Open Systems

Production systems within this category rely entirely on natural ecological processes to address the three major functions. These systems are normally natural bodies of water that are now being stocked for commercial production. Many of these systems could be considered stock enhancement rather than aquaculture. Biomass densities are usually low enough that natural processes can provide sufficient oxygen for the biomass being supported. The oxygen can be sourced from diffusion, photosynthesis by natural algal communities, or both. Waste products are also removed by natural processes within the systems, operating at natural rates. Bacterial breakdown of solid wastes is by heterotrophic bacteria and fungi. Nitrogenous waste products, such as ammonia excreted by the animal, are either flushed away or processed into less toxic forms by the chemoautotrophic components of the natural nitrogen cycle (nitrification) or assimilated by algae. Water temperatures in these systems are ambient. In open systems, site selection is the major control factor the producer has for all environmental services.

Cage culture is an open system production method. It basically represents a "fencing-off" of a portion of the natural aquatic habitat. Some cages are literally fenced compounds in shallow water. The bottom of the cage is the mud bottom of the bay or lake. In others, the cages have net bottoms and are suspended off of the bottom by flotation. These can be small cages (1–4 m^3) floating in shallow freshwater ponds. Larger cages used in marine environments are usually referred to as net pens.

Semiclosed Systems

Within this category we still rely largely on nature to provide the three basic ecological services of proper temperature, sufficient oxygen, and waste removal. However, within the semiclosed category the production units themselves are now largely manmade and includes ponds and raceways. Within the production units we now have the ability to add or remove water. Also, there is more management input in these systems and the first steps toward supplementing or enhancing natural processes.

In semiclosed systems water is taken from a natural source such as rainfall, springs, streams, or rivers. The water is then gravity flowed or pumped into specially designed and constructed production units. The water can be used once and discharged or constantly cleaned and re'oxygenated by natural processes. Compared to open systems, semiclosed systems have several advantages. One is much higher production rates, as much as 1000 times the productivity of an open system. This is due to the greater control and inputs into these systems and the fact that their physical parameters can be maximized for greater productivity.

Other advantages include easier and more efficient use of prepared feeds, control over water depth or water replacement, mechanical aeration can be practical and cost-effective, poaching and predation are more easily controlled, competitors and predators can be eliminated, water quality deterioration and diseases can be more easily detected and rectified, and there is some potential for temperature control. However, there are also negatives. Construction and equipment costs can be significant, there are more management demands monitoring and intervention, energy and feed inputs are higher, and a greater likelihood that water quality issues and diseases will occur.

Raceways are semiclosed systems and are basically large manmade earthen or concrete troughs. A typical length/width/depth ratio in linear raceways is 30:3:1 (Stickney, 2000). High quality water flows into and through the trough bringing in needed oxygen and flushing away wastes. Water sources are usually ground waters coming to the surface in the form of springs or surface water from snow melt or rain runoff from higher elevations. The water can often be reused several times as the water flows through multiple raceways in series

In raceways the oxygen is provided by the incoming water. It must come into the raceway saturated with oxygen. Wastes produced in these systems are passed on for processing further downstream in the receiving waters, or onsite in designed treatment units. Temperatures in raceway systems reflect their water source. Retention time is low so temperature changes little within the system.

Ponds are also examples of semiclosed production systems and there are several types. The simplest and easiest to construct is to build a watershed or impoundment pond. These are constructed by building a dam across a natural waterway to retain the rain runoff at a level set by the dam. The pond's shape is largely dictated by the land's topography.

A purpose built pond for aquaculture is usually a leveed pond. They commonly have a 2:1 length to width ratio. Ponds used in commercial aquaculture production vary widely in size. In ponds most of the oxygen budget is based on oxygen production by photosynthetic phytoplankton. In the past this was the limiting factor for production within these systems. Without supplemental feeding the natural carrying capacity of a pond is around 250–500 kg/ha. With supplemental feeding this can be increased to about 1500 kg/ha. However, at this biomass density and the accompanying feeding rate of 30–40 kg/ha/day, the chance of low oxygen periods during the night or early morning starts to become unacceptably high (Boyd, 1979). In most commercial scale pond production systems man has intervened by providing mechanical aeration. With this change, feed rates can be increased to about 100 kg/ha/day and production can be increased over three fold to >4500/kg/ha.

Ponds still rely on natural processes to remove waste products. Again, solid wastes are broken down primarily by heterotrophic bacteria and detritivores on the pond bottom. Ammonia (NH_4^+) excreted by fish or shrimp is directly assimilated by algae or converted to less toxic nitrite (NO_2^-) by *Nitrosamonas* bacteria then on to nitrate (NO_3^-) by *Nitrobacter* bacteria. The nitrate form can then be assimilated by algae. Since the advent of mechanical aeration, the efficiency of this nitrogen removal system is now the primary bottleneck in further pond production intensification. Water temperatures in these systems are basically ambient. They lag

behind, but reflect, the mean air temperature in the region. Near the equator there is little seasonal fluctuation. As you move further from the equator seasonal fluctuations become more pronounced and can either affect growth or even produce mortality. There has been some work in using waste heat from power plants and other industries to warm pond waters. However, fish production is usually a secondary consideration. The needs of the primary industry usually take priority and created problems during shut down for repairs or maintenance.

In ponds, a significant portion of the food for the culture organism can also be generated internally. If this is the primary food for the system it is said to be an extensive pond system. The natural carry capacity of an unfed pond is in the range of 250 kg/ha. This carrying capacity can be increased by adding nutrients to the system. In most extensive or low-input systems these nutrients are supplied in the form agricultural by-products, or animal (or human) waste. This is known as organic fertilization. If needed nutrients are supplied in their purely chemical form (often derived from petrochemicals) they are knows as inorganic fertilizers. Again there are positives and negatives to each.

Positives of organic fertilizers include low costs, slow release of nutrients, and sustainability aspects of reuse. Negatives include the need to handle bulk and sometimes wet (and heavy) materials for small amounts of nutrients. To be made available to the phytoplankton and food web these materials must first be decomposed by microbes, which can be fairly slow and this is an oxygen consuming process These products can also directly deteriorate water quality (by yielding ammonia etc. . .) if misapplied. Inorganic fertilizers have the positive aspects of acting quickly, without deteriorating water quality through added nitrogenous wastes. However, inorganics can be more expensive and can actually work "too well" if misapplied. A slight over application of phosphorous can cause of a rapid phytoplankton bloom which can die off just as rapidly. This can result in oxygen depletion as the phytoplankton decomposes.

Closed Systems

In closed systems you are reusing the same water within a manmade culture system. Also, there is human intervention of some type and at some level in *all* of the basic processes. The major advantage of closed systems is that they provide the operator complete control over all of the environmental variables in the culture system. The major *disadvantage* of closed systems is that the operator now has complete *responsibility* for all aspects of the animals' environment.

In closed systems water temperature can be maintained very near the optimum growing temperature for the cultured animal. This can have a tremendous positive impact on not only growth rate but also efficiency, both of which are highly important in these systems. Because of this temperature control, we can now raise tropical animals in temperate zones, if that is where the markets are. Waste heat from industrial processes can provide economic advantages if the schedules and proximities of the systems are compatible.

With closed systems water can be constantly disinfected with ultraviolet (UV) lights or ozone to crop down pathogenic organisms. Predators and poachers can be completely eliminated. External environmental events like floods or cold snaps are no longer a problem. Feed can be efficiently administered and consumption and conversion accurately monitored. Water supply volumes become less of a concern. However, for large systems their loss of >5% per day can still become substantial.

Recirculating aquaculture systems (RAS) are examples of closed systems and are also known as closed loop systems, recycle systems, and intensive recycle systems. As these names imply, as opposed to trout raceways which have a constant inflow of new water, these systems use the same water over and over. They do this by constantly adding air or oxygen to the water and removing the waste products produced by the fish. If aeration is used, production is limited to about 40 kg/m^3 (0.33 lb/gal). With the use of pure oxygen (oxygenation) production can be increased to approximately120 kg/m^3 (1.0 lb/gal) (Timmons et al., 2002). To remove waste products most systems rely on mechanical filters to remove solid wastes then nitrogenous wastes, such as ammonias are detoxified to nitrite then nitrate, using the same nitrifying bacteria discussed in ponds. However, these bacteria are now cultured at very high densities inside containers known as biofilters. The nitrifying bacteria in the biofilter need a surface to attach to some special materials, known as media, are packed or suspended inside the biofilter to provide surface area for the bacteria to grown on. However, it is also important for the biofilter media to have sufficient open areas for the water to flow through and wash over the bacteria so that they can "consume" the inorganic waste and excrete less toxic versions.

In recent years, another type of closed or recycle system has been developed. Instead of relying on chemoautotrophic nitrifying bacteria, which utilize inorganic compounds such as ammonia for energy, these systems are colonized with heterotrophic bacteria which consume the organic wastes. These bacteria are not confined in biofilters but live suspended in the culture vessel along with the animal being cultured. Once this bacterial population is established and stabilized, very high production rates can be achieved (>5 kg/m^3). However, these systems also have very high oxygen demand and relatively little research has been conducted on their complex microbial ecology. These systems can quickly remove nitrogenous waste products from the animals by directly converting it to bacterial biomass. In traditional RAS quick removal of solids is important to their function. In heterotrophic or biofloc systems these solids are largely retained in the culture tanks and became colonized with heterotrophic bacteria, fungi, and protozoans into suspended particles called bioflocs. The bioflocs also recycle the wastes as they can be grazed by the animals and directly consumed as high protein forage.

Many new approaches in recent years are blurring the lines between the different production systems and even major categories (open, semiclosed, and closed). They take aspects of different systems and combine them in new ways to overcome the

shortcomings of one, capitalize on the positives of another, or break a system into its functional components so they can be individually manipulated.

In one hybrid system, termed aquaponics, the basic components of a recirculating system are utilized. However, the biofilter has been replaced by plants which assimilate the nitrogenous waste products and then turn it into saleable plant products. Aquaponics is increasingly of interest in areas where water availability is limited. Much of their early development has occurred on small islands where the supply of fresh fish and freshwater, fresh produce are all limited. There is increasing interest in evaluating these systems in arid countries, such as those in the Middle East. Now there are also efforts to apply these technologies to generating fresh fish and vegetables in or near major urban areas. These are meant to address the phenomenon known as "food deserts." These are urban areas where city dwellers do not have ready access to healthy foods at reasonable prices (Ford and Dzewaltowski, 2008). This makes these populations, especially certain ethnic groups, even more susceptible to health problems such as Type II diabetes and obesity. Urban aquaponics might represent an "oasis" of healthy foods in or near the food deserts.

Sustainability Advantages of Aquaculture

While it has been popular among certain groups and in the popular press to criticize aquaculture, an objective evaluation shows that it is, and can continue to be, one of the most eco-friendly methods to produce high quality protein for human consumption. Fish are inherently more efficient than other farm animals. Much of this is based on the fact that fish are cold-blooded (poikilothermic) animals. This means that they do not expend any energy maintaining their internal body temperature. They also do not expand energy fighting gravity (also giving them less investment in skeleton). Aquatic animals also excrete waste products more efficiently than terrestrial animals. These add up to fish converting feeds to flesh much more efficiently than other animals. Better conversion efficiencies also mean less waste produced.

The Future and the Challenge

As we have seen, the demand for fish increases each year. To even maintain the current level of per capita consumption, the fish supply will have to almost *double* in the next 20 years. That translates into almost 40 million tonnes of additional supply per year and basically, all of it has to come from aquaculture. As Melba Reantso of FAO described it, "aquaculture is *now* known as the emerging new agriculture, the catalyst of the "blue revolution," the answer to the world's future fish supply, the fastest growing food producing sector, and the future of fisheries." Still, the task ahead is daunting. Aquaculture is expected to supply global seafood security, nutritional well-being, poverty reduction and economic development by meeting all of these demands, but also accomplishing this with a minimum impact on the environment and maximum benefit to society.

Intertidal Zonation☆

Maya C Pfaff, Department of Environmental Affairs: Oceans and Coasts, Cape Town, South Africa
Ronel Nel, Nelson Mandela University, Port Elizabeth, South Africa

Glossary

Backwash The return flow of water down the beach face following a swash.
Biotic Of biological (and not physical) nature.
Biogeographic Referring to the distribution of species and ecosystems across large geographic scales and through geological time.
Desiccation Loss of water from organisms caused by exposure to air, which leads to physiological stress.
Intertidal zone The area on the coast that lies between the low-tide and the high-tide marks.
Littoral Coastal; but also with specific reference to the intertidal zone.
Macrofauna Benthic invertebrates that live on or in sediment and are >1 mm in length; this size-based grouping contains a diversity of taxonomic group.
Meiofauna Small benthic invertebrates that live in both marine and fresh water environments; this grouping is defined by size (45–500 μm) and contains a diversity of taxonomic groups.
Morphodynamic state A classification scheme for beaches based on sediment grain size, wave action, tidal amplitude, and resultant beach slope. Beaches are classified along a gradient from reflective to dissipative states.
Semidiurnal Having a recurrence period of half a day and a frequency of twice a day.
Swash The flow of water from a broken wave up the beach face.
Stress A situation that results in an organism's reduction of biological performance, such as growth, reproduction, or survival.
Suspension feeder An organism that feeds on particular organic matter suspended in the water column.
Tidal amplitude The difference in vertical height between high and low tide.

The Intertidal Zone

At the interface between land and sea exists a narrow band where tides and waves generate some of the most extreme environmental gradients on Earth. This is the intertidal zone, so called because it is the area between the low- and high-water marks. The intertidal zone is characterized by considerable fluctuations in moisture and temperature between high tide when it is submerged under the sea, and low tide when it is exposed to air and sun. It is also the place where ocean waves collide with the land, introducing an along-shore gradient of pounding forces and splash between wave-exposed headlands and wave-sheltered bays. Despite these extreme conditions, the intertidal zone features an abundance of organisms that are adapted for survival in various niches of this harsh environment. On rocky shores, high densities of sessile or sedentary organisms form characteristic horizontal bands that show remarkable similarities around the world (Fig. 1). This pronounced intertidal zonation has inspired generations of naturalists and scientists to decipher the ecological processes and mechanisms that produce such distinct biotic patterns. Rocky shores have consequently served a role as outdoor laboratories in which seminal ecological theories were forged and tested through a wealth of field experiments. Other intertidal habitats such as sandy beaches are also subjected to stratified environmental conditions and display biotic zonation patterns resembling those on rocky shores, although less obvious to the eye. Hence, intertidal zonation both of rocky shores and sandy beaches will be described in this article.

Rocky Shore Zonation

Rocky intertidal communities exhibit the most pronounced zonation patterns of all intertidal habitats. Successive horizontal bands of organisms are a unifying theme of rocky shores; however, various factors can modify these widespread patterns. The confinement of a species' distribution to a discrete level on the shore was originally attributed to its physiological limits, but several ground-breaking studies have since demonstrated that biological interactions can determine lower limits, and sometimes also upper limits, of biotic zones.

Environmental Gradients Imposed by Tides and Waves

Most shores experience semidiurnal tides, which correspond to two high tides and two low tides per day. Thus, twice a day conditions in the intertidal zone alternate between being more or less terrestrial to wholly marine, inducing a steep vertical

☆*Change History:* March 2018. MC Pfaff and R Nel updated the article. It has been completely re-written, and thus all sections have essentially been updated. This is an update of C. Robles, Intertidal Zonation, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 2003–2010.

Fig. 1 Examples of intertidal zonation on rocky shores around the world: Near the Cape of Good Hope in South Africa (*top left panel*; 34.2°S 18.5°E), the low shore is occupied by pink coralline algae and the territorial limpet *Scutellastra cochlear*, the mid shore by a mixture of algae and the introduced mussel *Mytilus galloprovincialis*, and the high shore by various barnacles; off Vancouver Island in Canada (*top right panel*; 48.9°N 125.3°W), the predatory starfish *Pisaster ochraceus* lives low on the shore preventing the downward expansion of mussels, and barnacles and algae inhabit the zones above; in northern Chile (*bottom left panel*; 29.0°S, 71.5°W), characteristic bands of algal growth are interspersed by a mid-shore belt where grazing limpets and bare rock dominate; and on the sub-Antarctic Marion island (*bottom right panel*; 46.8°S 37.7°E) encrusting coralline algae and the kelp *Durvillaea antarctica* dominate the lower part of the shore and cushions of green algae host a number of invertebrate species on the high shore. Photographs by M. Pfaff (South Africa, Canada, Marion Island) and M. Aguilera (Chile).

gradient of environmental factors (**Fig. 2**). Intertidal organisms need to be extremely well adapted and hardy to tolerate such contrasting environments. Species that live high up on the shore spend much longer periods emerged and exposed to air and sun than those lower down on the shore. They must be able to withstand desiccation, thermal stress from extremely high (or low) air temperatures, the damaging effects of UV radiation, and osmotic stresses due to changes in salinity through evaporation or precipitation. Abiotic stresses therefore increase the higher up on the shore an organism lives.

Many marine organisms draw vital resources from seawater. Algae, for instance, absorb nutrients directly from seawater, and many invertebrates feed on suspended particles in the water column. Organisms found on the high shore have less time available to access these resources because they spend more time emerged. Resource limitation therefore adds to the abiotic stresses incurred by the organisms high up on the shore. Growth rates, reproductive outputs, and body sizes of organisms are inversely related to physiological stress and resource limitation, and tend to increase toward the lower extent of the intertidal zone. Moreover, biotic cover, species richness, and biomass also increase down the vertical slope.

Another environmental gradient that fundamentally influences the ecology of intertidal shores is induced by the gradual decline of wave action between exposed headlands and sheltered bays. Wave splash ameliorates the physical stresses associated with emersion during low tide and thereby markedly alters intertidal conditions, especially high up on wave-exposed shores. Furthermore, waves continuously supply rocky shores with particulate food for suspension feeders and with planktonic larvae,

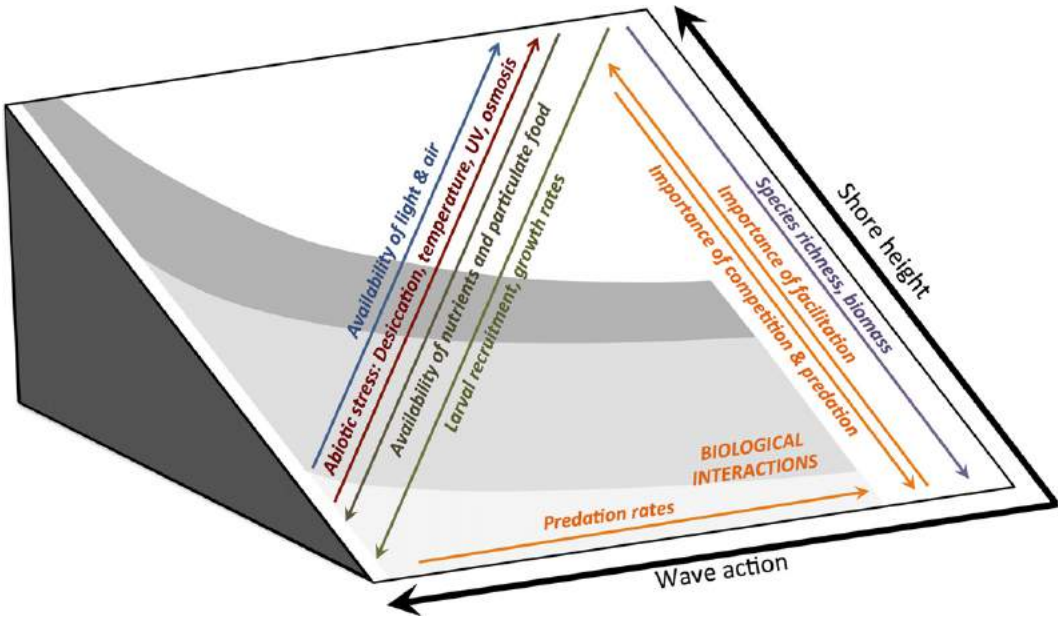

Fig. 2 Horizontal and vertical gradients of the abiotic and biotic factors that shape zonation patterns on intertidal rocky shores. The extent and alongshore compression of the three intertidal zones from wave-exposed toward sheltered shores is shown in gray shades (dark = high shore, medium = mid shore, light = low shore). Certain factors are more important for some species than others, and their importance might vary through time. Zonation patterns are thus often modified through complex dynamics and interactions of various processes.

which are important for the persistence of populations and communities. Last but not least, strong wave forces favor sessile or sedentary species that are firmly attached to the substratum and have streamlined body shapes. Along-shore differences in wave exposure gradient that exist between rocky shores of headlands and bays therefore shape characteristic along-shore patterns of biotic communities. These provide the backdrop upon which vertical zonation patterns are superimposed, and are therefore an integral part of descriptions of universal zonation patterns on rocky shores.

Zonation of Biota on Temperate Rocky Shores

Over the past two centuries, various zonation schemes have been developed for rocky shores. Zones have been defined by reference to dominant organisms, or in relation to particular levels of the tide, such as the mean high (or low) water level during neap and spring tides. Definitions based on physical criteria were initially considered to be more objective and were therefore more widely supported. However, they proved to be problematic in practice because tides are extremely variable and theoretical tidal levels do not necessarily have a clear manifestation on the shore. Moreover, zonation patterns are also influenced by factors other than tides, such as wave run-up, splash and spray, which rendered any classification based wholly on tides unsuitable for describing biological zones. Today, the most widely accepted framework is one that was proposed in 1949 by Anne and Allan Stephenson. They developed a classification scheme based on common patterns in the relative positions of certain community types along the intertidal gradient, which they had recorded during their extensive travels around the world. This so-called universal classification scheme for the zonation of rocky shores describes three zones, namely the "supralittoral," "midlittoral," and "infralittoral" zones (Fig. 3). While this scheme mostly holds true for patterns of temperate shores with moderate wave exposure, it is not always applicable since many factors modify and obscure the pattern, as discussed in further detail below (see "Modifications of the "Universal" Zonation Scheme" section).

Supralittoral fringe or high shore

Highest up on the shore, this zone is exposed to air most of the time and is only occasionally soaked by waves, spray, and spring high tides. Among the few organisms that can endure the long emergence times are encrusting lichens (e.g., *Verrucaria*), cyano-bacteria (blue-green algae), and large aggregations of tiny *Littorina* snails or other related genera (hence the occasional use of the term "Littorina zone" for this zone). In some locations, grapsid crabs, insect larvae, and isopods are common fauna of the high shore.

Midlittoral or mid-shore

The broad mid-shore zone encompasses the majority of the tidal gradient and is therefore usually divided into two: the "Upper Balanoid zone," where acorn barnacles (e.g., *Chthamalus*) dominate, as well as limpets (e.g., *Collisella*, *Patella*, *Scutellastra*); and the

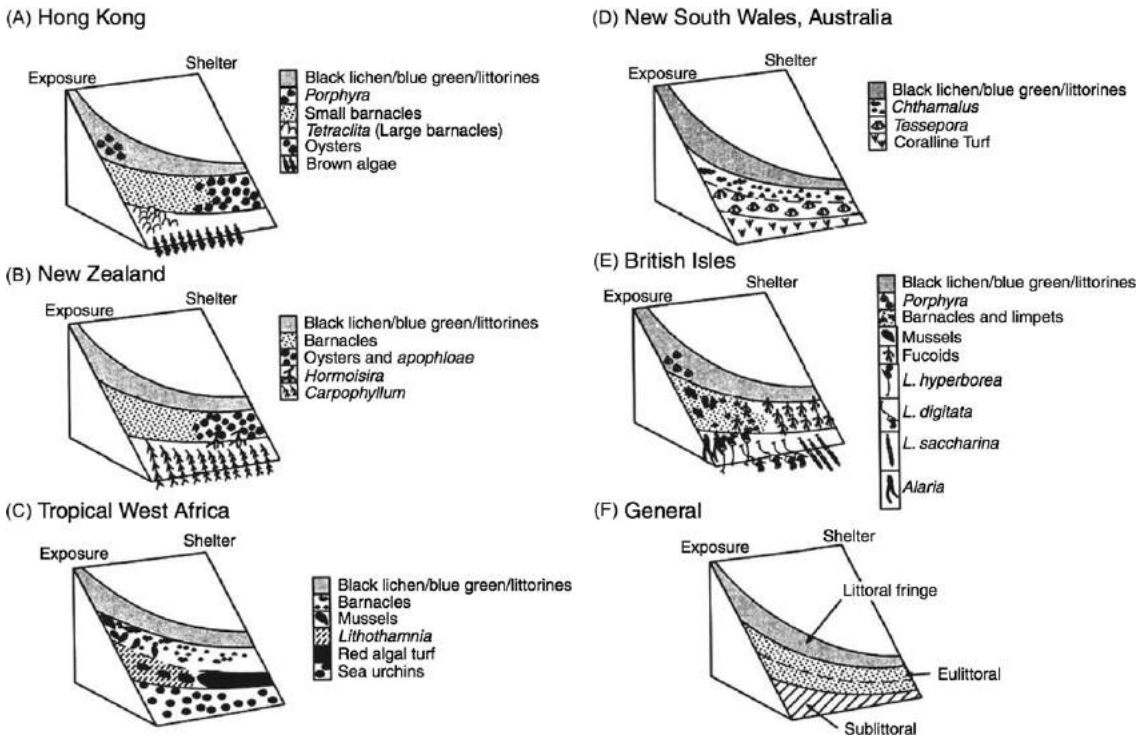

Fig. 3 Diagrammatic representation of intertidal zonation patterns in different parts of the world, and their modulation from exposed to sheltered extremes of wave exposure. Superficially, different regions show similar patterns; however, idiosyncrasies exist in each region depending on biogeographic context. Adapted from Raffaelli, D. and Hawkins, S.J. (1996). *Intertidal Ecology*. London: Chapman and Hall.

"Lower Balanoid zone," where suspension feeding mussels (e.g., *Mytilus*, *Aulocomya*), barnacles (e.g., *Semibalanus*), or oysters (e.g., *Crassostrea*) attain high densities. Depending on the geographic location, various species of macroalgae may also dominate in this zone.

Infralittoral or low shore

This narrower band at the bottom of the intertidal zone is only exposed to air during spring low tide. Red algae, including the pink encrusting and articulated coralline forms, dominate here. Where they exist, kelps (e.g., *Laminaria*, *Ecklonia*, *Durvillea*) or large tunicates can also prevail (e.g., *Pyura*).

Modifications of the "Universal" Zonation Scheme

A universal zonation scheme system is an attractive concept and provides a useful reference, but patterns in nature rarely adhere strictly to any one system of classification. Variations in zonation patterns exist across space and time and span a wide range of scales.

Spatial factors

At the broadest spatial scale, zonation patterns are modified by latitude. In the tropics (and also in high latitudes) extreme air temperatures are common, which makes life on the high shore taxing. In addition, tropical oceans are characterized by oligotrophic conditions and high grazing rates. Hence, productivity and biomass of algae on these shores tend to be very low.

At the scale of 1000s of km, marked differences in zonation patterns may exist between adjacent biogeographic provinces. A case in point is the shoreline of South Africa, which spans several biogeographic regions over 3000 km. On the west coast of the country, upwelling generates cold, nutrient-rich conditions, facilitating fast-growing giant kelps and high densities of the limpets *Scutellastra argenvillei* and *Cymbula cochlear* (**Fig. 1**A) in the low shore. The introduced mussel *Mytilus galloprovincialis* dominates the mid-shore and barnacles are scarce. On the warm-temperate south coast, low-shore kelps are replaced by the tunicate *Pyura* and a diversity of red and brown algae, while on wave-exposed shores the indigenous mussel *Perna perna* occupies the lower mid-shore, *M. galloprovincialis*, the upper mid-shore, and barnacles are very common on the high shore. Further north on the subtropical east coast, upright coralline algae, sponges, and mixed algal turfs characterize the low shore, various species of zoanthids cover the mid shore rocks, while on the high shore, a belt of oysters (*Saccostrea cucullata*) represents a distinctive feature of this region. Along this

remarkable biogeographic gradient, species richness and diversity increase from the cold west to the warm east coast, while biomass shows the inverse trend, increasing toward the west.

At the scale of 100s–1000s of meters, differences occur between wave-exposed and sheltered rocky shores of all regions. Most notably, the vertical range of intertidal species on wave-exposed shores is greater than at sheltered sites, with upper limits of some species extending considerably higher than the highest tide level (**Fig. 3**). This is a direct consequence of wave run-up, splash, and spray, which reduce the emersion time of the high shore during low tides and consequently reduce thermal stress and desiccation. Furthermore, suspension feeders benefit from food particles supplied by waves. The mid-shore of wave-exposed sites is therefore often dominated by dense mussel beds (lower mid shore) and barnacles (upper mid shore), both of which are suspension feeders. With decreasing wave exposure, mussels tend to be replaced by dense stands of algae while barnacles tend to decrease in density and co-occur with limpets, periwinkles, and algae.

Various processes cause significant small-scale heterogeneity in the vertical distribution of biota, which is reflected in the irregular rather than distinctly banded intertidal communities that occur at many locations. This patchiness is generated by physical and biological factors, such as slope, rock type, salinity, localized currents, sand inundation, and small-scale variability in settlement, recruitment, competition, and predation. The realization that localized processes commonly outweigh the effect of tides and waves has challenged the generality of zonation patterns and the usefulness of a universal classification scheme. Instead, it might be more valuable to recognize that multiple factors affect the spatial distribution of populations and communities, and that their relative contributions to vertical zonation patterns depend on scale and local context.

Temporal factors

Zonation patterns are driven by dynamic processes and are therefore also variable through time. Seasonal differences in the vertical distributions of mobile species and ephemeral algae are common and usually attributed to seasonal variability of one or more physical stressors, such as temperature and desiccation.

Marked shifts in zonation patterns have been observed over decadal time-scales, some of which reflect human impacts. For example, a fundamental transformation of many intertidal shorelines has occurred due to the invasion of introduced species. A well-known case is that of the Mediterranean mussel *M. galloprovincialis*, which has become spatially dominant on numerous temperate rocky shores around the world, displacing indigenous species and generating a wide mussel band where there was no such feature (**Fig. 4**). Long-term datasets that demonstrate the effects of climate change on rocky shore zonation are scarce. If, as predicted, the sea level rises due to ice melt and thermal expansion of the oceans, intertidal zones will most likely shift upward over time. However, if air temperatures continue to rise because of greenhouse gas emissions, the thermal stress gradient across intertidal zones will get steeper, forcing the spatial upper limit of most species downward. While accurate predictions of shifts in zonation patterns are difficult, if not impossible, it is likely that some species would expand horizontally or vertically, while others may contract or disappear in some regions.

Fig. 4 Changes in zonation patterns at Froggy Pond in False Bay, South Africa (34.21°S 18.46°E) between 1980 (*left*) and 2015 (*right*). A band of the introduced mussel *Mytilus galloprovincialis* has become a prominent feature of South African intertidal zones replacing indigenous species, such as algae and limpets. Photographs by G. Branch, adapted from Branch, G.M. and Branch, M. (2018). *Living Shores*. Cape Town: Struik Nature.

Causes of Zonation on Rocky Shores

Critical tidal levels

Initial explanations of intertidal zonation patterns were primarily based on observations of species distributions and their correlations with physical environmental gradients. The Critical Tidal Factors hypothesis, which was widely subscribed to during the first half of the 20th century, stated that the vertical limits of species distributions coincide with those sections on the shore where the gradient of physical stresses is particularly steep. At these critical levels, the physiological limits of species are exceeded and they are replaced by a different set of species, which are adapted to the changed conditions. Such critical levels were thought to exist because of the manner in which the tidal range varies over the course of a fortnightly lunar cycle (Fig. 5). During neap tides (around half moon), the highest levels of the shore remain exposed to air and sun but as the tidal cycle shifts to the spring tides (around full/new moon), tidal amplitudes become high and the whole intertidal slope gets submerged twice daily by the elevated high tides. Physical stress therefore changes in a stepwise fashion between critical tidal levels that can be defined according to how much time they are emerged for. Examples are the mean low-water mark during spring tides and the mean high-water mark during neap tides, both of which were thought to coincide with lower/upper species limits. Results of numerous laboratory experiments showing that high-shore species are more tolerant of aerial exposure than those found lower on the shore were taken as support of this theory.

A series of field experiments and novel quantitative analyses conducted during the 1960s and 1970s, however, conclusively demonstrated that the Critical Tidal Levels hypothesis was not supported by either physical or biological evidence. Since then, the focus has shifted away from correlative inferences of zonation patterns based on physical variables, toward experimental investigations of their causes. This important conceptual shift, in the manner that intertidal ecologists started linking patterns with processes and mechanisms, led to the understanding that biological factors, such as competition and predation, are in fact instrumental in determining the upper and lower limits of zonation patterns.

Causes of upper limits

There seems to be widespread acceptance that the upper limits of most intertidal species are determined by physical stresses, such as thermal stress and desiccation. Since most intertidal species are of marine origin, they require periodic wetting to fulfill some primary functions such as feeding, reproduction, and respiration, to survive. Furthermore, temperatures in the sea are less variable or extreme than those on land so that organisms occurring higher up on the shore are more likely to exceed their capacity to tolerate thermal extremes and perish. Young life stages tend to be more vulnerable to desiccation, and episodes of extreme temperatures periodically eliminate recruits of algae and sessile animals high up on the shore, thereby limiting the upper ranges of many species. Even lower down, extremely hot conditions on temperate shores have been known to cause bleaching and mortalities of red algae, indicating that their upper limits are periodically reset by physical extremes. However, physical stress does not have to be lethal to limit species distributions. Physiological adaptations may enable organisms to tolerate extreme conditions, but because of the associated high energetic costs, mobile organisms may rather select to settle on habitat where conditions are more moderate to minimize costs of maintenance and production. Moreover, the shorter emersion times higher up on the shore correspond to less time for marine larvae that are suspended in seawater to settle on the shore. The smaller likelihood of larvae settling high up on the shore further imposes upper limits to species distributions.

That the upper limits of species distributions are influenced by physical stresses has also been confirmed through several field experiments. Sessile organisms, such as algae or barnacles, when transplanted further up on the shore, showed decreased growth

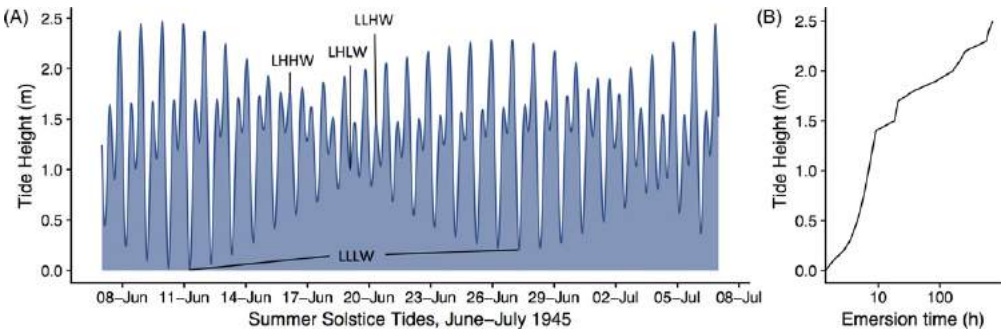

Fig. 5 (A) Tidal variation over the course of a month at Monterey Bay, California, showing mixed semidiurnal tides characterized by two different high- and low-tide amplitudes each day. Periods with greater tidal amplitudes (e.g., 7–14 June, 22–29 June) are referred to as spring tides and those with lower amplitude as neap tides (e.g., 15–21 June). The time period and region shown correspond with those for which the Critical Tidal Factors hypothesis was proposed (Doty, 1946). Levels considered as critical tidal factors are labeled according to the diurnal and spring neap variation in the tides. For example, LLLW refers to lower low low water, which is the spring (extreme) low of the lower of the two diurnal low tides. Other levels shown are lower high high water (LHHW), lower high low water (LHLW), and lower low high water. Intertidal zonation patterns were originally thought to correspond to discontinuities in tidal emersion (i.e., the time a particular shore level spends out of the water) shown in (B). However, this theory was later falsified by experimental proof of the importance of biological interactions in setting upper and lower limits of intertidal zones.

and eventually perished. Natural transplant experiments at the scale of whole communities have taken place when rocky shore ledges were lifted by earthquakes, as reported from Chile and Mexico. The communities that were displaced upward perished entirely and zonation patterns eventually re-established further down on the shore. Other experiments have manipulated moisture levels in high-shore zones and reported that species at the top of the shore shifted further upward, given enough moisture. However, to determine the exact mechanisms whereby environmental factors impose upper limits is difficult. There are various physical stress gradients that occur in the intertidal zone (**Fig. 2**) and the specific factor or combination of factors that determine the upper limits of a species may vary with location or time. It is therefore not always clear as to whether upper limits are in fact determined by physical factors, and alternative mechanisms have also been proposed, such as effects of food or nutrient limitation. Such factors can affect a species' performance and survival in a similar way to physical stress. Larval habitat selection can also be an important driver of zonation. Larvae of sessile species, such as barnacle cyprids, are known to carefully choose the substratum on which they settle, based on chemical cues, resulting in occupancy of a specific, preferred intertidal zone by adults. Vertical limits of some species are therefore the result of behavioral mechanisms, and not physical stresses.

In some cases, the upper limits of species are determined by biological interactions among species. In the British Isles, experimental removal of different species of fucoid algae, which naturally occur in discrete horizontal belts, has led to shifts of fucoids from lower zones into the higher, vacated zone, out of their natural range. These and similar experiments suggest that several mid and low-shore species are able to tolerate conditions higher up on the shore, but that their upper limits are set by competition with higher shore species. Grazing is another important biological factor responsible for upper distribution limits on rocky shores. In various temperate shores of the world, experimental removal of grazers, such as limpets, has allowed algae to extend further up the shore than where they occurred under grazed conditions.

Causes of lower limits

Since physical stress levels decrease further down the shore, lower limits of intertidal organisms are rarely set by physical factors, but are instead a product of biological interactions. However, as for upper limits, many different factors (as well as complex interactions between them) can determine lower limits, the most prominent being competition and predation.

A pioneering study that highlighted the importance of competition for zonation patterns focused on barnacles on the west coast of Scotland. There, the high shore is characterized by a distinct band of *Chthamalus* above a zone of the larger, faster-growing *Semibalanus*. Transplant experiments indicated that *Chthamalus* was able to settle and survive the physical conditions below its natural zone, but that it would then be crushed and smothered by *Semibalanus*, which in turn could not tolerate conditions higher up on the shore. Removal of the latter facilitated a downward shift of *Chthamalus*, convincingly showing that the lower limits of this species are determined by competitive interactions with *Semibalanus*.

Another influential experiment from the north-west coast of the United States proved the importance of predation for setting the lower limits of sessile invertebrates. On this shore, the mussel *Mytilus* forms dense stands along a clearly defined band in the intertidal zone, below which there is a zone dominated by the predatory mussel-consuming starfish *Pisaster*. For a 5-year period, starfish were cleared from the low shore at two sites, which facilitated a downward expansion of *Mytilus* to two meters below its natural lower limit. From this study emanated the concept of a keystone species. A keystone predator fulfills a central role in maintaining species diversity by limiting the abundance of a spatially dominant prey species, in this case *Mytilus*.

The lower limits of zone-forming algae, which are common features of rocky shores, tend to be imposed by competition or grazing. Several species of fucoid algae occur in different intertidal zones of Scotland. Experimental removal of a lower shore species allowed a higher shore species to expand downward. The competitive hierarchy of fucoids was found to be correlated with their growth rates, such that faster growing species dominate the lower shores while slower growing species are displaced up the shore. Low-shore kelps of cold-temperate shores, such as *Laminaria*, *Lessonia*, and *Durvillea*, have extremely fast growth rates and are therefore known to push other seaweeds upward.

Multi-factorial approaches

From the above it is clear that there are multiple biological and physical factors that can interact dynamically along intertidal gradients. This results in a highly complex web of interactions that are difficult to disentangle by experiments alone. With the advancement of numerical modeling, intertidal zonation patterns have been revisited within a multifactorial framework that is based on information from an extensive body of empirical studies, some of which are described above. These models have the advantage that physical stresses and vertical trends in recruitment and growth rates imposed by tides can be combined with biotic processes such as variable settlement, indeterminate growth, size-dependent competition, grazing, and predation. Several such models have successfully reproduced intertidal zonation patterns based on multifactor interactions. For example, an individual-based model of fucoid algae in the British Isles, for which inputs were derived from laboratory and field studies, was able to recreate and confirm a mechanism for algal zonation that was proposed more than a century ago, namely that the zonation was a result of the trade-off between growth rate and tolerance to desiccation. Another example, where the mechanisms underlying zonation patterns across a wave-exposure gradient were confirmed using a model, is the predation-based model of the *Mytilus–Pisaster* system.

Both the above models showed that zonation patterns can be shaped by complex interactions between physical gradients and various biological characteristics of a population, as opposed to simple direct effects of single physical or biological factors. According to this view, the upper and lower limits of a species are determined by multiple factors that are dynamic in time and

space. This means that the vertical extent of a species will vary in space and time and that where or when its lower and upper limits converge, conditions are such that the species cannot exist. This can come about at the range limit of a species, or represent a localized extinction due to unfavorable conditions.

Sandy Beach Zonation

At first glance, sandy beaches appear to be devoid of life, other than perhaps for crowds of tourists. While keen observers may recognize a few resident bird species, ghost crabs, or plants on vegetated dunes, it might seem unlikely to them that beaches are in themselves ecosystems with unique biota distributed in specific zones across the shore. However, pronounced physical gradients similar to those described for rocky shores also exist on sandy beaches, and faunal assemblages mirror them in their vertical and horizontal distribution patterns.

Dependence of Beach Slope on Particle Size, Waves, and Tides

Like rocky shores, sandy beaches are characterized by wave action and fluctuations of the tides, which continuously reshape the unconsolidated sediments that these shores are composed of. This creates a dynamic, three-dimensional environment in which most animals are buried below the sand surface during low tide. Three "super parameters," namely sediment particle size, wave action, and tidal range, interact in predictable ways to create beaches with a variety of slopes and different morphodynamic states. When a breaking wave rolls up the beach, the "swash" moves sediment up the shore, and the "backwash" carries it back down. If the beach consists of coarse sand, water drains quickly into the permeable substrate on the upwash, accreting the beach and forming a steep beach face... Fine sand, on the other hand, gets waterlogged due to its low permeability, resulting in equally strong upwash and backwash processes. Thereby sand particles suspended in the swash are removed, the beach gets eroded and the beach face flattens. Thus, given constant wave action, the beach slope steepens with an increase in grain size.

Wave action and tidal range furthermore affect the beach slope. Stronger wave action on exposed shores is associated with increased swash action and more waterlogged beaches. The stronger swash processes cause erosion of the beach face and thereby create flatter beaches. Beaches with a large tide range, where large amounts of water move up and down the intertidal zone during a tidal cycle removing particles, tend to be wide and flat.

Beach Morphodynamic States

Based on beach slope, particle size, and wave action, beaches can be classified according to various morphodynamic states. At the extremes of the spectrum are "reflective" or "dissipative" beaches. Reflective beaches are characterized by small waves, fast swashes and coarse sand. They are steep, with narrow or no surf zones, and the wave energy arriving on the beach face is reflected back out to sea. Reflective beaches are considered physically harsh for intertidal life and are characterised by depauperate communities. By contrast, dissipative beaches have large waves with long and slow swashes, and fine sand. They have flat slopes and wide surf zones, where most energy is dissipated and little of this energy reaches the beach face. Thus, conditions on dissipative beaches are benign and they feature relatively high species richness and abundances. Most beaches are intermediate between these two extreme states. Where fine sand and large waves occur in combination with tidal ranges exceeding two metres, ultra-dissipative conditions develop.

Physical Zonation Schemes

The most widely recognized zonation scheme for sandy beaches is that developed by the French ecologist Salvat in 1964. In contrast to the universal zonation scheme for rocky shores, which is based on biotic patterns, this sandy beach zonation classification is based on physical features. Four zones are defined, based on vertical changes in the hydrodynamic properties of the intertidal zone, namely the zones of saturation, resurgence, retention, and drying (**Fig. 6**). The zones are most clearly identifiable during spring low tide; however, due to the dynamic nature of beaches and lack of a permanent reference points, zones are not fixed and may vary between spring and neap tides. The saturation zone is the area where the sediment is permanently saturated with water, or waterlogged. Oxygen levels in the sediments of this zone are frequently low due to high bacterial activity and low exchange rate of water, especially on fine-grained beaches. The resurgence zone is the compact zone extending from the low tide mark upward and is characterized by wet sand during low tide. Moisture is retained through capillary action and exchanged throughout a tidal cycle. The resurgence zone is difficult to distinguish visibly and it blends into the neighboring retention zone. The retention zone is located on the upper shore, and is characterized by damp (not wet) sand. Physically it extends from about 20–30 cm above the low tide water table (which is the upward extent of capillary action) to the neap high-tide level of the shore, and water permeates into the substrate during incoming tides. Due to frequent replenishment and contact with air, oxygen levels are highest in this intertidal zone. The highest level of the shore is the drying zone. It is only under water during spring high tides, and mostly constitutes dry, loose sand. For convenience, the zones on sandy beaches are commonly referred to as "supralittoral" (drying zone), "littoral" (retention and resurgence zones), and "sublittoral" (saturation zone). In further sections, these terms will be used to describe biotic zonation patterns.

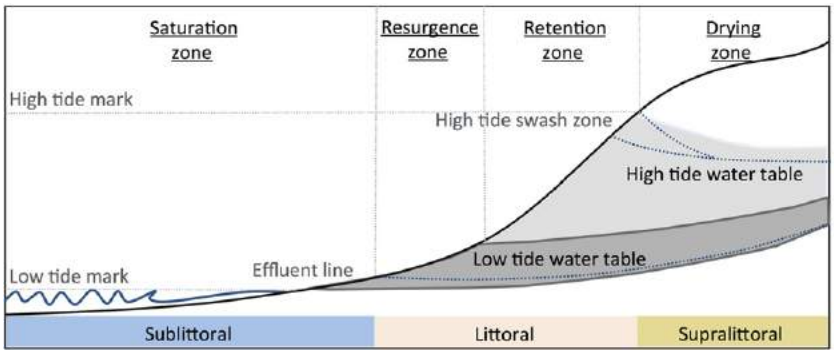

Fig. 6 Diagram showing the sandy beach zonation scheme of Salvat (1964). Four vertical zones (Saturation, Resurgence, Retention, and Drying zones) are defined based on physical characteristics, such as the wetness of the substratum. Adapted from McLachlan, A. and Defeo, O. (2018). *Ecology of Sandy Shores*. London: Academic Press.

Faunal Zonation Patterns

Macrofauna

Characteristic macrofaunal assemblages are associated with the physically defined vertical zones of sandy beaches; however, biotic zonation patterns also vary horizontally along the gradient of morphodynamic beach states (**Fig. 7**). On reflective beaches, only two biotic zones can be distinguished: a littoral zone of marine species on the lower shore and a supralittoral zone of air breathers higher up. On intermediate and dissipative beaches, these biotic zones are found higher up and a third sublittoral zone exists low down on the shore. Nearer to the ultra-dissipative extreme, the sublittoral saturation zone widens and a fourth biotic band can be distinguished (**Fig. 4**).

The physical harshness of reflective beaches allows for only highly robust organisms to persist. Under the most extreme conditions on steep reflective beaches only supralittoral oniscid pill bugs such as *Tylos*, wrack feeding sand hopper amphipods (*Talitrus* or *Orchestia*), and ocypodid ghost crabs survive in the supralittoral zone. In the mid intertidal, or littoral zone, a number of crustaceans are commonly found, especially generalists such as cirolanid isopods (*Excirolana* or *Eurydice* species). Lowest on the shore, just beyond the lower boundary of the intertidal zone by definition, are fast burrowing hippid crabs (*Hippa* or *Emerita*) and donacid bivalves. The more benign conditions that occur lower down on the shore are associated with a greater availability of niches; this is reflected in the greater number of specialist species on intermediate and dissipative shores. Polychaetes (*Scolelepis*) and amphipods (*Urothoe*) are more abundant here and scavenging whelks, such as *Bullia* or *Olivella*, thrive. The saturation zone can be considered an upward extension of the surf zone, and it is characterized by filter-feeding and deposit-feeding crustaceans, polychaetes, and donacids, as well as bentho-planktonic forms such as mysid shrimps (e.g., *Gastrosaccus*).

Species richness increases linearly along the spectrum from reflective to dissipative beaches, whereas abundance and biomass increase exponentially. With an increase in the density and diversity of biota, biological interactions such as predation and competition are more likely to have a structuring effect on communities. However, manipulative experiments to confirm interactions and mechanisms are difficult in this highly dynamic environment.

In comparison to rocky shores, the physical and macrofaunal zonation patterns on sandy beaches are more dynamic and their boundaries shift with the tides. Also, species found on sandy beaches are not tightly restricted to any one zone; they can be distributed over multiple zones and across a range of physical conditions. To cope with these changing conditions, sandy beaches are dominated by mobile species, in contrast to rocky shores that are dominated by sessile or sedentary organisms. The ability to run, burrow, or swash-ride makes it possible for animals to escape unfavorable conditions across the beach and move with the changing tide. In this three-dimensional habitat, biological interactions are less important in structuring communities, and intertidal across-shore zonation is more tightly linked with physical gradients. The exceptions are ultra-dissipative beaches, where species occur in higher densities and biological interactions may become more influential in structuring the zonation of intertidal communities.

Meiofauna

On a scale that is virtually invisible to the naked eye, sandy beaches host an astonishing diversity of life forms, known as meiofauna. Almost all known metazoan phyla are present in the meiofauna. Whereas macrofauna are adapted to displace sediments with their robust exoskeletons, most meiofauna live in the moist spaces between the sand grains, and therefore typically have slender or worm-like body shapes. Meiofaunal communities are also characterized by intertidal zonation patterns, which closely reflect water saturation levels of the sediment. The supralittoral dry zone on the high shore is dominated by small nematodes and oligochaetes. Lower down, in the littoral zone where the sand is moist and oxygen saturation is consistently high ($>50\%$), a variety of species coexist, including harpacticoid copepods, nematodes, mystacocarids, Oligochaetes, and turbellarians. In the sublittoral zone, where oxygen levels tend to be depleted through bacterial decay of organic matter, low densities of

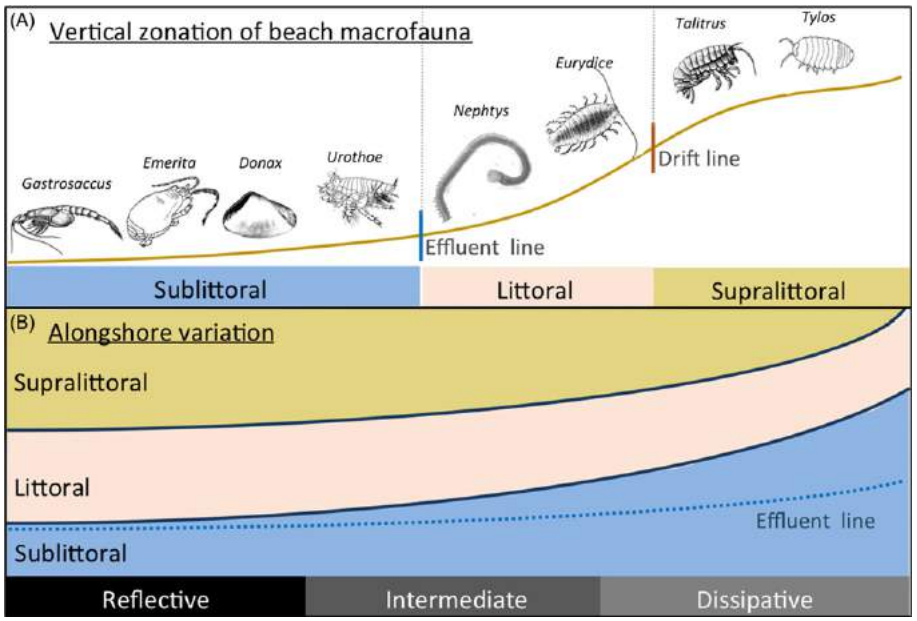

Fig. 7 Zonation scheme for sandy beach macrofauna with (A) the typical organisms occupying different levels across the shore (and names of most common genera) and (B) the alongshore modulation of the scheme according to morphodynamic beach state. Two zones get exposed during low tides on reflective beaches, three on intermediate beaches, and four on dissipative beaches. Modified from McLachlan, A. and Defeo, O. (2018). *Ecology of Sandy Shores*. London: Academic Press.

nematodes are found. The abundance of meiofauna increases with an increase of filtration rates from dissipative to reflective beaches, which is contrary to the pattern observed for macrofauna.

Impacts of Zonation Research

The ubiquitous zonation patterns that exist along the intertidal stress gradient have inspired numerous ecologists to investigate their underlying mechanisms. Several of these studies were instrumental in pushing the envelope of community ecology by introducing novel ideas of community regulation through species interactions (see "Causes of Zonation on Rocky Shores" section). Field experiments on intertidal rocky shores, in particular, have made important contributions toward understanding the roles of predation, competition, grazing, facilitation, and the interactive effects of physical and biological factors on structuring communities. Despite extensive research, intertidal zonation remains a field of current interest. New challenges include understanding how the impacts of human-induced pressures, such as introduced species, pollution, exploitation, and climate change, will affect the interplay of physical and biological drivers that shape intertidal zonation patterns.

Maximum Sustainable Yield

Athanassios C Tsikliras, Aristotle University of Thessaloniki, Thessaloniki, Greece
Rainer Froese, GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany

Introduction

Although the term "over-fishing" was coined already in the mid-1850s (Cleghorn, 1854), the overexploitation of marine fisheries resources was only realized in the early 1900s, when the first study (Garstang, 1900) and articles on overfishing (Petersen, 1903; Kyle, 1905) were published. By that time, the need for simple and easy to understand guidance on catch limits emerged. The maximum catch that a population can support seemed to be an excellent reference point for fisheries management.

Maximum Sustainable Yield (MSY) is the most well-known acronym in fisheries science and, as a concept, has a history of around 100 years (Baranov, 1918). It was formulated in the 1930s when mathematical models were introduced in population ecology (Hjort et al., 1933) and bloomed in the 1950s with the development of surplus production models.

Today, MSY has been adopted by the vast majority of regional management bodies (Hilborn and Walters, 1992; Quinn and Deriso, 1999; Mace, 2001; Hart and Reynolds, 2002; EC, 2009; Pauly and Froese, 2014) and it is therefore widely used as a reference point in the assessment of exploited populations (stocks) around the world.

The MSY Concept

Definition of MSY

MSY (also called maximum surplus production, maximum equilibrium catch, maximum constant yield, maximum sustained yield, sustainable catch: Ricker, 1975; Hilborn and Walters, 1992; Quinn and Deriso, 1999; Mace, 2001) is the highest theoretical equilibrium yield that can be continuously taken from a stock under existing (average) environmental conditions (FAO, 2001). It is the highest catch that still allows the population to sustain itself indefinitely through somatic growth, spawning, and recruitment (Graham, 1943; FAO, 2001).

MSY was formally introduced by Milner Schaefer (Schaefer, 1954) who developed the model named after him based on the logistic curve of population growth (Fig. 1). Plotting the first derivative (= the slope) of that curve over the corresponding biomass (the collective weight of the individuals at a certain time) shows the increase in biomass (termed surplus production or yield) with time, in the form of a parabolic curve (Fig. 2). The interpretation of the parabola is easy: at the left end there is zero biomass and therefore zero yield. At the opposite end, where the population is at carrying capacity of the ecosystem for this stock, there is no surplus production by definition and thus again zero yield. In other words, initially the population grows exponentially, unrestricted by environmental conditions. But as population size approaches carrying capacity, growth slows down and eventually seizes. Because of the symmetric shape of the logistic curve, maximum surplus production or yield is reached at half of maximum population size in the Schaefer model (Fig. 2; see "Methods to Estimate MSY section"). Taking away this maximum surplus production by fishing prevents the population from growing any further, basically keeping it at half of maximum population size, producing maximum surplus forever; hence this is the point of MSY.

In this simple model, the rate of population increase r is a linear function of biomass, maximum at zero population size, and zero at carrying capacity (Hart and Reynolds, 2002; Quinn and Deriso, 1999).

Various explanations have been offered for the typical S-shape of population growth, such as improved somatic growth at low population size versus increased intraspecific competition at high densities (Hart and Reynolds, 2002). Carrying capacity (K) has

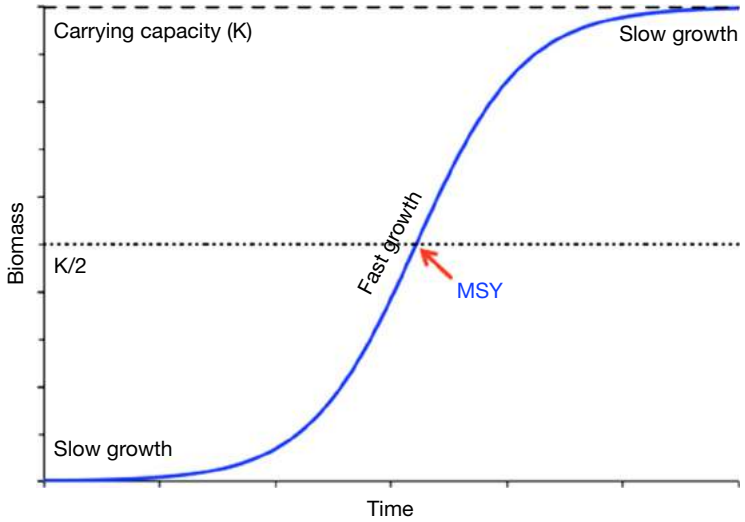

Fig. 1 The logistic (sigmoid) curve of population growth over time. The carrying capacity (K) and MSY (=K/2) are indicated along with phases of slow and fast population growth.

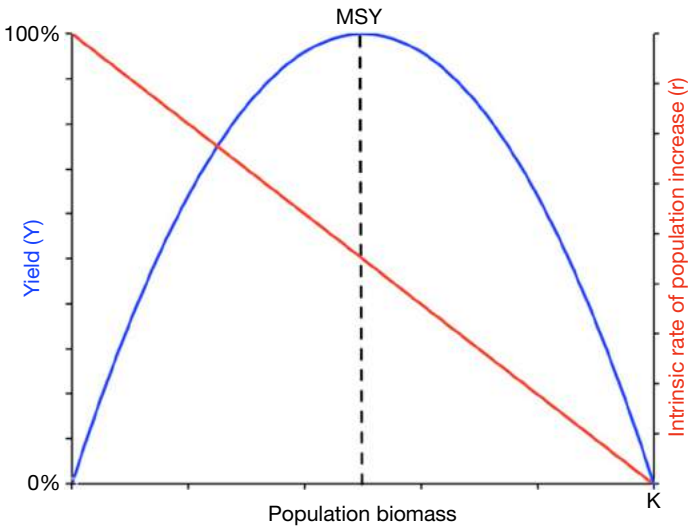

Fig. 2 The parabolic curve of surplus production or equilibrium yield (as % of MSY) as a function of population biomass (as % of carrying capacity, *K*). The second *Y*-axis shows the intrinsic rate of population increase r, which in the Schaefer model is maximum at zero biomass and declines linearly to zero at carrying capacity. Note that MSY is produced at half of r_{max}.

been interpreted in Malthus' terms as being caused by limited food availability (Seidl and Tisdell, 1999). However, today most ecologists agree that the main driver of population growth is the interplay between reproductive success and mortality (Charnov, 1993; Sibly et al., 2012): once the number of new individuals equals the number of deaths population growth seizes. At low population sizes, new individuals exceed the number of deaths and population growth is exponential. But while the number of deaths remains proportional to population size, the production of new individuals slows and reaches a more or less constant value once the population has grown beyond about a quarter of carrying capacity. As a result, the exponential growth slows to a linear growth at about half of carrying capacity and declines thereafter, approaching carrying capacity in an asymptotic curve (Fig. 3). Density effects causing death by starvation are thought to apply mostly to early life stages (Houde, 1987; Bailey and Houde, 1989; Hüssy et al., 1997) and cause a limit to reproductive success, as indicated by the green curve shown in Fig. 3.

Today, the MSY definition most widely used is the one proposed by Ricker (1975). According to "the green book" of Ricker, MSY is defined as the largest average catch or yield that can continuously be taken from a stock under existing environmental conditions but for species with fluctuating recruitment the maximum catch may be obtained by taking fewer fish in some years than in others (Ricker, 1975).

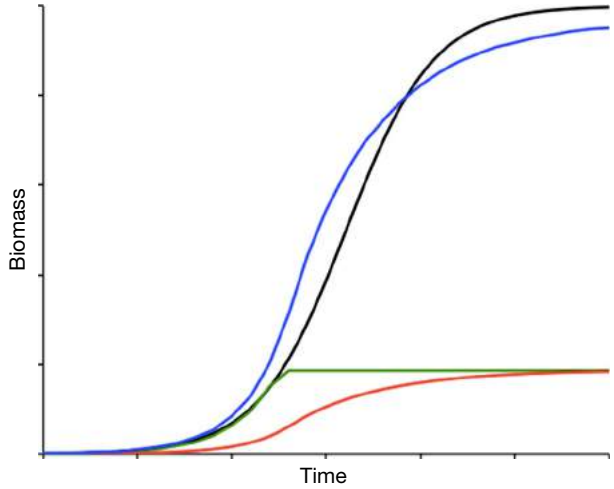

Fig. 3 The theoretical logistic curve of population growth over time (*black line*) compared with a hypothetical curve (*blue line*) resulting solely from the number of deaths (mortality: *red line*) and the number of replacements through recruitment (reproductive success: *green line*), which is more or less constant above about a quarter of carrying capacity.

Related Biological Reference Points

Current fisheries management is based on fishing mortality and biomass reference points that correspond to MSY, although MSY itself is rarely used as a reference point. Two related reference points are applied: one is the fishing mortality or fishing pressure (F_{MSY}) that, if applied over a time span similar to generation time, will eventually result in a catch equal to MSY (Fig. 4) where F describes the part of the total mortality rate that is caused by fishing. For example, $F = 0.6$ means that about 60% of the fish that are there on average over the year will be killed by fishing. The other related reference point is the biomass at MSY, B_{MSY}, which is the smallest stock size that can support catches equal to MSY, and which is the biomass corresponding to the peak in Fig. 2.

In age-structured assessment models, the fishing mortality that results in the maximum yield per recruit (F_{MAX}) is close to F_{MSY} if the yield per recruit versus F curve has a well-defined peak. However, if that peak is less well defined, as in Fig. 4, then F_{MAX} may be substantially larger than F_{MSY} (Longhurst, 2006).

Methods to Estimate MSY

MSY, $F_{MSY,}$ and B_{MSY} can be estimated from surplus production models, which require catch and effort or an index of biomass or relative abundance (e.g., catch per unit of effort) as input. Alternatively, these or similar reference points can be obtained from age-structured models, which are, however, more data demanding.

Surplus Production Models

Surplus production models are used to assess stock status and exploitation in data-limited areas where reliable information on age and length structure and natural mortality are not available (Beverton and Holt, 1957; Punt, 2003). They are applied not only to stocks with available commercial catch data and some index of exploitable biomass, such as catch per unit of effort (CPUE) derived from scientific surveys, but also to migratory stocks and crustaceans that are difficult to age (Polacheck et al., 1993). They assume that sustainable catch is a simple function of population biomass, regardless of the size and age composition of that biomass (Holt, 2014).

The most widely used surplus production model is the one developed by Schaefer (1954):

$$B_{t+1} = B_t + r_{max}B_t\left(1 - \frac{B_t}{K}\right) - C_t$$

where B_t is the biomass of the stock at time t and $t + 1$, r_{max} is the maximum intrinsic rate of population increase, K is a parameter which corresponds to the unfished equilibrium stock size or carrying capacity, and C is the catch per unit of time (usually a year).

Surplus production or yield (Y) is calculated as:

$$Y = r_{max}B_t\left(1 - \frac{B_t}{K}\right)$$

MSY is calculated as:

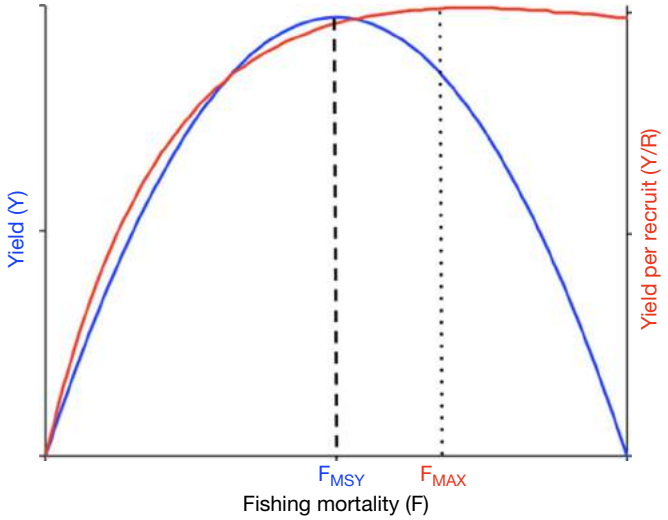

Fig. 4 Difference between the position of F_{MSY}, the fishing mortality expected to yield MSY in a surplus production model (*blue line*) and those of F_{MAX}, the mortality from yield-per-recruit curves (*red line*).

$$MSY = \frac{r_{max}}{2} \times \frac{K}{2} = \frac{r_{max}K}{4}$$

where $r_{\max}$ is the maximum intrinsic rate of population increase, B_t is the population biomass at time t, and K is the carrying capacity of the ecosystem for this population (Schaefer, 1954).

Another surplus production model was developed (Fox, 1970) that assumes a logarithmic relation between biomass and catch:

$$B_{t+1} = B_t + r_{max}B_t\left(1 - \frac{\log(B_t)}{\log(K)}\right) - C_t$$

where variables and parameters are as defined above.

In the Fox model surplus production or yield is calculated as:

$$Y = r_{max}B_t\left(1 - \frac{\log(B_t)}{\log(K)}\right)$$

MSY is calculated as:

$$MSY = \frac{r_{max}K}{e}$$

In the Schaefer model, maximum yield (MSY) is obtained at 50% of carrying capacity and in the Fox model at 37% of carrying capacity. Pella and Tomlinson (Pella and Tomlinson, 1969) proposed a model with a third parameter p that determines the shape of the yield curve and allows maximum production to occur at any biomass.

The Pella-Tomlinson model is:

$$B_{t+1} = B_t + \frac{r_{max}}{p}B_t\left(1 - \frac{B_t}{K}\right)^p - C_t$$

where variables and parameters are as defined above and p is a shape parameter that results in the Schaefer curve if $p = 1$ and approximates the Fox curve if p approaches 0.

Surplus production or yield is calculated as:

$$Y = \frac{r}{p}B_t\left(1 - \left(\frac{B_t}{K}\right)^p\right.$$

MSY is calculated as:

$$MSY = r_{max}K\left(\frac{1}{1+p}\right)^{\left(\frac{1}{p}+1\right)}$$

The Schaefer surplus production model is the one most commonly used in fisheries management because of its simplicity and applicability in data-poor stocks.

Age-Structured Models

In cases where age and length data are available, surplus production models have been replaced by age-structured models that also provide estimates of MSY and relevant reference points but these models are data demanding (Hilborn and Walters, 1992; Mace, 2001) and require population age and length, growth parameters, mortality and maturity, as well as selectivity of the main gears. Estimates of MSY, F_{MSY}, and B_{MSY} are typically obtained from stochastic simulations.

Age-structured models are widely used in assessing stocks and require estimates of mortality, maturity, catch, and abundance per age group, but these models are not suitable when only catch and biomass data are available.

Economic Considerations

Only 150 years ago, the advisor on fisheries to the British Government (Huxley, 1884) declared that humans were unable to overexploit marine fish stocks. The subsequent advent of steam trawlers and the collapse of North Sea herring (Dickey-Collas et al., 2010) proved him wrong and for over 75 years it was well understood that fisheries need to be regulated to sustain fish stocks and profitable fisheries (Graham, 1943). This can be easily demonstrated by adding cost of fishing (which increases about linear with effort) and profits (the difference between the value of the catch and the cost of fishing) to the parabola graph of the relation between yield and effort (Fig. 5). In most fisheries the cost of fishing at the MSY level is less than the value of the maximum sustainable catch and maximum profit or maximum economic yield (MEY) is actually obtained with even less fishing effort, simply because the linear decline in cost is steeper than the corresponding decline in catch near the peak of the parabolic curve (Fig. 5). Unfortunately, effort in most fisheries in the world is far above the MSY level resulting in low catches and economic loss (Costello et al., 2012; Froese et al., 2017). This is possible because governments give handouts (= subsidies) to the fishers, which lower the cost of otherwise economically unsustainable overfishing.

MEY is the antidote to the illusion of most fishers (and some politicians) that higher fishing effort results in higher profits. In reality, profits decline once effort exceeds the MEY level and catches decline once effort exceeds the MSY level (Fig. 5).

History and Legal Status of MSY

MSY is based on the classical ecological concept of logistic population growth that was developed in the 1830s (Verhulst, 1838), continuing the earlier work of Robert Malthus on demographics (Malthus, 1798). The first application of the logistic model on

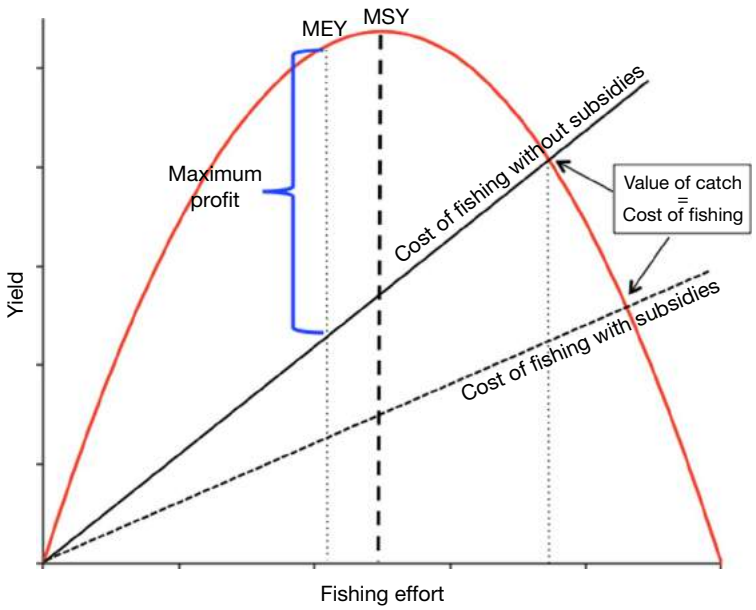

Fig. 5 Yield (*red line*) as a function of fishing effort, with cost of fishing with (*dashed black line*) and without subsidies (*continuous black line*) assumed to increase about linearly with effort. Profit is the difference between the value of the yield and the cost of fishing, with a maximum economic yield (MEY, *dotted vertical line*) obtained from effort and catches below the MSY level (*dashed vertical line*). If costs of fishing are lowered by subsidies, fishing can continue beyond the break-even point, where the value of the catch equals the cost of fishing (second *dotted vertical line*).

marine species was by Johan Hjort and his colleagues in the 1930s, who studied the blue whale fishery, based on mortality and reproduction data (Hjort et al., 1933). They developed the notion of optimal catch, which occurred at intermediate exploitation levels based on their observations on fin whales in Iceland, cod and herring in Norway, and plaice in the southern North Sea (Holt, 2014). Hjort et al. (1933) showed that the greatest rate of population growth increase occurs when the population size is about half its ultimate size and that there was a maximum catch that could be sustained, later termed MSY (Hart and Reynolds, 2002).

Shortly after Hjort's work, Michael Graham further developed the logistic population growth equation and applied it to fisheries data (Graham, 1935, 1943). He identified slow and fast population growth phases, with fast growth, low density and younger fish at low population sizes and slow growth, high density and many old fish at large populations near carrying capacity (Graham, 1935). Based on his observations from several species, he argued that "*a lower fishing rate would give as great a yield when the stock became stabilized at that rate*" (Graham, 1935). Later, Graham concluded that "After a certain point the total yield of a fishery does not increase any more, whatever the fishermen do" and clearly linked exploitation to economics when he wrote that "the benefit of efficient exploitation lies more in economy of effort than in increase of the yield" (Graham, 1943).

Schaefer (1954) developed the eponymous Schaefer model using the logistic growth curve on Californian sardine. He replaced population numbers with biomass and defined surplus production as yield. Thus, he formally introduced the concept of MSY, then termed maximum equilibrium catch (Schaefer, 1954). Schaefer preferred the expression maximum equilibrium catch to optimum catch "as being more descriptive of exactly what is meant" (Schaefer, 1954). Schaefer, who was working with tuna, had to ignore age composition because there was not, at the time, a way of determining the age of an individual tuna (Holt, 2014).

In fact, MSY was in use as a theoretical concept a few years before the publication of Schaefer's surplus production model, when it was adopted as the scientific foundation of the US High Seas Policy, in 1949 (Chapman, 1949; Finley, 2011). MSY adoption was largely based on Graham's theoretical analysis (Graham, 1943; see the section "History and Legal Status of MSY") and his conclusion that less fishing can provide in some cases more fish. It was later that MSY was quantified with the Schaefer's surplus production model, and then, in 1955, adopted as the goal of international fisheries policy at the Rome Conference on fisheries problems (Smith, 1994).

After the late 1950s, MSY has been adopted as the primary management goal by several international organizations (IWC, IATTC, ICCAT, ICNAF) and countries (Mace, 2001; Froese et al., 2011). The United Nations Convention on the Law of the Sea (UNCLOS, 1982) made the MSY approach mandatory for fisheries in the exclusive economic zones (EEZs) of its signatories, which were obliged to include the MSY concept into national or regional fisheries legislation (Mace, 2001). All 39 then existing regional fisheries organizations (RFMOs) agreed to manage their mandated stocks such that they were capable of producing MSY (Longhurst, 2006). The follow-up conference on the United Nations Fish Stocks Agreement (UN, 1995) clarified in its Appendix II that during a phase of reducing excessive fishing effort, the one associated with MSY could be used as a target, but that once that target had been reached, MSY had to be treated as a limit, that is, fishing effort should be less than the one resulting in MSY.

For example, in the MSA (2006) the goal of fisheries management is defined as "optimal yield," which is "prescribed on the basis of the MSY from the fishery, as reduced by any relevant economic, social, or ecological factor" (Froese et al., 2011). In addition, fisheries management based on MSY has been formally implemented in New Zealand (MFNZ, 2008), Australia (DAFF, 2007), and Europe (EC, 2013). In most of these areas MSY-based policies have been quite successful in rebuilding stock biomass (Hilborn, 2007a; Mesnil, 2012).

Critique of MSY

The implementation of MSY as a catch that can be taken continuously independent of recruitment, stock size, stock structure, and environmental conditions has been questioned and criticized early on (e.g., Beverton and Holt, 1957; Larkin, 1977; Sissenwine, 1978). Its assumptions, uncertainties, limitations, and misapplications have been repeatedly pointed out (Hilborn and Walters, 1992; Caddy and Mahon, 1998; Punt and Smith, 2001; Hilborn, 2007b; Kesteven, 1997; Holt, 2009). For example, MSY cannot be determined for a stock unless this stock is overexploited, that is, the top of the parabola (=MSY) needs to be well surpassed for it to be determined. Therefore, MSY and optimum fishing effort cannot be predicted in early stages of developing fisheries and stock assessments should focus on detecting it as rapidly as possible (Hilborn and Walters, 1992). Once MSY is detected, fishing effort should be reduced by up to 30% in order to achieve sustainability (Hilborn and Walters, 1992). Also, the assumption of average recruitment and average environmental conditions may lead to wrong advice in highly fluctuating stocks (Hilborn and Walters, 1992). The dependence of MSY on size at first capture and age structure in the stock is ignored (Longhurst, 2006; Holt, 2009; Anderson et al., 2008). MSY is achieved by setting limits on fishing mortality but, as different fishing gears select and target different composition of species and some species are not targeted at all, MSY is rarely attained simultaneously for all species within an area (Maunder, 2002). The social aspects mentioned in UNCLOS (1982) have often been misunderstood as allowing for temporary overfishing to secure employment. The recovery potential of depleted stocks is overestimated by the simple parabola (Quinn and Deriso, 1999; Hutchings and Reynolds, 2004).

It is argued that surplus production models are too simple to fully describe the dynamics of populations subject to variability in recruitment, interactions with other species, catchability, selectivity, environmental conditions, and changing climate (Pella and Tomlinson, 1969) and they require a good contrast between fishing effort and stock abundance (Hilborn and Walters, 1992).

Improving MSY

The epitaph for MSY of Larkin (1977) was rather premature (Barber, 1988) as it was referring to the early, simplistic application of MSY that was considered a viable fishing target with constant catch removal. MSY has been conceptually transformed through time and improved (Kesteven, 1997; Mace, 2001) to become a limit that should be avoided (*target reference point* refers to a desirable state at which management should aim while *limit reference point* refers to an undesirable state which management should avoid: Caddy and Mahon, 1998), which brings the MSY concept in line with contemporary scientific views (Mace, 2001; Mesnil, 2012). Concerning the social issues, there is no conceivable scenario where overfishing is good for society because it results in subsequent lower catches and food supply, and lower future profits and fewer jobs in the sector.

The wide-spread critique that MSY ignores environmental conditions and species interactions is actually overstated (Froese et al., 2017), because the key parameter r_{max}, the maximum intrinsic rate of population growth, summarizes in a single value the interplay of natural mortality (caused mostly by predation), somatic growth (driven by food availability), and recruitment (strongly determined by environmental conditions). In other words, environmental and climatic effects are summarized in their impact on the survival of adults, that is, natural mortality (M), the availability and nutritional value of food, and the effort associated with acquiring it are summarized in somatic growth (k), and the interannual variability in environmental conditions that determine the survival of eggs and larvae are summarized in recruitment (i.e., the number of individuals surviving to join the exploited population) (Pauly and Froese, 2014). In other words, varying food availability, interspecific relationships, environmental/climate changes, and selectivity of the fishing gear are all incorporated in r_{max}. Increasing size at first capture will increase MSY, overfishing of prey species will decrease MSY.

Because of species interactions such as competition for resources and predator–prey relationships it is not possible for all populations to deliver MSY at the same time (Walters et al., 2005). But achieving, for example, 90% of MSY for all commercial fish and shellfish will already result in a substantial overall reduction of anthropogenic mortality for most target and nontarget species and will restore their biomasses to levels that should allow them to fulfill their roles as prey and predators in the ecosystem (Mace, 2001).

Forage fish (anchovies, herrings, sardines, and sand eels) are the crucial link between lower and upper trophic levels in the food web because they transport energy from millimeter-sized phytoplankton and zooplankton to the larger fish eaters of the food web (Baxter, 1997; Pikitch et al., 2012). For that reason they must be fished less and should be used for human consumption rather than for animal feed (Froese et al., 2016a).

Conclusion

It is now well established that fisheries management failed to preserve fish populations and some scientists have blamed it on the MSY concept (e.g., Mesnil, 2012). But is it a matter of science or a matter of administration and policy if stocks are in bad shape? So far, MSY has not been proven wrong as a concept but its estimation was not always correct and the administrative measures taken for its adoption were often inadequate or inappropriate (Kesteven, 1997). After its reform and continuous update, MSY remains a useful concept and a realistic approach to fisheries management and administration (Kesteven, 1997) and according to an anecdotal quote attributed to John Gulland "MSY is the most important concept in fisheries management" (Mangel et al., 2002). On top of that MSY carries a simple message that appears sensible to politicians and stimulates support by the public (Mesnil, 2012) and for that reason it is still widely used in assessing stock status and exploitation. It can be easily improved by considering size structure and setting catch length (L_C) close to optimum length (L_{OPT}) (Froese et al., 2016b). If $F < F_{MSY}$ and L_C is close to L_{OPT}, "pretty good" catches below but close to MSY are possible, with minimized impact on stock and environment. Pretty good yield (PGY) is a term introduced by Alec MacCall (National Marine Fisheries Service, Santa Cruz, CA, United States, retired) in 2000, proposing catches of about 80% of MSY as a meaningful and realistic target.

Micro- and Macroplastics in Aquatic Ecosystems

Imogen E Napper and Richard C Thompson, Plymouth University, Plymouth, United Kingdom

Glossary

Contaminant A foreign substance or impurity that is introduced into an environment where it is not normally found.
Ghost fishing This results from abandoned, lost or discarded fishing gear (ALDFG) in the environment. This gear continues to fish, trap and potentially kill animals, smother habitats, and act as a hazard to navigation.
Marine litter Marine litter is human-created waste that has been deliberately discarded, unintentionally lost or transported by wind and rivers into the sea and on beaches. It mainly consists of plastics, wood, metals, glass, rubber, clothing, and paper. Land-based sources account for up to 80% of marine litter—these include tourism, sewage, and illegal or poorly managed landfills. The main sea-based sources are shipping and fishing.
Microplastic Microplastics are small plastic pieces less than 5 mL in diameter.
Persistent organic pollutants Hazardous organic chemical compounds that are resistant to biodegradation and therefore remain in the environment for a long period of time.
Plastic Plastics are synthetic polymers made from organic molecules. They are typically derived from fossil oil and gas reserves, but they can also be made from renewable sources such as plants. Plastics are light weight, inexpensive, durable and versatile materials that can be used for many different applications.
Pollutant A harmful or hazardous substance, which can cause an adverse effect in the environment.

Introduction

Plastics are synthetic or semi-synthetic organic polymers. They are typically lightweight, strong, inexpensive, durable, and corrosion-resistant (Derraik, 2002; Thompson et al., 2009b). Most plastic items are composed of hydrocarbons derived from fossil oil or gas feedstocks (American Chemistry Council, 2015). During the conversion from resin to product, a wide variety of additives (such as fillers, plasticizers, flame retardants, thermal stabilizers, antimicrobial agents, and coloring agents) may be added to enhance performance and appearance (Andrady and Neal, 2009). As a consequence, plastic materials can take many forms including rigid items together with more flexible films, adhesives, foams, and fibers. The most commonly used polymers are high-density polyethylene (HDPE), low-density polyethylene (LDPE), polyvinyl chloride (PVC), polystyrene (PS), polypropylene (PP), and polyethylene terephthalate (PET), which cumulatively account for approximately 90% of total plastic production. These plastics bring a wide range of societal benefits in healthcare, agriculture, transport, construction, and packaging (PlasticsEurope, 2016). The versatility of plastic materials has resulted in a substantial increase in their use from 5 million tons globally in the 1950s to over 300 million tons today (Andrady and Neal, 2009; PlasticsEurope, 2015).

Despite the durability of plastics, the main uses are in relatively short-lived applications, such as packaging, which accounts for around 40% of all production. While packaging can help protect food, drink, and other items (thus reducing damage and wastage of products), it also results in rapid accumulation of persistent plastic waste. This has led to one of the most ubiquitous and long-lasting recent changes to the surface of our planet; the accumulation and fragmentation of plastic debris (Barnes et al.,

2009). Plastics represent a substantial fraction of the municipal waste stream and around 75% of all marine litter is plastic. This debris is widely reported in the environment where it has accumulated at the sea surface (Law et al., 2010), on shorelines of even the most remote islands (Barnes, 2005), in the deep sea (Bergmann and Klages, 2012; Woodall et al., 2014), and in arctic sea ice (Obbard et al., 2014). There is also increasing awareness of the accumulation of plastic litter on land as well as in freshwater habitats (Eerkes-Medrano et al., 2015). The accumulation of this litter presents a range of negative economic and environmental consequences (Werner et al., 2016).

Once in the environment, exposure to ultra-violet radiation, heat and oxygen can cause plastics to become brittle and physical action can then cause them to break down into smaller pieces, including microplastics. The timescale for degradation of discarded plastics is not known with certainty and will depend on the chemical nature of the material, the characteristics of the environment in which they persist and the manner in which degradation is measured (Andrady and Neal, 2009). However, some polymer chemists suggest that all of the conventional plastic that has ever been produced, with the exception of any material that has been incinerated, still persists in the environment in a form too large to be biodegraded (Thompson et al., 2005).

Definitions of Plastic Litter

Plastic debris can be defined and described in a variety of ways including by shape, color, polymer type, origin and original usage (e.g., packaging). Plastics enter the aquatic environment in a wide range of sizes (Cole et al., 2011; Hidalgo-Ruz et al., 2012) and have been reported hundreds of meters in length to microns in diameter. There are three categories that are typically used to describe the size of plastic contamination; macroplastic (>20 mm diameter), mesoplastic (5–20 mm), and microplastic (<5 mm) (Barnes et al., 2009; Thompson et al., 2009a). Although there is uncertainty about absolute quantities of plastic in the environment, or the ultimate sinks for this debris, there is evidence of increasing quantities over time (Jambeck et al., 2015; Thompson et al., 2004).

Macro and Mesoplastic

Macroplastic refers to plastic items larger than 20 mm. Due to its high visibility, contamination of the environment by macroplastic may be perceived as one of the most concerning forms of plastic pollution. The accumulation of macroplastic has been reported in a wide range of habitats (Browne, 2015; Ryan et al., 2009). Clean-up campaigns typically focus on these larger items and there is wide geographical variability in abundance, which increases the difficulty of analyzing potential trends. However, due to the size of this debris, it is often possible to categorize items according to their original usage; for example, packaging, fishing or sewage related debris. Plastic debris that is larger than 5 mm but smaller than 20 mm is termed mesoplastic.

Microplastic

Microplastic is used as a collective term to describe a heterogeneous range of small plastic particles and fibers. In 2008, the National Oceanographic and Atmospheric Agency (NOAA) of the United States hosted the first International Microplastics Workshop and as part of this meeting formulated a working definition to include all plastic particles less than 5 mm in diameter (Arthur et al., 2009). The lower size limit is typically set by the capacity of capture methodology or analytical identification equipment and is currently around 20 μm. However, it is widely believed that plastic debris is present in the environment in the nano-size range (Mattsson et al., 2015). As with macroplastics, microplastics can differ in specific density, chemical composition, and shape (Fig. 1B) (Duis and

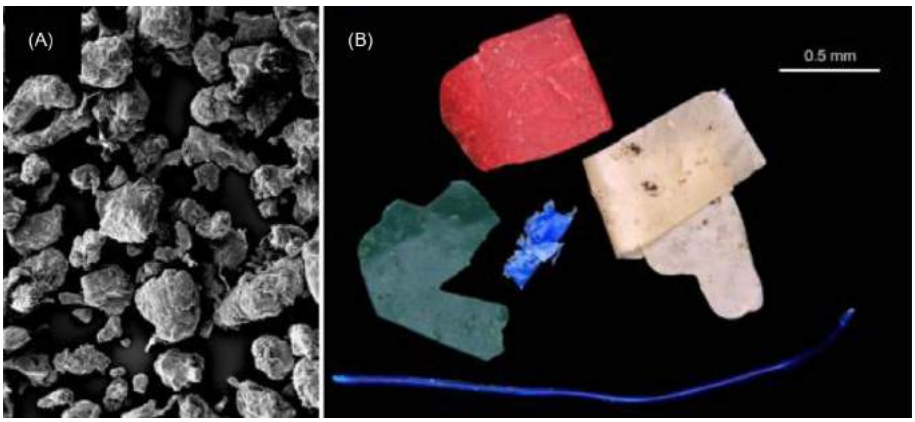

Fig. 1 Pictures showing typical microplastic samples: (A) Polyethylene particles extracted from a cosmetic product. (B) Fragments of microplastic collected from a shoreline near to Plymouth, UK. *Note*: Scale bar applies to both pictures. (A) Napper & Thompson, Plymouth University Electron Microscopy Suite. (B) Thompson, Plymouth University.

Coors, 2016; Law and Thompson, 2014). Microplastic can then be further divided into categories based on their origin; primary and secondary microplastics.

Primary microplastic

Particles that directly enter the environment in the microplastic size (<5 mm in diameter) are described as primary microplastics. Primary microplastics are produced through extrusion or grinding, either as a feed stock for manufacture of products (Turner and Holmes, 2015) or for direct use (Browne, 2015); for example in cleaning products (Cole et al., 2011; Derraik, 2002), cosmetics (Fig. 1A) (Napper et al., 2015; Zitko and Hanlon, 1991), and as air-blasting media (Gregory, 1996).

Secondary microplastic

Secondary microplastics are those formed in the environment from the fragmentation of larger items of plastic debris (Cole et al., 2011; Law and Thompson, 2014). This degradation occurs as a consequence of ultra-violet (UV) radiation and oxidation, which overtime can reduce the structural integrity of the plastic, resulting in fragmentation. This can be facilitated by physical forces from abrasion, wave-action, and turbulence (Barnes et al., 2009; Browne et al., 2007). The process is ongoing, with fragments becoming smaller and smaller over time (Cole et al., 2011; Galgani et al., 2010). Even if emissions of larger items of plastic to the environment were to cease with immediate effect, it is likely that we would still see an increase in the quantity of microplastic as a consequence of the fragmentation of larger items that are already in the environment. Secondary microplastic can also be generated as a consequence of wear during the use of a product. For example, fibers generated from the laundering of clothes or from the wear of tyres.

Sources

The majority of plastic in the sea originates from inland sources and is emitted to the oceans from coastlines or by rivers (Jambeck et al., 2015). In addition, quantities are released from ocean-based sources such as shipping and aquaculture (Andrady, 2011; GESAMP, 2015). Smaller particles may also be carried in the air and deposited at sea (Dris et al., 2015). It has been estimated that on a global scale, the input of plastic into the oceans from land based sources is in the region of 6.4 million tons per annum (Jambeck et al., 2015). Furthermore, assuming there are no improvements in waste management infrastructure, the cumulative quantity of plastic waste available to enter the marine environment from land could increase by approximately three times over the next decade (Fig. 2) (Jambeck et al., 2015). However, a more precise estimate will require direct measurement of the input rates of plastic waste by wind, tidal and ocean wave transport. It will also require a methodical measurement of waste generation, collection rates, classification, and waste disposal methods for rural areas and urban centers in countries around the world (Law, 2017). Microplastics have been detected at very high levels globally in rivers and lakes which could further add to this estimation (Auta et al., 2017; Free et al., 2014; McCormick et al., 2016).

Sources of Macroplastic

Much of the litter in aquatic environments enters as macroplastic from land-based actions such as general littering, dumping of waste and loss during waste collection as well as that from inappropriately managed landfill sites (Jambeck et al., 2015; Mehlhart

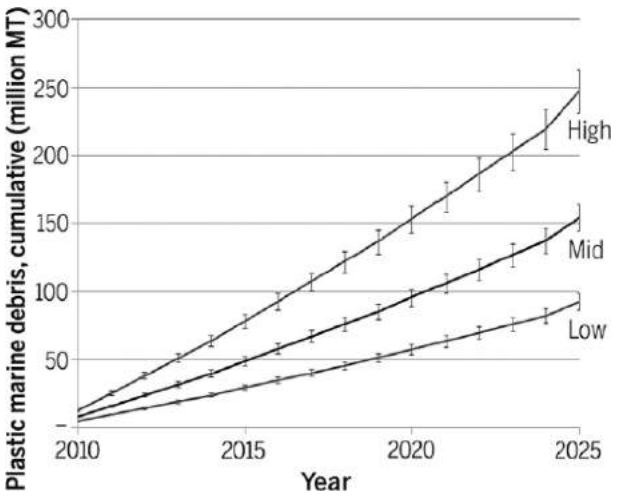

Fig. 2 The estimated mass of mismanaged plastic waste (millions of metric tons) input into the ocean by populations living within 50 km of a coast in 192 countries, plotted as a cumulative sum from 2010 to 2025 (Jambeck et al., 2015).

and Blepp, 2012). Plastic waste is collected, and then contained in a waste management framework which is designed to help minimize loss to the environment. From these land-based sources, plastic litter then has the potential to end up in municipal wastewater and freshwater systems (Cole et al., 2011; Leslie et al., 2013). This can result from windblown litter escaping into the wider environment (Barnes et al., 2009; Mehlhart and Blepp, 2012; Pruter, 1987). In industrialized countries, waste that is deposited in landfills is usually covered regularly with soil or a synthetic material, and the landfill is cordoned by a fence to prevent any debris accidentally leaving. However, in developing regions this is often not the case (Barnes et al., 2009; Jambeck et al., 2015). The residues from plastic recycling could also unintentionally escape into the environment (Moore, 2008).

Some items of plastic litter are also released directly from industrial activities, such as commercial fishing. Studies have indicated a significant relationship between the number of ocean-based plastic items found on beaches and the level of commercial fishing activity (Cunningham and Wilson, 2003; Ribic et al., 2010). In 2010, the amount of fishing gear lost to the environment was estimated at around 640,000 tons per year (Good et al., 2010). Discarded fishing items, which include monofilament lines and nylon netting, can float at a variety of depths and result in "ghost fishing" and entanglement of aquatic organisms (Good et al., 2010). Furthermore, unintentional loss of in-service macroplastic products can occur when catastrophic events, such as tsunamis, hurricanes, or floods, carry large amounts of material of all kinds into the marine environment (Law, 2017).

Sources of Microplastic

Primary microplastic can result from spillage/mishandling of industrial preproduction plastics or from the use of cosmetics (Duis and Coors, 2016; Law, 2017; Napper et al., 2015). Plastic microbeads from facial scrubs are an example of a cosmetic use source. After their intended use, these microbeads are likely to enter household wastewater and some will escape the waste water treatment system into the environment (Murphy et al., 2016). It has been estimated that 94,500 microbeads could be released from an exfoliant in a single use, accumulating to the United Kingdom alone to be emitting 16–86 ton per year (Napper and Thompson, 2016). Other potentially important sources of microplastics are from microplastic used in medicines, drilling fluids for oil/gas exploration and in industrial abrasives (i.e., for air-blasting to remove paint from metal surfaces) (Derraik, 2002; Duis and Coors, 2016; Gregory, 1996; Mintenig et al., 2014; Sundt et al., 2014).

Further sources of microplastic to the marine environment occur as a consequence of the breakdown of larger plastic debris (secondary microplastic). These can then enter the marine environment through two different pathways; a "direct" (sewage or storm water) or an "indirect" (fragmentation of existing plastic debris) source. Washing of clothes made from synthetic materials is an example of a direct secondary microplastic source. Again, this microplastic can enter the environment via wastewater after the release of fibres from a washed garment. Some fabrics release fibres more readily than others; research by Napper and Thompson (2016) reported that a wash load of 6 kg of acrylic clothing could release over 700,000 fibres.

For primary and secondary microplastic pieces larger than around 20 μm, it is possible to identify what type of plastic polymer a particular piece of marine debris is made out of (Thompson et al. 2004). However, it is extremely difficult to trace back the debris to its origin.

Waste Water Treatment Plants

For any plastic that enters waste water treatment plants, the efficiency of capture (i.e., before the effluent is discharged into the environment) depends on the particular treatment process. However, there is limited information on the efficiency of waste water treatment plants to capture plastic; particularly microplastic. Some studies indicate extremely high capture rates (>95%) of plastic particles (Carr et al., 2016; Murphy et al., 2016). Given the large volume of influent daily, even low loss rates could result in detectable concentrations of these plastic particles in the environment (Browne et al., 2011; Eriksen et al., 2013). Murphy et al. (2016) predicted that waste water treatment plants could release 65 million microplastics every day (Murphy et al., 2016). Wastewater and any plastic debris therein can also bypass treatment as a consequence of sewage overflows. Even if microplastic is intercepted during wastewater treatment, the resultant sewage sludge is often returned to the land as a fertilizer, hence plastic is still released to the environment (Kirchmann et al., 2017).

Source Trends

The trends of production, consumer-use and demographics all point to a further increase of plastic use in the future (Auta et al., 2017; Sutherland et al., 2010). Hence there are considerable concerns that the problems of plastic pollution will escalate unless disposal practices change. Given the large amount of macroplastics entering the environment, it is generally assumed that most microplastics have arisen from the fragmentation of larger items (Andrady, 2011; Hidalgo-Ruz et al., 2012). The fragmentation rates of macroplastics are largely unknown, and as a result little quantitative information is available on the relative contribution of primary and secondary microplastics to the overall amount in the environment (Koelmans et al., 2014; Law and Thompson, 2014; Sundt et al., 2014). It is also clear that substantial quantities of fibres have accumulated in the environment (Dris et al., 2015; Mathalon and Hill, 2014). These are widely reported in microplastic samples and likely originate from abrasion of textiles during use or as a consequence of laundering (Browne et al., 2011; Mathalon and Hill, 2014; Napper and Thompson, 2016).

Distribution

Plastic debris has been reported at the sea surface (Cózar et al., 2014), suspended in the water column (Lattin et al., 2004) and in sediments, including those in the deep sea (Fischer et al., 2015; Van Cauwenberghe et al., 2013; Woodall et al., 2014). Airborne transport may also be relevant for very small microplastics; for example, microplastics escaping from uncovered landfills (Rillig, 2012), or the dispersal of particles formed by wear in service such as textile (Napper and Thompson, 2016) and tyre wear (Kole et al., 2017).

Plastic debris of all sizes can accumulate in the oceans (Thompson et al., 2004), estuaries (Browne et al., 2010), and even in remote locations such as in arctic ice (Obbard et al., 2014). Plastic debris has also been found in freshwater environments showing that this is an aquatic system issue, not just limited to the marine environment (Ivleva et al., 2017; Mani et al., 2016; Wagner et al., 2014). However, there are no definitive estimates of the total quantity of litter in the environment. Estimates based on counts at sea suggest between 7000 and >250,000 tons of plastic are now present in the open-ocean surface (Cózar et al., 2014; Eriksen et al., 2014). Per annum it has been predicted that 6.4 million tons enters the ocean from land based sources (Jambeck et al., 2015).

Rivers can transport considerable quantities of plastic (micro–macro-size) to the oceans and some of this debris can travel from locations far inland. In rivers, microplastic concentrations have been found to vary along and across the river, reflecting various sources such as waste water treatment plants, tributaries, and weirs (Claessens et al., 2011; Klein et al., 2015; Mani et al., 2016). Once released into the environment, and due to their durability, plastic debris has the potential to become widely dispersed via wind and currents (Faure et al., 2015; Lambert et al., 2014; Ryan et al., 2009).

At the water surface, smaller pieces of plastic present lower rise velocities and are more susceptible to vertical transport (Reisser et al., 2015; Song et al., 2014). Some polymers such as polyvinyl chloride (PVC), and polyethylene terephthalate (PET), are denser than water and are more likely to sink, while polyethylene (PE), polypropylene (PP), and polystyrene (PS) are more likely to float. However, microplastics typically accumulate fouling from microorganisms as well as sediment particles on their surface. Over time this increases their apparent density causing even some of the less dense polymers to sink (Zettler et al., 2013). Hence, the sea bed could be the most likely long-term place for the accumulation of plastic debris.

Impacts

There is a reasonably extensive evidence base relating to the harm caused by marine litter. This can have a range of negative impacts on commercial fisheries, maritime industries, and infrastructure. It has also been found to affect a wide range of marine organisms; as a consequence of entanglement and ingestion (Gall and Thompson, 2015; Sutherland et al., 2010; Wang et al., 2016). Over 700 species of marine organisms have been reported to encounter plastic debris, which can result in severe physical harm and death, or more subtle effects on behavior and ecological interactions (e.g., the ability to escape from predators or migrate) (Gall and Thompson, 2015). It is likely that there are also a range of sublethal effects that have not yet been recognized.

Impacts of plastic vary according to the type and size of the debris, and can occur at different levels of biological organization in a wide range of habitats (Browne, 2015). Encounters between plastic litter and organisms can negatively affect individuals and a substantial proportion of some populations can be contaminated with plastics; for example, over 40% of sperm whales beached on North Sea coasts had marine litter including, ropes, foils, and packaging material found in their gastrointestinal tract (Unger et al., 2016), while over 95% of the population of northern fulmars (*Fulmar glacialis*) may contain plastic litter in some European waters (Van Franeker et al., 2011).

Over 330 species (50 marine mammals) have been found to become entangled or ingested plastic debris (Kühn et al., 2015). However, evidence of harm from entanglement is easier to observe and report than ingestion. This is because ingestion typically only becomes apparent when the carcass of an animal opens; either as a result of dissection or decomposition. It has been reported from UK surveys that there is an incidence rate of entanglement between 2% and 9% for some populations of seabirds and marine mammals (Werner et al., 2016).

The ingestion of meso- or macroplastic litter has been reviewed for numerous marine species; particularly mammals, birds, and turtles (Derraik, 2002; Gall and Thompson, 2015; Gregory, 2009; Kühn et al., 2015; Laist, 1997). Studies have also shown that both freshwater invertebrates and fish ingest microplastic (Imhof et al., 2013; Phillips and Bonner, 2015). The potential for ingestion is greater with pieces in the microplastic size range since their small size makes them readily accessible for ingestion by a wide range of organisms (Davison and Asch, 2011) including whales, fishes, mussels, oysters, shrimps, copepods, and lugworms (Cole et al., 2013; Ferreira et al., 2016; Lusher et al., 2015a,b).

However, ingestion also depends on properties other than size including shape, density and color. For instance, low-density (i.e., buoyant) microplastics are potentially more likely to be ingested by pelagic feeders and high-density microplastics by benthic feeders (Scherer et al., 2017; Wright et al., 2013). With very small particles, including those in the nano-size range, there is also the potential for uptake across cell membranes, but little is known about any associated impacts (Koelmans et al., 2014). Organisms at lower trophic levels can ingest and accumulate microplastic particles, and it has been shown that microplastics can transfer between trophic levels in the food-web (Watts et al., 2014). Ingestion has shown to lead to physical effects that include physiological stress responses and even signs of tumor formation (Rochman et al., 2013).

There are also concerns about the potential for ingestion to facilitate the transfer of chemicals to marine life (Bakir et al., 2014). Hydrophobic organic pollutants readily sorb onto plastics, and can accumulate at concentrations several orders of magnitude higher than in seawater (Mato et al., 2001). These chemicals can then be released to organisms upon ingestion. However, modelling estimates indicate the amount of chemical transfer from water to organisms via plastic is probably not a major pathway leading to harm (Bakir et al., 2016).

Additive chemicals incorporated into plastic products at the time of manufacture may also transfer to marine organisms upon ingestion (Tanaka et al., 2013). These chemicals are intentionally added during the manufacture or processing; for example to enhance the plastics durability and corrosion resistance (Andrady, 2016) or act as stabilizers, plasticizers or flame retardants. Some additives, such as plasticizers, are used at high concentrations (10%–50%) to ensure the functionality of the product. Degradation of plastic containing these additives may result in the additives leaching out and becoming bioavailable to organisms (Oehlmann et al., 2009; Talsness et al., 2009). Although, there is currently little evidence of harmful effects associated with the release of additives from plastic litter in the environment.

A further source of concern is colonization of organisms on plastic debris; species found on plastic debris can differ from the free-floating microbial communities in the oceans (Zettler et al., 2013). For example, microplastics collected in the surface waters of the North Atlantic were colonized by a variety of organisms including bacteria, cyanobacteria, diatoms, ciliates, and radiolaria (Zettler et al., 2013). As plastics have been reported to travel over long distances, they may contribute to the dispersal of alien or invasive species (Barnes, 2002).

Contamination of the marine environment with plastic debris can also have negative economic consequences on tourism, aquaculture, navigation, and fisheries. With fisheries, plastic litter can reduce or damage catches and vessels. For example, the total cost of removing litter of all types from 34 UK harbors was estimated at approximately £236,000. Based on this, it was estimated that marine litter costs the ports and harbor industry in the United Kingdom approximately £2.1 million each year (Mouat et al., 2010). Estimates indicate cleaning of UK beaches costs local authorities around £15.5 million (Mouat et al., 2010). Tourism can be affected as visitors to the marine environment consider litter annoying and hence litter can influence the locations they chose to visit (Brouwer et al., 2015). There is also emerging evidence that even small quantities of litter on beaches can have a negative effect on human well-being (Wyles et al., 2016).

Solutions

The potential threats to aquatic ecosystems presented by plastic debris have been identified as a major global conservation issue and a key priority for research (Sutherland et al., 2010). To fully understand the sources and scale of this contamination would require an internationally coordinated effort with comparable sampling and microplastic extraction techniques, as well as standardized recording methodologies to map and evaluate distribution (Waller et al., 2017). However it is clear that substantial quantities of litter are entering the aquatic habitats daily (Jambeck et al., 2015; Mani et al., 2016). Critically, it must be recognized that the accumulation of plastic in the oceans is actually a symptom of a wider more systemic problem of linear use of materials and the rapid accumulation of waste, including end of life plastic. Hence the overarching solutions to the problem of marine litter lie on land. Even in the absence of complete information on distribution and impacts, it is clear that the key action must be to reduce the quantity of litter entering the oceans from the land.

There are some management strategies and policies in place to reduce plastic contamination (GESAMP, 2015). Banning microbeads in cosmetics is an example of such legislation (Hirst and Baker, 2017). However, based on the levels of concern and the scale of problems outlined in this article it would appear that the measures currently in place are insufficient. In some cases, there are difficulties associated with enforcement; for example, the regulation of dumping at sea (MARPOL) is extremely difficult to enforce. Even in highly developed countries with robust waste management infrastructure, there are unnecessary obstacles to recycling, including the lack of availability of collection points, contamination of recycling feedstock, and the limited marketability of some recycled material (Andrady, 2005; Law, 2017).

Benefits of citizen focused activities such as beach cleaning are well recognized for their educational value as well as in terms of the litter removed (Nelms et al., 2016). Annual clean-up operations are now organized in many countries (Barnes et al., 2009) and are often run by voluntary organizations. They can remove substantial quantities of litter from beaches and the coastline. Volunteer involvement in two of the largest clean up schemes in the United Kingdom (Marine Conservation Society Beach Watch and Keep Scotland Beautiful National Spring Clean) has been estimated to provide a value of approximately £119,500 in term of cleaning, which suggests that the total cost of voluntary action to remove marine litter is considerable (Mouat et al., 2010).

Current rates of entry for litter into the marine environment far exceed the potential for removal by clean-up. Additionally, while awareness is being raised by opportunities associated with relatively low-cost beach cleaning activities, there are concerns about the viability and efficiency of large scale mechanical clean-up operations at sea. If clean-up is seen as a substantive solution, it must be acknowledged that there will be a need for such clean-up in perpetuity. Therefore, the main priority must be to focus on preventing litter entering the oceans in the first place and a better understanding in the behaviors that lead to littering, as well as those that lead to engagement in recycling (Pahl and Wyles, 2017). Most plastics are inherently recyclable, yet many single-use items are not compatible with recycling. A key challenge therefore is to ensure end-of-life disposal via recycling is appropriately considered at the design stage.

There are also some potential distractions to the key solutions; such as altering the carbon source used to make plastics by utilizing plant base carbon rather than fossil carbon from oil and gas. While this utilizes a renewable and hence a more sustainable carbon source, it will not reduce the generation of waste nor the accumulation of litter. Biodegradable plastics are another potential distraction; while products that have been designed to degrade rapidly may reduce the amount of highly visible macroplastic waste, many of these items merely fragment compromising the potential for product reuse and accelerating the production of microplastic fragments (Thompson et al., 2009b). Biodegradable or compostable plastics only present a solution in very specific settings where the associated waste collection is specifically managed, provides conditions suitable for degradation and products are labelled accordingly to facilitate appropriate disposal.

Education, outreach and awareness are effective ways to promote change in limiting indiscriminate disposal. However, in the past, approaches to address marine litter have mostly focused on end-of-pipe measures; in order to develop long term sustainable solutions there needs to be education and change in behavior right along the supply chain and this could be facilitated by greater dialogue between the various stakeholders from design, through production and use, to disposal. In short, what is needed is a much better stewardship so that the benefits of plastic can be realized without the accumulation of unnecessary waste in managed systems and in the environment.

Summary

While the problems of this litter are especially evident in aquatic ecosystems, most litter originates from land-based sources. Therefore, to help manage and reduce emissions it is essential to better understand the relative importance of these sources and to assess regional variation. Once in the ocean, plastic debris has the potential to travel considerable distances away from its original location. The debris can be micro to macroplastic in size; depending on its original size, rate of degradation, and source. It can have implications for wildlife and economic consequences on tourism, aquaculture, navigation, and fisheries. Education, outreach, and awareness will be effective in limiting the indiscriminate disposal of plastic waste. However, strategies and policies should also be in place to minimize the amount of plastic waste produced and promote appropriate waste management; for example, via recycling. For effective long-term change, it will be particularly important to apply these solutions internationally to minimize inputs of plastic litter into the ocean.

Microbial Communities

Cristiana Callieri, Ester M Eckert, and Andrea Di Cesare, National Research Council, Verbania, Italy
Filippo Bertoni, ASCA—University of Amsterdam, Amsterdam, The Netherlands

Introduction

Aquatic microbial communities encompass all the organisms living in (marine, fresh, and brackish) water habitats that are not visible to the naked eye (conventionally, less than 1 mm), thus including representatives from all three domains of life—*Archaea*, *Bacteria*, and *Eukarya*. Viruses, together with viroids, plasmids and other non-cellular life forms, are excluded from the three domains system, but, given their impact on microbial populations, are usually included in microbial community studies. Unlike a population—which includes only individuals of the same "species"—or a guild—which groups metabolically related populations—a community is not defined by phylogeny or functional traits but by its habitat. Thus, an aquatic microbial community can be defined as an *assemblage* of co-occurring, and potentially interacting, microscopic "species," present in a defined habitat in space and time.

Despite the small size of these organisms—and the related challenges in studying them—microorganisms are key to the ecological dynamics of the biosphere. As it reaches even the most extreme environments, microbial life's sheer biomass is consequential to the entire planet: in the oceans alone, microbes contribute to as much as 90% of the total biomass. And while oceans cover over 70% of the World's surface (1.3×10^9 km^3), meaning that most water on Earth (~97%) is seawater, inland waters—including lakes, ponds, rivers, streams, wetlands, and groundwater—and ice confined in polar caps and glaciers only account for ~1% and ~2% of the hydrosphere respectively, but have a similarly crucial role for life in the biosphere. All these aquatic environments are dominated by microbial communities. But microorganisms are not only the most diffused life form; they are also characterized by an incredible functional and genetic diversity, contributing to most, if not all, biogeochemical processes on Earth. As such, microbial communities represent a crucial component of global dynamics, and an important repository of genetic diversity.

In aquatic environments their abundance is significant, with concentrations—even excluding microbial eukaryotes—around approximately 10^6 cells per milliliter of marine or fresh water. They are responsible for the ongoing production and recycling of organic matter and are involved in fundamental energy flows, exhibiting the ability to perform a range of biogeochemical transformations.

The planetary impact of microbial communities and of their diversity (Fig. 1)—all the more evident when considering the crucial contributions they offered to the history of life on this planet, like the Great Oxygenation Event—depends on the accumulation of smaller causes into effects at a larger scale. But, given the vast nature of the environments the microbes inhabit, microbial life is most commonly approached at a large scale and through its cumulative effects. This is why, in this overview, we will focus especially on planktonic communities and on large-scale interactions and dynamics. In the conclusions we will get back to the importance of microscale dynamics and their interactions with macrobiota, to briefly consider the possibilities they open for novel research.

Microbial Lifestyles in Aquatic Habitats

In aquatic habitats there is a major distinction in lifestyles that structures research on microbial communities: this is the division between microbial organisms living suspended in the water column and therefore drifting with water currents, known as *plankton* (from the Greek term for vagabond), and those living attached to a substrate and in the sediment deposited at the bottom of water bodies, known as *benthos* (Greek for depth).

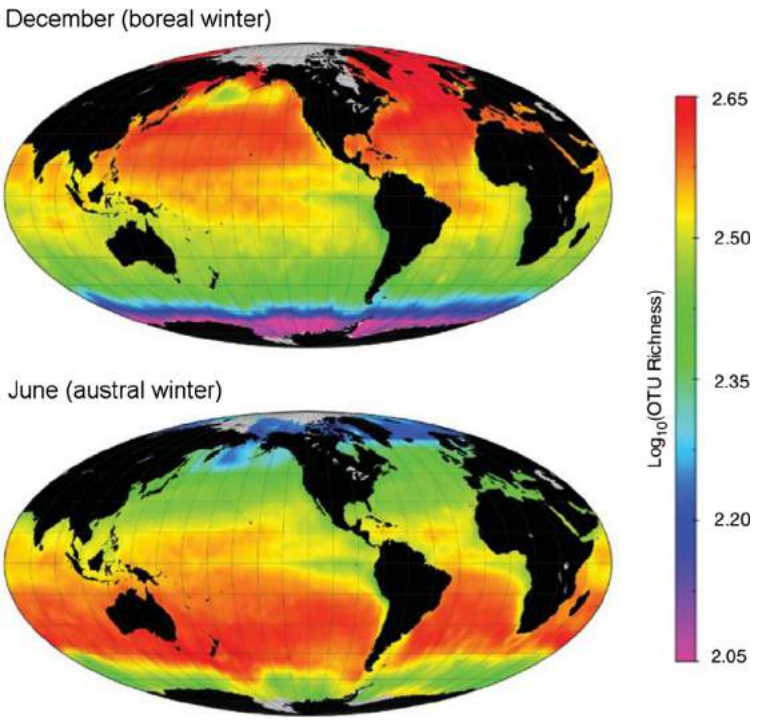

Fig. 1 Maps of predicted global marine bacterial diversity (modified from Ladau, J., et al. (2013). Global marine bacterial diversity peaks at high latitudes in winter. *ISME Journal* **7**, 1669–1677). Color scale shows relative richness of marine surface waters as predicted by Species Distribution Modeling (SDM). In December, the Operational Taxonomic Unit (OTU) richness peaks in temperate and higher latitudes in the Boreal Hemisphere. In June, OTU richness peaks in temperate latitudes in the Austral Hemisphere. Predicted richness during the spring and fall is intermediate.

Planktonic microorganisms are transported by water currents or simply by the turbulence created by water layers at different temperatures (i.e., density). Their growth is therefore strongly driven by physical forces that can transport them in layers enriched with nutrients or, conversely, can segregate them to deep waters (called hypolimnetic, in lakes and bathypelagic, in oceans). Despite this general dependence on water dynamics, some planktonic organisms possess locomotion appendages like flagella or cilia, or internal gas vacuoles by which the cells can regulate their buoyancy. Therefore, even at slow velocity and in calm water conditions, the motile cells can regulate their position. Usually considered as free-living cells, these organisms can also form aggregates of various kinds in different environmental conditions.

Benthonic microorganisms live attached to a fixed substrate or at the interface between water and sediment. Collecting organic material settling from above, the benthos takes part in the sedimentation processes and is usually more concentrated than the plankton. These organisms usually form aggregates embedded in an extracellular matrix composed of extracellular polymeric substances (EPS), called biofilms, which facilitate transport and exchange of chemicals, nutrients, and signaling compounds, while helping in protecting against predation. Early mats of similar biofilms are thought to have had an important role in the evolution of life (see Box 1). Within these aggregates, bacterial community composition varies based on the substrate, the broader habitat, and the species included. For example, the *Cytophaga-Flavobacteria-Bacteroidetes* (CFB) group mostly dominate the biofilm on macrophytes, followed by alpha- and betaproteobacteria. The presence of *Planctomycetes* on plant biofilms depends strongly on the nutrient content and plant age, as these bacteria can be affected by organic compounds produced by plants.

Box 1 Living at the interface: *the phycosphere*

Far from capturing the complexity of microbial lifestyles, this foundational division sometimes gets in the way of studying more detailed, micro-scale interactions and habitats. Indeed, as it is often true in ecology, even at the microscale the interface between two different environments tends to be more productive and rich in interactions. Microhabitats like marine snow particles, or the phycosphere of algae—the halo of organic compounds excreted by phytoplanktonic cells—are crucial to microbial communities, especially in environments otherwise characterized by low nutrient concentrations. In the phycosphere, bacteria or other microorganisms can be found as free-living single cells near algal cells or directly attached on their surface, in biofilms (Fig. 2). The study of the phycosphere at single-cell level has shown how this microenvironment is a hot-spot of bacteria–phytoplankton interactions, where the exchange of infochemicals and metabolites is very high. One of these substances is dimethylsulfoniopropionate (DMSP), a source of sulfur and carbon for heterotrophic bacteria, which is actively exudated by algae and produced during cell lysis. The lifestyle of bacteria in aggregates has the advantage to protect them against small flagellate predation (hetero- and mixotrophic nano flagellates), to increase the sedimentation rate and to offer a nutrient richer microenvironment. While challenging our categorizations of microbial life, microenvironments and their microdynamics remind us of the importance of paying attention to life at any scale—as even the smallest niche might reveal key to the history of life on Earth.

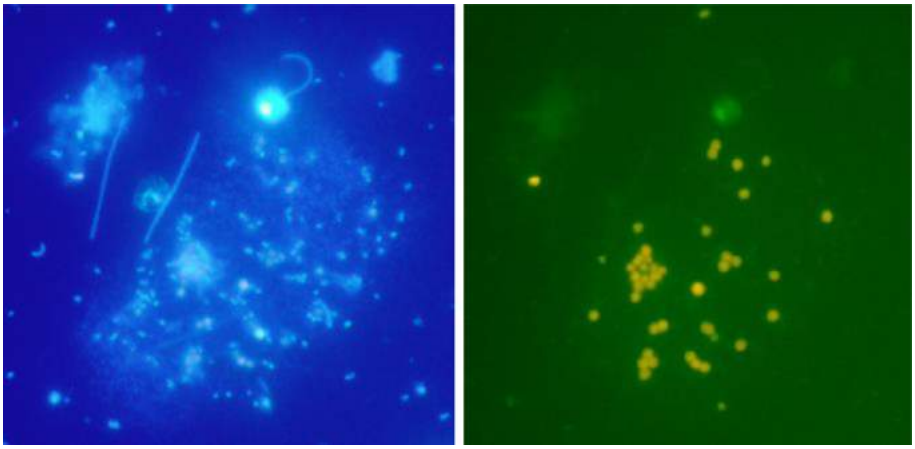

Fig. 2 An example of phycosphere: a microenvironment where bacteria, cyanobacteria and eukaryotes meet. *Left*: DAPI colored and visualized at epifluorescence; *Right*: the same field without DAPI where only autofluorescence is visible (1250 ×).

Microbial Diversity of Planktonic Communities

Prokaryotes

Prokaryotes are defined by their cell structure, which lacks membrane-bound organelles and nucleus. They include the whole domains *Bacteria* and *Archaea* and can perform autotrophic and heterotrophic metabolisms. An important subdivision in this group is that between Gram-positive bacteria, bounded by a single-unit lipid membrane and a thick layer of peptidoglycan, and Gram-negative bacteria, with an outer membrane, a lipopolysaccharide layer, but a thin peptidoglycan layer. This rough classification, based on the result of a staining procedure, remains still valid, despite the changes brought about by molecular biology in the classification of microorganisms. This is because the composition of the outer part of the cells, which is identified by the Gram stain, strongly determines the capacity of cells to resist to stressing environmental conditions or to communicate with other microorganisms, making it a key for cell taxonomy (see Box 2).

The marine bacterium *Pelagibacter ubique*, belonging to the SAR11-cluster of *Alphaproteobacteria*, is the most abundant microorganism on earth. *Actinobacteria*, *Alphaproteobacteria* and *Betaproteobacteria*, *Flavo-* and *Sphingobacteriales* numerically dominate the freshwater bacterioplankton. The acI clade of *Actinobacteria* and the Beta I and II clades of *Betaproteobacteria* comprise 30%–50% of the total bacterial cells in the water column. Similarly, the ultramicrobacteria of freshwater LD12 lineage, sister group of the marine SAR11, previously considered rare in lacustrine ecosystems, have been recently found to reach abundances comparable with those of the oceans. This discovery has opened a new view on the dispersal of microorganisms between marine and freshwater habitats.

Another important phylum of photosynthetic bacteria is composed by *Cyanobacteria*. These microorganisms come in a variety of forms (including both coccoid and filamentous forms) and lifestyles (from single free-living cells to colonial aggregates) and are ubiquitous in aquatic environments. This is because, thanks to their long evolutionary history, they possess a variety of metabolic

Box 2 Estimating Microbial Diversity

The definition of species for Prokaryotes is hampered by various traits, including their poorly developed morphology and the fact that the vast majority of these organisms remains uncultured, and thus little is known about their physiology and behaviour. The main source of information on bacterial and archaeal diversity derives from environmental surveys of DNA sequences. Species are often defined through similarity thresholds of marker sequences, such as the small-subunit rRNA (16S and 18S rRNA gene for prokaryotes and eukaryotes, respectively). Taxonomic grouping of the sequences is considered operational, meaning that it is based on the dataset of a specific study, and the term species is replaced by *Operational Taxonomic Unit* (OTU). However, even such molecular microbial diversity is far from being fully explored, and recent estimates of the global number of OTUs of Archaea and Bacteria differ as much as between millions and billions. This is because many taxa are very low in abundance, as in many sequencing campaigns a large part of the sequences is presented only once in the whole dataset (Fig. 3). Such sequences can be related to active species that are very low in number, to dormant or dead cells, to free DNA or simply due to sequencing errors. Thus, the actual richness of this so-called rare-biosphere is difficult to estimate. The upper pelagic zone of the ocean alone is estimated to harbor more than 35×10^3 prokaryotic species, whereas richness in the deep sea is around an order of magnitude poorer. In general, temperature seems to be a driving factor of richness in the oceans. Estimates of freshwater diversity are also in the range of tens of thousands and terrestrial ecosystems are an important source of diversity of freshwater ecosystems. Therein sediments are particularly rich in OTUs. Molecular richness of microbial eukaryotes found in aquatic environments is predicted to be more than 100×10^3 with similar numbers of OTUs in the sea and in freshwaters. These numbers far exceed the numbers of species determined morphologically (morpho species). This is, on the one hand, due to the fact that some species look the same but are genetically different (many fungi, e.g., but also diatoms), in which case morphological identification underestimates species diversity. On the other hand, some species have more than one copy of the 18S rRNA gene in their genome, which can be very polymorph (e.g., in some Ciliate species over 40 polymorphic sites of the 18S rRNA gene were found) and thus diversity is vastly overestimated by molecular technics.

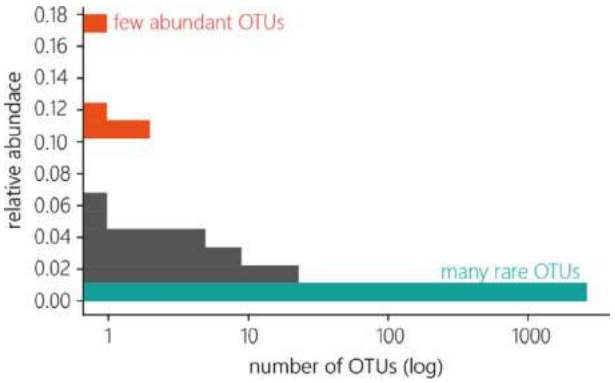

Fig. 3 Potential outcome of a meta-sequencing study of the 16S rDNA gene diversity clustered into Operational Taxonomic Units (OTUs). Most of the OTUs are very low in abundance in the dataset and therefore rare, only very few OTUs have high relative abundances and are considered abundant.

pathways that give them competitive advantage and facilitate their adaptation to diverse environmental conditions, from the most eutrophic to pristine oligotrophic waters. Because of this adaptability and plasticity, they are particularly successful in changing, adverse conditions: hence the current increase in occurrence of toxic cyanobacterial harmful algal blooms (CHABs), facilitated by anthropogenic climate disruptions on a planetary scale—which associated cyanobacteria to environmental distress.

One of the most enigmatic microbial groups in the oceans is the Marine Group I (MGI.1a) of Archaea: the *Thaumarchaeota* (formerly 1.1a Crenarchaeota). These Archaea are commonly found in oceanic and freshwater plankton, mainly in mesopelagic and hypolimnetic waters, where they comprise up to about 40% of the microbial community. Members of the MGI.1a clade have also been found in high-altitude lakes during stratification, whereas the clade SAGMGC-1 was retrieved in high densities in surface water in winter.

Microbial Eukaryotes

Microbial eukaryotes, whose cells are recognized by the membrane-bound nuclei and organelles, are massively abundant; in the euphotic zones of the world's oceans alone, there are 10^2–10^4 protist cells per mL. The definition of eukaryotic microbes is usually arbitrarily based on size, including everything smaller than 3 μm. Thus, representatives of the whole domain *Eukarya*, except for vertebrates, are included in this category, like many unicellular algae (e.g., Chlorophyta, Diatoms, Dinoflagellates). Functional classification is mainly based on their metabolism, meaning whether they sequester carbon through primary production, heterotrophy or mixotrophy—in which the same cell can fix CO_2, as well as assimilate it from dissolved or particulate organic carbon. Considering that many species are capable of this versatile metabolism, comparably little attention has been devoted to mixotrophy, mainly due to technical difficulties in identifying whether a pigmented cell is currently following a purely autotrophic lifestyle or not.

The most common eukaryotic freshwater primary producers, referred to as *phytoplankton*, include members of *Chlorophyta*, *Haptophyceae*, *Bacillariophyceae*, *Cryptophyta*, *Chrysophyceae* and *Dinoflagellata*. In the euphotic zone of the open ocean *Dinophyceae*, *Dictochophyceae*, *Bacillariophyceae*, *Pelagophyceae*, *Synurophyceae*, and *Chrysophyceae* are particularly abundant. Unpigmented microbes include but are not limited to small aquatic fungi, choanoflagellates, cercozoans, ciliates, and *Chrysophyceae*. In addition to these widespread groups, a large portion of eukaryotic plankton diversity seems to reside in heterotrophic protistan groups, particularly those known to be parasites or symbiotic hosts. To date many eukaryotes remain uncultured, such as the abundant flagellated bacterial predators classified in the marine *Stramenopiles* groups 4 and 1 (MAST-4 and MAST-1C), which include *Bacillariophyceae* and *Chrysophyceae*. On marine snow (sinking organic particles) fungi and *Labyrinthulomycetes* seem to dominate the biomass of the community. Despite this, and their likely importance in aquatic environments, aquatic fungi are still poorly understood and deserve more attention, since they are highly diverse in terms of function and phylogenetic diversity.

Virioplankton

Despite their still controversial classification, viruses are abundant and crucial to ocean life. It has been estimated that ocean waters harbor about 4×10^{30} viruses, most of them infecting heterotrophic and autotrophic bacteria. The ratio between viruses and bacteria is comprised between 3 and 10. Through the water column, viruses mainly occupy the euphotic layers and their abundance drops as depth increases; contextually, virioplankton is more abundant near the coast and decreases in the open ocean. Although generally viruses are small acellular organisms, composed almost exclusively by a genome coding for few proteins, the diversity of the mechanisms employed in their replication and biochemistry is higher than that observed for cellular organisms. Moreover, viruses harbor high genetic and biological diversity, and seem to have played—and still play—a key role in the evolution of life.

Microbial Functional Pathways in Aquatic Systems

Aquatic microbial communities show a large variation of metabolic activities, ranging from primary production to the heterotrophic utilization of organic compounds. The conversion of inorganic carbon (or other electron acceptors) into organic living material—which characterizes both photoautotrophic (relying on the energy of light) and chemoautotrophic (dependent on chemical energy in minerals) microorganisms—is performed by the producers that are at the base of the trophic chain. Autotrophic picoplankton (microorganisms smaller than 2 μm, including picocyanobacteria and picoeukaryotes) contribute substantially to primary production, both in marine and freshwaters. In the oceans, *Prochlorococcus* and *Synechococcus* contribute around 75% to CO_2 fixation, but in lakes the contribution of *Synechococcus* ranges from 5% to 65% of total phytoplankton production (Lake Constance, Germany), with higher contribution measured in ultra-oligotrophic lakes (80% in Lake Baikal). These estimates have been obtained by the use of radioactive compounds that are good tracers even when measuring low activities.

With the diffusion of molecular biology techniques functional pathways became easier to study, as it is now possible to quantify the presence of specific functional genes, and to better characterize the transcription products, thus demonstrating the functionality of genes. Alternative heterotrophic metabolisms performed by *Bacteria* and *Archaea* in addition to the well-known glycolysis (crucial to sugar metabolism), have been studied in details. Important among them is the pentose phosphate pathway to generate NADPH and pentose, studied through the presence of genes codifying for different enzymes in the pathway.

Another important metabolic pathway in aquatic systems is nitrification, the two-step metabolism, which oxidizes the ammonium to nitrate and then to nitrite. The microorganisms involved in the first step are nitrifying bacteria that include ammonia-oxidizing bacteria (AOB) like *Nitrosomonas* and *Nitrosoccoccus* and ammonia-oxidizing archaea (AOA) like Thaumarchaeota. The *amo*A gene, encoding for the alfa-subunit of the ammonia monooxygenase enzyme, which catalyzes an important step of bacteria nitrification, is associated with an archaeal metagenomic fragment. This discovery underlines the ecological importance of Archaea in aquatic ecosystems, by emphasizing their role in the first step of nitrification and their possible competitions and relations with nitrifying Bacteria.

Another pathway that recently received more attention is the dark inorganic carbon assimilation that can be performed by chemoautotrophs affiliated with Bacteria and Archaea. Chemolithoautotrophic bacteria fix CO_2 in the dark through a variety of carboxylation reactions to satisfy metabolic requirements such as the synthesis of fatty acids, nucleotides and amino acids or anaplerotic demands. Thaumarchaeota too can perform dark assimilation, but they use the hydroxypropionate–hydroxybutyrate carbon assimilation pathway.

The dichotomy between autotrophic and heterotrophic organisms—also thanks to molecular biology—became increasingly insufficient to describe the scaffold of microbial functional pathways. Like for macrobial eukaryotes, also the microbial world is rich in cells combining different metabolic strategies. Despite this richness, the combination of autotrophic and heterotrophic metabolisms to sustain growth and maintainance can be an energetic cost for the cell. For example, the light-harvesting apparatus needs a high investment in energy terms, but can be a resource in case of organic matter limitation in some oligotrophic systems. Even the opposite strategy can prove successful, as in the case of *Synechococcus*, a picocyanobacteria abundant in marine and freshwaters, that consumes organic sulfur compounds, playing an important role in the cycle of dimethylsulfopropionate and methanethiol. The ability of *Synechococcus* and *Prochlorococcus* to take up amino acids and urea has been demonstrated in axenic cultures, showing how these cyanobacteria can occupy different trophic levels, also contributing to the secondary production in aquatic environments.

Some bacteria can use chromophores like proteorhodopsin, which works as a light-driven proton pump, therefore allowing these organisms to act as a photo-organoheterotrophic bacteria. Important groups like SAR11 (*Pelagibacter ubique*) and some *Flavobacteria* are among the bacterial group containing proteorhodopsin. Another illustration of the metabolic complexity of microbial communities is the discovery of a group of anoxygenic photosynthetic bacteria that use bacteriochlorophyll *a* (Bchl-*a*) for photosynthesis in the absence of oxygen, thus being able to also survive in aerobic conditions. The unexpected abundance of new metabolic pathways in microbial communities we briefly described here is allowing microbiologists to revise our understanding of nutrient and energy flows in aquatic ecosystems.

Extrinsic and Intrinsic Drivers Structuring the Microbial Community Assembly

When considering microbial community assembly in aquatic habitats, the Baas-Becking hypothesis ("everything is everywhere, but the environment selects") is a useful heuristic selection on the part of the environment—and its variables and (micro) dynamics—that can help understanding how communities form and are organized. In addition, microbial dispersal is a passive process but not an entirely stochastic one, so that microbial biogeographical patterns are affected by the organisms' fitness to the environment (or specific niche) and by microbial life history traits. The forces that influence the structure and function of aquatic microbial communities can be extrinsic—meaning they act at a broader, regional scale—and intrinsic—such as food-web interactions that are more site-specific. The former ones impart a sort of synchronization to different populations in the community by the action of a local array of factors like temperature or meteorology. Intrinsic factors further affect the pattern of synchronized microbial population, resulting in fluctuations in the community that are harder to predict.

Extrinsic Drivers

The extrinsic drivers regulating microbial communities can be broadly grouped in physical ones, like temperature, and currents, and chemical ones, like salinity, dissolved oxygen, nutrients, metals, and antibiotics. Considering the current climatic changes brought about by CO_2 and other greenhouse gases emissions, and the subsequent prediction of a global rise in ocean temperatures in the order of 2–4°C, temperature as a physical extrinsic driver has been receiving much attention—especially considering its profound impact on biological processes. Recent studies directly linked temperatures to changes in richness and diversity of microbial communities. Moreover, temperature was also documented as one of the extrinsic driver associated with the increase of the relative abundance of *Vibrio* spp. (a genus comprising different pathogens for humans and animals) resulting in a possible threat for human and animal health.

In addition to temperature, in aquatic environments currents are important drivers because of their effect on the geographic dispersal of bacterial communities, which can strongly affect their composition. In particular, planktonic microbial communities drifting in the ocean experience a temperature variability up to 10°C greater than the estimated seasonal fluctuations, resulting in a selection of bacteria more tolerant to this thermal exposure.

Among the chemical drivers affecting microbial communities, salinity is certainly one of the main factors responsible for community assemblage composition, sometimes even more important than temperature, informing the many differences between marine and freshwaters. In addition to salinity, dissolved oxygen (DO) also occupies a central role in community dynamics because of its influence on biotic interactions and on nutrient flows within aquatic ecosystem. In particular, it has been found that higher DO concentrations, positively correlates with *Alphaproteobacteria* biomass while negatively affecting bacterial diversity, that dramatically decreases in anoxic waters.

Nutrient availability determines a "bottom-up" pressure in the regulation of aquatic microbial communities. It is generally considered that the availability of phosphorus is limiting the growth of planktonic communities in most freshwaters and nitrogen and iron in many marine systems. Additionally, a shift in nutrient availability will strongly impact community composition, especially when coupled with temperature. However, given the complexity and interlinked nature of these dynamics, it is not always easy to identify a direct effect of nutrients on the whole community examined; this might result in smaller effects, for example a change limited to the composition of variable taxa only. The challenges of understanding the dynamics of the aquatic nutrient pool are worsened by anthropogenic impacts on nutrients concentrations, and even by particular climatic events like strong winds (possibly associated with dust dispersion in water) and volcanic eruptions (characterized by the release of ash and pumice in water altering the carbon/phosphorous ratio).

In addition to these extrinsic drivers, two other factors have a strong impact on microbial communities and are often linked to anthropogenic pollution: antibiotics and metals. Originally, antibiotics are natural compounds released by microorganisms to kill other microbial competitors, and that have an important role as signal molecules, affecting the structure of microbial communities. The artificial isolation, synthesis and overuse of antibiotics in human and animal medicine and aquaculture, constitutes a massive and growing source of pollution, as these compounds are released through excreta into aquatic environments and accumulate, with unpredictable outcomes on microbial life. This is because antibiotics, regardless of their concentration, can exert a selective pressure, altering the structure of microbial communities in terms of both phenotypic distribution and composition, and promoting the spread of antibiotic resistance genes, thus constituting a major threat for human health.

While some metals (i.e., copper, zinc, nickel, lead, cadmium, mercury, silver, gold, and chromium) are necessary in small concentrations to microbial metabolisms for several cellular functions, in high concentrations they can be toxic for microbial life. Other metals, like uranium and antimony, are always toxic for microorganisms. Given their importance in contemporary human industries (mercury in electronics, dental and health care industry; copper and zinc as growth promoters in husbandry), metals are released and eventually accumulated in aquatic environment at an alarming rate. This anthropogenic contamination shapes microbial communities, engendering a strong reduction of microbial diversity, affecting metabolic pathways, and negatively influencing the expression of enzymes.

Intrinsic Drivers

The intrinsic (site-specific and biotic) drivers that structure microbial communities are those related to the interactions between species within the same environment. Interactions between microorganisms can be categorized in five broad groups: (1) *predation*, when one organism feeds on another one; (2) *commensalism*, when one organism benefits from another one without affecting it; (3) *mutualism*, when both organisms benefit each other; (4) *parasitism*, when the parasite benefits and the host is harmed; and (5) *competition*, when the organisms do not directly interact with each other but compete for the same resources. Some of these interactions can act directly on species composition, as for example predation, or indirectly by the production of allelopathic substances with beneficial or detrimental effects.

The classical, and highly simplified, food chain would comprise primary producers that are eaten by primary consumers, which in turn are eaten by secondary consumers and so on up to the top predators. However, the photosynthesis performed by phytoplankton is not 100% efficient in terms of carbon fixation into biomass, and an estimated 13% of dissolved organic carbon is directly released into the water. These high quality substrates, such as sugars, are readily taken up by aquatic bacteria, which then themselves are consumed by primary consumers. These organisms are in turn eaten by zooplankton species and thereby the organic carbon is channeled back into the classical food chain, reaching higher organisms. Since this pathway is like a loop attached to the

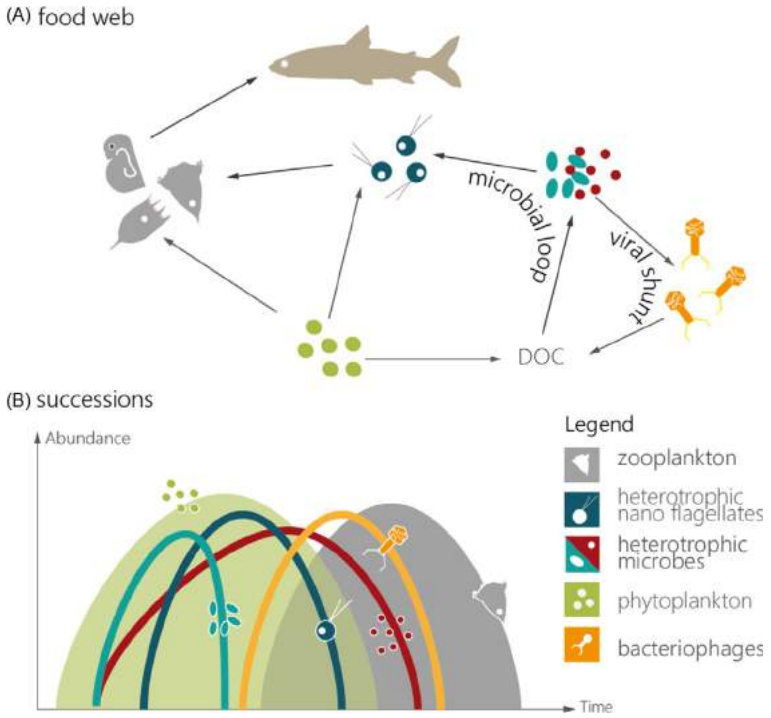

Fig. 4 (A) Simplified scheme of an aquatic food web including the microbial loop and the viral shunt; (B) examples of potential successions of microorganisms observed in aquatic habitats.

simplified food chain, it has been termed "the microbial loop" (Fig. 4A). This concept was established for marine bacterioplankton in the early 1980s and easily applies to freshwater ecosystems too. Given the privileged role that macroscopic life has been granted for most of the history of science, the microbial loop is generally considered an attachment to the classical food-chain. Nevertheless, it has been argued that, given the impressive biomass and energy turnover in the microbial loop, its diffusion, and its importance to the biosphere and its evolution, the classical food chain should be seen as an appendage to microbial trophic interactions. The two main pathways of the microbial loop (DOC—Dissolved Organic Carbon uptake, and predation) highlight the two most important factors defining the niche space of aquatic microbes: availability of organic and inorganic nutrients (bottom-up control) and agents of mortality such as viruses and HNF (top-down).

Consequently aquatic bacteria are often classified in two main guilds: fast-growing and grazing-resistant bacteria. Some of the fast- or opportunistically-growing bacteria are free-living, while others attach to particles, where organic carbon concentrations and turnover are typically higher. These bacteria are known for their efficient substrate uptake machinery, as well as their high vulnerability to protistan grazing. Typical members of this guild are *Alteromonas* and *Flavobacteria*, and *Limnohabitans*-affiliated bacteria, in marine and freshwaters respectively. A different survival-strategy is the investment in protection against protistan grazing, which is characteristic of the so-called grazing-resistant bacteria. Such protection can be due to morphological and structural features, as very small cells (*ultramicrobacteria*) with rigid cell walls, and long filamentous cells, are less commonly ingested by predators. Ultramicrobacteria are highly abundant in aquatic systems and include the ac1 group of *Actinobacteria* in freshwaters and *Pelagibacter ubique* (SAR11) in the oceans.

Dissolved organic carbon found in natural waters is composed by a variety of substrates including sugars, amino acids, humic acids and many others. On the one hand, different phytoplankton species release different carbon compounds, that is, *Chryptophytes* release more sugars than many *Cyanobacteria*. On the other hand, there are also numerous other sources of organic carbon, such as bacterial growth and mortality, sloppy-feeding by zooplankton or substrates deriving from terrestrial input. As a consequence, co-occuring heterotrophs have been seen to have very different substrate uptake preferences: whereas some genotypes seem to be specialized in the uptake of amino acids, other prefer glucose, for example. Such differences in meal-preference help explain why so many different bacterial genotypes can co-exist.

As we already mentioned, the two main causes of mortality in microbial communities are flagellate predation and viral lysis. The effect of flagellated predators on microbial communities is often seen as a shift in the composition and morphology. Some bacteria are able to change their growth strategy in the presence of predators by, for example, aggregating with other cells or elongating into filamentous shapes, which allow them to avoiding predation due to increased size. But such grazing defense strategies are often evolutionarily costly. This becomes clear when considering an experiment involving a bacterium (*Sphingomonas* sp.) kept under grazing pressure for a long time: after the experiment, the bacterium aggregates also in absence of the predator, but lost part of its genome related to carbon degradation. In fact, many highly abundant marine and freshwater ultramicrobacteria are characterized by so called *streamlined* genomes, genomes that contain only the minimum genes needed for survival. Simultaneously, though,

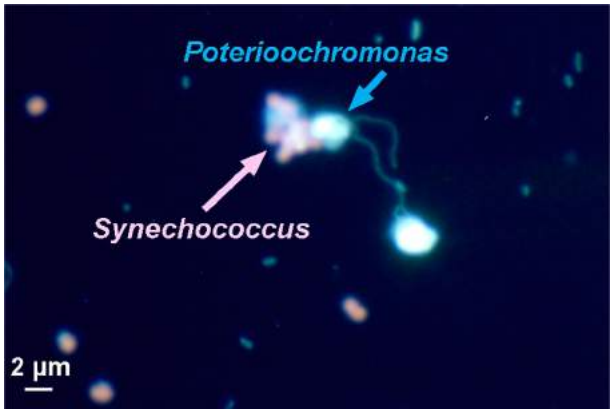

Fig. 5 *Synechococcus* cells (prey) and *Poterioochromonas* sp. (mixotrophic nano-flagellate predator) interaction in a culture, giving rise to the presence of microcolonies (photo by C. Callieri).

flagellate grazing is also known to stimulate bacterial growth, probably also due to the egestion of incompletely digested prey, which can serve as a substrate to other bacteria and regenerate nutrients. In the case of picocyanobacteria, the effect of nanoflagellate predation was to affect the shift from single cell morphotypes to microcolonial aggregates (Fig. 5), thus contrasting the effect of this intrinsic driver.

Viruses are potentially able to infect all of the components of aquatic microbial communities, however they primarily infect the most abundant bacteria and eukaryotic microbes (killing-the-winner hypothesis). Due to their ability to infect microbial hosts, in order to survive and replicate they directly affect, at the community level, the structure and composition of the microbial life and, at level of the single infected hosts, their physiological status. Therefore, viruses also play an important role within the food web. In fact, they lyse the infected bacteria, determining the release of their cellular content, which is converted in particulate and dissolved organic carbon usable by non-infected prokaryotes (viral shunt) (Fig. 4A). The actual consequence of this flow of matter through the food web is the increase of the respiration rate of the community and the decrease of the efficiency of carbon transfer toward the higher trophic layers. Together with carbon, also other nutrients are released, which can sometimes almost satisfy the particular nutrient need of certain organisms.

Based on these food web interactions, typical successions of aquatic organisms can be observed (Fig. 4B), initiated by the steep increase of phytoplankton biomass (e.g., early spring). These primary producers exude organic carbon (OC), which serves as a substrate for heterotrophic bacteria. In turn, the increasing numbers of bacteria promote the growth of heterotrophic nanoflagellates (HNF), which feed on the bacterial assemblage and provide a niche for alternative bacterial groups, not affected by grazing. Mortality among these bacteria is probably mainly caused by viral lysis. Generally, phytoplankton blooms are terminated by high abundances of zooplankton species.

While these classical food web interactions provide a useful handle to imagine such dynamics, many more interactions characterize microbial communities alongside them; they are termed non-trophic interactions. One example of these interactions can be found in microbes that grow as symbionts, epibionts or parasites. Some parasites can be highly abundant, such as members of the marine Alveolata MALV-IV group that attach to many different higher organisms. Some of these associations are only transient: bacteria may benefit from zooplankton as a refuge from threats such as grazing and abiotic stressors, or use zooplankton as a mean of transport from lower to higher water layers. The association of the cholera-causing agent *Vibrio cholerae* with planktonic copepods enables the survival, proliferation and transmission of the disease. Attached bacteria and eukaryotes can be metabolically highly active. Since they are preyed upon together with their host, they might form a shortcut through the trophic chain, directly transferring organic carbon from the dissolved fraction to the top predators. Another example is co-aggregation or attachment, through which bacteria can attach, for example, to phytoplankton cells and reduce substrate competition with other bacteria due to their vicinity to the primary producer.

Conclusions and Perspectives

In this article, we focused on the broader processes that characterize microbial communities in aquatic environments. This scope provides a better grasp of the main questions and concerns informing the study of these organisms, and allows to foreground their impact on a global scale. This is also because much research on these communities concentrated on such more readily apparent dynamics. These planetary biogeochemical transformations are the results of processes working at the microscale and resulting in a fragmented and diverse micro-heterogeneity of aquatic habitats (Fig. 6). The prevalence of the microscale gradients in aquatic systems forces us to seriously reconsider the importance of studying aquatic microbes at single-cell level, and at a scale that is more commensurate with their own dynamics and lives. The new opportunities offered by genomics, single-cell technologies like nanoSIMS (nano secondary ion mass spectrometry), microfluidics, and atomic-force microscopy opened new frontiers for

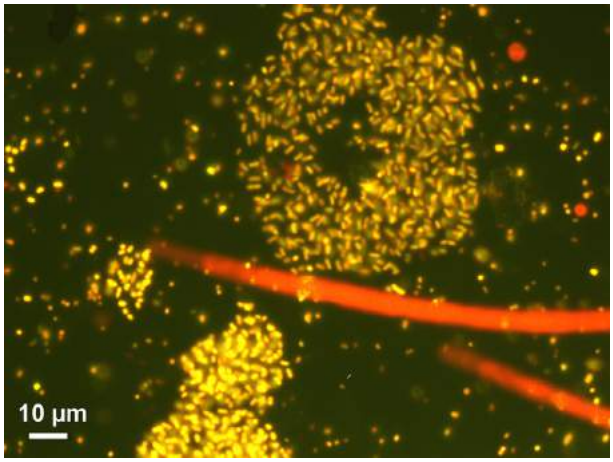

Fig. 6 Micro-heterogeneity in a drop of lake water (photo by C.·Callieri).

understanding the functioning of microorganisms and their interactions with the environment, paving the way to a micro-scale focus on microbial communities.

Despite these novel approaches, and the vast range of molecular and computational techniques that revolutionized our understanding of microbial life since the 1980s, our understanding of these life forms and the vital processes they shape still faces many challenges, and constantly stumbles upon surprising findings that redefine how we understand life on Earth and beyond. For this reason, the study of the microbiota, its micro-scale dynamics, and its interactions with the macrobiota require us to think outside the box, to work collaboratively across disciplinary boundaries, and to remain open to the awe-inspiring workings of our planet's ecosystems. This is the hard and yet rewarding task inherited by the younger generations of scientists, thinkers and explorers to whom this article is dedicated.

Age Structure and Population Dynamics☆

Louis C Bender, New Mexico State University, Las Cruces, NM, United States

Age structure in populations can take a variety of forms and have a range of effects on population dynamics. Species can be comprised of multiple age classes in a single-stage life cycle (hereafter, age-class structuring), such as in most birds, fish, and mammals. Species can also show multi-stage life cycles, where different stages in the life cycle are analogous to age classes (hereafter, stage structuring). Such life cycles are common in invertebrates, amphibians, and plants. Species can also show both types of age structuring; typically this involves a stage-structured life cycle where the longest lived stage (usually the adult or reproductive stage) also shows ≥ 2 distinct age classes. For example, trees have both multiple life stages (seed, plant) and age classes within the plant stage (i.e., seedling, sapling, mature tree).

Both age-class structuring and stage structuring in populations can affect population dynamics, albeit typically at different scales. Stage-structuring is commonly an adaptation to habitats that show extreme temporal or spatial heterogeneity in resource availability. As such, stage-structured populations generally have ≥ 1 life stages which can persist through long periods of unfavorable environmental conditions, or are capable of rapid long distance dispersal. When favorable conditions return, these species can "irrupt" or rapidly increase in numbers and distribution because of their high reproductive potential. This allows these species to quickly colonize or occupy all available ephemeral habitats. Such species are often characterized by very high fecundity and display extreme *r*-oriented population dynamics in ≥ 1 life stage. Examples of stage-structured populations include many irruptive insect "pests" such as the eastern spruce budworm (*Choristoneura fumiferana*).

In contrast, age-class structured populations are comprised of ≥ 2 age classes of individuals born at the same time, or cohorts, in a single-stage life cycle. Often age-class structuring can be complex, such as in long-lived vertebrates which can have many age classes, including newborns and multiple subadult and adult age classes. In contrast to irruptive population dynamics, age structure in age-class structured species generally affects population dynamics through more subtle changes in annual population growth rate in response to annual variation in habitat quality and population density. Because of differing sensitivity to habitat conditions, this variation can affect survival and fecundity rates of different age classes unequally, resulting in often subtle effects on population rates of increase and compensatory effects among age classes. However, the effects of age-class structuring on population dynamics are extremely varied, and go well beyond simply differences in age-specific survival or fecundity. Such species are typically more *K*-selected and show more typical *K*-selected population dynamics, such as a general trend towards density dependent regulation, although this is not always the case. Extreme examples include megaherbivores such as African elephants (*Loxodonta africana*) and black rhinoceros (*Diceros bicornis*).

Some species show both age-class structuring and stage structuring, and their population dynamics include aspects of each. Usually, survival and fecundity is dependent upon age and phenotypic quality as in age-class structured species, but individual reproductive output can be enormous and ≥ 1 life stages can persist through long periods of dormancy to allow rapid colonization or recolonization of habitats. Examples include fire-adapted tree species with serotinous seed cones, such as lodgepole pine (*Pinus contorta*).

Age-structuring is extremely important in management of populations and species. For example, harvest management of game species and commercial fisheries manipulates age structure to achieve optimal sustainable yields. Integrated pest management programs preferentially target certain life stages of pests to limit damages associated with agricultural or other pests. Thus, understanding age structuring in its varied forms can facilitate biodiversity, sustainable yield management, and limit conflicts between humans and other components of ecosystems.

☆*Change History:* October 2017. L Bender updated the text and further readings to the entire article, including adding additional examples and new Figures 1 and 3.

Age Structure Effects in Age-Class Structured Species

In age-class structured populations, the effects of age structure on population dynamics arise primarily because of varying age-specific mortality and fecundity rates and differences in the viability of individual cohorts. Age structure can also influence population dynamics through effects on timing and length of breeding seasons, population-level productivity, total population-level mortality, and sensitivity to population regulating mechanisms such as density dependence. In turn, age structure can be influenced by actions such as harvesting and environmental variations including severe weather events, age-specific predation or parasitism, and presence of disease.

Age class effects are most definitively seen in populations that show ≥ 3 distinct age classes, including juveniles, prime-aged adults, and senesced adults. Although effects of population age structure can be seen in populations with ≤ 2 distinct age classes, they are generally less pronounced. Moreover, individuals in each cohort may be independently influenced by environmental conditions experienced by their mothers (maternal effects) or experienced by all individuals in the cohort as juveniles (cohort effects), and this variation can persist throughout life and lead to differences in fitness among cohorts that affect many aspects of population dynamics (see *Cohort effects* below). Because age structure has such a strong effect on the productivity and mortality patterns of populations and can vary markedly between years within a population, even for long-lived *K*-selected species, the annual rate-of-increase of populations can also vary markedly simply because of annual changes in the age structure of a population.

Age Structure in Populations

The age structure of populations is driven primarily, but not exclusively, by age-specific mortality rates (Fig. 1). In general, juveniles have relatively low but highly variable survival; prime-aged adults have high and relatively constant survival; and aged, senesced adults have lower and variable survival. Age-specific mortality rates determine both how long individuals in a population can potentially live and the proportions of individuals surviving into each successive age class.

For example, if the natural mortality rate of all age classes in a population is 0.10, then on average 90% of individuals in a given age class will survive the year and be recruited into the following age class. The result of incremental mortality through years is that populations tend to show a "pyramid-shaped" age structure, with fewer individuals in each successive age class (Fig. 1). Numbers of individuals in each successive age class is dependent upon (1) numbers in the previous age class the previous year, (2) age-specific survival, and (3) possibly emigration and immigration. However, if additional mortality such as additive hunting harvest is placed on adults in a population, mortality rates for each age class would increase and the number of individuals in each successive age class would be lower (Fig. 1). Similarly, mortality factors that preferentially act on juveniles, such as predation, can result in cases

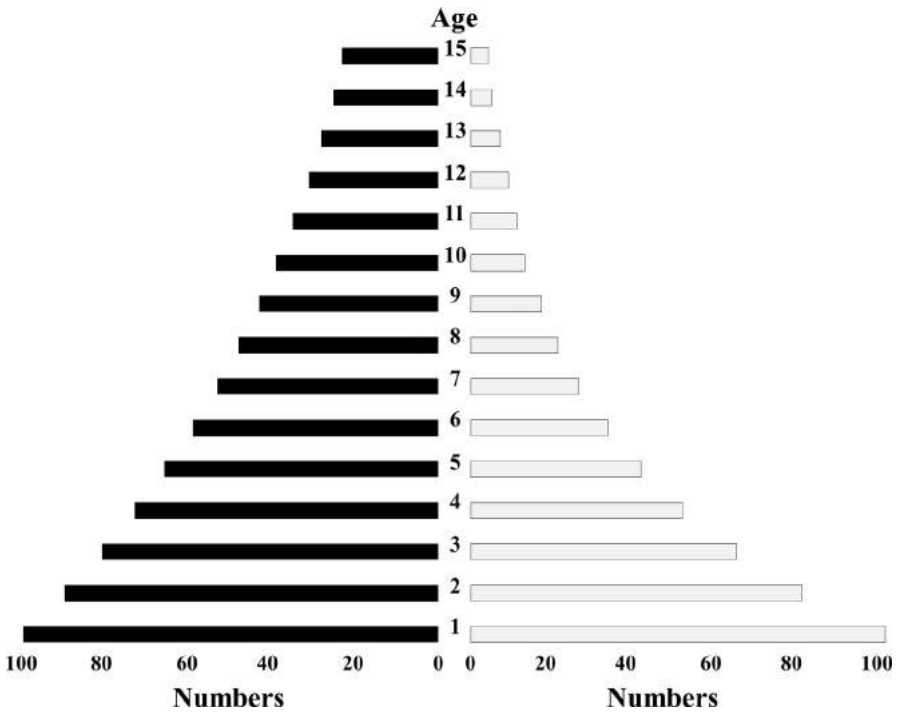

Fig. 1 Age structure of a North American elk population showing "pyramid-shaped" age structure and differential survival into older age classes based on an adult survival rate (S_{adult}) of 0.90 (▪) and 0.80 (□). Note that more individuals survive into older age classes as survival rates increase. Mean age of the population is 6.1 and 4.4 years-old at $S_{adult} = 0.90$ and 0.80, respectively, showing that population age structure declines (becomes younger) as population mortality rates increase. In this simulated population, no individuals survive beyond age 15.

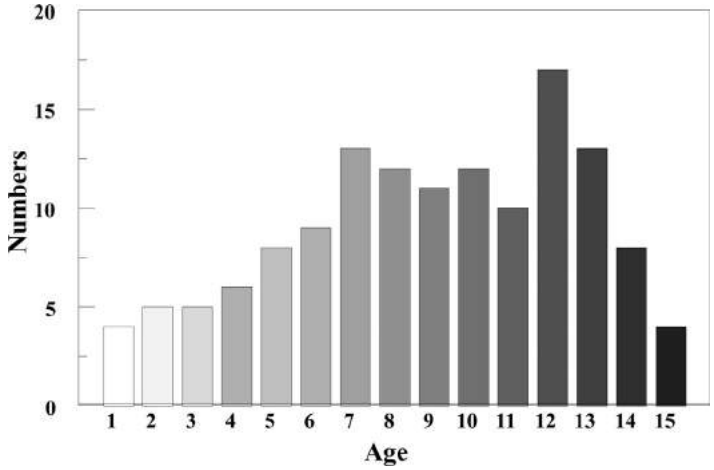

Fig. 2 Age structure of a North American elk population experiencing very high levels of predation on newborn calves. Note that successive recent years of poor recruitment into the population result in a population age structure that is shifted to the right or dominated by older age class individuals. Such an age structure would further decrease potential recruitment because older individual elk show reproductive senescence and produce fewer juveniles than do individuals in their reproductive prime (ages 2–8).

where a population is primarily comprised of older adults (Fig. 2). Therefore, under most conditions the age structure of a population, and the effects of that age structure on population dynamics, are driven by sex and age-specific mortality rates. Because changes in age structure affect the numbers of individuals that will die or be born each year, the age structure of a population can have a marked effect on year to year changes in population size.

Management of populations in most cases involves managing population productivity, or production and survival of juveniles, because productivity typically accounts for the majority of variation in annual rate of population increase. The more productive a population, the greater the potential return, regardless of whether that return is a sustainable harvest or a high rate of population increase for recovery of a rare species. The effects of age structure on population dynamics are most obviously manifest in population productivity through effects on individual fertility, fecundity, and probability of raising a juvenile to weaning or recruitment (see *Effects of female age structure*, below). However, age structure can also influence many other components of population dynamics including sensitivity to density dependent effects (see *Effects on population regulation*, below) and consequently population-habitat relationships, and numbers of individuals that die annually due to differing age-specific mortality rates (see *Effects of age-specific mortality*, below).

Effects of Female Age Structure

Age of females is an important contributor to different levels of fertility, fecundity, and survival of offspring. Generally, juveniles have much lower fecundity than do adults, and prime-aged adults have much higher fecundity than do older or senesced adults (Fig. 3). The larger and longer-lived a species, the greater these age-related differences. For example, desert mule deer (*Odocoileus hemionus eremicus*), fecundity of which is illustrated in Fig. 3, can live to be 20 years-old. Thus, there are many more age classes in the older, senesced category ($\geq$ 7 years-old = 14 age-classes) than in the juvenile categories (fawns and yearlings). Consequently, a population with an older adult age structure (i.e., one that has a greater mean age, because of more individuals in older age classes) tends to be less productive than a population of the same species with a younger age structure because more individuals are present in reproductively senesced age-classes. Actions aimed at maximizing productivity thus often try to increase mortality rates on the population above those attributable to natural mortality alone. The goal of these strategies is to decrease the age structure of the adult population in order to have a greater proportion of the population in prime reproductive categories (Figs. 1, 3, and 4), thus maximizing per capita productivity.

Maternal age can also influence the likelihood of successfully raising a juvenile to recruitment, or age of reproduction. This can be due to experience of mothers; prime-aged mothers are more likely to be larger and have a higher social rank in long-lived species, which leads to better territories and greater capture of resources, both of which result in greater production and survival of juveniles and hence greater lifetime reproductive success for these individuals. Moreover, birth attributes of neonates such as size or birth mass tend to be lower for older, senesced mothers and younger, inexperienced mothers, and birth attributes are strongly related to juvenile survival in many species. However, this can also be due to phenotypic quality of eggs or juveniles. For example, older (but non-senesced) fish of many species (e.g., Atlantic cod [*Gadus morhua*], black rockfish [*Sebastes melanops*]) produce higher quality eggs with consequent greater larval survival. The higher quality offspring show faster growth rates and greater resistance to starvation. While female size has long been recognized as affecting production and survival of offspring in many fish species, female age may be a much better predictor of larval performance in some species.

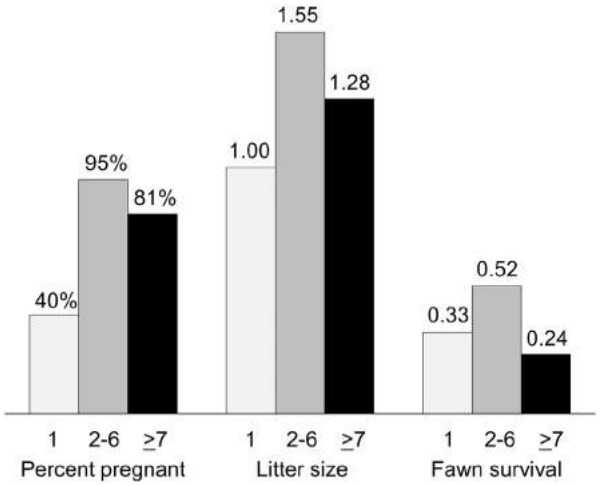

Fig. 3 Age effects on probability of pregnancy, numbers of juveniles produced, and fawn survival of desert mule deer. Because deer can live to be 20 years-old, there are potentially many more older, reproductively senesced age classes in the population. Thus, populations that show older mean ages tend to be less productive than populations with younger age structure. In this example, prime-aged adult females recruit 0.76 (90% CI = 0.60–0.94) fawns/year, compared to 0.11 (0.00–0.44) and 0.24 (0.10–0.42) for yearling and senesced females, respectively.

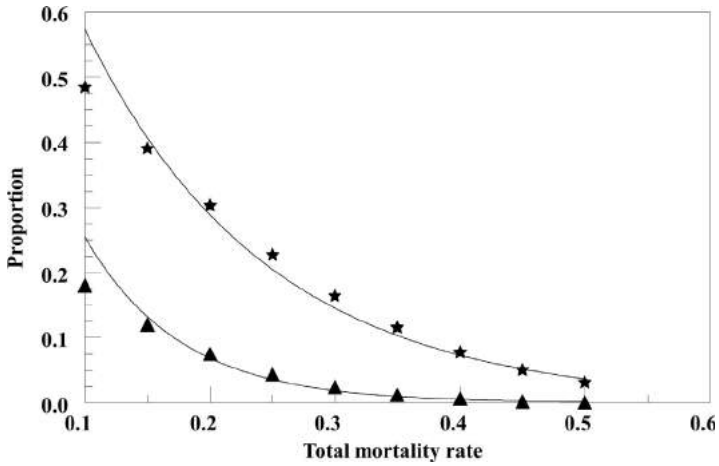

Fig. 4 Effects of increasing adult mortality rate on the proportions of oryx (*Oryx gazella gazella*) > 5 (★) and >10 (▲) years-old on White Sands Missile Range, south-central New Mexico, USA. Note that as total mortality rate increases, a smaller proportion of individuals are able to survive into older age classes. Observed total mortality rate in this population (approximately 0.26) results in a decrease of approximately 52% and 78% from the proportions of >5 and >10-year-old oryx in the population given an approximate "natural" annual mortality rate of 0.10.

Maternal behavior also varies according to age of females and number of pregnancy experiences, which can affect survival of juveniles. Prime-aged mothers are more successful in rearing juveniles than are younger females, particularly when threatened by predation. In large mammals, age of the mother has been associated with losses of neonates in the first week of life, when most newborns die; far more juveniles from primaparous females are lost compared to multiparous females. Experienced mothers are less likely to orphan juveniles due to a breakdown in the imprinting process. For many species, prime-aged females protect juveniles better than younger females. For example, when subjected to human disturbance or simulated predator threats, prime-aged female white-tailed deer (*Odocoileus virginianus*) move their fawns to more secure bedding sites, whereas young mothers often do not. Experienced females also commonly show complex distraction behaviors that can lead a predator away from juveniles, and may also actively defend juveniles by attacking predators.

Effects of age are often correlated with body mass or size, as older females tend to be larger. Juveniles born to larger mothers often show greater survival, likely because juveniles born to heavier mothers are larger and size at birth is strongly related to survival to recruitment (e.g., mammals) or because juveniles show faster growth rates and greater resistance to starvation (e.g., fish). Similar effects may be seen as litter size increases. For example, roe deer (*Capreolus capreolus*) fawns born to relatively light mothers or in twin or triplet litters have higher mortality rates than those born to heavy mothers or in smaller litters, because single-born fawns usually weigh significantly more than individual twins or triplets. For many species maternal mass in late pregnancy is correlated with

juvenile birth mass, and probability of survival is lower for juveniles born to females with lower than average body mass. Consequently, maximum juvenile-rearing success occurs when physically mature, multiparous females comprise the bulk of the breeding population, rather than juvenile or senesced adults. Senescence may not be solely a product of age, but may also be influenced by reproductive performance early in life. For example, birds with large clutches early in life tend to senesce more quickly, as do red deer (*Cervus elaphus*) that rear more calves early in life.

Age of the mother may also affect the sex ratio of juveniles, although climatic and other environmental conditions can also affect sex ratio of juveniles through effects on condition of mothers during gestation. In longer lived species, prime-aged females in good condition often produce more male offspring than females in poor condition, and both senesced and younger females are frequently in poorer shape and thus may produce more female young. The age structure of a population can consequently affect both juvenile and adult sex ratios, and thus the potential rate of increase of populations, simply by influencing the proportion of females born into the population. Having more adult females in prime reproductive classes increases population rates of increase because of their higher fecundity and greater likelihood of successfully raising a juvenile (Fig. 3).

Effects of Male Age Structure

Age structure of males can influence breeding dynamics of age-structured populations. In polygynous species, populations with greater numbers of older, prime-aged males have earlier, shorter, and less socially-disruptive breeding periods. Conversely, where fewer older males are present, breeding periods tend to be longer and females are frequently bred later in the season. Because later breeding may lead to later birth dates, and later birth dates lower juvenile survival, the age structure of the male population can potentially influence both pregnancy rates and survival of juveniles, thus affecting population rate of increase. However, this cascade of effects has not been conclusively demonstrated in free-ranging populations. Other factors such as female nutritional condition may overwhelm any effect of male age structure and breeding date by allowing females to shorten the length of gestation. Further, ages of males tending harems may not be dominated by prime-aged males until male/female ratios are very high even in polygynous species; thus, younger males may breed a significant proportion of females regardless of male age structure. Consequently, observed recruitment of juveniles has been shown to be independent of adult sex ratios and male age structure in several polygynous ungulate species. High harvest rates of males have also driven male age structure and male/female ratios well below thresholds theorized to affect population-level productivity, without any significant decreases in population productivity being documented in free-ranging populations.

Effects of Age-Specific Mortality

Survival rates of age-structured species can vary among age classes. Generally, juveniles have low but extremely variable survival whereas prime-aged adults have high and relatively constant survival. As individuals become older and move into the age classes that show reproductive senescence, survival rates typically decline. Gaillard et al. (2000) reviewed survival studies of cervids and found preweaning juvenile, postweaning juvenile, prime-aged adult female, and senescent adult female survival (CV) of 0.62 (0.25), 0.71 (0.28), 0.86 (0.09), and 0.79 (0.14), respectively, with similar patterns seen in bovids. Although fairly invariant with respect to large mammals, these patterns may be less pronounced in other taxa, such as rodents. Importantly, not only is survival of juveniles and older, senesced females lower than prime-aged females, but it is also from 2 to 3 times more variable.

Increased mortality rates in senesced adults can be due to a variety of factors, including decreased body mass, hormonal imbalances, lower individual nutritional condition, wear of teeth, and decreased immuno-competence. For juveniles, smaller body size, lower energy reserves, greater energy requirements per unit body size, and inexperience all increase vulnerability relative to adults. Because of their sensitivity to environmental variation, juveniles are particularly affected by temporal variation in environmental conditions and hence the annual variation associated with survival rates (as well as fecundity) is much higher than in adults. Lowered survival rates in senesced adults results in their lowered fecundity having less impact on overall population-rate of increase than if survival remained comparable to prime-aged adults.

The sensitivity of juveniles to annual variation in resource availability can strongly affect population-level production and mortality. If density or resource stress is low, juveniles can attain sexual maturity and breed earlier in life, and productivity of young females may equal that of prime-aged adults. These effects are important when one considers proportional contributions to population rate of increase. Adult female survival has the greatest potential effect on rate of increase (i.e., the highest elasticity) but, as noted above, typically varies little annually. Conversely, juvenile fecundity and juvenile survival have much lower elasticity, but vary greatly annually. Consequently, the majority of the variation in annual changes in population size is a result of changes in juvenile survival and fecundity. Population age structure can thus exert a strong regulating effect on population rate of increase by dampening potential population declines when mortality of adults is higher as well as increasing population rates of increase during periods of high resource availability through density dependent changes in survival and fecundity of juveniles. Despite their lower fecundity and survival as compared to prime-aged adults, juveniles can be critical contributors to population-level productivity.

Compensatory Mortality in Age-Class Structured Populations

The age structure of a population can help buffer populations from changes in the mortality patterns of specific age classes. An important but poorly understood aspect of population-level mortality patterns is the concept of compensatory mortality, which

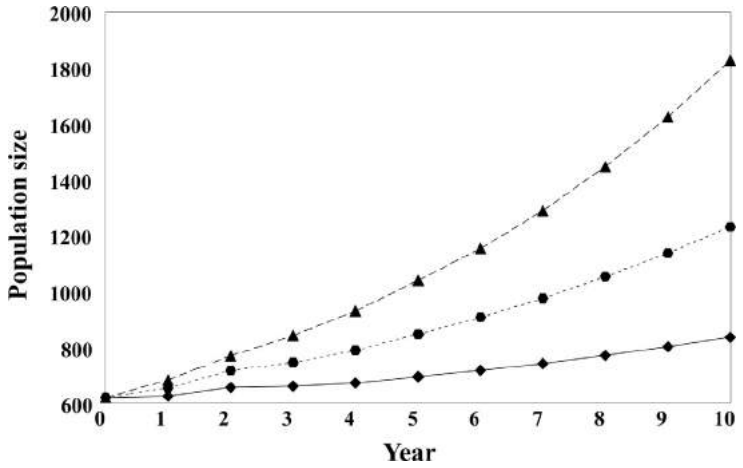

Fig. 5 Dynamics of females in a North American elk population showing effects of partial compensation in juvenile survival rate for changes in adult survival (compensatory mortality). Curves show population growth when $S_{adult} = 0.85$ and $S_{juvenile} = 0.50$ (▲); growth when S_{adult} is decreased to 0.75 by some additional mortality factor such as harvesting and $S_{juvenile}$ remains unchanged (♦); and partially compensatory growth when S_{adult} is decreased to 0.75 but $S_{juvenile}$ increases to 0.60 in compensation (●).

postulates that an increase in any mortality factor(s) can result in declines in other mortality factors, such that the total mortality rate either does not change or increases less than if the additional mortality was completely additive to existing mortality (Fig. 5). Because adult survival in most age-structured populations is high and shows little variation under conditions less than significant resource stress, less opportunity exists for mortality to be compensatory among adults in a population simply because adult mortality rates are typically at or near the chronic minimum, i.e. there is little excess mortality to "trade off" among mortality sources. However, age structuring of a population presents a mechanism whereby mortality at the population-level can be compensatory even if additive within certain or most age classes (i.e., adults) through compensatory responses in juvenile survival (Fig. 5).

Because juveniles are smaller and have a higher metabolic rate, they require greater resources per unit of body mass, are more susceptible to density stress and other resource limitations, and thus are more vulnerable to most causes of mortality as compared to adults. Consequently, any reduction in population size disproportionately benefits juveniles because they are more resource stressed than adults in any given set of environmental circumstances. Therefore, even if mortality is primarily additive on adults, the reduction in numbers of adults may result in a density dependent increase in juvenile survival. Hence, age structuring within a population provides a mechanism whereby compensatory effects can act to dampen changes in population size due to mortality factors such as harvesting. This is another means by which age structuring helps to regulate populations, buffering populations from large annual changes in population size potentially brought on by age-selective mortality factors such as harvesting (Fig. 5). The need for replacement of adults is also one reason why most *r*-selected and even some *K*-selected species significantly overproduce young. This "doomed surplus" provides ample recruits to replace adults despite very high juvenile mortality.

Cohort Effects

A "cohort effect" is a phenomenon where cohorts of a population differ from each other in some key attribute(s), such as body mass. Fetal sex ratio, birth mass, birth dates, rate-of-growth of juveniles, survival over the first winter, age of first reproduction, and adult survival rates are often related to the influence of the year of birth, which itself is a product of the environmental conditions cohorts face at birth as well as the nutritional condition of their mothers (itself a reflection of environmental conditions faced at or prior to birth). Environmental conditions that can influence birth and early growth attributes include droughts, abnormally high rainfall, late snowfall, and high population density. These and other factors influence birth attributes and early development of juveniles, and these early effects may persist and affect phenotypic quality throughout the lifetime of the cohort. Because many cohort effects such as lower body mass are tied to survival and reproductive fitness, cohort effects can influence population dynamics above and beyond the effects associated with typical age-specific reproductive potential or survival patterns.

Cohort effects are most often expressed as lowered reproductive output in the population as a whole as well as lowered lifetime reproductive success of individuals in that cohort. Differences among cohorts in lifetime reproductive performance have been demonstrated in a diverse array of taxa including large mammals, marine mammals, birds, fish, insects, and plants. Although populations need not have complex age-class structure to show cohort effects (e.g., annual plants), cohort effects most commonly occur because of environmental or density stress, which most commonly affect relatively *K*-selected species that also tend to have a complex age-class structure.

Cohort effects can be either short-term or long-term. Short-term cohort effects influence age structure and population dynamics by affecting the numbers of individuals in the cohort that live to be recruited. Long-term cohort effects affect overall reproductive

success of cohorts over time through their effects on phenotypic quality. Cohort effects can also vary by sex; for example, cohort may affect growth of males but not females due to the greater reproductive activities of males in polygynous species.

Age-Class Structure and Population Regulation

Age structuring in a population can help regulate numbers through a variety of processes noted above, usually associated with density-dependent changes in juvenile survival and fecundity rates in response to resource stress. These mechanisms allow age-class structured populations to exhibit much higher levels of population productivity during periods of resource abundance because of earlier sexual maturity and greater fecundity of juveniles. Further, increases in juvenile survival rates can compensate for decreases in adult survival to some degree, making the population more resilient to additional mortality such as associated with harvesting (Fig. 5). The mechanism behind this response is also density dependence. Thus, age structuring in a population, through variation in age-specific survival and fecundity rates, contributes significantly to density dependence as a regulating mechanism of populations. Typically, the more age-structured a population, the greater the number of potential density dependent responses available (i.e., increases in juvenile survival or fecundity; increases in young adult [yearling] survival or fecundity; increases in fecundity of older, senesced females, etc.) and hence the more sensitive density dependence becomes as a means of population regulation.

However, extreme age structuring in a species can limit the sensitivity of density dependence as a population regulating mechanism. Megaherbivores such as the African elephant can potentially have a dramatic effect on the vegetation of their habitat through foraging. The long life ($>$50 years) and large number of juvenile (pre-reproductive) age classes ($\geq$12) contributes significantly to the potential of these species to impact vegetation communities through herbivory. Even if reproduction is shut down due to density effects, there are still $\leq$12 cohorts of juvenile elephants that will grow and increase in individual mass, adding to the existing adult biomass. Larger elephants consume greater amounts of plant biomass, and it is the total biomass of elephants that determine herbivory levels more so than total numbers. Because adult biomass declines only very slowly due to extremely high survival rates (which allow the long life span) and juveniles continue to grow, total elephant biomass may actually increase for up to 12 years after density dependence has shut down reproduction in the population due to resource (food) stress. Thus, plant communities can be impacted by feeding above their sustainable levels; the increase in total elephant biomass continues well after the capacity of plant communities to support elephants is exhausted. Consequently, elephants can potentially overutilize their habitats because the extreme age structuring in the population makes density dependence a relatively insensitive means of balancing population biomass with available resources.

Age Structure Effects in Stage-Structured Species

Multi-stage life cycles generally represent an adaptation to environments that show extreme temporal or spatial heterogeneity in availability of key habitats. The *r*-selected dynamics, storage effect, and high dispersal potential seen in some life stages allows for very rapid population responses when ephemeral habitats become available. Many of the effects of age-class structuring on population dynamics detailed above are seen to some degree in at least 1 life stage in stage-structured species as well. However, population dynamics of stage-structured populations are also influenced by each life stage potentially having a unique life history. For example, different life stages of many invertebrate and amphibian species may have completely different physical forms and ecological requirements, and behave as distinct life forms with unique niches rather than as different age classes of the same life form. Because effects of age structure on age classes in the different life stages of multi-stage species can be similar to those detailed above for age-class structured single-stage species, this section will emphasize unique aspects of population dynamics driven by the distinct stage-structuring of these species.

Dynamics of Stage-Structured Populations

High fecundity and ecological complexity resulting from the multi-stage life cycle result in stage-structured populations showing a greater range of population dynamics than age-class structured populations. Although generally much more density independent than age-class structured populations, population dynamics of any life stage can range from density independent to intensely density dependent (i.e., amphibian larvae in ephemeral pools). At the population level, dynamics can range from density independent to populations that show multiple stable states or equilibrium points. At the extreme, high fecundity and extremely differing life stages can result in chaotic behavior in population dynamics.

For example, populations of spruce budworms and other insect "pests" may show multiple stable equilibrium points. Usually, the lower is associated with habitat conditions of low quality (such as immature balsam fir [*Abies balsamea*] and white spruce [*Picea glauca*] forests in the case of spruce budworms) in combination with predation and parasitism on the 6 larval instars (caterpillar) and adult (moth) stages. As habitat quality increases (forests mature) budworm populations can achieve a "critical mass" that allows them to irrupt to population levels orders of magnitude greater than the low density equilibrium. The irruption is facilitated by the highly mobile adult (moth) stage, which can disperse hundreds of kilometers in a single generation. Because of high mortality of host trees associated with large-scale outbreaks, conditions necessary for outbreaks may occur approximately only every 30 years. The time span between irruptions allows affected forests to regenerate and adjacent forests to attain a suitable mature forest structure, highlighting both the temporal and spatial variability in suitable habitats for this stage-structured species.

Stage Structuring and Colonization Ability

Multi-stage life cycles allow full use of habitats that are ephemeral in space or time. Generally, these more *r*-selected species are able to colonize new areas much faster than *K*-selected species. Thus, they are often early pioneers in succession. Some of this mobility is due to age structuring. For example, seeds can lie dormant for years until ecological conditions initiate germination and development into adult plants. Similar dormant phases are seen in many invertebrates and this phenomenon is called the "storage effect." Age structuring in such species allows the species to persevere in an area despite adverse environmental conditions, and thus allows the population to rapidly increase when conditions again become favorable. Such an age structure effect on population dynamics is a significant advantage over species which maintain a similar life form in all age classes; the latter may be extirpated during adverse periods if adverse conditions last longer than a generation, and would be dependent upon dispersal from favorable areas to recolonize. An age structure comprised of distinct life forms, especially if one or more is capable of extended dormancy, allows rapid population responses during favorable periods and is thus a significant advantage for early successional or pioneer species, or for species existing on the fringe of habitable conditions. Highly mobile life stages allow rapid colonization of habitats even if no "storage effect" is present.

Habitat and Population Dynamics of Different Life Stages

A diverse array of species, including plants, insects, and amphibians, have life stages with different life forms, and thus show unique population dynamics because of this life history. Ecological factors that limit one life stage (such as insect larvae) may have no effect on other age classes (such as the adult insect). Consequently, population dynamics of these species are less influenced by subtle changes in environmental conditions than are *K*-selected species. This, in combination with high fecundity, results in population dynamics being far more density independent. For example, outbreaks of many insect pests depend upon an environment that has (1) habitats which provide for growth and development of eggs and larvae and (2) habitats that allow adults to survive, reproduce, and disperse. Habitat limitations for any life stage can result in populations being limited at relatively low levels regardless of how suitable environmental conditions are for the other life stages. Even under suitable conditions, a minimum population size may be necessary to achieve a "critical mass" and allow the population to rapidly increase numbers and extent of distribution. Such a dynamic is called a manifold or break-point in the species growth curve; if ecological conditions allow the species to grow beyond this breakpoint, the species can irrupt.

The environmental conditions necessary to trigger rapid population establishment and growth may be extremely different among life stages. At one extreme, the environmental effect that triggers the irruption of juveniles may be the destruction of the adult life stage. For example, fire-adapted shade-intolerant trees such as lodgepole pine require full sunlight, mineral soil, and heat (to open serotinous cones and free seeds) to germinate. These environmental conditions usually only occur following a stand-replacing fire, which kills the existing population of overstory lodgepole pine trees. This in turn creates the conditions necessary for rapid germination of seeds and widespread establishment of seedlings. Without loss of the adult overstory, germination and establishment of the new cohort of lodgepole pine would not occur.

Conversely, habitat conditions necessary for rapid population growth can be similar for all life stages. Outbreaks of spruce budworms require extensive areas of mature spruce/fir forest to occur, as this forest structure provides necessary habitats for larvae to feed, molt, and pupate, as well as for adult moths to lay eggs. Thus, large scale outbreaks may only be ended by extensive mortality of preferred host trees due to defoliation, which decreases available feeding habitat for larval instars and egg laying habitat for adult moths. Consequently, numbers decrease to levels where population size can be limited by natural predators, limited resources (i.e., lack of mature spruce/fir forests), and weather, despite the ability of the adult moths to disperse widely and find most suitable trees.

Implications of Different Life Stages

The irruptive dynamics of many stage-structured species can result in significant conflicts with humans, such as seen with agricultural or forestry pests. In such cases, the differing habitat requirements and unique vulnerabilities of life stages are frequently exploited in control strategies. Integrated pest management specifically targets the most vulnerable life stage(s) of economic pests; once the lifecycle is understood, optimal intervention points in the lifecycle can be identified. For example, noxious annual weeds can be controlled with mulches and pre-emergent herbicides to prevent germination of seeds more easily than the adult plant stage can be controlled. Species such as mosquitoes (Culicidae) are frequently targeted with larvaecides or by limiting the availability of larval habitat, i.e., stagnant pools of water.

The greater the number of life stages, the greater the opportunity to find and exploit a vulnerable life stage. For example, the diamondback moth (*Plutella xylostella*) is a severe economic pest of cruciferous vegetables including cabbage, kale, and broccoli. Its life stages include egg, 4 larval instars, pupae, and adult, and the egg, larval, and pupae stages are each vulnerable to a different species of parasitoid wasp. Thus, rapid control of outbreaks can be attained by concurrent application of all wasp species, whereas long-term control may by attained by limiting management to use of only 2 species such as the larval and pupal parasitoids. Such life stage-based biological control allows management of the pest without eradication or the use of pesticides (both of which may have other undesirable consequences in the ecosystem) by exploiting vulnerabilities in stage (age) structure to interrupt irruptive population dynamics.

Altruism

KR Foster, Harvard University, Cambridge, MA, USA

Introduction

> This brings us to the central theoretical problem of sociobiology: how can altruism, which by definition reduces personal fitness, possibly evolve by natural selection? (Wilson, 1975, p. 3)

Altruistic behaviors, which reduce the personal reproduction of an actor and benefit another individual (**Fig. 1**), are found in a diverse set of organisms, ranging from microbes, through social insects, to higher vertebrates and humans (**Fig. 2**). Altruism presents a conundrum for evolutionary thinking because Darwin's theory of natural selection appears to suggest that selfish and competitive strategies are favored over evolutionary time. Why would natural selection select for a behavior that reduces personal reproduction?

As we will see, altruism can evolve when the actor and recipient carry the same genes, at one or more loci – the actor can then increase copies of their genes through the recipient's reproduction. This explanation, which comes from what is called inclusive fitness (or kin selection) thinking, remains the key solution for the problem of altruism, as originally defined in the evolutionary literature. However, more than one usage of altruism has developed in behavioral ecology and with alternative definitions came other explanations, which will be discussed.

Care with definitions becomes even more important when one looks outside of biology. In common parlance, altruism is often taken to indicate an actor's psychological `intention' to act selflessly. The biologist's focus on `outcome' and evolutionary fitness (**Fig. 1**), therefore, can contradict the mainstream meaning of altruism in at least two ways. First, it allows the possibility of altruism in simple organisms, like microbes, that lack conscious intention. In addition, a gene for altruism will only be selected when the action increases its carrier's fitness – genes cannot be selected to produce behaviors that decrease their frequency. Evolutionary discussions of altruism, therefore, typically involve hidden genetic benefits, which can be troublesome for those that require altruism to be truly selfless.

The Birth of the Idea

It may be no coincidence that the concepts of altruism and natural selection were developed simultaneously in the mid-nineteenth century. Social philosophy was being much discussed and contrasting opinions abounded. On the one hand, Auguste Comte was popularizing altruism as part of his secular positivist religion, which argued for selfless acts that aid humanity and founded the new science of sociology. On the other hand, Herbert Spencer's individualism was fueling the fires of British industry. It was into this environment that Darwin proposed his individual-centered theory of evolution – natural selection.

With altruism based upon selflessness, and natural selection on selfishness, their conceptual collision would appear inevitable. However, this collision was barely evident at first. While Darwin did not use the term, his writings sowed the seeds for all modern explanations for altruism: the *Origin of Species* confidently proposes a mix of family relations, colony-level benefits, and parental manipulation to explain social insect workers (**Fig. 2**); and the *Descent of Man* appeals to both group-level thinking and reciprocation to explain what he called human sympathy. Furthermore, Herbert Spencer explicitly discussed altruism in biology and explained it through both family life and competition among tribes. It is also noteworthy that Spencer often took an outcome-based definition, showing that there have long been parallel traditions of thinking about altruism, one based on intention and the other on behavior (see the introduction). This said, Spencer's views differed significantly from modern definitions by taking reproduction itself to be altruistic.

In the hundred years following the *Origin*, evolutionary discussions of cooperation and altruism are spotty, and often less clear than Darwin's original writings. This includes Kropotkin's extensive discussion of cooperation, which appeals to both group selection and a, sometimes flawed, species-level argument. By the mid-twentieth century, however, it is clear that many authors understood how cooperative acts like worker sterility and human sociality could evolve through kinship, group selection, and reciprocal benefits. These include H. G. Wells (with Julian Huxley and G. P. Wells), R. A. Fisher, A. H. Sturtevant, A. E. Emerson, J. L. Lush, and Sewell Wright. However, these authors rarely used the term `altruism' – the notable exception being J. B. S. Haldane who colorfully compared his reader altruistically rescuing some drowning relatives to sterility in insect workers – and the concept anyway was given little space or attention. No one seemed to think that altruism was all that important:

> There will also, no doubt, be indirect effects in cases in which an animal favours or impedes the survival or reproduction of its relatives… Nevertheless such indirect effects will in very many cases be unimportant… (Fisher, 1930, p. 27)

Effect on actor \ Effect on recipient	+	–
+	Mutualism	Selfishness
– or 0	Altruism	Spite
	Cooperation	Competition

Fig. 1 The four types of social action based on their effect on the direct fitness (lifetime personal reproduction) of the actor and recipient. Altruism and spite can either have no or a negative fitness effect on the actor.

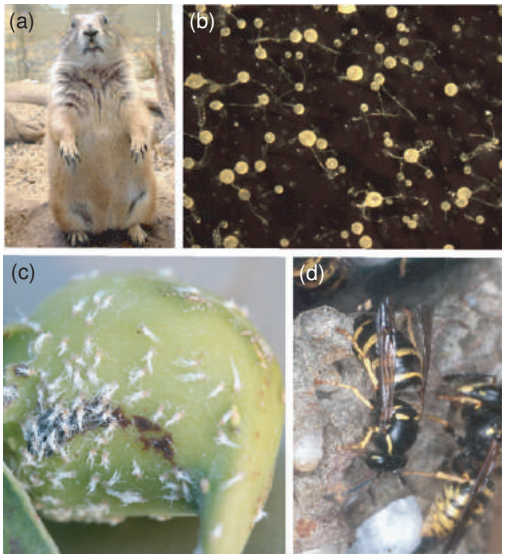

Fig. 2 Species that display altruistic behaviors. (a) Prairie dogs live in family groups in communal burrows or `towns'. When danger approaches, guard individuals will bark and warn others, at apparent cost to themselves. They also display cooperative brood care. (b) Fruiting bodies of the slime mold *Dictyostelium discoideum*. Thousands of cells aggregate together in these groups and many die altruistically to form a stalk that holds the others aloft as dispersal spores. (c) The gall-dwelling aphid *Pemphigus obesinymphae*. When disturbed, soldier aphids emerge and attack intruders. (d) The yellow-jacket eusocial wasp, *Dolichovespula saxonica*. Workers both altruistically work and lay eggs (shown) in this species. The level of worker reproduction, however, is kept low by both genetic relatedness and policing behaviors (Fig. 4). (c) Photo used with kind permission of Patrick Abbot.

Altruism via Inclusive Fitness (Kin Selection)

This all changed in the hands of a lonely London student, called Bill Hamilton, who dedicated himself to the first formal evolutionary analysis of altruism. His results are summarized with the following simple rule: altruistic behaviors will be favored by natural selection when

$$rb > c \qquad [1]$$

where b is the reproductive benefit to the recipient, c is the cost in terms of lifetime reproduction for the actor, and r is the genetic relatedness between actor and recipient (Fig. 3a). For example, selection can favor helping a sister ($r=0.5$) to raise her offspring when one can raise more than twice as many of her offspring (indirect fitness), than one's own (direct fitness), because this will increase the overall propagation of copies of the actor's genes. The sum of fitness effects through indirect effects and direct effects is the `inclusive fitness effect' of a behavior.

Semantics

Hamilton's definition of altruism requires the action to carry a cost to lifetime reproduction; a position solidified by E. O. Wilson who used this altruism as a center piece for his highly influential book *Sociobiology*. Hamilton's work also emphasizes the clarity that can come with gene-level thinking, which was later popularized by Dawkin's *The Selfish Gene*.

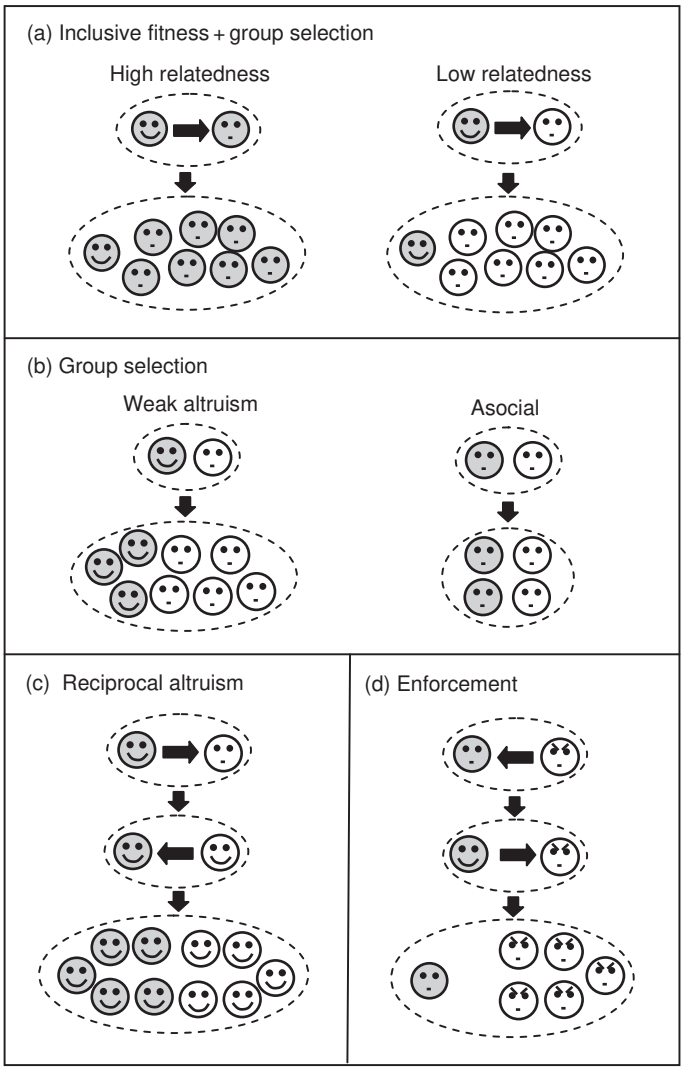

Fig. 3 Four nonmutually exclusive processes that generate altruism or altruism-like behaviors. Altruists are smiling and same-color individuals are genetically related. (a) Strong altruism can be selected when individuals are genetically related (left-hand side) but not when they are unrelated (right-hand side). (b) Weak altruism (gray, left-hand side) can be selected when helping the group feeds back on the actor, even though this increases the fitness of other group members more (white, left-hand side), because it increases reproduction relative to the population as a whole (right-hand side). (c) Reciprocal altruism can increase personal reproduction. (d) Enforcement: one individual forces altruism-like behavior from another individual that may or may not obtain a fitness benefit from their action. Note that the behaviors in (b) and (c) increase the personal reproduction of the actor, and are therefore not altruism in the original strict sense of Hamilton, which required a decrease in the personal reproductive fitness of the actor. Also, actions that arise purely through enforcement (d) are better viewed as adaptations of the enforcer, rather than altruistic adaptations of the helping individual.

Examples

The social insects are among the best and most discussed examples of Hamilton's altruism in behavioral ecology (Fig. 2d). Not only are they social, they are eusocial, with their division of work and reproduction among colony members. Comparable altruism occurs in other insects including some gall-forming aphids and thrips, which have a defensive soldier caste (Fig. 2c). In social vertebrates, sibling care is common that is no doubt often formally altruistic (Fig. 2a). However, individuals can usually reproduce later on, making it difficult to distinguish between true altruism, and behaviors with a delayed reproductive benefit. An interesting potential exception, however, is human menopause, which appears to reduce personal reproduction in order to help raise grand-offspring and under some definitions would constitute altruism. Altruism is also found in microbes (Fig. 2b). For example, individual cells often pay a growth cost to release a shared product, like digestive enzymes, which benefit other cells. There are good data to support the idea that relatedness drives altruism in the social insects (Fig. 4) and vertebrates, and the altruistic release of shared products in microbes has been shown to require genetic relatedness among cells.

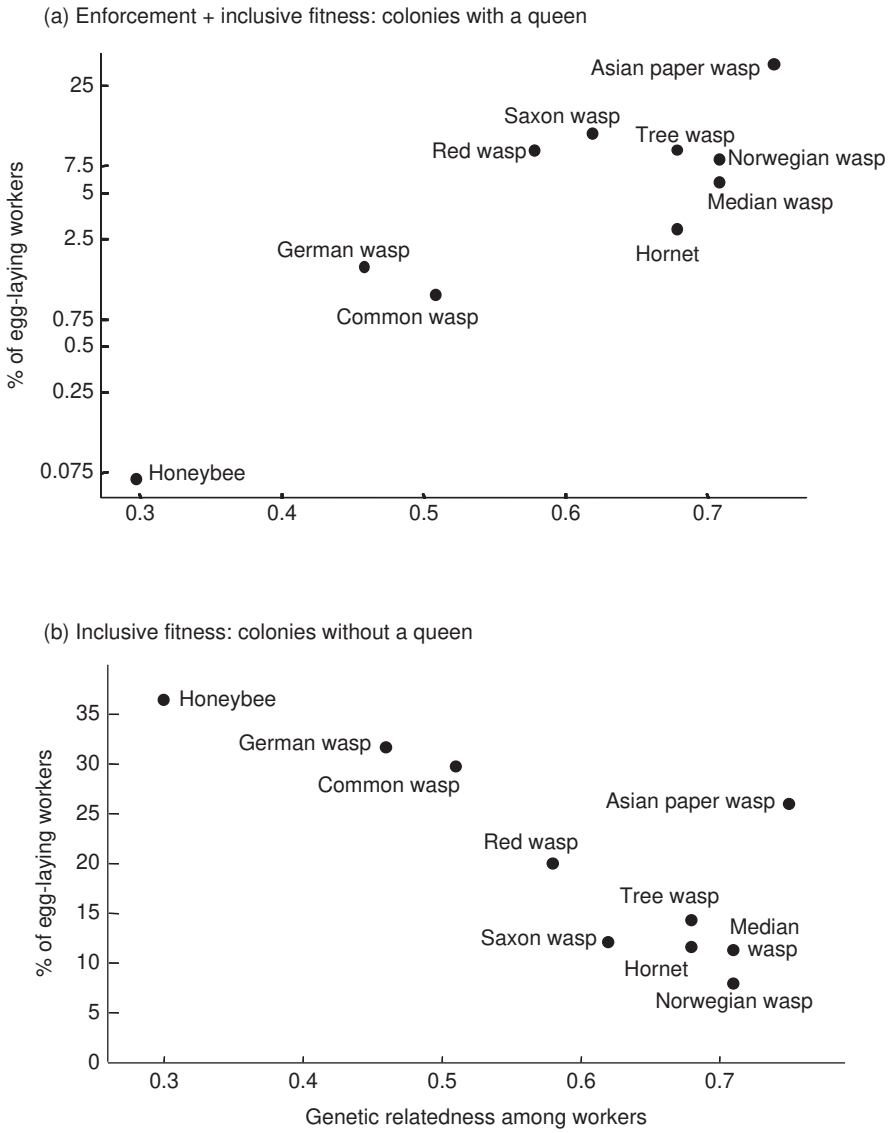

Fig. 4 Worker altruism is driven by a combination of inclusive-fitness effects and enforcement in social insect colonies. (a) Altruistic self-restraint due to enforcement. In colonies where the mother queen is alive, the workers can raise either the queen's or other workers' eggs. In species where relatedness among workers is high, they tend to raise the workers' eggs because they are highly related to them, but in species where relatedness among workers is low, like the honeybee, workers `police' each others' eggs and remove them. This reduces the benefits to worker reproduction which, alongside indirect fitness benefits, promotes reproductive self-restraint. (b) Altruistic self-restraint due to inclusive-fitness effects. If the queen dies the workers compete to lay eggs. However, when relatedness is high, many show altruistic self-restraint and do not attempt to reproduce. Reproduced from Wenseleers T and Ratnieks FL (2006) Enforced altruism in insect societies. *Nature* 444: 50.

Altruism via Group Selection

Another way to phrase the above explanation for altruism is in terms of group selection: when groups contain genetically related individuals (there is between-group genetic variance), selection can favor altruistic actions that invest in the group and increase its productivity. Importantly, and despite occasional misguided claims to the contrary, this logic is fully compatible with and complementary to inclusive-fitness theory: one can explain worker sterility by focusing on benefits to relatives (inclusive fitness), or the benefits at the colony level (group selection), but in the end both genetic relatedness and benefits are required for Hamilton's altruism (**Fig. 3a**). Like inclusive fitness, group-selection thinking can be traced back to Darwin (and also Spencer), and there were brief but explicit mathematical models by Haldane and Wright in the mid-twentieth century. However, it then got a bad name when Wynne-Edwards applied it uncritically to groups of unrelated individuals, such as large vertebrate populations, where individual-level selection will dominate and suppress altruism. It was correctly reformulated in the 1970s with the work of George Price, D. S. Wilson, and, once more, Hamilton. Price's work, specifically the Price equation, has since been central to the development of many branches of social evolution theory. This includes the development of cultural models of cooperation,

where imitation within groups increases between-group variance and promotes the spread of cooperative traits through `cultural group selection'. But there remains a point of departure between group selection and inclusive fitness when it comes to definitions.

Semantics

In the group-selection framework, altruism has been defined as cooperative acts that lower reproductive share in the group. However, this can include actions that increase personal reproduction (Fig. 3b), which is not altruism by Hamilton's definition. Consider, for example, a prairie dog (Fig. 2a) that contributes to the tunnels in its town and suffers a 10% decrease in its reproduction relative to another group member. This can evolve through selfish benefits alone if the tunnels allow all town members to double their reproduction. This is illustrated by a simple extension of Hamilton's rule:

$$\overbrace{\frac{b}{n}(n-1)r}^{\text{Indirect/kin benefit}}+\underbrace{\left(\frac{b}{n}\right)}_{\text{Direct/individual benefit}}.1>c \qquad [2]$$

where n is group size, b is the group benefit of which each individual gets a share b/n, and c is the individual cost. The individual-benefit term contains relatedness of the actor to itself, $r_{self}=1$, and even with no relatives in the group ($r=0$), tunneling can still evolve if there are feedback benefits to the actor. This type of behavior has been termed `weak' altruism (Fig. 3b) because it carries a personal (direct fitness) benefit, which distinguishes it from Hamilton's (strong) altruism, like that of sterile insect workers (Fig. 3a).

Examples

Because of the conceptual overlap, group-selected altruism includes all of the inclusive fitness examples above. Furthermore, feedback benefits of the sort that generate weak altruism must be common in many societies but are difficult to distinguish from inclusive fitness benefits. One example of weak altruism, however, is cooperative next founding by unrelated social insect queens. Here, co-investing in the colony can provide feedback fitness benefits when queens are later able to contribute to sexual offspring.

Altruism via Direct Fitness

In addition to weak altruism, several other processes that increase the personal reproduction of the actor (direct fitness) have been proposed to explain altruism-like behaviors. In the 1970s, Robert Trivers showed that helping can be selected when it increases the chance of return help, which he termed reciprocal altruism (tit for tat; Fig. 3c). A closely related idea is that of indirect reciprocity, whereby helping others improves reputation, which then increases the chance of being helped. More generally, feedback benefits to personal reproduction (direct fitness) are central to all manner of cooperative behaviors, including cooperation among genes and species, for example, plants provide nectar and insects pollinate in return:

> individual flowers which had the largest glands or nectaries, and which excreted most nectar, would oftenest be visited by insects, and would be oftenest crossed; and so in the long-run would gain the upper hand. (Darwin, 1859)

Semantics

A focus on direct fitness has led to a third general approach to modeling social evolution, called direct fitness or neighbor-modulated fitness theory, which again complements the inclusive-fitness and group-selection approaches. However, an action that evolves purely through direct-fitness feedbacks means increased personal reproduction and departs from Hamilton's altruism. Curiously, however, Hamilton started his original papers with a neighbor-modulated model (the fitness effect of others on the focal individual), before making a switch to inclusive fitness (the fitness effect of the focal individual on others) on which he based his rule.

Examples

Reciprocal altruism and indirect reciprocity are extremely important in human cooperation, but the requirement for recognition and memory of others means that they occur in relatively few other species. Potential examples include other primates and vampire bat blood-sharing, but inclusive fitness and group benefits also occur in these systems. More generally, however, cooperation that is selected due to direct-fitness feedback benefits is fundamental to social evolution, including between-species cooperation.

Altruism via Enforcement

Most recently, explanations for altruistic-like behaviors have focused upon a somewhat sinister mechanism: enforcement. This idea can be traced not only to the 1970s and Richard Alexander who proposed parental manipulation to explain insect workers (Fig. 3d), but also to Darwin, whose writings suggest something similar. While policing and punishment can explain apparent acts of altruism, however, one still needs an explanation for how policing, which carries a personal cost, can evolve the so-called `second-order problem'. For this, one must appeal again to some or all of the above theories: inclusive fitness, group selection, and direct benefits.

Semantics

If a helping behavior has arisen completely through enforcement, the primary evolutionary adaptation is in the enforcer, rather than the helping individual. The helping behavior, therefore, should probably not be considered an altruistic adaptation. This objection can be overturned, however, when an altruistic action evolves through a combination of enforcement and inclusive-fitness effects, as occurs in the social insects (below).

Examples

Enforcement, punishment, and policing are central to cementing the altruism in many social groups. This includes queen and worker policing in many species of social insects, whereby the queen and workers suppress the reproduction of other workers. The suppression means that natural selection favors workers that invest more in the indirect fitness from helping than direct fitness from their own reproduction, which increases altruistic self-restraint (Fig. 4). In addition, dominant males in macaque societies police and punish noncooperative individuals, and dominance hierarchies help to resolve breeding conflicts in many insect and vertebrate groups.

A Synthetic View of Altruism and Cooperation

Altruistic behaviors are a central component of many social systems. Any judgment on the extent of altruism in the natural world, however, will always depend upon definition. A requirement for conscious intention restricts altruism to creatures with sophisticated cognition, such as humans. However, the fitness-based definition of behavioral ecology reveals a wealth of additional examples, which typically arise through a combination of mechanisms. Centrally though, actions that decrease lifetime reproduction can readily evolve when there are indirect benefits that increase overall inclusive fitness. This is nowhere more obvious than in the social insects, where workers spend their entire life building, guarding, and foraging to raise a myriad of their relatives' offspring.

Animal Home Ranges☆

Paul R Moorcroft, Harvard University, Cambridge, MA, United States

Glossary

Contact structure A description of the probability of contacts between individuals within a population. Relevant for the spread of infectious diseases.

Cost-benefit models A framework for assessing the performance of an individual exhibiting a particular type of behavior (such as territorial defense of a home range) compared to an alternate pattern of behavior (such as no defense of a home range). The metric of performance varies, but often is measured in terms of energy or resource acquisition.

Negative density dependence A reduction in the per capita rate of population growth caused by increasing population size or density.

Triangulation The process of determining the location of a point by calculating the angle between the point and two or more known locations.

Trophic level The position of an organism within a food chain or food web (e.g., primary producer, primary consumer (herbivore) or secondary consumer (predator)).

Introduction

Fig. 1 shows the spatial extent of relocations of two carnivores, a wolf and a coyote, as a function of time from the first measurement of an individual's location. Initially, their space-use increases rapidly, but as sampling continues, the spatial extent of the relocations saturates. This phenomenon is widespread among mobile animals and reflects the fact that they typically do not move randomly through their environment, but instead restrict their movements to particular areas. In some species, such as many carnivores and birds, this localizing tendency arises from the need to provision offspring located in a den or nest site resulting in these locations acting as a focal points for the movements of adults during periods of breeding—so-called "central place foraging." In other species, such as primates and deer, the existence of a localizing tendency in the movement of individuals is linked to the exploitation of particular resources such as foraging areas or watering holes. Observations such as these underlie the concept of an animal's home range, "the area in which an animal normally lives, exclusive of migration, emigration, or other large infrequent excursions" (Burt, 1943).

Ecological Correlates of Home Range Size

The spatial scales at which individuals exhibit a localizing tendency in their movement behavior can vary widely, even among closely related species. Not surprisingly, in many animal groups, home range size is correlated with body size. The energetic

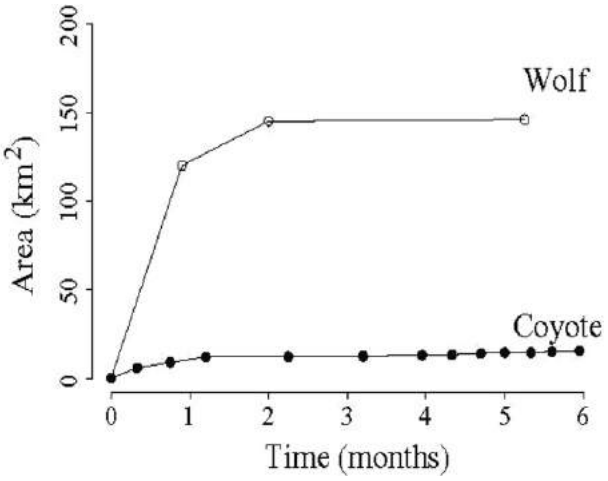

Fig. 1 Increase in the areal extent of wolf and coyote relocations as a function of the length of radio-tracking. Data re-plotted from Messier, F. (1994). Ungulate population models with predation: A case study with the North American moose. *Ecology* **75**(2), 478–488.

☆*Change History:* February 2018. Paul R Moorcroft updated the text and further readings to the entire article.

This is an update of P.R. Moorcroft, Animal Home Ranges, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 174–180.

 doi:10.1016/B978-0-12-409548-9.11095-4

requirements of endotherms generally scale in proportion to $M^{0.75}$, where M is the body mass of a species, and therefore it might be expected that home range size would scale in a similar manner. However, recent analyses have shown that home range size scales as $M^{1.0}$, indicating that home range size increases more rapidly with body size than would be expected from simple metabolic considerations (Fig. 2, solid line). One explanation is that as a result of increased difficulty of defending large home ranges, home range overlap increases with increasing body size, scaling as $M^{-0.25}$. When combined with the scaling of metabolic rate with body size ($M^{-0.75}$), this results in the observed scaling of home range size as $M^{1.0}$. Evidence in support of this explanation comes from the fact that while home range size scales as $M^{1.0}$, per individual area (i.e. the inverse of population density) scales as $M^{0.75}$ (Fig. 2, dashed line). This difference between these two relationships is consistent with the notion of increasing home range overlap in larger-sized animals.

Another important factor influencing animal home range size is its diet. At higher trophic levels, the losses of energy associated with the capture, digestion and utilization of resources markedly reduces the availability of food resources per unit area, and

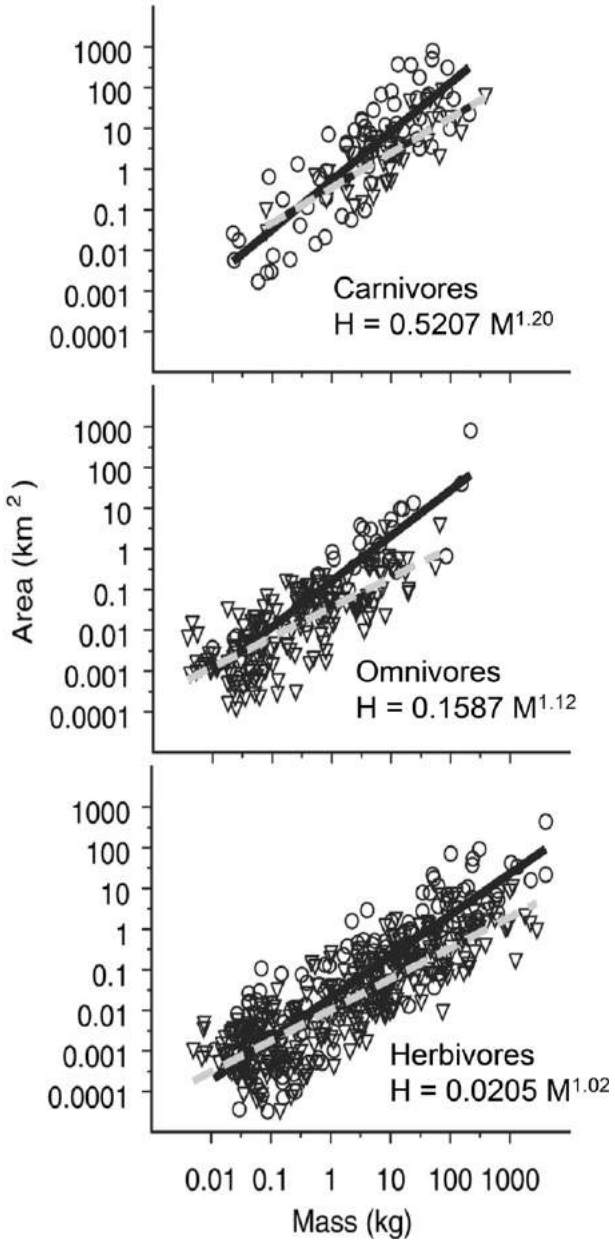

Fig. 2 The scaling of home range size with body mass across carnivores, omnivores and herbivores. In each panel, the *circles* and *solid line* indicate, respectively, the observed and fitted relationship between body size (M in kg) and home range size in (H, km). The coefficients of the relationship are also shown. The relationship between 1/population density (i.e., area per capita) and body mass is also plotted (triangles, and dashed line). In all three cases, the slope of this line is shallower than the slope of the relationship between home range size and body size.

consequently home range is strongly affected by trophic level. As the relationships plotted in Fig. 2 illustrate, the home range sizes of omnivores are approximately 10–15 times higher than those of equivalently-sized herbivores, and the home range sizes of predators are 25–60 times higher than that of equivalently-sized herbivores. What is also apparent in Fig. 2 is that while body size and trophic level account for a significant amounts of variation in animal home range size, there is a ~1000-fold level of variation around the relationships plotted in Fig. 2, emphasizing the fact that the characteristic home range size of a particular species is also significantly influenced by a variety of behavioral and ecological factors other than its body size and trophic level.

Measurement and Analysis of Animal Home Range Patterns

The measurements of home range size shown in Figs. 1 and 2 come from animals fitted with radio telemetry collars, a technology developed in the late 1950s that revolutionized the study of animal movement, enabling routine, systematic measurement of animal locations by triangulating their position on a landscape. Radio telemetry has been successfully used to study the movement behavior of mammals, birds, reptiles, amphibians, fish, and even insects. However, the subsequent advent of global positioning system (GPS)-based telemetry in the 1990s has begun to yielding important new insights into the fine-scale movements of animals, allowing researchers to track animals—in some cases in near real-time—regardless of weather conditions, distance moved, and terrain covered.

The spatial distributions of animal relocations recorded in telemetry studies are translated into estimates of home range size using statistical home range models. A widely used approach is the minimum convex polygon (MCP) method, which characterizes the animal's home range as the smallest sized polygon encompassing the observed relocations (Usually 5%–10% of the outermost relocations are excluded as outliers) (Fig. 3A). A number of density estimation methods have also been developed, in which the animal's home range is characterized using two-dimensional statistical probability density distribution fitted to the observed distribution of relocations (Fig. 3B).

Statistical home range models such as those shown in Fig. 3 provide a useful way to summarize observed spatial patterns of space-use; however, the models are purely descriptive, and thus yield little insight into the underlying causes for an animal's pattern of space-use. Another approach, resource selection analysis, has become a widely-used method for identifying underlying environmental correlates of animal space-use patterns. In contrast to the spatially-explicit nature of statistical home range models, resource selection analysis uses a spatially-implicit approach to identify habitats that are used disproportionately in relation to their occurrence through the examination ratios of habitat utilization relative to a measure of habitat availability. For example, Table 1 shows a resource selection analysis of elk home range relocations in western United States. The measurements in the table indicate that the elk preferentially utilize habitats that have intermediate levels of forest canopy cover. A plausible explanation for this is that the elk utilize habitats that balance their competing needs of having access to open areas that contain forage, and forest cover that provides a degree of protection from predators.

More recently, a new framework for analyzing patterns of animal home ranges has emerged in the form of mechanistic home range models. This involves formulating a mathematical model for the process of individual movement in which the fine-scale movement behavior of individuals is characterized as an underlying stochastic movement process that specifies the probability of an animal situated at a given location moving to a subsequent location in the time between relocations (Fig. 4A). Relevant behavioral and ecological factors influencing the movements of individuals can be incorporated into this description of the fine-scale stochastic movement process. In contrast to resource selection analysis, mechanistic home range models yield a spatially-explicit prediction for patterns of animal space-use that results from the process of individual movement. For example, a recent analysis of coyote home ranges in Yellowstone used a "prey availability plus conspecific avoidance" (PA + CA) mechanistic home range model to account for the observed patterns of coyotes home ranges within the park. In the PA + CA model, individuals exhibit: (i) an avoidance response to encounters with foreign scent marks, (ii) an over-marking response to encounters with foreign scent marks, and (iii) a foraging response to prey availability, in which individuals decreased their mean step length in response to small mammal abundance.

As Fig. 4B shows, the patterns of space-use predicted by the PA + CA mechanistic home range model correctly capture the observed spatial distribution of relocations of five adjacent coyote packs in the study region, implying that the combined influence of resource availability and avoidance responses to neighboring groups is responsible for the observed pattern of coyote space use across the region. A nice feature of the mechanistic approach of "modeling the movement process" is that mechanistic home range models can be used to predict patterns of space-use following perturbation. For example, analysis showed that the PA + CA model shown in Fig. 4B correctly predicted the shifts in patterns of coyote space-use that occurred following the loss of one of the packs in the study area. Mechanistic home range models, similar to one described above, have been used to characterize patterns of space-use in other species including wolves, badgers, and meerkats.

The emergence of a characteristic home range from mechanistic model of individual movement behavior requires that individuals have a centralizing tendency in their fine-scale movements. In the model for coyotes described above, the centralizing tendency arose from the scent-mark mediated avoidance interactions between individuals in neighboring groups, which biased the movements of individuals towards their respective den-sites. This model is appropriate for species with a well-defined focal point for their movement behavior, such as den-sites in many carnivores, burrows in small mammals, and nest sites in birds. However, as noted in the "Introduction" section, other animals, such as deer and many primate species, occupy characteristic home ranges in the absence of a well-defined center of attraction. This implies that other forms of underlying movement behavior must be responsible for the formation of home ranges in these species. This has led to interest

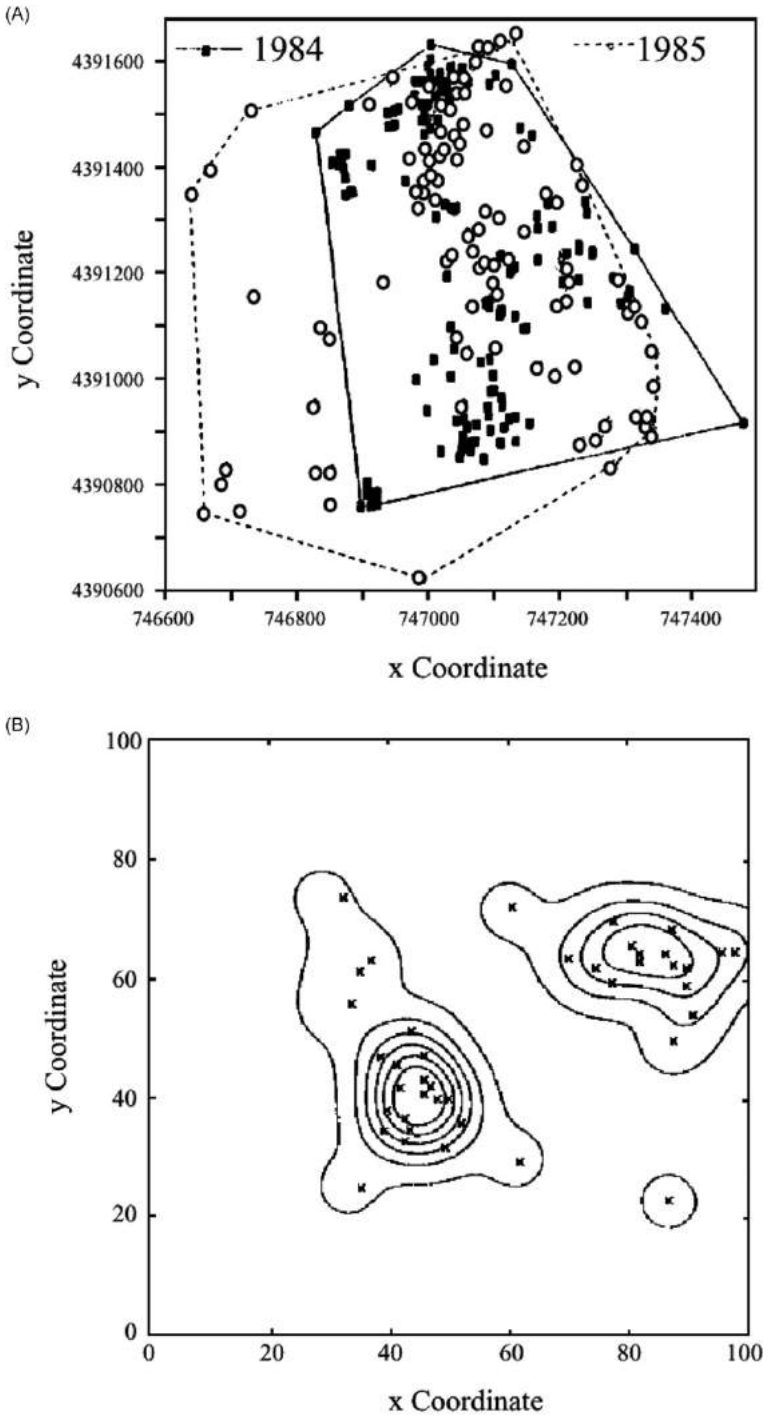

Fig. 3 Examples of statistical home range models. (A) Minimum convex polygon method, and (B) kernel method. Redrawn from White, P. J. and Garrott, R. A. (1997). Factors regulating kit fox populations. *Canadian Journal of Zoology* **75**(12), 1982–1988 (panel A) and Worton, B. J. (1989). Kernel methods for estimating the utilization distribution in home-range studies. *Ecology* **70** (1), 164–168 (panel B).

in the role that memory plays in the formation and maintenance of animal home ranges. The impacts of memory on movement can be described mathematically in terms of so-called "self-attracting random walks"—mechanistic movement models in which an individual's movements are biased towards previously visited locations. Recent work has shown that depending on the details of the underlying formulation, models of this kind can give rise to stable home ranges, or quasi-stable home ranges in which an animal's movements are spatially-localized into a home range, but on a slower timescale the center of the animals' home range drifts around the landscape.

Table 1 Estimated habitat preferences of elk for habitats with different levels of forest canopy cover

Forest canopy cover class	*# of relocations* (U_i)	*Landscape availability* (A_i)	*Expected utilization* $E_i = A_i{*}SU_i$	*Selection ratio* $w_i = U_i/E_i$	*Standardized selection index* $B_i = w_i/Sw_i$
0%	3	0.075	24.4	0.12	0.04
1%–25%	90	0.305	99.1	0.91	0.29
26%–75%	181	0.420	136.5	1.32	0.42
>75%	51	0.200	65.0	0.79	0.25
Total	325	1.000	325	3.14	1.0

Values of the selection ratio >1 indicate habitats that are utilized at a higher frequency than their availability. As the numbers indicate, elk preferentially use habitat with intermediate (26%–75%) canopy cover rather than habitats with either more open or more closed canopy cover.

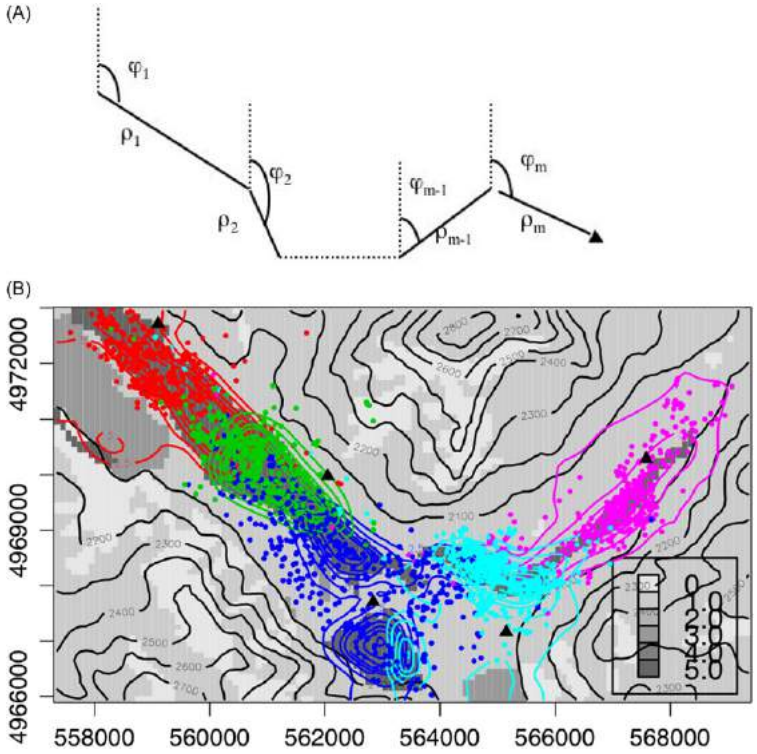

Fig. 4 (A) Schematic illustrating the underlying model of individual movement behavior that underpins a mechanistic home range model. The movement of trajectory of individuals is characterized as a stochastic movement process, defined in terms of sequences of movements between successive relocations ($i = 1...m$) of distance ρ_i and directions φ_i drawn from statistical distributions of these quantities that are influenced by relevant factors affecting the movement behavior of individuals. (B) Colored contour lines showing fit of a mechanistic home range model to relocations (filled *circles*) obtained from five adjacent coyote packs in Lamar Valley Yellowstone National Park. As described in the text, the PA + CA mechanistic home range model used in this study incorporates a foraging response to small mammal prey availability plus a conspecific avoidance response to the scent-marks of individuals in neighboring packs. The home range centers for each of the packs are also shown (▲), and the grayscale background indicates small mammal prey density (kg ha^{-1}) in the different habitat types.

The Functional Significance of Animal Home Range Patterns

Since an animal's home range is intimately linked to its utilization of resources (food, shelter, mates, etc.), and some of these will be in limited supply, competition often favors a spacing-out of animal home ranges across landscapes. This can arise from overt territorial aggression between individuals, such as the contests between male dragonflies that occur over ponds during their breeding season, and the contests that occur between red squirrels occupying neighboring home ranges. In other cases, however, spacing out arises from individuals passively avoiding other individuals, either via direct detection and avoidance of individuals, or, more commonly, in response to auditory and olfactory signals that indicate occupation, such as singing in birds and scent marking in mammals.

A central question in the study of animal home ranges has been to ask under what conditions should animals engage in territorial defense of their home range? A logical argument is that evolution should favor territorial defense of home ranges whenever relevant limiting resources for individuals are "economically defendable." In other words, animals should engage in

territorial defense whenever this results in increased fitness relative to alternate strategy, such as passive avoidance, or ignoring the presence of other individuals.

Key factors influencing the defendability of a given resource are: its distribution in space, its predictability, and the number of competitors for the resource. Sparsely distributed, low quality resources, such as the spatial distribution of forbs and grasses grazed by elk in Yellowstone National Park, are difficult to defend energetically, and thus do not tend to favor territorial defense. In contrast, resources that are clumped into patches in which resource levels are high tends to favor territorial defense. Examples of this phenomenon include: the clumped distribution of tree fruits within a tropical forest that favors territorial defense by groups of primates; and the clustered distribution of female southern elephant seals, which arises when the females haul up onto beaches to breed, that favors territorial defense of the females by male elephant seals. Resource predictability is also important. For example, pied wagtails defend territories along river banks where winter food resources are predictable, but in areas where food resources occur in transient, unpredictable patches, they abandon territorial defense and move around in flocks. The effects of competitor density on resource defendability are more difficult to characterize since intruder pressure is often correlated with food availability. One of the best examples of an effect of competitor density comes from a study that used a statistical approach to separate out the effects of food availability and intruder density on home range defense of sanderlings foraging along the California coast. The analysis showed that in areas with low resource levels, where the density of competitors was low, individuals defended home ranges, while in resource rich areas where competitor density was high, individuals abandoned territorial defense.

Simple cost-benefit models have been widely used to predict how changes in the environment should affect the size of home range that an animal defends (**Fig. 5**). In general, we might expect that the fitness payoff arising from occupying and defending home range will initially increase rapidly as home range size increases, but then saturate as its size increases further (curve B). The costs of defending the home range (curve C) will also tend to increase with increasing size. In the example shown, defense costs increase in an accelerating manner, as would occur for example, if the difficulty of detecting and evicting intruders increases markedly as a home range gets larger.

The optimal home range size is one that maximizes the difference between the two curves. An increase in resource richness causes the benefit curve (B) to steepen, shifting its position from B to B′, which causes the optimal territory size to decrease as resource richness increases (**Fig. 5**A). In a similar manner, increased costs of defense cause the cost curve (C) to steepen, shifting its position from C to C′, which, also causes a reduction in the predicted optimal territory size (**Fig. 5**B). Evidence in support of these kinds of responses has come from a number of studies. For example, blue tits in England have been shown to decrease their territory size in response to increased food resources supplied by artificial provisioning, and the breeding territories of male great tits have been shown to be inversely related to their population density during the previous year.

Note however, that the apparent simplicity of cost-benefit analyses such as the one depicted in **Fig. 5** belies a great degree of complexity in predicting how different ecological factors affect the size of an animal's home range. Theoretical analyses have shown that the predictions of cost-benefit models can vary depending on the proximal measure of fitness used, the precise shape of the benefit and cost curves considered, and the constraints on performance incorporated into the analysis. These differences can lead to entirely opposing predictions for the consequences of changes in resource availability and number of competitors on home range size. Additional complications arise because in reality changes in the cost and benefit curves depicted in **Fig. 5** are often not independent. For example, as noted above in the case mentioned earlier of sanderlings foraging along the Californian coast, increases in resource density also strongly affect home range defense costs due to increases intruder density in resource rich areas. Thus, like other aspects of animal home range behavior, analyzing the functional significance of differences in territory size is inherently challenging because the fitness of an individual exhibiting a particular behavior depends strongly on the behavior of other competing individuals present on the landscape (i.e., it is an *n*-person game), leading to complex responses to changes in ecological conditions.

Home Range Size and Population Social Structure

When faced with shifts in resource levels or intruder pressure, individuals that are occupying a home range can respond in ways other than adjusting their home range size. One alternative is to accept one or more additional individuals into their home range, and then cooperatively defend it against competing individuals. This kind of response is seen in the pied wagtails, which, as noted earlier, defend territories along river banks in England during the wintertime. At moderate resource levels, individuals occupy and defend individual home ranges. However, as resource levels increase, rather than decreasing their range size as might be expected from a simple cost-benefit model of territory size such as the one depicted in **Fig. 5**, owners begin to share their territory with an additional individual who shares the home range, but forages independently of the owner.

A simple model for evaluating the economic profitability of sharing a home range considers the costs individuals incur as result of reduced food availability versus the benefits that arise from reduced per capita defense expenditures when sharing a home range with one or more additional individuals. A key factor influencing the costs of sharing on the food intake of individuals is the dynamics of resource renewal (i.e., how quickly resource levels increase after having been depleted). A resource that is shared between individuals will be exploited at a higher rate than one exploited by a single individual. If the resource renews slowly, then the increase in the exploitation rate will have a significant impact on the foraging efficiency of the individuals. In contrast, if the

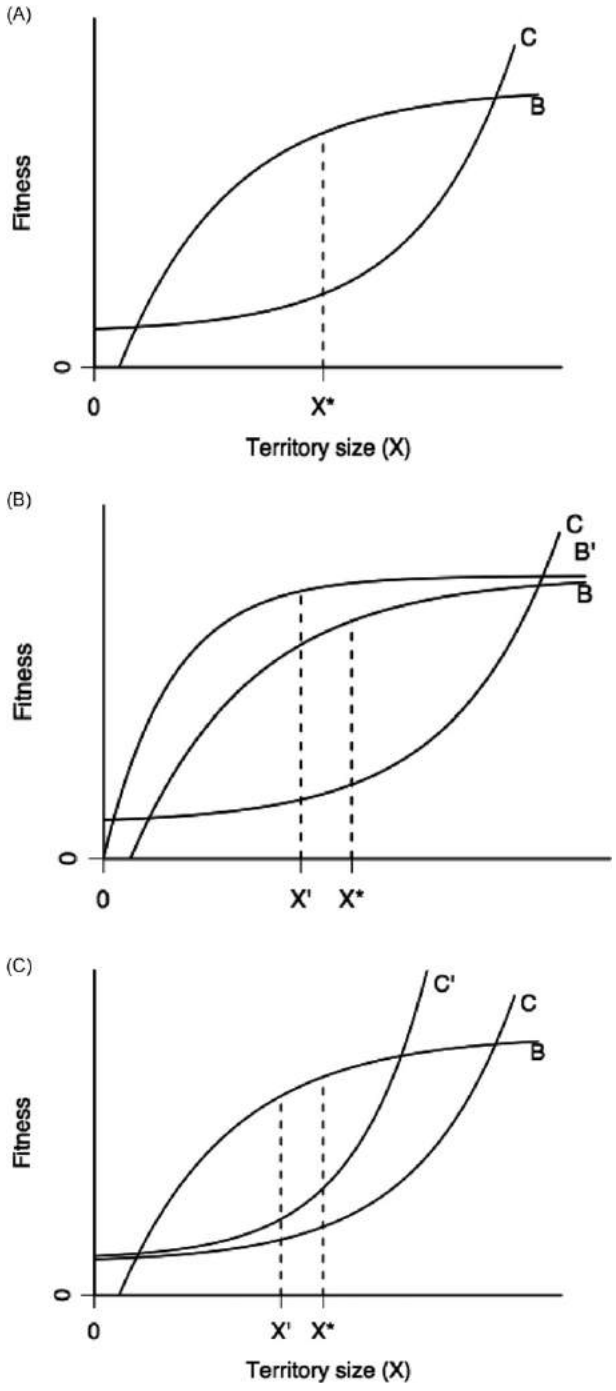

Fig. 5 A simple graphical cost-benefit model of territory size. (A) The optimal size occurs at X* where the difference between the fitness benefit (B) and the fitness cost (C) is maximized. (B) Increased resource availability shifts the benefit curve from B to B′, causing a decrease in the optimum territory size. (C) Increasing defense costs shifts the cost curve C to C′, also causing a decrease in the optimum territory size.

resource renews quickly, then the increased exploitation rate may have a relatively small effect on the foraging efficiency and resulting per capita food intake of individuals.

A second key factor affecting the costs of sharing a home range is the spatial distribution of resources. The "resource dispersion hypothesis" proposes that in situations where a species is foraging on a patchily-distributed, ephemeral resource in which each patch, when available, can supply enough resources to meet the needs of more than one individual, an economically-defendable home range that is large enough to sustain an individual or a mated pair of individuals is likely to support the foraging needs of one or more additional individuals. Two animals whose home range patterns appear to fit this reasoning are red foxes and badgers in England. Due to the patchy, ephemeral nature of earthworm abundance – a key prey resource for both species – mated-pairs of

badgers or mated pairs of foxes defending a home range large enough to satisfy their own energetic requirements incur relatively little cost from resource consumption of additional individuals and benefit from the cooperative defense of a shared home range. Similar arguments have been made for other carnivores, and for species in other animal groups, including primates, ungulates and birds.

A distinguishing feature of the resource dispersion hypothesis is that it argues that it is the spatial and temporal dynamics of the underlying resources, rather than the benefits of cooperative hunting or cooperative defense against predators, that favor the occupation and defense of shared home-ranges by groups of individuals. Additional benefits of group living, such as improved hunting success, improved predator detection and defense, and the inclusive fitness benefits when sharing a home range with relatives, will, however, increase the benefits and reduce the costs of group living. Distinguishing predictions of the hypothesis are that: (i) group size should more strongly correlate with patch richness and heterogeneity rather than territory size; and (ii), that territory size is primarily determined by the patterns of resource dispersion. These predictions have been borne out in several studies of fox and badger populations, as well in studies of other species, including spotted hyenas, mara, and magpie jays. Thus, the spatio-temporal distribution of resources, in conjunction with other benefits of group living, such as shared defense costs, improved foraging success, or predator defense, can favor the occupation and defense of shared home ranges by groups of individuals. An important implication of this is that the size, shape and degree of exclusivity of home ranges is a key determinant of the different social organization and mating systems found within species.

Effects on Population Demography

Since the spatial extent and degree of exclusivity of an animal's home range influence its access to important resources – such as food, shelter, and mates – patterns of animal space use can also exert a powerful influence on the demography of animal populations. This is particularly the case in species where individuals are territorial and actively defend home ranges against other individuals for all or part of the year as occurs in many birds, such as great tits and red grouse; in many vole and other rodent species; and in carnivores, such as coyotes and wolves. In such populations, the active defense of home ranges results in significant numbers of individuals being forced into either dispersing and setting up home ranges in marginal habitats, or existing as non-resident "floaters" within the population. Usually juveniles or lower-ranking adults, these non-resident individuals tend to have diminished rates of survival, and have either reduced fecundity or do not breed at all.

It has been argued that in species with cyclical population dynamics, such as red grouse and a number of vole and other rodent species, home range defense acts as a destabilizing factor on population abundance, due to delayed negative density dependence between the response of individual home range sizes and levels of defense to changes in population abundance. More commonly however, the existence of a reservoir of "surplus" non-resident individuals arising from home range defense is considered to act as a stabilizing factor on population size, reducing the propensity for fluctuations and increasing a population's resilience to perturbation. This has implications for efforts for management of populations in which it occurs: for example, research has shown that in coyotes and badgers non-resident individuals rapidly replace breeding individuals killed in control efforts, severely hampering efforts to reduce their population sizes through culling.

Secondary Ecological Interactions

Evidence from field studies indicates that the spatial pattern of home ranges within a species can affect the spatial distribution of prey and competitors. For example, in northeastern Minnesota, white-tailed deer are found primarily in the "buffer zones"—areas of low space use that occur between adjacent wolf pack home ranges. This negative correlation between the spatial distribution of wolves and deer arises as a result of differential predation rates between the interior of wolf home ranges and the buffer zones that separate them.

For the same reasons that within-species (intraspecific) competition for resources often favors defense of a home range area against utilization by individuals within a population, between-species (interspecific) competition can favor individuals defending their home range against utilization by individuals of competitor species. This phenomenon occurs in the carnivore community of Yellowstone National Park. Prior to wolf re-introduction, packs of coyotes, usually 4–6 adults, occupied and defended contiguous home ranges across the landscape. However, following the wolf re-introduction, coyotes have radically altered their patterns of space-use: the packs have broken up and individuals now move around individually or in pairs, restricting their movements in space and in time to areas where wolves are not present. These kinds of interactions between the spatial distributions of home ranges in co-occurring competing species can have important consequences for animal conservation. For example, in Africa, efforts to conserve the endangered African wild dog have been complicated by their competitive interactions with lions and hyenas, which have prevented them from setting up home ranges in favorable habitats, reducing their survival and breeding success.

The spatial distribution of animal home ranges also has implications for the incidence and spread of infectious diseases within populations. This because the rate at which a disease spreads through a population is strongly influenced by the probability that different individuals encounter one another, a property known as the contact structure of the population. For example, a study of Channel Island foxes living on islands off the coast of California found that both the number of contacts per day and the duration of contacts between individuals were positively correlated with their degree of home range overlap. Such effects of animal home

ranges on the contact structure within animal populations can have important implications for attempts to control disease outbreaks. For example, studies examining the impacts of culling badger populations upon the transmission of Tuberculosis (TB) from badgers to cattle in the United Kingdom found that, while culling reduced the incidence of TB in cattle in the areas where badger population sizes were reduced, it increased its incidence in neighboring areas due to shifts in badger home range patterns caused by the culling that elevated the rate of contacts between badgers and cattle.

Anti-Predation Behavior

Lee A Dugatkin, University of Louisville, Louisville, KY, United States

Introduction

The biology behind antipredator behavior is, in a sense, unique, in that mistakes with respect to predators can lead to an animal having a future fitness of zero. As such, natural selection should operate very strongly on antipredator behavior. And it does: the array of antipredator adaptations in nature is dazzling. Consider, for example, antipredator behaviors in schooling species of fish. In addition to the potential hydrodynamic and foraging benefits accrued by living in groups, fish in schools display a wide array of antipredator tactics. When a predator is sighted, schooling fish school more tightly, allowing for the following antipredator tactics:

1. Fountain effect—schools maximize their speed, split around a stalking predator, and then reassemble behind the putative danger.
2. Trafalgar effect—when animals school tightly, information about a predator spreads from individual to individual more quickly than in loose schools. Because this resembles the quick transfer of information of battle signals in Lord Nelson's fleet at the battle of Trafalgar, it has been dubbed the Trafalgar Effect.
3. Flash Explosion—schools of fish "explode," with individuals swimming off in all directions, confusing predators and allowing individuals to escape. Schooling fish often add to this effect by moving around in erratic, unpredictable patterns.
4. Predator Inspection—a small number of individuals break away from a school and approach a predator to gain various types of information (e.g., is the predator hunting?), and then return to the school, where this information may spread across individuals.

Group Size and Antipredator Behaviors

One of the most fundamental antipredator strategies is to live in large groups, as group life confers a suite of potential antipredator benefits. The most basic benefit of living in large groups results from a simple statistical property. If a predator is to going to strike at one member of a group of size N, then the odds that any particular individual will be its victim is 1/N, which increases with group size. The larger the group size, the safer is each individual in the group (the situation is more complicated if predators prefer to attack larger groups). Individuals obtain benefits with respect to antipredator behaviors because as group size increases, there are more and more individuals vigilant for predators, making all group members safer: the "many eyes" benefit of group life. One benefit of "many eyes" is that each group member can spend less time being vigilant, and more time doing other activities, since vigilance can be parceled across more individuals as group size increases.

Large groups also provide positional benefits because individuals in the center of the group are often safer than those on the periphery (though again, the situation is complicated, as this will often lead to a scramble among prey to get positioned at the center of their group).

Living in groups provides other benefits with respect to safety. Groups can often respond to potential predation threats in coordinated ways that solitary individuals cannot, and the activity levels in large groups may overload a predator's sensory input mechanisms, making a successful strike less likely.

Behavioral Tradeoffs Associated with Predation

There are opportunity costs associated with antipredator behavior. Instead of avoiding predators, individuals may be foraging, mating, resting, and so forth. To examine such trade-offs, consider the case of antipredator behavior and foraging. Predation pressure affects virtually every aspect of foraging, from when a forager begins feeding to when it resumes feeding after an interruption, to where it feeds, what it eats, and how it handles its prey.

Work on predation and foraging in the gray squirrel (*Sciurus carolinensis*) has demonstrated that squirrels alter their foraging choices as a result of predation pressure from redtailed hawks (*Buteo jamaicensis*). Squirrels who could either eat their food items where they found such items or carry the food to cover were more likely to carry items to an area of safe cover when predation threat was significant—the closer the refuge from predation, the more likely they would use such a shelter when foraging.

Alarm Calls

Alarm calls are one of the more dramatic forms of antipredator behavior. Belding's ground squirrels give alarm calls when a terrestrial predator is sighted, with females being much more likely to emit such calls than males. The reason for this sex difference

in alarm calling is tied to the demography and genetics of Belding's ground squirrels. Male Belding's ground squirrels emigrate to new populations when they mature, but female squirrels spend their entire lives in their population of birth. This difference in dispersal creates an asymmetry in the way that adult males and females are related to others living in their populations. By remaining in the populations in which they were born, females—both young and old—are surrounded by genetic relatives. Mature males, who emigrate to new populations, however, find themselves interacting with fewer genetic relatives than do adult females. By giving alarm calls, females get indirect benefits, in that they help protect their blood kin—males receive no such benefits, and call at much reduced rates.

Alarm calls need not be vocal. In ungulates, individuals are known to "flag" their tails after a predator has been sighted. Such flagging occurs as part of a sequence of antipredator behaviors, and often involves an individual lifting its tail and "flashing" a conspicuous white rump patch. Flagging often, but not always, occurs when a predator is at a relatively safe distance from its potential prey. Flagging may: (1) warn conspecifics (kin and nonkin) of potential dangers, (2) "close ranks" and tighten group cohesion, (3) announce to the predator that it has been sighted and should therefore abandon any attack, (4) entice the predator to attack from a distance that is likely to result in an aborted attempt, and (5) cause other group members to flee, thereby confusing the predator, and making the flagger itself less likely to be the victim of an attack.

Alarm calls can be very complex. Vervet monkeys, for example, make very distinct and different calls in response to leopard, snake, and eagle predators. Vervets run to the trees when they hear a leopard alarm call, but they hide in bushes when a fellow vervet utters an eagle alarm call, suggesting that these monkeys are using alarm calls to indicate the mode of predator attack.

Interpopulational Differences in Antipredator Behavior

One way to examine how natural selection has operated on antipredator behavior is to compare the behavior of individuals that live in populations under different predation pressures. If antipredator tactics differ across these populations, it suggests that natural selection has been operating on these behaviors.

The population comparison method for studying selection and antipredator behavior has been employed in many animal systems including ground squirrels, guppies, sticklebacks and minnows. For example, researchers have examined antipredator behavior in two different populations of minnows (*Phoxinus phoxinus*). Minnows from the Dorset area of southern England and the Gwynedd area of northern Wales were chosen, because the Dorset minnow population is under strong predation pressure from pike predators, while pike are absent from the Gwynedd population of minnows. While individual fish from southern England and northern Wales both look like minnows, and are generally the same size, their antipredator repertoires are different.

In the laboratory, before exposure to a predator, Dorset minnows (those from high pike predation areas) swim around in larger groups than Gwynedd minnows. Dorset minnows also seemed to have more stable groups, with less movement of individuals from group to group than the Gwynedd fish. Once a predator was experimentally introduced to these laboratory populations, individuals in both minnow populations dramatically increased their group size but it took the Gwynedd minnows significantly longer to adjust their group size back to normal: not only did the high-predation Dorset minnows have generally stronger antipredator responses, but they were also quicker to respond to the removal of danger by resuming normal, nonpredator-based activities. In addition, when a predator was present, Gwynedd minnows ceased eating, while Dorset minnows, who are accustomed to foraging in the face of danger, curtailed their foraging activity, but not nearly to the extent of Gwynedd fish.

Interpopulation differences in antipredator behavior have also been studied in guppies native to the Northern Mountains of Trinidad and Tobago. In many of these streams, guppies can be found both upstream and downstream of a series of waterfalls. These waterfalls, however, act as a barrier to many of the guppy's predators. Upstream of such waterfalls, guppies are typically under only slight predation pressure from larger species of fish; while downstream populations of guppies are often under strong predation pressure from numerous piscine predators.

Guppies from high-predation sites mature faster, produce more broods of (smaller) offspring, and tend to channel their resources to reproduction when compared to guppies from low predation cites. These all appear to be antipredator adaptations. At high predation sites, guppy predators tend to be large and can eat a guppy no matter how large it gets. At these sites, producing many smaller fish should be favored by natural selection, as this is akin to buying lots of lottery tickets and hoping that one is a winner.

At low predation sites, only a single small fish predator (*Rivulus hartii*) of guppies exists. If guppies can get past a certain size threshold, they are safe from *R. hartii*. As such, natural selection favors females producing fewer, but larger offspring, who can quickly grow large enough to be out of the zone of the danger associated with *R. hartii*, and this is what researchers have found. Indeed, transplant experiments demonstrate that when low predation fish are transferred to high predation sites, natural selection quickly acts, and after only a handful of generations, descendants of the transplanted fish have converged on the traits associated with living in high predation. Reciprocal experiments have found the same result when high predation fish are transferred to low predation sites.

The interpopulation, experimental, approach to studying antiprdator behavior can be also be used in the wild. A nice example of this comes from work in the Bahamas archipelago, which has thousands of small rock islands, often just a few hundred square meters in size. Lizards abound on many of these rock islands. One of the prey items of the curly-tailed lizard (*Leiocephalus carinatus)* is the smaller brown anole lizard (*Anolis sagrei)*. Although many of the rock islands of similar size and vegetation are home to *A. sagrei*, only a subset of those also have curly-tailed lizards. This sets the stage for experimentally introducing predators

to a series of rock islands where they are otherwise absent, and examining both the short-term and long-term affects of the introduction on prey behavior and prey morphology.

Researchers added Curly-tailed lizard predators to five rock islands where they were absent, but brown anoles were present. As controls, they observed brown anoles on islands of similar size and vegetation, but which had no curly-tailed lizard predators added. Brown anoles responded behaviorally to the addition of predators in a quick and dramatic fashion. On the control islands, brown anoles typically were found in vegetation about 10 cm above the ground. On islands to which predators had been added, brown anoles moved to higher, thinner branches, presumably to avoid the new danger present. This behavioral response occurred within a year of the experimental manipulation.

These results allowed the evolutionary ecologists to examine a long-standing question regarding evolution and behavior: if a behavioral change occurs as a result of predatory pressures, will natural selection be weaker or absent on any additional morphological traits that might be important with respect to predators? In the case of the rock islands, does the behavioral shift to higher perches mean that selection will be weak or absent on morphology in prey, since the prey have moved to safer areas? What researchers found was strong evidence for natural selection acting on morphology, even after behavioral changes. Selection on islands with experimentally introduced predators produced males with longer limbs who were faster at escaping from predators, and larger females, who were both faster at escaping predators and harder for predators to consume should they be caught.

Social Learning and Antipredator Behavior

Motmots, a group of tropical bird species, *instinctively* fear poisonous coral snakes. The coral snakes that are dangerous to motmots have a specific color pattern—red and yellow bands. When baby motmot chicks are presented with a wooden dowel with red and yellow bands painted on it, the chicks instantly fear it. However, if green and blue bands or even red and yellow stripes—neither of which resemble snakes dangerous to the motmot—are painted on a dowel, motmot young no longer treat it like a danger.

The motmot solution to knowing who the enemy is works well under certain conditions, namely when the predatory species involved are few and constant through evolutionary time. If, however, there are lots of predators to handle and/or if the kinds of predators are constantly changing, innate fears may be an inadequate or inappropriate solution to the "know your enemy" problem. Under such conditions, selection may favor learning who the enemy is by observing how others respond to potential threats. This type of antipredator learning has been documented in blackbirds.

Once a flock of blackbirds spot a predator, some of them join together, fly toward the danger, and aggressively attempt to chase it away. Such mobbing behavior often works well enough to force predators to leave the blackbirds' area. Another function of this mobbing behavior may be to help predator-naive blackbirds identify what constitutes a predator. Experiments indicate that when young blackbirds see a particular species being mobbed, they learn that this species is in fact a predator.

Predation and Hatching Time

Antipredator behavior has even been documented in embryos. Work on red-eyed treefrogs (*Agalchnis callidryas*) and their predators demonstrates how natural selection can produce behaviors on the part of embryos that reduce their risk of predation. Red-eyed treefrogs attach their eggs to the various types of vegetation that hang over water, and once tadpoles hatch, they immediately drop down into their aquatic habitat. Both the terrestrial habitat of the egg and the aquatic habitat of the tadpole have dangerous, but different, predators that feed on treefrogs. If terrestrial predation from snakes and wasps is weak, embryos hatch late in the season. Such late hatching allows the frogs to grow to a size that lowers the levels of fish predation, once they hatch and fall into the water.

Both snakes and wasps are terrestrial predators on treefrog eggs, with the latter taking one egg at a time, but the former capable of much more damage per attack. When predation from snakes and wasps is high, it often pays to mature early and drop into the water, away from heavy terrestrial predation. Eggs in clutches that are not disturbed by predators often hatched at about 6 days. When comparing eggs from these undisturbed clutches to clutches that have already suffered some predation by wasps, hatching rates are significantly different. Eggs hatched at a much quicker rate when their clutch had been the victim of some wasp predation, with most eggs from attacked clutches hatching at 4 or 5 days (as opposed to six).

Biological Rhythms

R Refinetti, University of South Carolina, Walterboro, SC, USA

Introduction

Rhythmicity is found in a multitude of biotic and abiotic factors. The examples of environmental cycles shown in **Table 1** document the wide range of frequencies of cycling abiotic factors. Some environmental cycles have well-known effects on organisms – such as the rhythmic change in foraging behavior of intertidal organisms caused by the ebb and flow of the tides. Other cycles, such as the change in the path of the Earth's revolution around the Sun (the orbital eccentricity rhythm), can potentially affect organisms by causing slow weather changes over thousands of years. A few well-known biological rhythms – some of which are and some of which are not controlled by environmental cycles – are listed in **Table 2**. Biological rhythms involve repetitive processes ranging in frequency from more than once per second, such as the spontaneous firing rate of neurons in the mammalian central nervous system, to less than once every decade, such as the oscillation in the wild population of the Canadian lynx (*Lynx canadensis*).

Most research on biological rhythms conducted during the past 50 years has dealt with daily/circadian and annual/circannual rhythms and has concentrated on basic behavioral, physiological, neural, and molecular processes studied in a small number of species in the laboratory. Few studies have examined interspecies differences in basic processes, and fewer yet have addressed ecological issues in natural environments. Thus, this article will start with a brief review of what has been learned in the laboratory about the basic processes of biological rhythmicity and will then examine what little we know about the behavioral ecology of biological rhythms.

Basic Processes

Environment, Endogenesis, Entrainment

The matching of the cycle duration of some environmental cycles with that of some biological rhythms might suggest that biological rhythms are mere responses of organisms to the rhythmicity of their abiotic environment. Extensive research has clearly established, however, that the relationship between environmental cycles and biological rhythms is much more complex. In some cases, biological rhythms are indeed mere responses to environmental cycles. An example is the tidal rhythm of burrowing in some (but not all) species of crabs. In other cases, biological rhythmicity is endogenously generated and does not respond to environmental cycles. An example is heart beating: the rhythmic activity is endogenously generated by the cardiac pacemaker, which can be modulated by sympathetic and parasympathetic stimulation but is not synchronized by natural environmental cycles. Finally, in some cases, biological rhythmicity is endogenously generated and this rhythmicity is modulated (entrained) by environmental cycles. The best-known example is the entrainment of circadian rhythms by the regular alternation of day and night (i.e., the alternation of light and darkness).

In strict sense, only rhythms that are endogenously generated and that can be entrained should receive the circa designation. Laboratory research has documented only four classes of circa rhythms: circatidal, circadian, circalunar, and circannual rhythms. If a given variable does not exhibit circa rhythmicity, or has not been proved to exhibit it, it should be named without the circa designation. Tidal, lunar, and annual are commonly used descriptors. Dian is never used; instead, daily is recommended – although diel and nycthemeral are also used.

It should be pointed out that observation of rhythmic behavior in a natural environment is necessarily insufficient to characterize the nature of the rhythmicity. Whenever a new rhythmic pattern is observed, controlled laboratory investigation is necessary to attribute the rhythmicity to environment, endogenesis, or entrainment. Accurate identification of the modality of rhythmicity is essential for the understanding of ecological and evolutionary significance of the observed rhythmic process.

Rhythmic Variables

Different types of biological rhythmicity may affect the regulation of one or more physiological or behavioral variables. Estrous rhythmicity in rodents, for example, has been shown to affect at least hormonal secretion, behavioral sexual receptivity, the pattern of vaginal discharges, and the amount and temporal organization of locomotor activity. Circadian rhythmicity has been shown to affect locomotor activity, eating and drinking, excretion, learning capability, heart rate, blood pressure, body temperature, hormone secretion, sexual activity, parturition, suicide, susceptibility to heart attack, and many other variables. It is still unclear which of these multiple rhythmic variables are controlled directly by the circadian pacemaker and which are simply caused (masked) by the rhythmicity of variables controlled by the pacemaker. It has been demonstrated that the circadian rhythm of body temperature

Table 1 Some environmental cycles on the Earth

Duration of cycle	Phenomenon
2×10^{-15} s	Oscillation of electromagnetic waves in visible light
2×10^{-2} s	Voltage oscillation in alternated current (home electricity)
12.4 h	Tides (attractive forces of the Sun and the Moon)
24 h	Days (Earth's rotation)
30 days	Months (Moon's revolution around the Earth)
365 days	Years (Earth's revolution around the Sun)
10 years	Cycle of sunspots
22 000 years	Precession of the equinoxes
41 000 years	Variation in Earth's obliquity (axial tilt)
96 000 years	Variation in Earth's orbital eccentricity

Table 2 Some biological rhythms

Duration of cycle	Phenomenon
10^{-1} s	Spontaneous firing rate of cortical neuron
1 s	Human heart rate
1 h	Pulsatile secretion of hormones
12.4 h	Tidal and circatidal rhythms
24 h	Daily and circadian rhythms
4 days	Estrous cycle of rat
7 days	Human work-rest week
30 days	Lunar and circalunar rhythms
110 days	Estrous cycle of elephant
12 months	Annual and circannual rhythms
10 years	Oscillation in the wild population of Canadian lynx

is not caused by the rhythm of locomotor activity, whereas the rhythm of urea secretion is simply a consequence of the rhythm of food ingestion, but generally very little is known about the inter-relationships among the various rhythms.

Entraining Agents

The circa rhythms can, by definition, be entrained by environmental cycles. Circatidal rhythms are often entrained by the cycle of inundation, whereas circannual rhythms are often entrained by the seasonal variation in photoperiod (i.e., the fraction of daylight in a day). Circadian rhythms are strongly entrained by the light–dark cycle and less strongly by daily variations in ambient temperature, food availability, and physical exercise. Many environmental cycles that may not entrain a rhythm can nevertheless mask it.

Substrates

Circadian rhythms have been demonstrated in almost ever species ever tested, from bacteria to humans. Although transcriptional/translational loops seem to underlie the intracellular process of generation of circadian rhythmicity in all organisms, the specific genes involved are not conserved across domains, kingdoms, or phyla. At the systems level, likewise, the pacemaking structures and the sensory receptors necessary for entrainment vary with the complexity of the organism. In mammals, a major circadian pacemaker is located in the suprachiasmatic nucleus (SCN), a small nucleus in the ventral hypothalamus composed of several thousand neurons. Each neuron in the SCN is an autonomous pacemaker, and the various cells are synchronized mainly through synaptic communication.

The mammalian circadian system relies exclusively on the eyes to acquire photic information necessary for entrainment, although other vertebrates and invertebrates possess a variety of additional photosensitive structures. Both classic photoreceptors (rods and cones) and photoresponsive ganglion cells in the retina of the eyes provide photic information to the mammalian circadian system. Very little is known about how the circadian pacemaker acquires the information about temperature and nutritional state that is needed for nonphotic entrainment. Temperature signals are available from cold- and warm-sensitive cells on the skin and in the body core. Hunger and satiety signals are available from the blood concentration of nutrients, taste and smell of the food being ingested, gastric distension, gastric contents, and blood levels of various hormones secreted by the stomach, by the intestines, and by fat cells.

The efferent pathways responsible for communication of circadian rhythmicity to the various organs are not well known but seem to involve neural as well as humoral mechanisms. One mammalian efferent pathway has been described in detail: the control of rhythmic melatonin secretion by the pineal gland is achieved through a tortuous pathway from the SCN to the

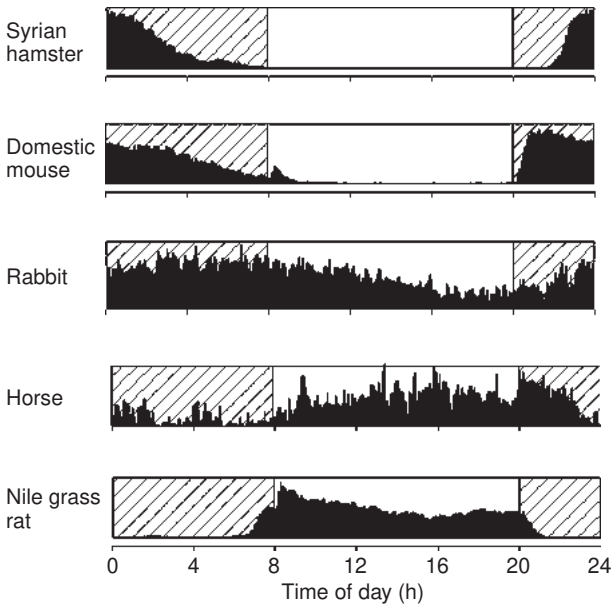

Fig. 1 Representative activity records of five mammalian species. In all cases, data were collected in a controlled laboratory environment where the light–dark cycle (indicated by the hatched and clear boxes) was the only prominent 24-h environmental cycle. The ordinates in each graph are set in arbitrary units to facilitate comparison between different species. Notice the differences in diurnality/nocturnality among the five species. Original figure from data collected in the laboratories of the author and his research collaborators.

paraventricular nucleus of the hypothalamus, to the intermediolateral column of the thoracic spinal cord, to the superior cervical sympathetic ganglion, and finally to the pineal gland.

Ecological Aspects

Evolutionary Advantage

Because extant bacteria exhibit circadian rhythmicity, it is usually assumed that endogenous rhythmicity was present already in the earliest life forms and was retained in all divergent branches along the evolutionary tree. In the absence of fossil evidence, however, it is equally possible that circadian rhythmicity evolved *de novo* multiple times in various taxonomic groups. Early life forms exposed to sunlight had to deal with the conflict between obtaining life-sustaining energy from solar radiation and being damaged by the Sun's strong ultraviolet emissions. Resolution of this conflict – in the form of daily vertical migration in the ocean – may have been the driving force for the evolution of circadian rhythmicity.

In general terms, it is often assumed that endogenous rhythmicity evolved as a mechanism that allowed organisms to prepare for predictable daily changes in the environment. For instance, photosynthetic plants could wait for sunlight each day, but those with an innate mechanism capable of anticipating sunrise would get an early start by initiating preparatory adjustments during the last part of the night. Similarly, nocturnal rodents could wait for the darkness of the night before getting ready to leave their burrows, but those with an innate mechanism capable of anticipating sunset would prepare in advance for the rigors of foraging. On a limited scale, experimental research has demonstrated enhanced reproductive fitness or survival in normal organisms as compared to organisms with deficient circadian systems.

Diurnality and Nocturnality

Phenomenology

Perhaps the most fundamental ecological issue in circadian physiology is an organism's adoption of a nocturnal niche or a diurnal niche. Evolutionarily, it is not certain whether the choice of a temporal niche was relevant to early life forms. If the first organisms were photoautotrophic and relied on energy from the Sun, then the choice of a diurnal niche would certainly have been important. However, if the first organisms were chemoautotrophic and relied on geothermal energy from deep-ocean vents, then the alternation of day and night on Earth's surface would have been of very little importance. Millions of years later, when living beings – particularly heterotrophic ones, such as animals – abandoned the ocean and colonized terrestrial environments, the choice of a nocturnal niche was probably necessary as a means of preventing desiccation. Thus, invasion of the diurnal niche likely became possible only after the evolution of integuments capable of preventing water loss.

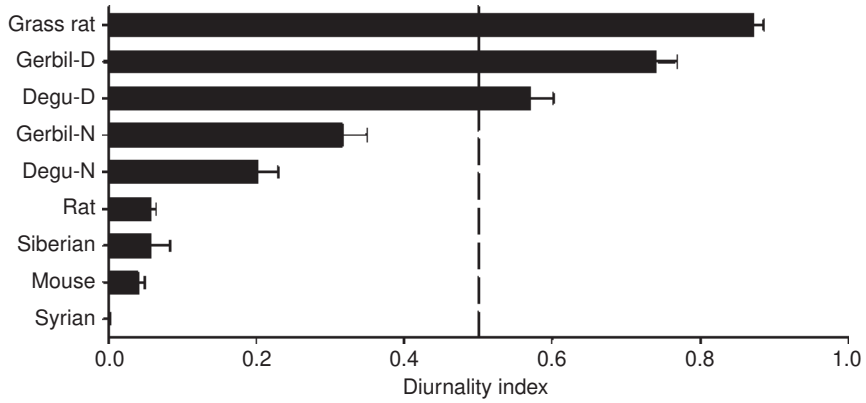

Fig. 2 Mean diurnality scores of nine groups of small rodents. The diurnality score was computed as the ratio of the number of activity-wheel revolutions during the light portion of the light–dark cycle and the number of wheel revolutions during the whole day, so that larger scores reflect greater diurnality. The dashed line indicates the theoretical separation between nocturnal and diurnal animals (i.e., equal amounts of activity during the light and dark portions of the light–dark cycle). Notice the gradient from predominant nocturnality to predominant diurnality. Adapted from Refinetti R (2006) Variability of diurnality in laboratory rodents. *Journal of Comparative Physiology A* 192: 701–714.

Although many organisms today can be classified as either nocturnal (night-active) or diurnal (day-active), many others defy classification. Representative activity records for five mammalian species are shown in **Fig. 1**. Under a light–dark cycle with 12 h of light and 12 h of darkness per day, Syrian hamsters (*Mesocricetus auratus*) are exclusively nocturnal. Domestic mice (*Mus musculus*) are predominantly nocturnal, but their active phase is quite long and extends slightly into the light portion of the light–dark cycle. Rabbits (*Oryctolagus cuniculus*) are not clearly nocturnal or diurnal. Horses (*Equus caballus*) are predominantly diurnal but have a long active phase that extends into the dark portion of the light–dark cycle. Finally, Nile grass rats (*Arvicanthis niloticus*) are almost exclusively diurnal.

A laboratory study involving seven species of small rodents revealed a gradient of temporal niches running from predominantly diurnal species to predominantly nocturnal species with many chronotypes in between, including species exhibiting wide intraspecies gradients of temporal niche (**Fig. 2**). Domestic mice (*Mus musculus*), laboratory rats (*Rattus norvegicus*), Syrian hamsters (*Mesocricetus auratus*), and Siberian hamsters (*Phodopus sungorus*) were found to be predominantly nocturnal, with small intra- and interspecies variability. Nile grass rats (*Arvicanthis niloticus*) were found to be predominantly diurnal, again with small intraspecies variability. Curiously, degus (*Octodon degus*) and Mongolian gerbils (*Meriones unguiculatus*) were found to be naturally distributed into two distinct groups – one predominantly diurnal and one predominantly nocturnal – so that a downward gradient of diurnality was observed from Mongolian gerbils classified as diurnal, degus classified as diurnal, gerbils classified as nocturnal, and degus classified as nocturnal.

Great intraspecies variability in diurnality, with some individuals showing predominantly diurnal activity patterns and others showing predominantly nocturnal activity patterns, has been described in other species as well. In goldfish (*Carassius auratus*), about 80% of individuals tested in the laboratory were found to be diurnal, whereas 10% were nocturnal, and 10% displayed very weak rhythmicity. In carpenter ants (*Camponotus compressus*), approximately 70% of individually tested animals were found to be nocturnal, whereas 30% were diurnal. Likewise, in subterranean mole-rats of various species, some members of the species were found to be diurnal and some were found to be nocturnal. Even some instances of intraindividual variability (i.e., the same individual being diurnal under some circumstances and nocturnal under other circumstances) have been reported. For instance, wolves (*Canis lupus*) are normally nocturnal; however, when traveling over long distances, they travel during the day. Conversely, migratory birds are normally diurnal, but they do most of their migratory flight at night.

Some authors have used the term cathemerality to refer to activity patterns that are not clearly diurnal or nocturnal. It has been suggested that cathemerality (lack of circadian rhythmicity) may be an adaptive feature that allows animals to optimally exploit the available resources without the temporal restrictions imposed by circadian rhythms. Of course, this reasoning is the very opposite of that used to explain the existence of circadian rhythmicity, but it is not absurd to assume that circadian rhythmicity provided selective advantage to some species and not to others.

Causality

Very little is known about the causes of temporal niche selection beyond the obvious fact that some species inherit a diurnal preference while others inherit a nocturnal preference or no preference at all. In animals, eyes specialized for day vision (i.e., eyes possessing retinal cones in addition to retinal rods) evidently facilitate adaptation to a diurnal niche, but image-forming photoreception is not essential for circadian entrainment because the photosensitive ganglion cells can provide sufficient photic input to the SCN. Researchers who have tried to identify the mechanisms responsible for diurnality or nocturnality have generally found that there is no clear difference between diurnal and nocturnal organisms except for the obvious difference in the phase angles of entrainment – that is, diurnal animals are diurnal because they are active during the day, and nocturnal animals are nocturnal because they are active at night.

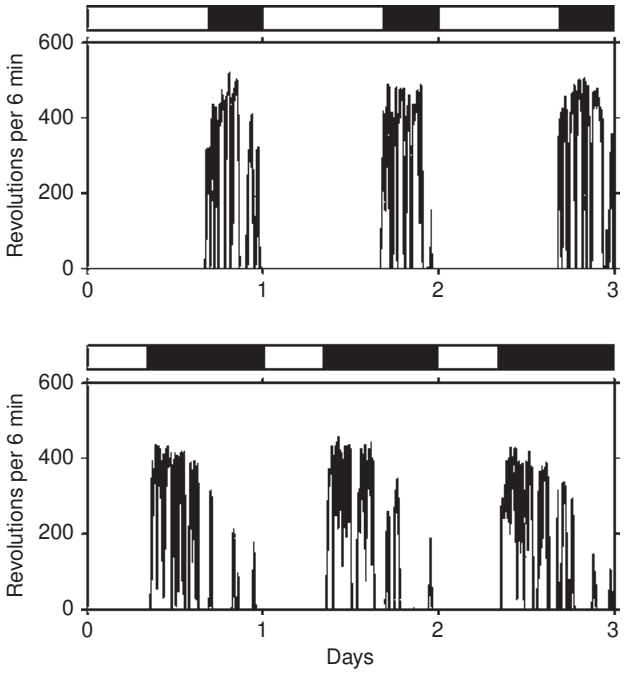

Fig. 3 Three-day segments of the records of running-wheel activity of a domestic mouse housed in the laboratory under a light–dark cycle with 8 h of darkness per day (top) or 16 h of darkness per day (bottom). The white and black horizontal bars denote the light and dark portions of the light–dark cycle, respectively. Notice that the active phase of the activity rhythm is longer when the nights are longer. Original figure from data collected in the author's laboratory.

Although we do not know why diurnal organisms differ from nocturnal ones, we do know that temporal niche selection depends on the interplay of two basic mechanisms: entrainment and masking. Entrainment results from the resetting of the pacemaker by photic stimulation at the appropriate time of the circadian cycle, whereas masking refers to the inhibition (negative masking) or disinhibition (positive masking) of behavioral activity without a direct effect on the pacemaker. Resetting of the pacemaker follows species-specific phase-response curves that do not differ between diurnal and nocturnal organisms except for the fact that diurnal organisms are responsive to light during their inactive phase, whereas nocturnal organisms are responsive to light during their active phase (i.e., both diurnal and nocturnal organisms are responsive to light at night). Similarly, the masking effects of light are equivalent in diurnal and nocturnal organisms except that light generally causes positive masking in diurnal organisms and negative masking in nocturnal organisms.

Naturally, entrainment and masking need not be restricted to photic stimuli. Outside the controlled conditions of the laboratory, organisms are subject not only to a light–dark cycle but also to rhythmic and nonrhythmic variations in food availability, ambient temperature, and intra- and interspecies competition. One case of interspecies competition that has been relatively well studied is that involving mice of the genus *Acomys*. In natural settings in rocky deserts of the Middle East, common spiny mice (*A. cahirinus*) share a foraging microhabitat with golden spiny mice (*A. russatus*). Normally, common spiny mice are nocturnal, whereas golden spiny mice are diurnal. However, if the common spiny mice are removed from the area, the golden spiny mice become nocturnal. This suggests that the golden spiny mice are normally forced into the diurnal niche by the competition for resources. Indeed, when golden spiny mice are trapped in the field and immediately tested individually in the laboratory, they exhibit a nocturnal pattern of activity. Thus, the phase reversal in spiny mice is quite interesting from an ecological point of view. It shows how masking mechanisms may supplant entrainment mechanisms in the determination of the temporal niche of species in the wild.

Seasonal Adjustments

Much research has dealt with the interaction between annual rhythms and circadian rhythms. Except at the equator, nights are longer in the winter and shorter in the summer, and it is well known that this seasonal variation in photoperiod causes a temporal compression or expansion of circadian rhythms. The phenomenon has been observed in natural settings (where the change in photoperiod is accompanied by changes in temperature and food availability) as well as in the laboratory (where only the photoperiod is changed). An example of expansion of the active phase (α) of a mouse under long nights in the laboratory is shown in Fig. 3. Notice that the expansion of α is accompanied by a reduction in exertion at each time point, so that the overall amount of activity (number of wheel revolutions, in this case) is conserved. As it would be expected, α is expanded under long nights in nocturnal organisms but under long days in diurnal organisms. As a rule, wintertime is associated with rhythm compression in

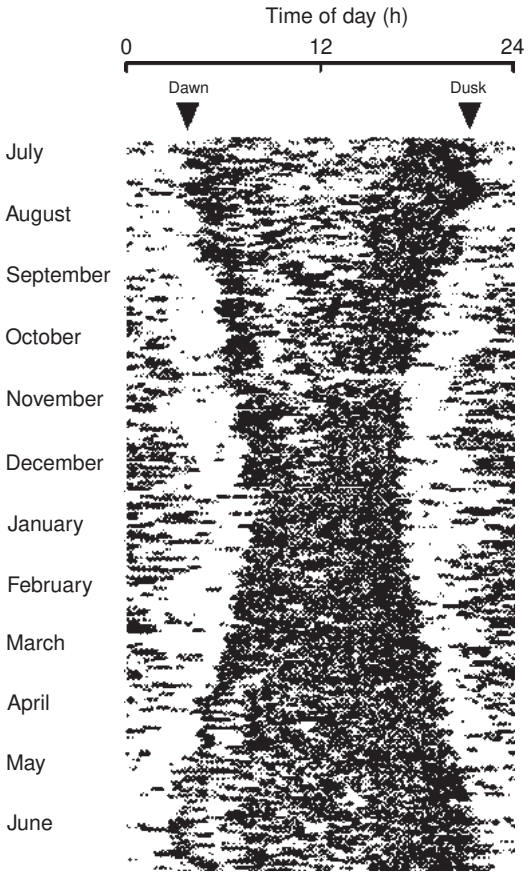

Fig. 4 The daily feeding rhythm of a mouflon sheep (*Ovis musimon*) maintained outdoors in Germany for a full year. Notice the gradual contraction – and later expansion – of the feeding rhythm as the days become shorter in the winter – and longer again in the summer. Adapted from Berger A, Scheibe KM, Michaelis S, and Streich WJ (2003) Evaluation of living conditions of free-ranging animals by automated chronobiological analysis of behavior. *Behavior Research Methods, Instruments, and Computers* 35: 458–466.

diurnal animals and rhythm expansion in nocturnal animals, whereas summertime is associated with rhythm expansion in diurnal animals and rhythm compression in nocturnal animals. A full-year record of feeding activity of a mouflon sheep (*Ovis musimon*) housed outdoors in Germany is shown in **Fig. 4**. This diurnal animal spent many more hours grazing during the summer than during the winter.

Seasonal variations have also been documented in other parameters of circadian rhythms, such as phase, amplitude, and period. An interesting seasonal modulation of rhythm amplitude is observed in beavers (*Castor canadensis*). During the winter, in Canada and northern United States, beavers remain essentially sequestered in their lodges or underneath the ice cover, so that their daily rhythm of activity is almost flat, whereas robust rhythmicity is present in the summer.

The interaction between annual and circadian rhythms occurs also in the opposite direction, as circadian rhythmicity can affect annual rhythms. Perhaps the best example of this interaction is the circadian modulation of entry into and arousal from hibernation. Studies conducted on several species of squirrels and hamsters have generally shown that entry into torpor is restricted to a narrow segment of the day (and, therefore, is modulated by the circadian system), although there is disagreement about the circadian modulation of arousal. **Fig. 5** shows the results of a study conducted on European hamsters (*Cricetus cricetus*). The animals were kept in the laboratory under simulated winter conditions of short photoperiod (8 h of light per day) and low ambient temperature (8 °C). Each dot in the figure corresponds to an episode of entry into or arousal from a deep hibernation bout. Although the temporal distribution of entries into torpor is not very tight, almost all entries occurred between 18.00 and 06.00. Arousals from torpor were scattered all over the day in this study. Some investigators have found that arousal from hibernation is restricted to a narrow segment of the day (and, therefore, is modulated by the circadian system), whereas others have not. Because the conflicting findings have been obtained in different species, they may be explained by species differences. The central question is whether the circadian system remains functional during hibernation, as a functional clock is required for the timing of arousal. Some researchers have observed circadian rhythmicity of body temperature (with very small amplitude) during hibernation, whereas others have not. A study of metabolic activity of various brain areas identified high activity in the site of the master circadian pacemaker (SCN) during hibernation, which constitutes evidence that the circadian system remains functional during the maintenance stage of hibernation.

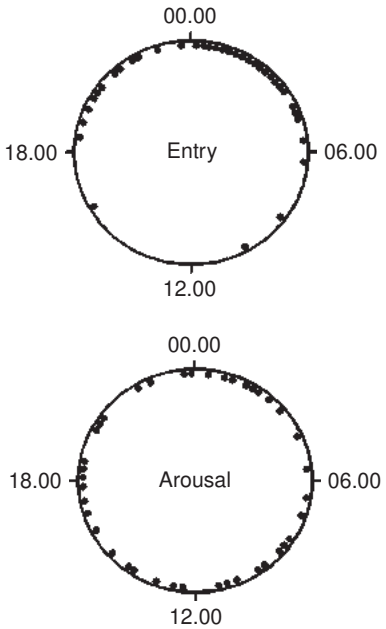

Fig. 5 Distributions of the times of entry into and arousal from deep hibernation bouts of eight European hamsters (*Cricetus cricetus*) maintained in the laboratory under simulated winter conditions (8 °C, 8 h of light per day). Notice that the distribution for entry into torpor is clustered around the late evening and early morning. Adapted from Waßmer T and Wollnik F (1997) Timing of torpor bouts during hibernation in European hamsters. *Journal of Comparative Physiology B* 167: 270–279.

Future Directions

Laboratory research on biological rhythms has concentrated on basic processes studied in a small number of species, mostly rodents. Few studies have examined interspecies differences in basic processes, and fewer yet have addressed ecological issues in natural environments. Field studies, on the other hand, have lacked the methodological sophistication necessary for the attribution of rhythmicity to environment, endogenesis, or entrainment, which is an essential step in the understanding of the ecological and evolutionary significance of the observed rhythmic process. The future hopefully will bring numerous studies that combine the rigor of laboratory experimentation with the realistic complexity of natural environments into groundbreaking investigations of the interplay of environmental cycles that modulate biological rhythmicity.

Glossary

Allelopathic chemistry The activity where one organism or species produces biochemicals that have negative or positive effects on the germination, growth, development, survival, and reproduction of other species.
Fecundity The ability to produce offspring.
Natural selection A mechanism of evolution, where there is differential survival of individuals based on differing phenotypes that lead to changes in heritable traits of a population.
Parasite-mediated competition An ecological relationship where a parasite disproportionally affects one of two species that compete for common resources and influences the outcome of the competitive interaction.
Quorum sensing A system of stimuli and responses associated with the biochemical activity of microbial populations that changes with population density.
Sexual cannibalism An activity where one sex of a species consumes the individual of the same species prior to, during or after copulation; this is often in the form of the female consuming the male.
Sexual dimorphism A phenotype where two sexes of the same species have different morphological or behavior differences that are different from gonads or sexual organs (body size, color, song).
Sexual selection A form of natural selection where organisms make preferential selection of mates based on differing traits or characteristics.

An Introduction Using a Narrative Case Study: Competition of Microbes and Insects

The existence of microbes on earth has been documented to extend nearly 3.5 billion years ago during the Precambrian period (Crippen *et al.*, 2015; Waggoner, 1996). Most bacteria form community assemblages of cells attached to a substrate creating a biofilm (Lang *et al.*, 2016). Such biofilms are ubiquitous, and include being found on and in plants, animals, substrates and decomposing animal carcasses, or carrion; and while these microbial assemblages are critical the decomposition of carrion (Parmenter and MacMahon, 2009; Crippen *et al.*, 2015; Nemergut *et al.*, 2011), interactions with microbes and other organisms (e.g., insects) may be quite intense and rather complex creating a competitive struggle for the resource. These interactions can be in the form of competition among the microbial communities, invertebrates, and vertebrate scavengers (Rozen *et al.*, 2008; Benbow *et al.*, 2015b). Carrion has often been characterized as a rich yet ephemeral resource patch, or a decomposition island (Carter *et al.*, 2007), and whether it takes the form of a deer lying alongside a roadway or a whale at the bottom of ocean, it can be the source for intense competition among organisms representing different kingdoms and domains of life. Because of the patchy and ephemeral nature of carrion (a temporary, but highly rich resource) (Benbow *et al.*, 2015a), it stands as an excellent example of how competition for any resource affects individual organisms and structures populations, communities, and ecosystems. We introduce this article on competition with a brief example of how questions related to carrion decomposition demonstrate several aspects of competition. The questions and hypotheses posed here can be applicable to other resources that are under competition within and among species, such as space and mates. An initial question is: What are the evolutionary and ecological factors that have driven contest between eukaryotic and prokaryotic organisms to secure such an ephemeral resource?

To answer this question when pondering decomposition ecology in the tropics, entomologist Janzen (1977) hypothesized of the evolutionary reason, if any, of why fruits rot, seeds mold, and meat spoils. Janzen (1977) reasoned that the stakes are high in this contest for the microbial communities associated with these resources, since arthropods often quickly find and consume the decomposing organic matter, including the consumption of the microbes competing for the newly available nutrients and energy. For the microbes, the cost of defeat for this resource is death, additionally, the arthropods may be exposed to similar risks by feeding on microbes in a form of chemical warfare (Janzen, 1977). In other words, toxins produced by microbes may be detrimental to both other microbes in the form of antibiotic-type toxins as well as making it objectionable and toxic to higher organisms (e.g., the consequences of eating spoiled meat in humans is foodborne illness from bacterial toxins). Such selective pressures might favor arthropods evolving ways to ignore such objectionable flavors or odors or select for behaviors that allow for detoxification; these interactions result in an evolutionary "arms race" between microbes and arthropods for competing for the limited resource.

How could the microbes win out in this battle? As Janzen (1977) later proposed, bacteria could render this food resource unpalatable via a number of evolved strategies. For example, he hypothesized that microbes could alter the nutrient composition, thus rendering it objectionable by the consumer; or they might select an alternative strategy by producing toxins that might repel the consumer. In turn, the animals that fed on fruit (or carrion) should evolve counterstrategies to compensate for the negative effects of competition with microbes. The early work by Janzen (1977) not only provided the foundation for a more thorough

 doi:10.1016/B978-0-12-409548-9.10597-4

Fig. 1 A larval mass of *Nicrophorus* sp. that was feeding on a salmon carcass. Photo credit: Bob Armstrong.

examination of the adaptive significance of animal–microbe competition but also unknowingly suggested at the time how this example may have been more complex than he realized. More than four decades later, Rozen *et al.* (2008) realized that there were little experimental data that tested Janzen's hypotheses related to decomposing fruit and other organic matter like carrion. Data were limited with respect to antimicrobial strategies that might allow animals to utilize decomposing organic matter be they fruits or meats. As Rozen *et al.* (2008) suggested, such work would need to be done to understand the evolutionary and ecological ramifications of competition between animals and microbes.

As Janzen (1977) discussed the cost of defeat for a carrion resource for the microbes was death, Rozen *et al.* (2008) reasoned that there were likely differences between facultative and obligate vertebrate scavengers, where both would suffer fitness effects during competition with microbes, obligate scavengers could also suffer with death if they lose the resource. This would be facultative scavengers can move and consume different food sources if competition with other consumers (or microbes) is intense, but the obligate carrion scavengers are restricted to the patchy and limited nature of such resources: if they are outcompeted, they suffer severe fitness costs or death. To test this scenario, researchers investigated how an obligate carrion consumer, the burying beetle (*Nicrophorus vespilloides*) utilized parental care and carcass choice as antimicrobial strategies (**Fig. 1**). From a fitness perspective, Rozen *et al.* (2008) understood that larval growth and body size were important fitness components that would influence adult survivorship and overall success in competition for breeding by adult beetles. To examine this relationship, they tested the effects of competition of microbes with beetles and evaluated their reproductive success.

In a suite of lab experiments, Rozen *et al.* (2008) used small containers with either fresh or old mouse carcasses, introduced mated female beetles and then manipulated beetle brood size. This manipulation allowed observation of parental behavior in terms of choice to breed and larval behavior associated with food begging on the two resources. The fresh carcasses had not decomposed and represented a resource with less intense microbial competition and presumed less microbial metabolic activity producing toxins and noxious odors. The old carcasses represented increased microbial activity, and thus increased competition for the resource.

The researchers found that larval size was significantly reduced on old mouse carcasses compared to those reared on fresh carcasses, indicating that the increased competition negatively affected the offspring of the beetles. They further explained that adult female and larval behaviors may be altered depending on the degree of microbial competition they encounter. For example, they also demonstrated that with old, microbe-laden carcasses, larvae begged significantly more indicating that they were stressed from a nutritionally poor diet associated with old carcasses, suggesting that the microbes had lowered the quality of the resource for the larvae. Female beetle behavioral results were mixed, where females preferred old carcasses to feed upon but then switched to fresh carcasses upon which to rear their broods (**Fig. 2**). This finding implies the level of parental care may influence any negative effects of larval competition with microbes.

The work by Rozen *et al.* (2008) confirmed and expanded upon Janzen's (1977) hypotheses explaining how higher carrion feeding organisms compete with microbial communities associated with decomposition through a variety of behavioral strategies. In reality, the interaction may be more complex than either group of scientists fathomed. Scientists have documented that the toxins and secondary metabolites produced by microbes do serve multiple purposes from repelling higher organism consumers to having antibacterial capacities that may reduce competition with other microbes (Lam *et al.*, 2009).

Recently, it has been shown that many microbes in such biofilms on carrion may be sending chemical signals using quorum sensing (bacterial cell-to-cell signals) mechanisms that communicate not only among other microbes but also to invertebrate carrion feeders (Ma *et al.*, 2012). Scientists know that these microbial communities change during the process of decomposition and affect how insect scavengers colonize the resource (Pechal *et al.*, 2014). The process by which chemical signals sent from microbes to insects affects competitive outcomes is an alternative to the toxin hypothesis proposed by Rozen *et al.* (2008); however, such signals may also change competition outcomes among microbes over the decomposition process as insects come

Antimicrobial strategies in burying beetles breeding on carrion. *Proceedings of the National Academy of Sciences*, ***105***, 17890–17895.

and go from a carcass. Such interactions imply that the complexity of competition is driven both evolutionarily and ecologically and that interactions such as in the above case study among microbes, insects, and vertebrates can determine that limited resources such as carrion can control the abundance of competing populations. In this article, we will expand on this case study and explore how communities are structured and how they change through a variety of species interactions, how competition is defined and identify the factors that affect competitive outcomes.

The Niche Concept

A common contention in evolutionary biology is that competition is a major driver of natural selection whether it is among conspecifics within a given population or different species with overlapping niches. Ecologists recognize that competition has been characterized in numerous fashions ranging from interactions among organisms of a single species to more than two populations of different species exerting negative effects on each other by for example, affecting growth, survivorship, and reproduction via a shared use of resources such as food, water, space, mates, or shelter (Ricklefs and Relyea, 2014; Bowman *et al.*, 2017). Shared resources are important, as they limit the degree of population growth even without constraining abiotic pressures such as temperature or humidity or biotic factors such as competition over those resources by other species. An important aspect of population biology is the *carrying capacity* of the environment, or the maximum number of organisms that can be sustained in a given habitat. Competition affects how two or more species utilize the resources in the environment and the carrying capacity can have important consequences on the outcome of competitive interactions: if the carrying capacity is high, there are more resources to be shared or competed for, while when it is low, there are fewer resources and the assumed competition for the limited resources becomes more intense. But just how species are able to occupy a place in natural ecosystem also depends on the different abiotic and biotic constraints on that species. When considering competition for a given resource, population limits are set based on the abiotic and biotic requirements that differentiate between the fundamental and a realized niche for each species (**Fig. 3** and see the following text).

It is important to distinguish the difference between these two niche types. The fundamental niche constitutes the range of abiotic conditions under which a particular species can exist, such as temperature, humidity, precipitation (Ricklefs and Relyea,

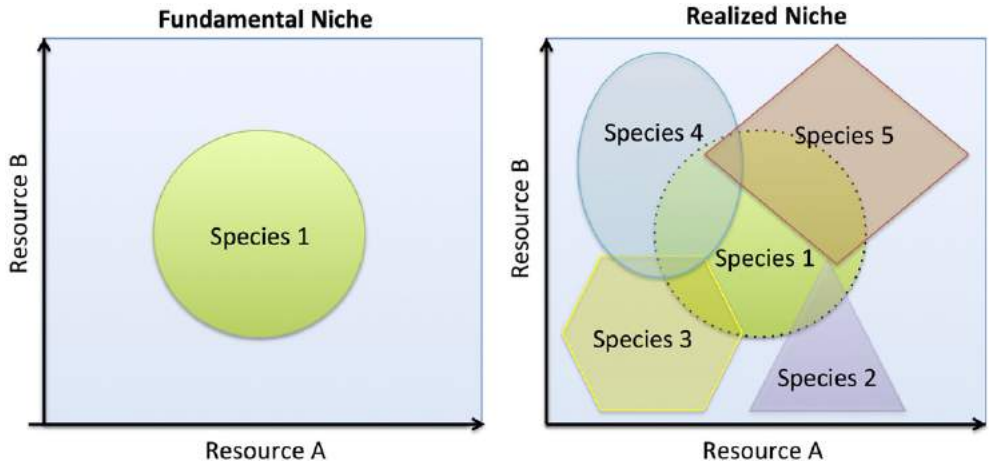

Fig. 3 This conceptualized schematic illustrates how in the left panel (A) a single species may be able to exploit two different resources in a fundamental niche within the *green circle*; however, resource use in reality is regulated by the interactions of two or more species as shown in the right panel (B) thus establishing the boundaries for a realized niche for species 1 but also the other species competing for resources 1 and 2. Modified from Fig. 14.3 in Bowman, W. D., Hacker, S. D., & Cain, M. L. (2017). *Ecology*. Sunderland, MA: Sinauer Publishers.

2014); or as the niche that would be occupied in the absence of competition from other species. For instance, certain plants are usually found in salt marsh environments and are rarely reported from freshwater habitats, and are often assumed to be "salt restricted." However, these water plant species can and do grow in freshwater but only in the absence of several other, but better plant species competitors. When the competitors are removed or are absent the "salt restricted" plants will expand their niche to include freshwaters. While many favorable geographic locations may be included in the fundamental niche range of species, the presence of competitors, predators, and parasites may exert biotic pressures that constrain the fundamental niche to a realized niche. Thus, the realized niche includes both abiotic and biotic conditions under which a species persists (Ricklefs and Relyea, 2014). The use of resources is shared by multiple species and their interactions affect the niche size of the other species. Thus, species interactions constitute a more restricted set of conditions that defines a realized niche for different species (Bowman *et al.*, 2017). In the example above, the "salt restricted" plant species have a realized niche of salt marshes, but have a fundamental niche of both salt and freshwater habitats: when their competitors are present they occupy their realized niche, but when the competitors are absent, they expand to their fundamental niche. Understanding the differences between fundamental and realized niches allows for a conceptual foundation important for determining how species interactions, and therefore competition, influence how species are distributed in space and change with time.

Species Interactions

Traditionally, competitive interactions among species have been characterized as pairwise comparisons that designate a negative, positive or zero effect type on the different individuals or species (Pianka, 1994). These interactions take various forms and are summarized in **Table 1**. A predatory interaction dictates that one organism, such as a cheetah, kills, and consumes another like the Thompson's gazelle (Lang and Benbow, 2013). In general, most predation occurs as interspecific interactions; however, cannibalism is common among both terrestrial and aquatic organisms (Greenwood *et al.*, 2010; Huss *et al.*, 2010). For example older mantids and spiders can be cannibalistic on younger individuals and sometimes even on mates (Elgar and Nash, 1988). For instance sexual cannibalism and sexual dimorphism have been well described for Golden Orb Weaving spider species (**Fig. 4**). In this species, the female is substantially larger ($>2\times$) than the males, demonstrating sexual dimorphism in body size; and as a result of this size difference, will often consume the much smaller male after they have mated (Yip *et al.*, 2016).

Similar to predation, herbivory is when a primary consumer such as grazing mayfly nymph grazes an algal covered rock in streams or how a three-toed sloth feeds on *Cecropia* leaves in the tropical forest canopy. Predation and herbivory differ in that herbivory does not always mean the death of the plant, whereas with predation one organism is killed (Lang and Benbow, 2013).

Symbioses such as mutualism, commensalism, and parasitism can either be obligate or facultative where two or more different species live in a close relationship, often one colonizing a host (Lang and Benbow, 2013). A mutualistic relationship dictates that the interaction is beneficial for both individuals such as the ant/acacia relationship where the acacia tree provides thorns and fruiting bodies to protect and feed the ants, and the ants provide protection against herbivores from grazing the acacia and against other competing plant species. A commensal relationship occurs when one individual benefits but the other is not affected positively or negatively. An example of commensalism is where phoretic aquatic mites colonize Carabidae beetles and the mites use the mobile insect to hitch a ride and disperse in the ecosystem without any measurable effect on the beetles (**Fig. 5**). Parasitism involves two organisms, the parasite and a host. In such interactions, the parasite benefits at the expense of the host by feeding on

Table 1 Summary of the types of pairwise biotic interactions between and among species

Interaction type	*Pairwise designation*		*Nature of interaction*
	Species A	*Species B*	
Mutualism, müllerian mimicry	+	+	Favorable interaction for both species
Commensalism	+	0	Species A benefits, but Species B is unaffected
Predation, herbivory, parasitism, batesian mimicry	+	−	Species A exploits Species B
Competition	−	−	Each species inhibits the other
Amensalism	−	0	Species A inhibited, Species B unaffected
Neutralism	0	0	Species A and Species B coexist without interactions

Designations are positive (+), negative (−), or no effect (0).

Fig. 4 A classic example of sexual dimorphism where the female is much larger than the male Golden Orb Weaving Spider (*Nephila* sp.). tissues or fluids of the host. A parasite also can influence competition between two species when one species is more susceptible to the parasite than a second (Lang and Benbow, 2013). For example, two species of *Anolis* lizards found islands are known to coexist under certain ecological conditions in Caribbean. Under average conditions, one species (*A. gingivinus*) is a better competitor and excludes the second species (*A. wattsi*) from certain parts of the islands; however, this better competitor is more susceptible to lizard malarial parasites, thus lowering its competitive advantage when the parasite is frequent in the populations (Schall, 1992).

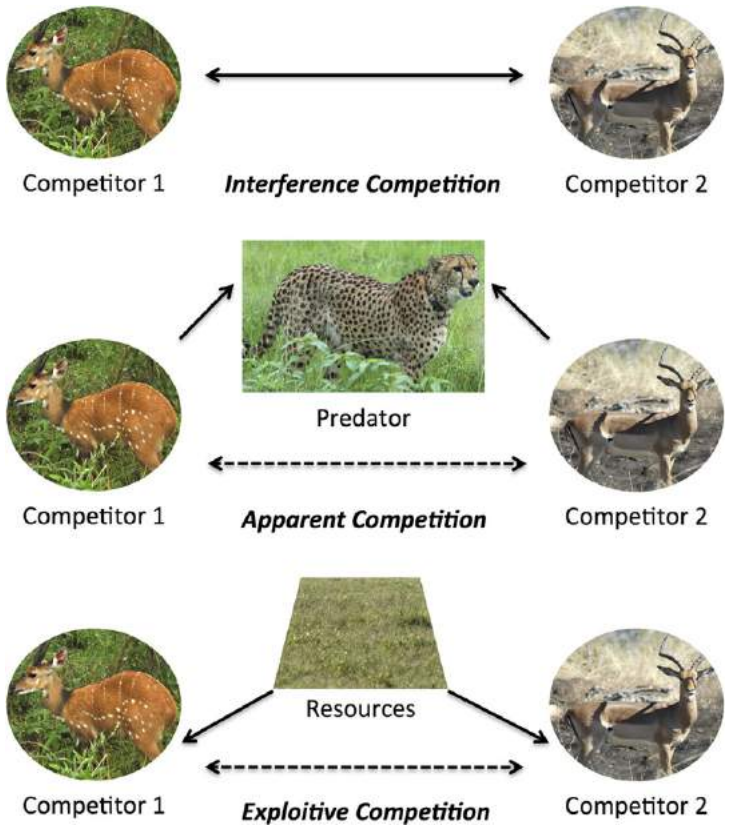

Fig. 6 A conceptual diagram showing the three major forms of competition: interference, apparent, and exploitive.

The ultimate outcome is that the two *Anolis* species only coexist when the malarial parasite is present (Schall, 1992), and this interaction is an example of parasite-mediated competition. Summarizing the breadth of ecological interactions that occur in nature, the next section will focus on the details and characteristics of competitive interactions.

Characteristics of Competition

Competitive interactions in ecological communities are often described within three main types: exploitive, interference, apparent and competition (**Fig. 6**). These forms of competition can either be an intraspecific interaction, where individuals of the same species compete for one or more resources; or through interspecific competition where individuals of different species compete for available resources (**Fig. 7**). Within these parameters, competition can occur indirectly between two or more species (or intraspecifically among individuals of a single species) that use a common and limiting resource in which such competition causes a depletion of the resource(s) and one species acquires the resource faster or more efficiently than the other species (Pianka, 1994). This type of competition has been characterized as resource or exploitative competition. For example, some plant species can acquire water and nutrients from the soil faster than other, nearby plant species, thereby reducing the resources for the less competitive species. Another example is the interspecific territoriality among birds for nesting sites, where some birds are better at occupying and defending common nesting locations that are limiting to another species (Stilling, 2002; Pianka, 1994). The bird species that is the better competitor for the nesting locations produces more offspring, thereby increasing their fitness and the population numbers in the next generation. The less competitive bird species produces fewer offspring with a resulting smaller population in the next generation. When this competitive advantage of one species over another continues for multiple generations without interruption it can lead to competitive exclusion, where the less competitive species is eliminated from that habitat. An example of competitive exclusion is the *Anolis* lizard species interactions of Caribbean islands that occur when the malarial parasite is absent in the populations, as described above.

Competition can also occur directly between two or more species (or individuals within a species) where one organism prevents access of another organism to a resource. This can take place in many forms; for example, via the production of toxins, such as with microbial populations described earlier in the case study of decomposing fruit and carrion; or by causing some other type of harm to the competing organisms that can range from behavioral threats to physical force (Stilling, 2002; Pianka, 1994). This type of competition is referred to as interference competition.

Fig. 7 (A) A romp of otters competing for a fish meal illustrates competition within a single species, or intraspecific competition (Photo Credit: John R. Wallace). (B) Hyenas compete with lions in the Serengeti for zebra prey but vultures also compete with hyenas for the scraps of lion, thus illustrating interspecific competition for food resources. Photo credit: John R. Wallace.

Another form of interaction that is not an obvious form of competition is apparent competition, where the negative affect of one species on another is mediated by the actions of shared natural enemies such as predators or parasites (Wootton, 1994; Morris *et al.*, 2004). The complexity of indirect interactions involving many species in changing environments makes apparent competition difficult to identify in nature. However, when two species that normally do not compete directly for a resource but can negatively affect each other through a mutual predator, apparent competition can exist. For example, Tompkins et al. (2002) determined that parasite susceptibility between ring-necked pheasants and gray partridges in the United Kingdom negatively influenced growth rate, fecundity, and survivorship in gray partridges simply because they were more susceptible to parasitic infections than pheasants. In some cases, however, apparent competition can occur in instances other than a shared enemy such as a predator or parasite, such as when one species facilitates the enemy of another (Ricklefs and Relyea, 2014). For example, when scientists were studying several species of shrubs near the California coast, they observed bare patches of soil around these shrubs (Bartholomew, 1970), an environmental characteristic that can be found in other habitats (**Fig. 8**). Hypothesizing that the patches were caused from allelopathic chemistry produced by the shrubs, they later determined that was not the case. What they found was that the purple sage (*Salvia leucophylla*), through its growth form, provided shade and refuge for mice herbivores to selectively consume seeds of the other, competitor shrub species (Ricklefs and Relyea, 2014). What appeared to be an example of interference competition was actually a case of apparent competition. The type and degree of competition often is dependent on the quality and type of shared resource, its availability and other environmental factors that mediate its acquisition (e.g., seasons in temperate forests).

Plants and animals compete for different resources. For example, plants often compete for sunlight, water, and nutrients (e.g., nitrogen and phosphorous) from the soil. Competition for these resources plays the primary role in how plants are distributed in the environment such as how desert grasses are distributed in central Idaho deserts (**Fig. 8**). In some ecosystems the distribution of certain plant species also has linked effects on the spatial distribution and feeding activity of many animal, that interact among themselves for the plant resources (**Fig. 9**).

Animals may compete for food, water, space, and mates. The latter two reasons for animal competition, space and mate procurement will be discussed in this section, as the other resources have been described above. A classic example for competition

Fig. 8 Nutrient competition for soil resources has contributed to this evenly spaced distribution of desert grasses in Crater-of-the Moons State Park, Idaho. (Photo Credit: John R. Wallace).

Fig. 9 The distribution of plant species in the African savannah may also have indirect effects on intra- and interspecific competition among grazing herbivores. In this photo, zebra, wildebeest, and gazelles or antelope compete within and among species for plant resources. Photo Credit: Richard W. Merritt.

for space has been well documented in Joseph Connell's foundational research where two genera of barnacles, *Balanus* and *Chthalmalus*, were described to compete for space along the high tide line within intertidal pools (Connell, 1961). In these habitats, the larger barnacle, *Balanus* would outcompete *Chthalmalus* for attachment sites on rocks; however, *Balanus* is unable to be survive exposure during low tides. Because *Balanus* requires total submersion in these tidal zones, *Chthalmalus* was able to outcompete *Balanus* for attachment sites above the low tide lines in these zones (Connell, 1961) (**Fig. 10**). Competition for attachment space based on desiccation tolerance differentiates the fundamental niche from the realized niche for *Balanus* barnacles (see the preceding text).

Competition for mates is best understood within the concept of sexual selection, and has been the primary driver in terms of the evolutionary mechanism for sex-specific traits for reproductive purposes: this can be in the form of males battling with other males (and sometimes females vs. other females) for access to female mates; or females choosing males based on characteristics such as size, plumage colors, song or behavioral characteristics. In other words, sexual selection is a result of natural selection in animals for sex-specific traits (Ricklefs and Relyea, 2014). For example, sexual dimorphism, defined as phenotypic differences between males and females of the same species (e.g., Golden Orb Weaving spider described above) includes traits of color,

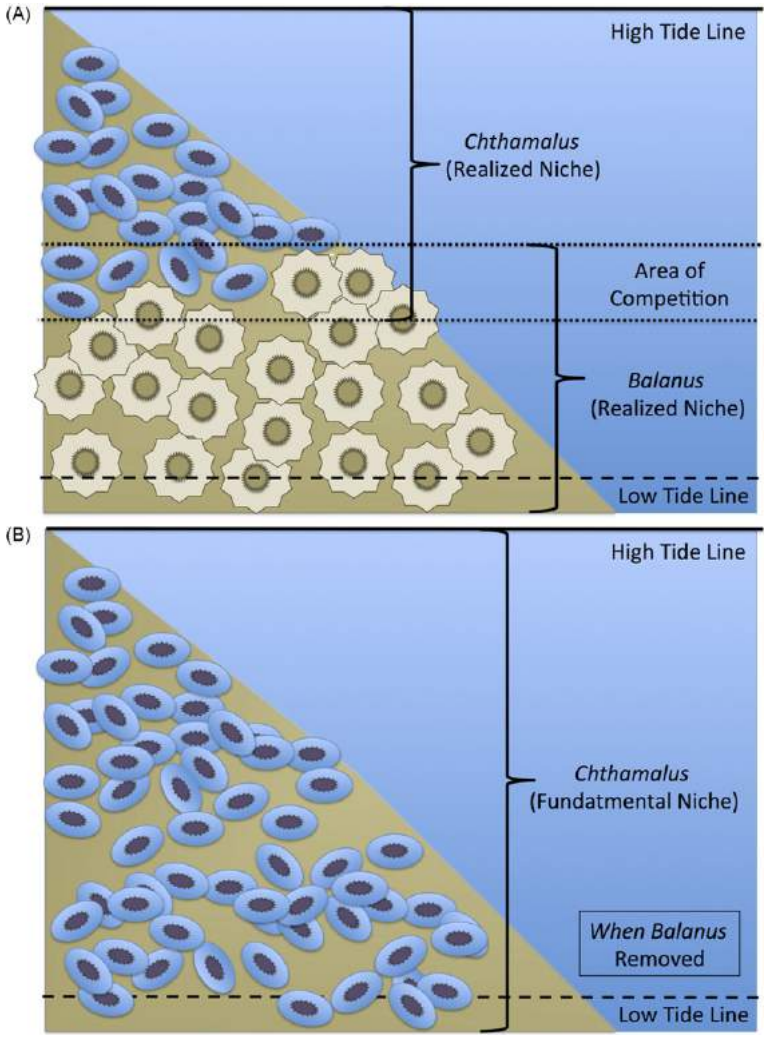

Fig. 10 Competition between two genera of barnacles, *Balanus* and *Chthalmalus*, for attachment space on intertidal rocks with (A) showing the outcome of competition when both species are allowed to colonize while (B) shows how *Chthamalus* spreads when *Balanus* is experimentally removed from the substrates. Figures redrawn from Connell, J. H. (1961). The influence of interspecific competition and other factors on the distribution of the barnacle Chthamalus stellatus. *Ecology*, ***42***, 710.

ornaments such as antlers, body size, gonads, song or behavior (Ricklefs and Relyea, 2014). Male size is often given as an example of sexual selection, where larger males often win out in competitive interactions with other males and either acquire the female, or based on the outcome the female chooses the winning male. This has been shown in many animal species, including classic examples of primates such as gorillas and other mammals (e.g., bears), fish, reptiles, and birds. When males compete with other males, sexual dimorphism can favor enhanced weaponry among males for physically competing to procure female mates, such as in some sheep (**Fig. 11**). Temporary weapons such as antlers of deer, elk, and moose as well as more permanent weapons such as horns of some sheep and mountain goats.

The evolution of female choice among competing males is tied to those features or behaviors that improve her fitness. Preferences by females generally are grouped within two types: (1) those that provide material benefits, such as food resources and; (2) those do not provide material benefits, such as shared parental care (Ricklefs and Relyea, 2014). Female choosiness may be connected to physical differences among males such as the covert feather length among male Resplendent Quetzals (*Pharomachrus mocinno mocinno*) or Wire-tailed manakins (*Pipra filicauda*), or behavioral differences such as courtship displays and dances among a variety of birds. In both cases, females choose males with longer outer covert feathers. The evolution of courtship behaviors especially among birds has driven male-to-male competition in terms of display dances or longer courtship songs especially among birds of paradise, bower birds and manakins in which the female chooses the male with the best dance, song or bower. There are two explanations as to why females might choose a male with a longer tail feather or a bower with better ornamentation, these include the good gene hypothesis and the good health hypothesis. The former refers to the female choosing a mate that might possess a superior genotype and the latter refers to female choice based on choosing the healthiest male (Ricklefs and Relyea, 2014): both traits are hypothesized to be beneficial to the females ultimate offspring.

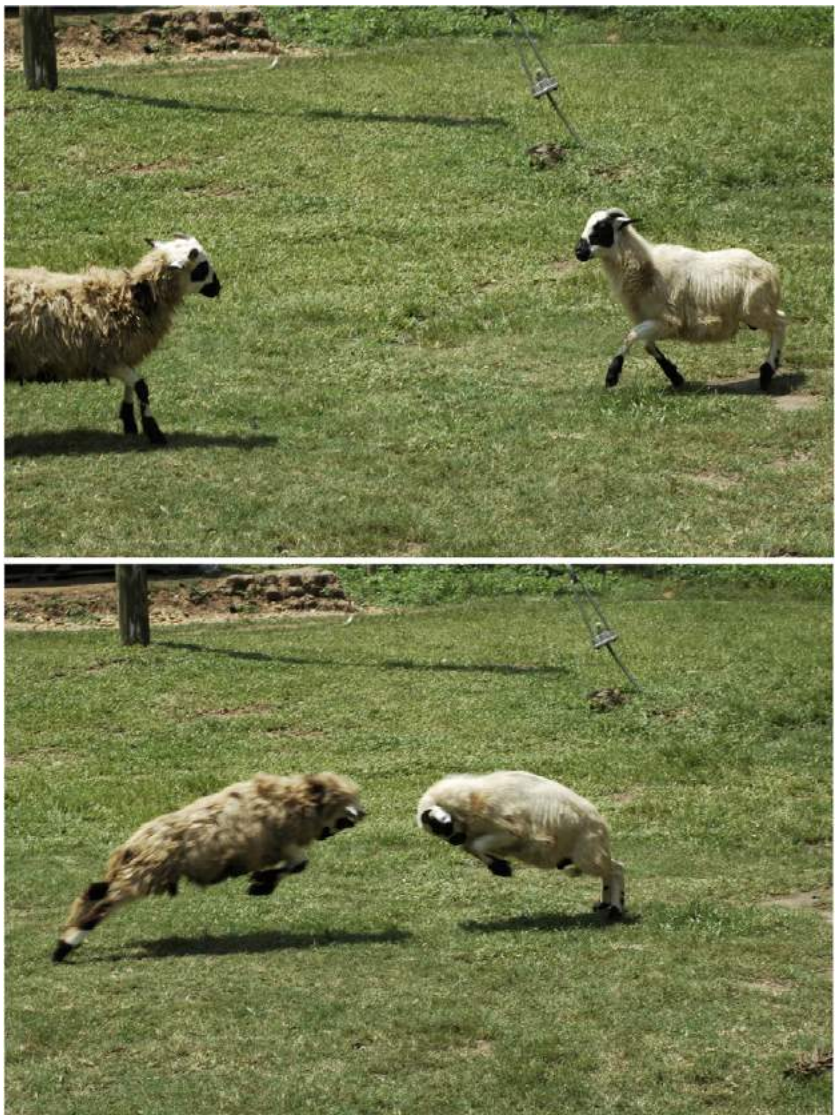

Fig. 11 Mate competition by two male sheep for access to a female. *Upper panel* showing males backing up from each other to get a running start. *Bottom panel*, males begin running toward one in other for a head-to-head collision. This competition can last hours until one is too hurt or tired to continue, losing access to the female. Photo Credit: M. Eric Benbow.

Limited Resources and Population Effects

Resources can be viewed as either renewable, or constantly regenerated, of finite and limited. An example of a renewable resource is the annual regeneration of seeds that are competed for by herbivores such as rodents and ants. A nonrenewable resource is one that is not regularly regenerated, such as colonizable substrata in a rocky intertidal zone (e.g., barnacle competition discussed above), or shelters as in the case of hibernating bears that require protection from freezing temperatures during winter months of very limited food (Ricklefs and Relyea, 2014).

Other types of resources that are the objective of competition are known to limit survivorship, growth, development, and reproduction of organisms. For example, silica in freshwater systems can decline in concentrations that limit growth and survivorship of some species of diatoms in aquatic ecosystems. While the silica is not a food resource, it is necessary for the structure of diatom cells (see below). A similar limiting resource is calcium carbonate in aquatic habitats that provides the structure to protective shells of clams and snails: if calcium carbonate is low in certain habitats, the protective shells are weaker, making the snails or clams more susceptible to predation. If there are multiple species in these aquatic habitats, the better competitor may use more of the silica or calcium carbonate, thereby having a negative effect on the other species that require and compete for these resources. Thus, competing organisms can reduce the availability and abundance of both renewable and nonrenewable resources having significant effects on the population growth and fitness of competing organisms. This phenomenon where a species population growth and survivorship are impacted by a limiting resources is known as Libieg's Law of the minimum.

By understanding what the minimum amount of a particular resource is for species, scientists are able to predict test for the outcome of competitive interactions by using both field and laboratory experiments. For instance, laboratory experiments by Tilman *et al.* (1981) illustrated how diatoms, *Asterionella* and *Synedra* competed for silica. Both freshwater diatom species require silica to construct their cell walls and in a series of elegant laboratory experiments Tilman *et al.* (1981) demonstrated that when either *Synedra* or *Asterionella* colonies were grown alone, both species of algae were able to reach stable populations levels even when the concentration of silica was experimentally reduced (see figures in Tilman *et al.*, 1981). However, when both species were grown together in the same aquarium, *Synedra* outcompeted *Asterionella* by reducing silica levels to a point at which *Asterionella* became extinct. The outcome between these two species of algae competing for silica is termed asymmetrical: while both species suffer negative effects, the harm is greater to *Asterionella* being the inferior competitor for the resource. As Darwin suggested and has been demonstrated through many studies, competition between species can influence the structure of ecological communities as well as the processes that create them. This result, where the superior species becomes dominant and thrives and the inferior species becomes locally extinct illustrates the principle of competitive exclusion (Bowman *et al.*, 2017). This principle states that when two species are limited by the same resource, they cannot coexist indefinitely if this resource is used the same way and one differentially acquires it over time (Ricklefs and Relyea, 2014).

In natural communities many species are able to coexist in some fashion despite sharing similar limiting resources. This situation is known as competitive coexistence (Bowman *et al.*, 2017). In order for competitive coexistence to occur, the competing species must be able to partition the limiting resource—sometimes referred to resource or niche partitioning. For example, in headwater streams of the northeastern United States, two species of stream dwelling caddisflies, *Pycnopsyche luculenta* and *Pycnopsyche gentilis* compete for leaves, wood and stones to construct larval cases used for to maintain balance in flowing systems. Both species are shredder caddisflies that feed on coarse organic material such as leaves. The life histories of these species overlap exactly, emerging as adults in the fall during leaf abscission, laying eggs from September to November, and growing as larvae from November to June the following year. Both species utilize leaves that they cut into disks and either arrange them so that they are made into flat cases or triangular in cross section during the winter or until larvae molt into the fifth larval stage (usually in March). By late spring, leaves are extremely limited as food or for case construction. To accommodate this reduction in leaf resource, *P. luculenta* will switch from leaves to using sticks for case construction and moves to the slow water along stream margins until pupation. In another strategy, *P. gentilis* switches its case from leaves to small stones from winter into spring and moves to the fast water of streams until pupation (Wallace *et al.*, 1992) (**Fig. 12**). Thus, competitive coexistence results from each species switching the limiting resource for case construction to alternative sources and by also moving to occupy different habitats where the alternative resources are more common.

In a terrestrial example, four species of Jamaican *Anolis* lizards were used as models to study resource partitioning (Schoener, 1974). Living together in the same trees and eating similar food, these four species separated themselves along the height and thickness of the perches of the trees. Similar to the caddisfly example above, the lizards spatially partitioned tree habitat and their food resources in order to compete less for these resources and coexist in the same tree. In addition to these examples of how competition can lead to coexistence, there are also other factors that affect the dynamics and outcomes of competition in ecosystems.

Anthropogenic Factors Affecting Competition

Competitive interactions among taxa can be fueled by either natural or anthropogenic activities. So far in this article only natural activities; however, anthropogenic (human-associated) activities can also affect competitive interactions and their outcomes. Fire suppression in parts of the southeastern United States in the early part of the 20th century is one example of how human modification to ecological processes affected the outcomes of competition. In this example, longleaf pine trees (*Pinus palustris*) dominated many forests of the southeast when human-induced fire suppression allowed this woody tree species to outcompete the grassy, herbaceous understory (Ricklefs and Relyea, 2014). The competitive interactions among herbaceous and woody species in this region were altered when fire suppression was stopped and fires were allowed to sweep through the area. Grasses such as the wiregrass were able to become established and reproduce because the fire frequency reduced the establishment of the longleaf pine trees, thus reducing its competitive ability. Fire managed habitats that were allowed fires at an intermediate frequency provided conditions where both species could coexist and also allowed for a greater overall plant diversity in these areas.

Another example is the anthropogenic reintroduction of once locally extinct wolves back into the Yellowstone National Park ecosystems. In this case, the disturbance was the hunting and removal of wolves from these areas by humans. When these apex predators were reintroduced into these systems the interactions of herbivores such as deer and elk, were found to shift the outcomes of competition among plant species: the grazing pressure of large ungulates such as deer and elk allowed for different plant species to thrive and flourish, allowing for competitive coexistence, and having additional effects on the numbers and diversity of smaller herbivores (such as mice and rabbits) that compete for herbaceous plant species in the ecosystems (Ripple and Beschta, 2004). This example demonstrates how complex ecosystems can be and that changes in certain biotic interactions (such as predation) have widespread ecological effects that are often mediated through shits in competitive outcomes for resources.

The introduction of nonnative species into new environments has had profound impacts on not only competition among native taxa but also reducing biodiversity in these systems. Native taxa have succeeded and evolved because of competitive success in these systems among native competitors. However, introducing an invasive species from another region may introduce a new

Fig. 12 Comparison of *Pycnopsyche gentilis* larval cases made from winter, transitional, and late spring materials. The larvae change their case construction to reflect resources in the habitat to avoid competition with other case building caddisflies (e.g., *P. luculenta*). Photo Credit: Bob Henricks.

competitor into the native ecosystem. Many examples have demonstrated that these invasive species may be better competitors than the native species, thus, becoming established and successful in spreading. For example, introductions of nonnative taxa into aquatic systems are a growing problem worldwide. The introduction of freshwater mussels whether they are zebra mussels (*Dreissena polymorpha*) into the Great Lakes or quagga mussels (*Dreissena rostriformis*) into the Colorado River in the southwest United States and other aquatic systems, is changing competition among other filter feeding organisms in these massive aquatic systems, as well as other organisms competing for food and space on substrate attachment sites (Strayer, 1999).

Another example is the introduction of the Nile perch and Nile tilapia into Lake Victoria in the late 1950s that not only caused a devastating decline in native haplochromine cichlid diversity but also caused shifts in cichlid mouthpart morphology and habitat preference. These biotic shifts changed the competitive outcomes among cichlids for different food types after the introduction nonnative Nile perch (Bwanika *et al.*, 2006). The Nile perch introduction led to the disappearance of several trophic groups of cichlids that in turn released macroinvertebrate species from predation. The released predation of macroinvertebrates, a major food resource of the insectivorous haplochromine cichlid (*Haplochromis pyrrhocephalus*), caused a resurgence of the haplochromine ciclid. The resurgence of this species was due to the increase in macroinvertebrate prey that was the shard resource by the other cichlid competitors; thus, the introduction of a nonnative species had foodweb wide effects that shifted competitive interactions and outcomes of several cichlid species (Bwanika *et al.*, 2006).

In addition to aquatic examples, terrestrial nonnative introductions have also had significant impact on ecosystems through changing competitive interactions. One classic example was the introduction of rabbits onto the continent of Australia. This introduction had numerous negative impacts, where rabbits were so abundant that they outcompeted native grazers such as

kangaroos for food. As burrowers, the high populations of rabbits also had significant impact on competing native burrows such as the only burrowing kangaroo, the boodie, but also with burrowing bandicoots (Stilling, 2002). Most recently, the introduction of Burmese pythons and African rock pythons into the Everglades National Park has created food resource competition with the American alligator. The alligator was the apex reptilian predator in the region but it has been replaced with these large nonnative pythons. Burmese and African rock pythons have caused a decline in mammalian diversity within the park but they have also outcompeted alligators for this food base such that alligators have now entered the food chain for pythons (Dorcas *et al.*, 2012). The outcomes of both native and anthropogenic species competition continue to be studied at both mechanistic and descriptive levels of inquiry with much research into developing and testing predictive models.

Modeling Competition and Predicting Outcomes

Population ecologists have long been interested in the factors that lead to population growth and decline, and one such factor is the role competition plays between populations of different species that share common resources. Such interactions can be modeled in several ways, but one classic and relatively simply approach has been the Lotka–Volterra competition model when such a resource is limiting between two different species. In general terms, the exponential growth of a population can be described by the following logistic growth equation:

$$\frac{dN}{dt} = r_1 N_1 \left(1 - \frac{N_1}{K}\right)$$

In this equation, $N =$ population size and the term on the left represents the rate of growth over a period of time. On the right, r is the intrinsic rate of increase, or maximum possible growth rate, for population N. The part of the equation on the far right factors in the carrying capacity of N_1, or the number at which the population tends to stop increasing: this term of the equation represents intraspecific competition for resources. This equation is quite useful if one wishes to examine the effect of competition between two different species on their population growth rate. To account for species interactions, one must consider competition coefficients (α and β). As defined by Ricklefs and Relyea (2014), these competition coefficients account for the interactions between the number of individuals of species 1 and the number of individuals of species 2. Now, using two equations that denote species 1 and 2 with subscripts, we are able to consider the effects of either species on the growth rate of the other; thus, allowing one to examine interspecific competition for a single resource:

$$\frac{dN_1}{dt} = r_1 N_1 \left(1 - \frac{N_1 - \alpha N_2}{K_1}\right)$$
$$\frac{dN_2}{dt} = r_2 N_2 \left(1 - \frac{N_2 - \beta N_1}{K_2}\right)$$

Both sets of equations examine how population size fluctuates relative to the carrying capacity of the environment. Moreover, these equations can be used to explain the dynamics between populations of species 1 and 2; that is, how their respective abundances change together. These relationships can be viewed graphically (**Fig. 13**). In this figure, when population N_2 is absent,

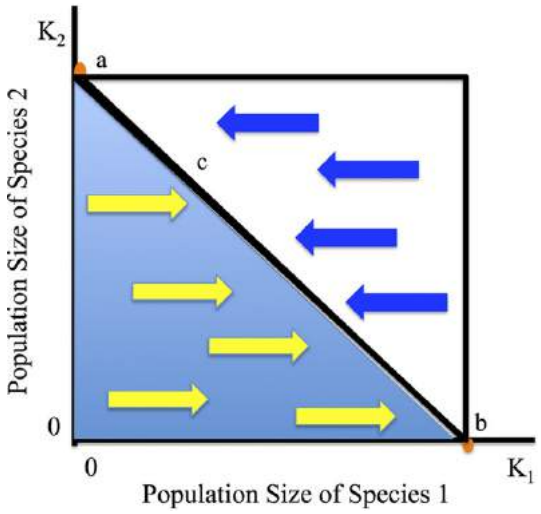

Fig. 13 Schematic represents changes in the population size of species 1 when competing with species 2. Populations in the *blue shaded* area will increase and reach an equilibrium along the diagonal line. Populations in the *unshaded area* will decrease as they approach the diagonal line. The letter a represents all resources being taken up by species 2 and none left for species 1; letter b represents no individuals of species 2 present and; letter c represents the zero growth isocline. From Stilling, P. (2002). *Ecology: Theories and applications.* Upper Saddle River, NJ: Prentice Hall Publishers—with permission.

population N_1 will increase until it reaches the carrying capacity. However, if this habitat is filled with population N_2, then N_1 cannot increase because N_2 has reached K_2. There are many combinations of N_2 and N_1 and these points fall along the diagonal line called the zero-growth isocline as described by Stilling (2002). When these figures are overlayed and vectors are added, there are four possible outcomes between these interacting populations: (1) species 1 becomes extinct; (2) species 2 becomes extinct; (3) depending on initial densities of both species, either one goes extinct and; (4) the two species coexist (Stilling, 2002). While quite simple, these modeling and visualization approaches are useful for testing how competition over resources affects the population growth of species. By understanding how and why populations change in nature and in response to biotic interactions, scientists can better predict how certain species will change over time and in response to a changing environment. This information also is important to understanding why species are distributed in certain environments and why some species are able to disperse and establish in many habitats, while other species are restricted to certain regions, ecosystems or local habitats. Many models are more complex and incorporate population responses to both abiotic and biotic conditions in efforts to predict the outcomes of changing environments on the distribution and abundance of species. These predictions are important for both understanding natural dynamics of ecosystems and for guiding natural resource management locally, regionally, and globally.

Conclusions

Ecosystems are community networks of organisms and populations of many species that interact within habitats that are defined by abiotic conditions that establish the initial restrictions to growth, development, and reproduction of a population. These conditions define the background within which organisms of each species interact in ways that change how they acquire necessary resources such as food, water, space, shelter, and mates that allows for continuous feeding, dispersal and reproduction; all factors that allow for each species to be sustained in the environment. While there are many ways that species interact for access to these resources, competition both among individuals of the same species and among individuals of multiple species often have strong and impactful effects on the coexistence or extirpation of species from habitats and ecosystems. Sometimes competition comes in the form of directly interacting with the other species, inhibiting them from acquiring the resources, or more indirectly through consuming the resources, and thus reducing them for the other species. It can also be much less obvious and more difficult to observe or quantify, as in the case of apparent competition. Nevertheless, the competitive interactions of species often define how scientists understand why and how species are distributed in different habitats; act as an area of research for understanding why certain human activities may affect the distribution and existence of species; and can be quantified to make predictions of species population biology dynamics in a changing world. Understanding and having the capacity to model such interactions provides scientists tools for defining factors that define ecological systems and the natural world, and for making predictions of how organisms, populations and communities respond to human-induced environmental changes.

Dispersal–Migration

AP Ramakrishnan, Portland State University, Portland, OR, USA

Introduction

Dispersal, or the movement and subsequent breeding of individuals from one area to another, strongly influences the population dynamics of a species. Dispersal can help regulate population size and density; many animals, such as aphids and female root voles, have increased dispersal rates under high density situations. Sometimes low density instead of high density is associated with greater dispersal rates. For example, during range expansions, peripheral populations of some grasshoppers may experience higher dispersal rates though they are of lower density than central populations, probably because of fitness costs associated with morphologies specialized for dispersal.

Such dispersal events can have large effects on neighboring populations. Marginal populations that are subject to high rates of immigration may experience a rescue effect, where despite poor genetic or ecological conditions, populations are able to persist. On the other hand, high dispersal rates can inhibit adaptation to novel environments due to constant influx of nonadapted individuals. Small populations that experience high rates of emigration may have a higher probability of extinction under such situations.

Natural populations in highly fragmented areas, such as agricultural or urbanized settings, may not experience sufficient levels of dispersal. Lack of dispersal can lead to high rates of inbreeding, which can lead to decreased fitness in many species. Because dispersal can have such strong effects on populations, dispersal patterns and processes are important when considering the potential spread of a biocontrol agent, pathogen, or invasive species into a new range. Dispersal also has implications for species redistributions due to climate change, as the dispersal rates and distances of a species will affect its potential to shift its range in response to climate change.

Two types of dispersal are commonly distinguished: natal dispersal, which is movement and subsequent breeding away from the birth territory or area, and breeding dispersal, which is movement from one area to another after the first breeding season. Dispersal of spores, or haploid life stages (such as pollen), strongly affects patterns of gene flow in a species, but the process is not generally considered to be directly associated with population dynamics. Dispersal in plants is generally limited to natal dispersal, as little to no secondary movement is possible, while many animals disperse multiple times.

All species disperse to some extent, in part because resources become limited locally as populations grow. Seedlings of plants must grow at some distance from the parent plant in order to obtain enough water, nutrients, and light to survive. Similarly, animals must disperse to avoid competing for resources such as mates, food, and territory. Depending on intraspecific patterns of resource limitation, dispersal is often sex-biased. In mammals, females tend to disperse more often than males; the trend is reversed in birds.

In areas with high temporal environmental variation, or in areas prone to frequent disturbances, species with greater dispersal abilities are expected to have a greater likelihood of survival. When one population's habitat is rendered untenable, if the species has a high dispersal rate, many individuals in that population will be able to move to a more suitable area. In the case of nonmotile organisms such as plants, high dispersal rates increase the likelihood that another population may be established even as the original population is rendered extinct. When studying populations that specialize in habitats with high temporal environmental variation, it is sometimes appropriate to distinguish between spatial and temporal dispersal. For example, many animals and plants that live in deserts with unpredictable rainfall will produce desiccation-resistant embryos that delay maturity until favorable environmental conditions cue further development. Instead of traveling long distances to reach suitable habitat, the individuals produce offspring that are able to lie dormant until the habitat is once again suitable for survival and reproduction. Because dispersal can enable escape from low-quality environments and access to higher-quality resources, many species that specialize in colonizing disturbed areas tend to have greater dispersal abilities than species that live in relatively stable habitats.

In some cases, dispersal can have a high cost associated with it, especially if individuals that disperse experience a higher mortality rate than those that do not disperse, or that disperse only a short distance. Because individuals are moving to an area that may not be as productive, and because they may have to travel through unsuitable habitats, mortality rates during the dispersal process may be high. The number of individuals that successfully establish in a new area may be far fewer than the number of individuals engaging in the dispersal process. In plants and other organisms with no choice involved in the dispersal process (passive dispersal), many propagules may never establish simply because they land in an unsuitable habitat. In animals where some choice may be involved in the final dispersal location (active dispersal), survival of dispersing individuals may be higher than individuals of species with passive dispersal, but there are still risks associated with dispersal, such as locating an appropriate territory, finding a mate, and successfully breeding in the new area. However, the benefits of dispersal can overcome the costs if mates and/or resources are limiting in the home range.

The process of dispersal is not necessarily as simple as suggested above, as it involves both emigration (leaving the original patch) and immigration (entering a new patch). The entire process of dispersal can be divided into approximately four different

stages: (1) emigration, (2) exploring or traveling through the surrounding habitat, (3) immigrating to a different patch, and (4) successfully breeding in the new patch. Each of these stages has a cost involved. Leaving the original patch involves leaving an area where resources are known to exist, but may have become limiting. The exploratory phase of dispersal can involve a high risk of mortality, as the individual may have to travel through territories with inadequate resources. In many plants and other passive dispersers, the exploratory phase entails a high rate of mortality, as seeds often land in areas unsuitable for growth. Even when a propagule successfully disperses to a hospitable environment, it may not be able to establish there, due to mortality rates associated with establishment. The risks involved with emigration, exploratory movement, and settling in a new patch can be outweighed by the potential benefits of dispersal if successful dispersal significantly increases the fitness of the individual.

There are varying degrees of active and passive dispersal, with many species exhibiting intermediate levels of participation in the dispersal process. In many animals, dispersal is active, involving a high level of choice during the dispersal process. In passive dispersal, there is little or no choice involved in selection of the final location. In many insects, many marine animals, and all plants, dispersal is largely passive, depending on air currents, water currents, or on the actions of vectors transporting the propagule. Larvae of many marine animals are often dispersed solely at the whims of the currents or in ship ballast. Insects are often at the mercy of the wind when entering a dispersal phase, especially if they cannot generate enough speed to overcome wind velocities. However, even dispersal of small insects need not be completely passive. Small insects, even if they are not large enough to overcome wind velocity, can have some level of choice as to where they land. They can begin exiting a wind stream when they decide to settle, then make short, self-powered trips to explore the surrounding area and find a suitable habitat.

Though considered passive dispersers, plants can regulate dispersal to some extent. Seed size, shape, and seed coat construction vary among species. Seed morphologies that aid dispersal include barbs (for attaching to animals), eliasomes (for attracting ants as dispersal vectors), or pappus scales (to assist in wind transport). However, because the seed itself is not actively involved in the decision process, it is still a passive process.

A species with little innate dispersal ability may be able to move greater distances and have higher survival than expected if it has the ability to be spread by a vector, such as ants, birds, or other animals. Plants commonly use vector-assisted dispersal, and there are many instances of adaptations by plants to use animals as dispersal agents. For example, mistletoe seeds are eaten by birds which then fly to another tree. The seeds are adapted to survive the digestive tract, and are subsequently deposited on the tree where the bird lands, which is usually a suitable tree for growth. Such assisted dispersal can lead to dispersal distances that would be impossible to achieve otherwise.

Most vector-associated dispersal regimes have evolved over hundreds of generations. Recently, however, many species of both plants and animals have serendipitously become associated with novel and extremely efficient dispersal vectors. Species associated with humans have always been dispersed in concert with human movements. However, the last few generations of humans have seen an exponential increase in the rates of movement around the globe. Many terrestrial and marine species have been spread at unprecedented rates through ship ballast and packing materials. In addition, ornamental plants and agriculturally associated species are deliberately transported from one location to another by humans, at distances and rates that would be impossible for each species to accomplish under its own power. Hundreds of species involved in these accidental experiments in dispersal and evolution have benefited tremendously, becoming the world's invasive species. Species such as cheatgrass in North America, *Caulerpa taxifolia* (an alga) in the Mediterranean, and the Nile Perch in Africa have successfully outcompeted hundreds of native species, often driving them to extinction.

Dispersal Patterns

There are several terms associated with dispersal patterns. Dispersal distributions, or dispersal curves, are frequency distributions of the proportion of individuals moving different distances; dispersal kernels are probability density functions used in modeling dispersal. Because a dispersal kernel describes the probability of a seed landing within a particular region, dispersal curves can be calculated from dispersal kernels. Dispersal modeled with a simple diffusion equation (a Gaussian kernel) generates a normal distribution curve, due to the random Brownian motion assumed in such simple diffusion models. Though accurate for some species, most species appear to have leptokurtic, or long-tailed dispersal curves.

The shape of a dispersal curve drastically affects estimated rates of population expansion, with normal curves having lower expansion rates than dispersal curves with longer tails. The fatter the tail of the distribution, the greater is the speed of the range expansion. Accurately estimating the shape of the curve is important, for example, in predicting spread rates of spread of the emerald ash borer. Rates and pattern of spread are often consistent with simple diffusion; however, some infestations in Michigan do not spread via simple diffusion, but have a higher frequency of long-distance dispersal events. If all control efforts and spread rate predictions are based on simple diffusion, management programs will be unprepared for long-distance dispersal events and the efficacy of management efforts will be greatly diminished.

If the tail is exponentially bounded, as in curves with moderately fat tails (i.e., a Laplace distribution) (**Fig. 1**), then models predict that the rate of expansion of a population will remain constant. However, in curves with unbounded tails (very fat tails, i.e., a Weibull distribution), the rate of expansion of a population can actually increase over time. Because different dispersal curves can drastically affect estimates of population expansion, it is important to choose appropriate dispersal curves when attempting to predict species' population dynamics.

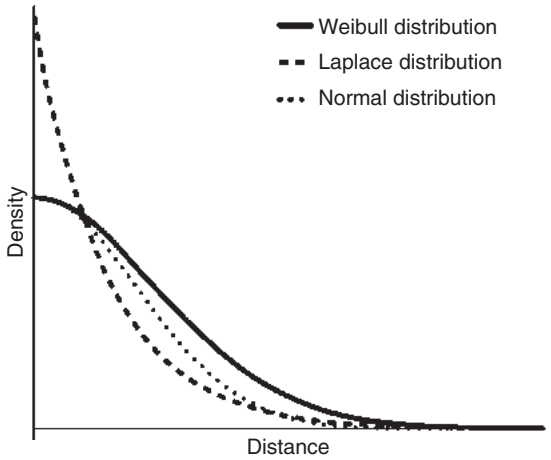

Fig. 1 Normal curves are drawn in each graph for comparison. The Laplace distribution is more peaked than the normal curve, and leptokurtic. The Weibull distribution shown here has a fatter tail than both the normal and the Laplace distribution. Graphs by Hyrum Paulsen.

Modeling Dispersal

A simple model of a species consists of one population, infinite in size, randomly mating, with no immigration or emigration. This idealized situation is never found in nature, though populations can approach this equilibrium. In real life, species are divided into populations that are subdivided to some extent, with dispersal occurring between the subdivisions at varying degrees. However, the idealized situation is often a good starting point for modeling species dispersal. Models investigating the effects of dispersal on population dynamics use several different approximations of natural situations. One of the simplest models of dispersal is a model proposed by Levins in 1969, one of the first metapopulation models. This model describes the colonization and extinction dynamics of sites under different rates of colonization (dispersal) and mortality. An individual produces offspring which then disperse to other sites. When a propagule reaches an empty site, it occupies it completely, and any propagules reaching that same site are subsequently eliminated. This model is termed a metapopulation model because it deals with colonization and extinction of sites. Though originally formulated as entire sites that are either colonized or not colonized, it can be viewed as a collection of sites where each site is the size of a single individual. In this way, a simple equation can be used to model the spread of a population through dispersal:

In this equation, the basis of the Levins model,

$$\frac{\partial s}{\partial t} = cs(1 - s) - ms$$

s represents the proportion of sites colonized, c is the rate of propagule production, and m is the mortality rate. Though not spatially explicit, spatial relationships are implied in this model by having a proportion of sites either available or not available. Some of the assumptions this model makes are that propagules are distributed randomly, and that each propagule can occupy any space in the habitat. A proportion of sites will be filled until the population reaches an equilibrium, determined by the relationship between the rates of mortality and propagule production. The population will grow at a rate that increases with lower mortality rates and increased propagule production. As long as mortality rates are less than propagule production, the population can persist. Though extremely simplified, this model has led to some interesting predictions about population dynamics. Because the final density of individuals is dependent on mortality rate in addition to propagule production, it will be impossible for a species to occupy every suitable patch in the population's habitat. When one individual dies, the point it occupied is empty until recolonized by another propagule. Thus, the population reaches an equilibrium where a certain percentage of sites are empty, rather than completely filling the entire habitat.

Though this model yields some interesting predictions about the way population dynamics depend on propagule production and mortality rates, one of the drawbacks of this simple approximation of dispersal is that propagules in real life cannot occupy any unoccupied site in a habitat. Real dispersal is restricted in distance, with a large spatial component that is only implied in the basic Levins model. The spatial component of the model is unrealistic, being essentially infinitely large and infinitely accessible.

To observe the effects of dispersal on population dynamics in more realistic situations, greater spatial detail is required. Incorporating spatial information into a model of dispersal is relatively simple by using a cellular automaton or lattice model. This type of model does not have an explicit mathematical solution but can be evaluated through simulations that can lead to predictions about population dynamics based on certain assumptions. In this type of model, individuals are placed on a grid of polygons. Each individual has a certain chance of mortality and of producing propagules. A propagule can travel a certain distance away from its current position, and its direction can be determined by either having the propagule move through a side or corner of the parental polygon. The propagule can be restricted to land within a certain area or not restricted at all. Again, any propagule that lands in an occupied site is lost. Parameters in these models are relatively simple to modify, and any combination of

requirements can be included. Different dispersal distribution curves, rates of long-distance dispersal, habitat extinction, propagule production rates, and mortality rates can all be included. However, more complex models will require more computational power, and they may not be as applicable to multiple species and/or situations as are more general models. One of the interesting predictions made by relatively simple cellular automaton models is that the distributions of individuals will be aggregated, even in a homogenous environment. The amount of aggregation of individuals depends on the average dispersal distance, the mortality rate, and fecundity. Some of these models have demonstrated that patchy spread is likely during population expansion simply through the stochastic nature of mortality and propagule dispersal distances. This is an important prediction, as patchiness need not be the direct result of unsuitable habitat, but instead can be merely the product of different dispersal patterns. Cellular automata models are often used in epidemiology, and have also been applied to species invasion dynamics.

Cellular automaton models are accurate if space, time, and population dynamics are best represented as discrete variables. In a species where many parameters are known, it is possible to reach a high degree of specificity in the simulations, which may be useful when trying to predict what may occur for a particular species under different scenarios. Less-specific models, though less applicable to a single species, can lead to more generalized predictions about the effects of dispersal on population dynamics.

Often, it is convenient to model a population or set of populations more generally, using mathematical equations. One such model involves a reaction-diffusion equation, describing the rate of change of the number of individuals in a population (N) over time (t):

$$\frac{\partial N}{\partial t} = rN\frac{(K-N)}{K} + D\frac{\partial^2 N}{\partial x^2}$$

This model consists of two parts: the reaction portion of the equation (which describes how the population acts in the absence of dispersal) and the diffusion portion (which is a partial differential equation that describes the movement of individuals in the population). The reaction portion can be as simple as the logistic equation for growth of a population, shown here immediately to the right of the equals sign, where r is the intrinsic rate of increase, and K is the carrying capacity. Other models of population growth can be used as well, such as adding an Allee effect, where propagule production rate declines at a lower than expected rate at low densities (e.g., when a mate is difficult to find). The diffusion portion of the equation is usually the mathematical representation of simple passive diffusion

$$\frac{\partial}{\partial t}N(x,t) = D\frac{\partial^2 N}{\partial x^2}$$

where D is the diffusion coefficient, t is time, N is the number of individuals, and x represents space. The diffusion portion of the equation can be more complex, incorporating directional movement, changes in velocity, or interactions among individuals. Increasing complexity is not always necessary to make meaningful predictions, as the simplest version of this equation matches observations seen in mark–release–recapture studies in several animals. In models of invasion dynamics, a reaction-diffusion model produces waves of invaders that advance at a rate dependent in part on the rate of increase of the population. This type of equation is most appropriate when the environment is homogenous, all individuals have similar dispersal patterns, and reproduction/dispersal occurs constantly. Such models generally produce a smooth traveling wave front with a linear rate of spread.

To incorporate the discrete reproduction events (and hence dispersal events) frequently seen in plants and animals, it is appropriate to use an integrodifference equation. Integrals allow each moment in time to be dependent on the previous moment in time, thus incorporating discrete time intervals into the model, as opposed to differential equations, which assume that time is continuous. Integrodifference models consist of two main parts: a dispersal kernel (a function that describes the dispersal patterns of a population) and a density function.

$$N_{t+1}(x) = \int_{-\infty}^{+\infty} k(x-y)f[N_t(y)]\mathrm{d}y$$

In this equation, $k(x-y)$ represents the dispersal kernel, or an equation that describes the movement of a propagule from the natal territory, x, to the final breeding place, y. The density function describes the density of individuals at the location y and time t. The various dispersal kernels used with these types of models are often derived from empirical data. There are many different dispersal kernels that can be incorporated into these models, including long-tailed (leptokurtic) kernels and other non-normal dispersal distributions. When production of propagules is not continuous, as is true in many animals and plants, this type of integrodifference model will better approximate reality than a reaction-diffusion model. In contrast to reaction-diffusion models, integrodifference models can show an accelerating rate of spread over time if long-distance dispersal is relatively common. Integrodifference models are more consistent with observed patterns of range expansion than reaction-diffusion models because of the accelerating rate of spread often observed. The waves of invasions seen in these models have smooth fronts, similar to the reaction-diffusion models. Space is still represented as continuous in these models, and spatial relationships are implicit, not explicit as in cellular automata/lattice models.

There are many other models that can be used to investigate the effects of dispersal on population dynamics. Stratified diffusion is a variant of the reaction-diffusion equation, where a proportion of individuals are assumed to travel long distances. Stratified diffusion models have accelerating rates of spread, similar to the integrodifference models. Metapopulation models are very applicable to modeling dispersal patterns and rates of spread, and are also applied to other problems in ecology such as persistence of groups of populations in specific spatial arrangements under various scenarios of habitat destruction. They are commonly associated with biogeographical studies. A variation on integrodifference equations that includes stochastic population dynamics (nonlinear integrodifference models) shows waves of invasion that are patchy, with variable spread.

Measuring Dispersal

Direct Measures

Generating an accurate picture of the entire process of dispersal in a species involves detailed demographic analyses in addition to tracking emigrating and immigrating individuals. In order to know what demographic parameters drive effective dispersal, it is important to know how many individuals leave, survive the exploratory process, and breed successfully in the new area. Ideally, all parameters of dispersal should be quantified. However, because the dynamics of a population are directly driven by effective dispersal, it may be unnecessary to conduct detailed studies of each stage of dispersal, depending on the particular goals of the researcher.

Mark–recapture methods and demographic analyses can assist in the estimation of many dispersal-related parameters, and though the route traveled by the individual captured in a new patch is often unknown, it is still possible to gain an estimate of immigration and emigration rates. Many studies focus on relatively local effects of dispersal, studying population dynamics in a few interconnected populations that are spatially tractable. These studies involve either mark–recapture methods, genetic methods, seed traps (for plants), or radio- or satellite-tracking methods. Animals and seeds can both be marked using tags, paint, or dyes. Tracking methods, such as by radio telemetry or satellite, show great promise for obtaining detailed information on dispersal patterns, especially on the tail of the dispersal curve. Genetic methods are becoming popular as well, because they can detect effects of very low rates of dispersal over long distances. Each method has advantages and disadvantages, and all these methods have assumptions and uncertainties associated with them, which must be taken into account when analyzing data and estimating dispersal curves.

Collecting data from the tail of the dispersal curve can be difficult, either hampered by the difficulty of maintaining sampling densities, or due simply to the rare and stochastic nature of long-distance dispersal events. The importance of long-distance dispersal in estimating the spread of populations was highlighted in scientific literature when the rate of post-Pleistocene expansion of treesin Europe estimated with models neglecting long-distance dispersal could not account for the rapid expansion rates observed as the glaciers receded. Incorporating long-distance dispersal by modeling spread with leptokurtic dispersal curves matched the estimated rates of spread more closely. Unfortunately long-distance dispersal events are extremely difficult to measure empirically, and hence estimating them has since received much attention.

For animals, one way of estimating dispersal patterns involves marking and releasing animals, then observing the animals when they are collected, usually during an annual harvest. In the case of mark–harvest methods, animals are only viewed twice, once during the marking process, and once when harvested. This type of data may be useful for estimating mortality rates associated with movement from one site to another if it is possible to assume that the animals in question always return to either the original marking site or to the final capture site. Prior knowledge of movement patterns is important; mortality cannot be estimated if a significant number of animals disperse outside of the sample area. If multiple mark–capture episodes are accomplished in one season, it is possible to estimate probabilities of survival and movement for a specific area. However, no models currently can estimate dispersal from one area to another using this type of data.

In a similar method, animals are marked, released, then re-sighted or recaptured and released again. Animals may be sighted multiple times with this method, and with a robust sampling design, immigration and temporary emigration rates can be estimated. If this type of method is employed on multiple sites, with site-specific markers, immigration and emigration probabilities in addition to transition rates can be estimated. If possible to employ, this type of design is quite useful, as it provides data necessary for estimating population dynamic parameters associated with dispersal. Long-distance dispersal events are difficult to detect with this method, due to the stochasticity associated with the occurrence and detection of such events.

Seed dispersal is often measured using seed traps to capture seeds at varying distances from the source. Seed traps usually involve pit traps or sticky traps placed in or near the ground. To identify seeds' origins, individual fruits can be marked, a chemical tagging method can be used, or a rare genetic variant can be used as a marker. The most common method is to measure the densities of seed deposited at various distances from a source. Because individual plants are not identified when only density of seeds can be recorded, likelihood methods are used to model dispersal curves. Seed traps work well for estimating dispersal curves near the source, but as distance from the source increases it becomes more and more difficult to detect dispersal events. If enough traps are used, long-distance dispersal events can be detected; however, such events will be rare, and their detection will be dependent on the resources available to the researcher.

Radio telemetry and satellite tracking provide excellent data, when practical. Such studies have documented that long-distance dispersal events are more common than estimates from mark–recapture methods suggest. Most studies involve large- to medium-sized animals, including marine mammals. Invaluable information about the long-distance travels of these animals has been collected, including information about movements of some seabirds. Ideally, a large proportion of a population could be followed individually, and detailed analyses made of their movements. In order to accomplish this, the radio or satellite transmission units should not inhibit movement or survival, and the batteries should be strong enough to allow signal detection at a distance for a long period of time. As technology advances, smaller tags can be used. For example, very small radar tags have lately been adapted for use on bumblebees, showing promise for generating detailed dispersal data for larger insects.

Indirect Methods

Genetic methods hold promise for estimating dispersal patterns, though it is important to remember that genetic methods only measure effective dispersal, and not dispersal of individuals that did not successfully breed in the new population. In addition, for

organisms with motile gametes, genetic patterns will likely reflect the movement of gametes among populations as well as the movement of diploid individuals. Most genetic methods involve collecting DNA from immature or mature individuals, then analyzing the DNA to try and identify the origin of a particular individual. In addition, if a dispersed individual has the same genetic signature as the individuals in the new population, the dispersal event will be undetected; this becomes less likely when highly variable markers are used. Another possible drawback to genetic data is the potential for unsampled source populations to contribute to apparent gene flow estimates between two sampled populations. Also, it is difficult to generate a detailed dispersal curve using solely genetic data, especially at local distances, due to the large amounts of data that would have to be collected and the heavy expense involved. Nevertheless, genetic data enable estimation of many parameters of interest, such as historical amounts of gene flow, effective dispersal rates among differentiated populations, and dispersal rates over long distances. Genetic data are also often (but not always) easier and faster to collect than detailed demographic data. These advantages can outweigh the potential difficulties with genetic data, depending on the parameters of interest.

The first genetic estimates of dispersal were derived from Sewell–Wright's equation

$$N_e m = \frac{1}{4}\left(\frac{1}{F_{ST}} - 1\right)$$

where N_e is effective population size (an estimate of the number of individuals in an idealized population that would show the same patterns of genetic diversity or levels of inbreeding), m is migration (dispersal) rate, and F_{ST} is a measure of population structure. This equation can be used to estimate dispersal among populations using DNA sequence data, DNA markers of variable length, or allozyme (protein) markers. However, more recently the use of this equation to estimate dispersal rates has come into question based both on unlikely assumptions made when calculating F_{ST}, and on the applicability of the above equation to natural populations as opposed to idealized populations. Some of the assumptions made include equal and constant population sizes, and equilibrium between gene flow and genetic drift (stochastic variation in genetic frequencies over time). In addition, F_{ST}-based methods do not distinguish between historical and contemporary gene flow. In some cases, however, as in well-established, large populations, F_{ST}-based methods may be sufficient for estimates of dispersal rates.

Parentage analyses and assignment methods are both techniques that use genetic marker data to estimate dispersal. They both assume that source populations are discrete and that there is no genetic linkage disequilibrium (nonrandom associations of genetic marker variants due to inbreeding or chromosomal proximity) among the different markers used. Parentage analyses are based on multilocus genotypes, and can generate data about local animal movement and both seed and pollen dispersal. However, parentage analyses require extensive sampling to ensure that all possible parents in the source area have been included in the study. If a parent present in source populations is not sampled, dispersal from an unsampled (possibly quite far away) population may be inferred, potentially altering dispersal estimates. Depending on the situation, parentage analysis can be expensive enough to outweigh the potential advantages of genetic analyses over demographic studies.

Assignment methods, on the other hand, use allele frequencies, or frequencies of different variants of genetic markers, to predict from which source a particular individual came. This means that exhaustive sampling of source populations is unnecessary. It is still desirable to have representatives from all possible sources. In order to distinguish sex-biased dispersal, sex-specific markers must be used. Assignment methods assume discrete source populations and no linkage disequilibrium, and often assume equilibrium of populations. However, methods that enable dispersal estimates when populations are not in equilibrium are being developed.

A method that has come into use recently for many questions in genetics involves Bayesian analyses. Bayesian methods can be used in nonequilibrium situations, such as during range expansions, with high levels of inbreeding, or with unequal population sizes. Information known about the populations in question is entered in the analysis in the form of prior probability distributions. This information, commonly known as a prior, is basically a guess about how the populations might act based on data already available, such as experimental data. If no information is already known about the populations, an uninformative prior can be used. Then the genetic data is used, in conjunction with the prior, to calculate posterior probabilities of the data using a maximum likelihood algorithm, given the parameters currently in place in the maximum likelihood model. Markov chain Monte Carlo resampling is then used to explore parameter space and find values that optimize the fit of the parameters in the model to the data. The accuracy of detecting dispersal events with these methods is still being explored. Factors affecting accuracy of dispersal detection include the level of genetic diversity in the populations, amount of dispersal occurring among populations, how many genetic markers are used, and the level of variability in the markers themselves. Depending on the population structure in the system in question, these methods may be equally viable both for detection of local dispersal and long-distance dispersal events.

As mentioned in the beginning of this article, dispersal in the context of population dynamics usually refers to the dispersal of diploid individuals. However, especially when genetic methods are used, movement of haploid gametes can affect dispersal estimates. Male and female gametic dispersal patterns often differ, and if not accounted for, can skew dispersal estimates from genetic data. Nuclear genetic markers come from both paternal and maternal sources, due to the combination of nuclear genetic material during fertilization. If gametic gene flow is significantly different than diploid dispersal patterns, such as with pollen in many plants, care must be taken not to confuse gametic patterns of gene flow with movements of diploid individuals. In plants, for example, the male pollen often travels farther than seeds, especially if the species in question is wind-pollinated. In order to distinguish the dispersal of diploid seeds from haploid pollen, sex-specific genetic markers must be used. In plants, the chloroplast genome is generally (but not always) maternally inherited, and comparing patterns of genetic differentiation between the

chloroplast and the nucleus can be used to estimate pollen versus seed dispersal patterns. If only seed dispersal is of interest, it may be sufficient to focus on chloroplast genetic markers, if the chloroplast is indeed maternally inherited in the species in question. Similarly, markers based on mitochondrial DNA will only show dispersal patterns of the female in animals. If dispersal patterns of both males and females are desired, both nuclear and mitochondrial markers must be used.

Because different analysis techniques have different strengths, weaknesses, and assumptions, it is important to consider what the goals of a given study are, and what methods are best suited to the questions at hand. Genetic methods hold promise for dispersal estimations, as data can be gathered relatively quickly and with less cost than demographic data. However, depending on the species and/or populations under consideration, estimates may require more genetic data than are currently available to optimize the parameters of a genetic analysis technique. If this is the case, then the cost of genetic analyses could equal or exceed the costs of demographic data collection. In addition, some data must be gathered through observation, such as detailed movement patterns among sites or populations and breeding success rates. Other data can best be estimated using genetic data, such as historical patterns of gene flow or long-distance dispersal events, depending on the organism in question. As techniques for measuring dispersal and its consequences improve, we will be better able to predict the survival, extinction, range expansion, and range contraction of populations and species. These predictions will improve estimates of the effects of habitat destruction and fragmentation on populations, a growing concern at multiple scales worldwide. In addition, accurate predictions of range expansion and contraction rates based on models of global warming will enable us to prepare for the possible effects of a rapidly changing climate on both marine and terrestrial species.

Dominance Hierarchy

Hilde Vervaecke, Odisee University College, Sint-Niklaas, Belgium
Jeroen Stevens, Royal Zoological Society of Antwerp, Antwerpen, Belgium and University of Antwerp, Antwerpen, Belgium

Glossary

Agonistic dominance In an agonistic dominance relationship, the dominant animal has the power to limit the behavior of a subordinate to some extent by means of aggression or fighting abilities. Agonistic dominance is expressed in the outcome of agonistic interactions.

Agonistic interaction Agonism refers to the combination of aggression and submission. Indices of winning or losing conflicts are frequently used as operational measures of agonistic interactions such as attacks or threats and withdrawals after an attack, or the spatial yielding of one individual to another.

Cardinal dominance rank Cardinal dominance rank quantifies rank distances between individuals, based upon their relative probability of winning or losing agonistic interactions.

Competitive ability Competitive ability reflects the capacity of an individual to obtain access to limited resources (usually food access is measured).

Dominance hierarchy It is the network of dominance relations among all the dyads in a group. A dominance relationship indicates a consistent asymmetry in the probability of winning a contest of one individual over another.

Dominance position Dominance position is based on the outcome of the dominance interactions, animals occupy an ordinal position in the hierarchy, being high, mid or low ranking, or more specifically number one, two, three, etc.

Formal dominance This is characterized by ritualized communication signals and greeting rituals of which the direction among dyads is consistent and does not vary with social context.

Linear hierarchy The network of dominance relationships can result in a figurative ladder with the highest ranking animal on top and the lowest ranking animal on the lowest rung. In a linear hierarchy one individual dominates all the other individuals, followed by the second ranking animal that dominates all the others except for the highest ranking individual, etcetera. The relationships are transitive: A dominates B, B dominates C, and A dominates C.

Ordinal dominance rank The rank order of individuals based on their probability of winning or losing an agonistic interaction.

The Concept of Dominance

The concept of dominance was developed to help to describe, explain and predict social relationships. It can be defined as "an attribute of the pattern of repeated, agonistic interactions between two individuals, characterized by a consistent outcome in favor of the same dyad member and a default yielding response of its opponent rather than escalation. The status of the consistent winner is dominant and that of the loser subordinate" (Drews, 1993). Individuals rarely engage in costly fights and contests are generally resolved quickly by one retreating individual.

A *dominance relationship* indicates a consistent asymmetry in the probability of winning a contest of one individual over another. Within each dyad, the *dominance status* of each individual refers to its relative higher or lower dominance rank. The *dominance hierarchy* is the network of dominance relations among all the dyads in a group. The *rank order* refers to each animal's position in the hierarchy, that is, number one, two, three, etc. based on the outcome of the agonistic interactions. In a linear hierarchy one individual dominates all the other individuals, followed by the second ranking animal that dominates all the others except for the highest ranking individual, etcetera. The hierarchy is completely linear if for every dyad A and B, either A dominates B or B dominates A. For every triad of individuals A, B, and C, the following relationships will be transitive and not linear, meaning: if A dominates B and B dominates C, then A dominates C. This results in a figurative ladder with the highest ranking animal on top and the lowest ranking animal on the lowest rung. The index of linearity in such a system will be consistent. In a nonlinear hierarchy, intransitive dominance relationships can be found: A dominates B, B dominates C, but C dominates A, resulting in an inconsistent linearity.

The mechanisms that can generate the linearity of hierarchies are learning by experiencing dyadic wins and losses, by watching others fight (Chase and Seitz, 2011), and by assessing the fighting ability and behavioral dispositions. Hemelrijk (1999) studies the characteristics of the hierarchy by manipulating simple parameters in a computer model such as frequency or intensity of aggression in order to detect the emergent phenomena. Interactions on a lower level clarify the macrostructure on a higher level and shifts the focus from the internal complexity of individuals (learning, fighting abilities, etc.) to social interaction patterns.

The study of dominance hierarchies has received considerable interest in behavioral studies. Its value lies in its' *general predictive value* of the outcome of future, not just agonistic interactions, but other social interactions as well (Syme, 1974). Based on the agonistic hierarchy, you can generally more broadly predict the outcome of contests and the direction of other social interactions.

 doi:10.1016/B978-0-12-409548-9.10565-2

Different Types of Dominance Relationships

In general, the descriptive, predictive and explanatory value of the dominance concept has greatly improved by distinguishing between *different types of dominance relationships*. de Waal (1989) made a distinction between three types of dominance: agonistic dominance, formal dominance, and competitive ability.

In *an agonistic dominance relationship*, the dominant animal has the power to limit the behavior of a subordinate to some extent by means of aggression or fighting abilities (Nöe *et al.*, 1980). Agonistic dominance is expressed in the outcome of agonistic encounters, and indices of winning or losing conflicts are frequently used as operational measures. Since conflicts may also be resolved by deference of the loser without escalation (Drews, 1993), the spatial yielding of one individual to another may provide a good operational measure of submission or deference. When an aggression is ignored or not followed by submission of the target individual, the interaction may not express a mutually acknowledged dominance relationship. Submissive interactions are therefore usually considered as better indicators of a dominance relationship.

Formal dominance is characterized by ritualized communication signals and greeting rituals of which the direction does not vary with social context. When the agonistic dominance relationship is accepted by the subordinate, aggressive conflicts are few and the subordinate acknowledges the higher dominance status of the other by showing formalized submissive signals. This implies that the formal and agonistic dominance relationships coincide. Unidirectional signals of subordination such as the teeth baring in rhesus macaques, the bowing and pant-grunting in chimpanzees or unidirectional dominance signals such as mock-biting in stump-tailed macaques are reliable ritualized expressions of formal rank (de Waal and Luttrell, 1985; de Waal, 1989). These behaviors are unidirectional and multicontextual, are expressed by different individuals, and covary with other selected measures of agonistic rank. The *competitive ability* reflects the capacity of an individual to obtain access to limited resources (usually food access is measured). The derived rank order does not necessarily correspond to the agonistic dominance rank. The ability and motivation to compete may vary according to the resource that causes competition (Syme, 1974). Temporal variation in competitiveness implies that an individual not always shows the same tendency to use competitive ability. It can show a certain degree of respect for possessions of others or can allow others to share a resource.

Van Hooff and Wensing (1987) suggest several criteria that a behavioral variable should meet in order to justify the adoption of a dominance model: the behavior should allow for a linear ordering in the group; it should be expressed in most dyads as a predominantly unidirectional interaction; and, it should be expressed not just in a few but in most of the relationships in the group expressed in its' "coverage" or proportion of dyads in which the relevant behavior is expressed at least once.

Structural Aspects of the Dominance Hierarchy

We can describe the structural aspects of dominance hierarchies at dyadic, group and individual level (overview Langbein and Puppe, 2004; de Vries, 1998; de Vries *et al.*, 2006; Flack and de Waal, 2004; Van van Hooff and Wensing, 1987).

At dyadic level, dominance characteristics can be expressed as the number of unknown (or zero or blanco) dyads: that is, number of dyads in which the two members of the dyad have not been observed to perform any agonistic interaction towards each other; the number of one-way dyads, that is, the number of dyads in which the behavior is shown in one direction only irrespective of the frequency of interaction within the dyads; the number of two-way dyads, that is, dyadic dominance interactions occurred at least once in both directions (from A to B and from B to A); the number of tied dyads in which the two members of the dyad have performed an equal number of agonistic interactions towards each other; and the number of circular dyads in which an intransitive relationship exists among A, B, and C.

At group level, the ordinal rank order can be obtained by reorganizing data on the outcome of dyadic agonistic interactions in actor-receiver matrices, with, in order to put the individuals in a linear rank order based on the minimization of the number of inconsistencies in the matrix and on the minimization of the total strength of the inconsistencies in the matrix (I&SI-method). The cardinal dominance rank quantifies the rank distances between the individuals, based upon their relative probability of winning or losing dominance interactions. The Clutton-Brock's Index and the David's scores provide a measure of individual competitive success in absolute terms and in relation to the wins and losses of all other individuals in the group. The relative strengths of the other individuals are taken into account and defeating a high-ranking animal is weighted heavier than defeating a low-ranking one, minimizing the chance of a highly dominant individual skewing the index. Alternatively, a Bayesian method can be used to provide cardinal scores with confidence intervals. The Elo rating method calculates the hierarchy by taking the sequential order of interactions into account and updates the rank of individuals as interactions occur. This method takes into account that the outcome of an agonistic interaction can be influenced by prior interaction success or failure.

Characteristics of a dominance hierarchy can be described by referring to the strength of the linearity, steepness and directional consistency. Linearity in a set of binary dominance relationships depends on the number of established relationships, and on the degree to which these relationships are transitive. If none of the relationships is undecided and all relationships are transitive, a perfect linear order exists. Linearity is expressed in Landau index (h) based on the number of dominated animals or the Kendall index K based on the concept of circular triads or the improved Landau index (h') in case there are unknown relationships. A value of 1 indicates complete linearity and a value of 0 indicates that each individual dominates an equal number of other individuals. The steepness or strength of a hierarchy refers to the size of the absolute differences between adjacently ranked individuals in their overall success in winning dominance encounters (i.e., dominance success) and can be inferred from cardinal dominance ranks. When these differences are large the hierarchy is steep; when they are small the hierarchy is shallow.

The directional consistency index (DCI) gives the frequency with which the behavior occurred in its more frequent direction (H) minus the number of times the behavior occurred in its' least frequent direction (L), divided by the total number of times the behavior occurred. The index varies from 0 (complete bidirectionality) to 1 (complete unidirectionality). The stability of a hierarchy can be tested by calculating the rank correlation coefficient between hierarchies over time and by a matrix correlation test of two matrices of each time period with agonistic interactions upon which the hierarchy is based.

At the individual level, dominance can be described as the dominance index DI_{dom} with the ratio of animals which are dominated by an individual in relation to all animals with which it has interacted, the dominance index DI_{AI} being the sum of the number of wins minus defeats to the number of all interactions, the ordinal rank number placing each individual into an ordinal rank according to the wins and losses of dyadic dominance encounters, the cardinal rank number quantifying rank distances between individuals based upon their relative probability of winning or losing dominance interactions, the agonistic index AGI referring to the number of agonistic interactions per individual and time unit, the aggressive index ARI describing the number of initiated agonistic interactions per individual and time unit.

Linear Dominance Hierarchies

In several animal species like dolphins, chimpanzees, hyenas and baboons the hierarchies are not strictly linear (Chase and Seitz, 2011) and in some species males and females form separate hierarchies, such as in mountain goats (*Oreamnos americanus*), and bighorn sheep (*Ovis canadensis*). Finding a linear dominance hierarchy requires sufficient observation effort. de Vries *et al.* (2006) warn that one should be cautious in interpreting the results with respect to observational zeroes in which some dyads have had no dominance interactions. Absence of linearity can only be concluded in case of sufficient observation effort and unbiased sampling. In some cases, a subordinate animal keeps a safe distance from a dominant one because there is a clear dominance–subordination relationship that has priorly been aggressively established (Hemelrijk, 1999). In this case it may be advised to include dyadic "avoiding at a distance" interactions to reduce the number of dyads with missing values. Alternatively, two animals may stay at a relatively large distance from each other and have an unresolved dominance relationship. In case two animals are regularly seen in each other's neighborhood, without having any dominance interactions with each other and without avoiding each other at a distance, these animals show that a clear dominance–subordination relationship between them is absent. In certain contexts, a dominance hierarchy can remain hidden and be rarely expressed in agonistic interactions. At periods of resource scarcity and competition, the asymmetry in agonism and in resource access can suddenly become overtly expressed, for instance in female European badgers (*Meles meles*) in case of breeding competition over males (Hewitt *et al.*, 2009). Bottleneck periods of scarcity have shaped the potential for hierarchy formation of many group living species and are a part of their environment of evolutionary adaptiveness. Animals that show few asymmetric hierarchical interactions at times of low competition, may express a high degree of agonistic asymmetry at times of scarcity. This may explain ambivalent claims in popular literature on certain species (e.g., dogs, wolves and cats) as either lacking or possessing a clear hierarchy.

Dominance Styles

The term "dominance style" was initially used to describe patterns of agonistic behavior by de Waal and Luttrell (1989), and later was broadened to include the covariation of traits related to conflict or conflict management (Flack and de Waal, 2004). In macaques, a despotic dominance style was linked to asymmetrical patterns of agonistic behavior, low rates of reconciliation, and a strong kin bias in affiliation. Macaques with a tolerant dominance style do not show a strict inheritance of dominance rank, they show low rates of severe biting, tolerance around limited resources, little agonistic behavior in response to the approach of others, maternal tolerance for infant handling, and triadic male–infant interactions (Thierry, 2000) (**Fig. 1**).

Stricto sensu, the dominance style describes the asymmetry in competition in terms of the frequency of aggression of the dominant individuals and the submission of the subordinates (de Waal and Luttrell, 1989). In a group of individuals in which a perfect linear dominance hierarchy exists and for which the wins in every dyad are completely unidirectionally distributed, the steepness score of the hierarchy will be high, indicating a steep and despotic style. Where cardinal rank distances are large the hierarchy is steep and despotic; where they are small it is shallow and egalitarian. The lower the unidirectionality, the shallower and more egalitarian the dominance style (de Vries *et al.*, 2006). This dominance style depends on socioecological factors, such as the distribution of the resources, the type and intensity of inter- and intragroup competition and the adaptive value of group living, and will determine the rank-dependent inequality among group members with regard to costs and benefits of group living (de Waal, 1989; de Waal and Luttrell, 1989). Within a group, dominant and subordinate animals reach some equilibrium between exploitation and cooperation (Vehrencamp, 1983). The higher the costs for the lower-ranking animals to leave the group, the higher the liberty of the high ranking animals to despotically claim the access to limited resources. In a despotic dominance hierarchy especially the low ranking animals may evaluate the fitness gain obtained by leaving the group. The outcome of this trade-off will be determined by the options outside of the group. A high predation pressure or a high degree of between group competition, may increase the value of remaining in a group. Whenever the outside options are limited, the subordinates will be likely to appease dominants to safeguard their membership to the group. Whenever the presence of the lower ranking animal confers certain benefits, we expect to find suppressed competitiveness by dominants and more egalitarian dominance

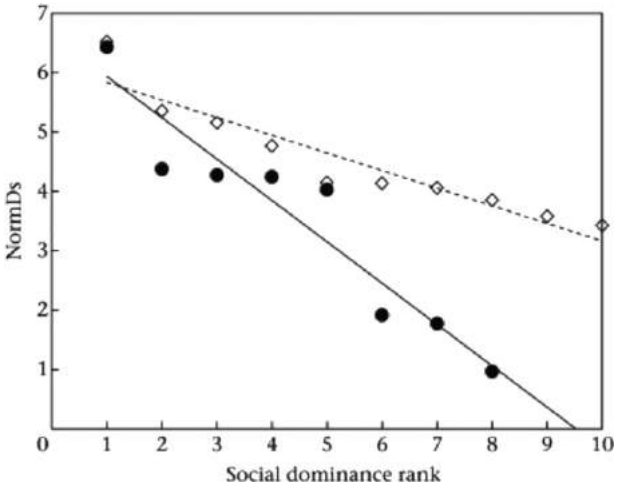

Fig. 1 Illustration of the quantification of dominance styles (Kaburu and Newton-Fisher, 2015). Dominance hierarchy steepness, indicated by the slope of the best-fit line of normalized David's score (NormDs) against dominance ranks among adult male chimpanzees of two study communities. Sonso chimpanzees (*solid line*, diamonds, $N = 8$) show a steep (despotic) hierarchy, while for M-group chimpanzees (*dashed line*, circles, $n = 10$), the hierarchy is shallow (egalitarian).

relationships. In the model proposed by Hemelrijk (1999) the differences in social behavior between despotic and egalitarian societies are the consequence of changing one simple parameter only, representing the intensity of aggression. A higher intensity of aggression increases the degree of variation in dominance values, resulting in a steeper hierarchy. A steeper gradient of the hierarchy in turn leads to several emergent phenomena, affecting cohesiveness, frequency of interaction, initial decline of aggression, rank relatedness of interaction, rank overlap between the genders and spatial centrality of dominants, etc. Between species, linear and steep hierarchies may be easier to detect among close-knit groups of social animals, but more difficult to find among individuals living in loose societies (de Vries *et al.*, 2006).

The concept of dominance style, sometimes referred to as "dominance gradient," has been used in several biological market models on behavior (Barrett *et al.*, 1999). The steepness of the hierarchy was used to predict the economic exchange and interchange of social interactions among dyads, for example, in Kaburu and Newton-Fisher (2015) who found that male chimpanzees trade grooming for agonistic support where hierarchies are steep (despotic) and consequent effective support is a rank-related commodity, but not where hierarchies are shallow (egalitarian).

Dominance Determining Factors

Several studies (review Chase and Seitz, 2011) showed that animals that are heavier and larger can dominate the lighter and smaller individuals. Some examples are weight in female American bison (*Bison bison)*; size in male semiterrestrial crab (*Neohelice granulate)*; size in cichlid fish; size in Japanese fluvial sculpin (*Cottus pollux*). Other physical attributes or signals that correlate with dominance include beak size in Greater sheathbills (*Chionis alba*), plumage characteristics in birds, urinary composition in the European lobster (*Homarus gammarus)*, facial patterns in paper wasps (*Polistes fuscatus*), comb size in roosters (*Gallus gallus*), ornament size in the swordtail fish (*Xiphophorus helleri*), UV reflectance in male wall lizards (*Podarcis muralis*).

Personality can predict the outcome of dominance interactions, such as boldness in trout (*Salmo trutta*), proactivity in rainbow trouts (*Oncorhynchus mykiss*), speed of exploration in mountain chikadees (*Poecile gambeli*), aggression, boldness and exploration in hermit crabs (*Pagurus bernhardus*), aggressiveness in sheepshead swordtail fish (*Xiphophorus birchmanni)*.

The genetic basis of dominance and aggression was examined in wild red deer (*Cervus elaphus)* and in graylag geese (*Anser anser*), as well as the tendency to be agonistically victimized in yellow-bellied marmot (*Marmota flaviventris*). A heritable component of aggressive behavior and dominance-related traits was found in many species, such as male bank voles (*Clethrionomys glareolus*), in dogs (*Canis familiaris*) and insects. The complex interaction between environmental and genetic determinants was studied in the cichlid (*Astatotilapia burtoni)*, where males can change in color and dominance several times throughout their lives depending on the available territories.

In many species, dominance will affect the *hormone levels* and vice versa. Watching fights will raise hormone levels in fish. Maternal aggression and *androgens* influence the rank-related behavior in the young. High ranking female spotted hyenas (*Crocuta crocuta*) have higher levels of androgens in the uterus resulting in more aggressive infants. Testosterone levels in the eggs are determined by maternal aggression, and affect the growth and dominance of young tree swallows (*Tachycineta bicolor*) in the nest. Kittiwake (*Rissa tridactyla*) nestlings with higher maternal androgens show increased sibling aggression and dominance. *Metabolic speed* was higher in high ranking rainbow trout (*Oncorhynchus mykiss*). Reproductive state affects dominance in wild female Hanuman langurs (*Semnopithecus entellus*).

Experience is known to play an important role in *dominance acquisition and maintenance*. An animal that has won an interaction in a previous conflict, has a higher probability to win the next conflict, known as the "winner effect." Winner effects are less common and less strong than loser effects and they last shorter. The loser effect implies that an animal that has lost a previous interaction, has a higher probability to loose the next conflict. It has been observed in several species and can last several days. The bystander effect implies that the animal that observed a conflict among two individuals, will alter its behavior in a subsequent encounter with one of the participants, in comparison to animals that did not observe the interaction.

Fitness Benefits

The costs and benefits of group living may be divided unequally among group members depending on their dominance rank. The probability of engaging in an agonistic interaction to attain or maintain dominance or of developing alternative strategies as subordinate individual can be calculated in a cost-benefit model. The success can be expressed in *fitness benefits* obtained directly or indirectly by rank-related access to resources (Smith, 1979). In groups with despotic dominance relationships, we expect to see a higher variation in reproductive success (Vehrencamp, 1983). Direct or indirect benefits of high rank may be multiple and varied including for instance food, peaceful cooperation by subordinates by the threat of punishment in the Goby (*Paragobiodon xanthosomus*), a coral-reef fish, increased growth and survival benefits in blue-footed boobies (*Sula nebouxii*) nestlings. Dominance hierarchies may have important consequences for the patterns of mating and reproduction. High ranking females can obtain a variety of sexually competitive benefits (review by Stockley and Bro-Jorgensen, 2011). In several species dominance relates to a higher female reproductive success, in primates (review Majolo *et al.*, 2012), in mice (*Mus musculus)* or rabbits (*Oryctolagus cuniculus*). In males, reproductive success has been related to dominance rank in many studies (such as in primates: Majolo *et al.*, 2012, American bison (*Bison bison*) or Japanese fluvial sculpin (*Cottus pollux)*.

Environmental Stress and Evolutionary Change☆

B van Heerwaarden and VM Kellermann, Monash University, Clayton, VIC, Australia
AA Hoffmann, The University of Melbourne, Melbourne, VIC, Australia

Introduction

Changes in the normal types of environmental conditions to which species are exposed can lead to dramatic reductions in the fitness of organisms, and these conditions are often referred to as 'stressful' (Hoffmann and Parsons, 1991). They may be catastrophic such as droughts or mass flooding events, or subtle such as small increases in sea or air temperature. Both types of changes potentially have an enormous effect on population density and ultimately lead to changes in species distributions and community composition. However, while stressful conditions are often seen in a negative light because they decrease biodiversity, they may also have positive effects by being linked to rapid evolutionary responses; for instance, species radiations within the fossil record have often been linked to periods of environmental change, and geographic regions with a high level of animal and plant diversity are often exposed to marked fluctuations in environmental conditions that produce periods of local extinction and expansion.

One reason why stressful conditions might produce evolutionary changes is that they represent periods of intense selection. Numerous laboratory-based experiments in model organisms like *Drosophila melanogaster*, mice, and *Escherichia coli* bacteria have demonstrated that rapid evolution can occur following intense selection (Hoffmann and Parsons, 1991). There are also numerous examples of natural populations of organisms adapting under intense selection due to stressful conditions, such as the evolution of highly resistant pest populations following exposure to chemicals, and evolutionary changes in both morphological and physiological traits in birds exposed to food shortages resulting from climatic stressors. Apart from producing more intense selection, stressful conditions can also influence evolutionary rates in other ways explored further below.

The question of how stressful conditions influence the evolutionary potential of populations has become increasingly important because human activities are rapidly producing habitat fragmentation, thermal and precipitation shifts associated with global warming and increasing quantities of pollutants entering the environment. There are numerous examples of species adapting in the face of such adversity but similarly there are many examples highlighting that not all species successfully adapt (Bradshaw and Holzapfel, 2006; Merilä, 2012). The low plant diversity typical of metal-contaminated soils and the loss of endemics in areas that are becoming warmer highlight the limitations of evolutionary responses. Under many circumstances strong directional selection will lead to adaptation but why do we see an absence of a selection response in other cases, and how might evolutionary changes be promoted in such situations?

In this article we consider conditions under which stress might increase or decrease the likelihood of adaptation. We focus on current human-induced disturbances such as habitat fragmentation, the direct and indirect effects of global warming, and the effects of insecticides and pollutants. Within this framework we discuss potential genetic and ecological limits that may prevent future adaptation and what this means for species conservation. We finish by highlighting current evidence for adaptation to human-induced environmental stressors and the potential to use genes and genetically-based polymorphisms as markers of environmental change. A theme emerging from work undertaken to date is that populations and species markedly differ in their propensities to evolve. This makes predictions difficult in specific instances, but generalizations may emerge about specific groups of organisms as more data are collected.

Stress and the Expression of Phenotypic Variation

Although selection acts at the phenotypic level, adaptive responses to stressors ultimately will be dictated by the presence of genetic variation in traits in the direction which selection acts (Falconer and Mackay, 1995; Lynch and Walsh, 1998). Typically, narrow sense heritability for a single trait ($h^2 = V_A/V_P$), which is the slope of the relationship between the additive genetic variance (V_A) and total phenotypic variance (V_P), is used to predict a population's response to selection ($R = h^2S$). An alternative predictor is evolvability, an expression of the ratio between the additive genetic variance and mean (x) of a trait, such as V_A/x^2. The additive genetic variance (V_A) is the proportion of the genetic component that contributes to the resemblance between parents and offspring, while the phenotypic variance includes additive genetic variance, genetic interactions between alleles within or between loci and environmental variance. Changes in any one of these components may alter a population's response to selection.

The debate as to whether narrow-sense heritability (V_A/V_P) or evolvability will decrease or increase as a consequence of stressful environments is still to be resolved (Charmantier and Garant, 2005; Hoffmann and Parsons, 1991). Empirical studies have emphasized the absence of simple answers to this question by showing both increases and decreases in heritability depend on traits and species measured (**Table 1**). Heritability is predicted to decrease under stressful conditions due to an increase in environmental variation, increasing phenotypic variation without changing V_A. In addition, stressful conditions can directly decrease V_A, as seems to happen in some animal populations when food is scarce and the proportion of V_P due to genetic factors decreases relative to environmental factors. Heritability and selection responses can increase under stressful conditions due to the release of cryptic genetic variation as a by-product of canalization, or through an increase in mutation or recombination rate in

Table 1 Trends in heritability estimates in stressful environments

Species	*Trait*	*Environment*	*Heritability*
D. buzzati (insect)	Wing Length	High temperature	(+)[a]
D. melanogaster	Wing Length	High temperature	(−)[b] (−)[a] (+)[a]
		Low temperature	(−)[c] (−)[a] (−)[a]
	Bristle number	High temperature	(+)[b]
		Low temperature	(+)[c]
	Development time	High temperature	(−)[b]
		Low temperature	(=)[c]
Stator limbatus	Egg length	Environmental quality	(+)[d]
	Lifetime fecundity		(+)[d]
Pholcus phalangioides	Body size	Food abundance	(−)[d]
	Development time		(+)[d]
	Body mass		(+)[d]
Rana temporaria (amphibian)	Development time	Desiccation	(−)[d] (−)[d]
	Mass		(+)[d] (+)[d]
	Body length		(+)[d] (+)[d]
	Tail length		(+)[d] (−)[d]
Bufo calamita	Survival to 25 stage Gosner	Osmotic stress	(+)[d]
Parus caeruleus (bird)	Nestling tarsus length	Parasite load	(+)[d]
Pica Pica	Tarsus length	Food abundance and quality	(+)[d]
	Body mass		(+)[d]
	Immune response		(+)[d]
Crassostrea gigas (bivalve molluscs)	Survival	Food abundance	(+)[d]
	Growth		(−)[d]
	Reproductive effort		(+)[d]
Salmo salar (fish)	Juvenile length	Habitat quality	(+)[d]
Ovis Canadensis (mammal)	Adult body mass	Seasons	(+)[d]
Ovis aries	Male parasite resistance	Seasons	(−)[d]
	Female parasite resistance		(−)[d]
Tamiasciurus hudsonicus	Growth rate	Annual quality	(−)[d]
Rhizoctonia solani (fungus)	Growth rate	High temperature and fungicide	(+)[e]

'+' indicates an increase in heritability while '−' represents a decrease and '=' means no change. Multiple estimates represent more than one study, while brackets indicate statistical significance was not tested or results were only suggestive.

stressed organisms. The results of numerous laboratory experiments and those undertaken in natural populations have emphasized that the heritability or evolvability of a trait are not stable measures but depend on environmental conditions.

Canalization refers to the process that maintains phenotypic constancy despite fluctuations in both the genotype and environment. A classic example of a 'canalized' trait is scuttelar bristle number in *Drosophila* (which rarely varies from four). A highly canalized phenotype will vary little within a range of conditions and this is often referred to as the zone of canalization; outside this range the trait may show an increase in variation. Canalization is thought to be maintained through genetic mechanisms and result in an accumulation of cryptic genetic variation not expressed within a trait's zone of canalization. However, stressful conditions may disrupt the buffering mechanism and lead to an increase in variation (Hoffmann and Parsons, 1991). A heat shock protein (Hsp90) has been implicated as a candidate mechanism for canalization; this protein is present in plants, fungi, and animals, and plays a role in folding proteins, particularly those involved in signal transduction, cell cycle, and cell death. Experiments on *Drosophila*, *Arabidopsis*, and fungi, have demonstrated increases in variation following suppression/disruption of Hsp90 with chemical inhibitors or temperature stress. Experiments manipulating Hsp90 expression in fungi demonstrated its involvement in the evolution of drug resistance; the suppression of Hsp90 allowed new mutations to have immediate effects on the phenotype (Cowan and Lindquist, 2005). Furthermore, the drug-resistant phenotype became stable without the suppression of Hsp90 following intense selection. This highlights the important role cryptic genetic variation and thus canalization may have in rapid evolution following an environmental stress. The idea of cryptic genetic variation in itself is interesting from an adaptive perspective; is cryptic genetic variation a by-product of canalization or a pre-adapted mechanism to cope with stressors?

Mutation is the ultimate source of genetic variation, and under stressful conditions mutation rates may increase, introducing new variation available for selection when variation is potentially needed most. For example, some studies of the bacterium *E. coli* suggest that the stressful starvation conditions encountered during stationary phase incubation result in a temporary increase in mutation rate due to decreased fidelity of DNA replication and a reduction in DNA repair (Bjedov et al., 2003). There is also evidence that recombination frequencies may be associated with stress levels and produce an increase in combinations of different alleles in offspring. Several experiments on *Drosophila* have shown increases in recombination frequencies under extreme culturing temperatures and starvation, while overcrowding in mice has also been found to increase recombination (Hoffmann and Parsons, 1991). Abiotic stress factors like heat and increased salinity can stimulate somatic recombination in *Arabidopsis*.

Although an increase in mutation and recombination rates may promote novel variation during environmental stress, there are also likely to be deleterious effects in stressful environments. Most mutations are deleterious and selection acts against them; an increase in mutation rate may increase the mutational load in a population exposed to stressful conditions. Many new combinations of alleles generated by recombination may also be deleterious, generating costs. It is often not clear if an increase in recombination/mutation rate is adaptive or simply a consequence of exposure to stressful conditions (Hoffmann and Parsons, 1991).

In addition to influencing the heritability and evolvability of traits directly, stressful conditions can also exert indirect effects through changes in population size. A decrease in population size is expected to lead to lower levels of additive genetic variance and decrease the adaptive potential of populations as alleles are lost in small populations due to genetic drift; however, the decrease in size often needs to be quite substantial to have much impact on trait heritability (Willi et al., 2006). The adaptive potential of small populations can also be reduced through a loss of fitness due to inbreeding.

Theory suggests that the effects of population size on evolvability can be unpredictable when there are nonadditive genetic interactions among alleles within (dominance) or between (epistasis) loci (Goodnight, 1988). In these cases additive genetic variation may increase when population size declines rapidly. This additive genetic variance, previously hidden from selection by epistatic or dominance interactions, may now contribute to a selection response, although the levels of inbreeding required may be substantial (Turelli and Barton, 2006). There is some empirical evidence that additive genetic variance can increase after a population bottleneck for morphometric and behavioral traits in the house fly, and viability in the flour beetle and *D. melanogaster*; however, these increases may not have much evolutionary relevance. In the case of viability in *D. melanogaster*, although the response to selection was higher in the bottlenecked lines, it was not high enough to overcome the initial level of inbreeding depression caused by bottlenecking (van Heerwaarden et al., 2008). As such, although a population bottleneck increased additive genetic variance, in this case it is not likely to be evolutionary significant.

Stress and Limits to Selection in Single Traits

Animal breeding and laboratory-based selection experiments on model species have shown that many species have the ability to evolve large phenotypic changes over short periods of time. Despite this there are many examples of evolutionary stasis within populations. Clearly, a simple explanation for this is an absence of genetic variance in traits under selection; however, a lack of genetic variance is rarely implicated when selection fails to produce a response. Nonetheless, examples of stasis in the presence of genetic variation are scattered throughout the literature so other factors must also be involved. There are several reasons why an evolutionary response may be low in populations including an absence of genetic variation, selection, negative consequences of low population sizes, asymmetrical gene flow and finally, complex genetic, ecological, or environmental interactions (**Figure 1**). These limits to stress adaptation are discussed below.

The most obvious factor that may limit stress adaptation is low levels of genetic variance. Variation is thought to be maintained in most traits through a balance between mutation and selection, and there is almost no empirical evidence in the literature for a

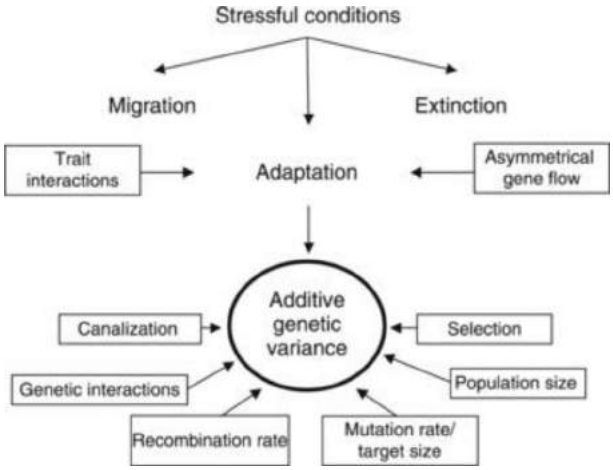

Figure 1 When faced with stressful conditions, organisms have three options: adapt, migrate, or face extinction. Migration will be influenced by ability to disperse and the availability of suitable habitat elsewhere. Adaptation is primarily influenced by the presence of genetic variance, which is influenced by population processes, including selection, population size, and genetic factors such as genetic interactions, mutation, recombination, and canalization. Trait interactions and asymmetrical gene flow may also limit adaptation to stress even when additive genetic variance is present.

lack of genetic variation in quantitative traits. However, the presence of additive genetic variance is required in specific traits for adaptation to occur. Although directional selection may increase genetic variation while rare beneficial alleles increase in frequency, if continued selection causes these alleles to increase in frequency and approach and reach fixation, genetic variance is predicted to be reduced. Mutation may be adequate to maintain variation in traits even under intense levels of selection if the mutational target is large (enough loci are involved). However, a small mutation target size (small number of loci) or a low mutation rate may limit the amount of new variation being generated, resulting in lower levels of additive genetic variance for key traits involved in adaptation.

Adaptive shifts may also be influenced by low population sizes (Willi et al., 2006). Low size can adversely affect populations due to the negative effects of inbreeding and the increased action of genetic drift decreasing additive genetic variance. Breeding between relatives increases homozygosity, unmasking unfavorable allele combinations which tend to lead to a reduction in fitness and limit evolutionary change. Furthermore, the effects of genetic drift are greater in small populations where favorable alleles may be lost by chance. Human-induced habitat fragmentation is increasingly reducing the size of many populations. Habitat fragmentation isolates populations, preventing gene flow and thus reducing effective population size. Restoring gene flow between habitats represents one effective way of reversing the effects of inbreeding and genetic drift.

Finally, interactions among alleles within (dominance) or between (epistasis) loci may enhance or constrain adaptation, depending on the intensity and directionality of the interactions. For example, positive epistatic interactions, where alleles systematically reinforce the effect of one another can increase a selection response, while negative epistatic interactions may constrain evolution by diminishing the effect of the interacting allele, 'hiding' this variation from selection. Chromosome inversion polymorphisms, where the arrangement of genes on particular chromosomes is reversed, can lock up particular combinations of alleles that are involved in an adaptive shift – because gametes become inviable when recombination occurs between inverted and noninverted chromosomes. Inversions and epistatic interactions are thought to evolve because certain combinations of alleles are favored in an adapted population. However, if environmental conditions shift, these interactions may no longer be favored and having alleles locked up could prevent an adaptive response.

While a lack of additive genetic variance can reduce the evolutionary potential of a population (Kellermann et al., 2009), many traits reach an adaptive limit with ample genetic variation for selection to act upon. There are several reasons why genetic variation does not always ensure a selection response.

One reason is that a trait may still fail to respond because of the way that selection influences a trait. Selection may act on a nonheritable component of the phenotype rather than the heritable component. For instance while there is heritable variation for antler size in red deer (*Cervus elaphus*) and directional selection for increased size, this trait has not changed for many years (Kruuk et al., 2002). It appears that only the environmental component of variation in antler size is under selection – this component reflects the nutritional state of the organisms and is unrelated to their antler genotype.

Another reason is that while low or infrequent migration can adversely influence the amount of genetic variation available for selection, high and/or asymmetrical gene flow can negatively influence a population's ability to respond to selection. Unidirectional gene flow from central/source populations may prevent local adaptation within marginal border/sink populations. As a consequence of asymmetrical gene flow, border populations will not be locally adapted to their surrounding environment, preventing further range expansion. This hypothesis may explain the presence of species borders in the absence of any geographical barriers. There is evidence for poorly adapted genotypes lacking diapause in high latitude populations of the cricket *Allonemobius socius* despite strong selection for diapause, in support of this hypothesis (Fedorka et al., 2012). However, there are also examples of

genetic differentiation in populations despite the presence of high gene flow. While asymmetrical gene flow has the potential to explain evolutionary stasis in the presence of stressful conditions, especially in border populations, empirical evidence for gene flow limiting adaptive responses exists in just a few cases.

Stress and Selection on Multiple Traits

Although we have so far focused on the effects of stressful conditions on single traits, there is a growing realization that the direction of evolution can be restricted by interactions among traits. Different traits can be genetically correlated, mostly due to the fact that the same genes can influence the expression of multiple traits (i.e., they exhibit pleiotropy). This means that variation in one trait will often be correlated with variation in different sets of traits. When selection is pushing a trait in one direction, the response to selection can be constrained because selection is at the same time pushing different traits into other directions (Lynch and Walsh, 1998).

The simplest form of pleiotropy that constrains selection on traits involves antagonistic pleiotropy. This process is commonly envisaged as occurring among two traits; for instance, increased cold resistance may be associated with a decrease in the early reproductive output of females. Selection under stressful conditions may act to increase cold resistance, but there will be an associated reduction in reproductive output, ultimately providing a limit on the extent to which cold resistance might increase. In reality, pleiotropic interactions involve multiple sets of traits, and several of these might be under selection. Identifying constraints to evolution depends on understanding whether the direction of selection can proceed when levels of genetic variation in a set of traits and genetic interactions among these traits are understood. The response to selection for a complex of traits is given by $\Delta z = G\beta$, where z is a vector of the response of individual traits, G is the genetic variance–covariance matrix, and β is the vector of linear selection gradients. The response of traits within the vector z depends critically on G, which is effectively a matrix that includes V_A in its leading diagonal (as a measure of genetic variance) and genetic interactions among traits in its off-diagonal components. Particular forms of G may mean that traits might not respond at all to selection or they may respond in a direction opposite to the one in which selection acts (Blows and Hoffmann, 2005).

A difficulty in making predictions based on G is that genetic interactions among traits, just like the genetic variance of traits, can change dramatically depending on environmental conditions particularly when these are stressful. For instance, there is a well-known interaction between development time and egg production (faster developing genotypes often have lower levels of egg production), but this interaction can change sign when organisms are exposed to stressful conditions such that rapidly developing individuals have a higher reproductive output.

Detecting Evolutionary Changes to Stressors

Anthropogenic disturbances such as pollution, habitat modification and destruction, climate change, and species exploitation are impacting on the distribution and abundance of many sensitive species. Monitoring and predicting the ability of populations to respond to different environmental stressors is vital to understand and minimize their impact on species. Individuals respond to stressors in various ways, depending on intensity and duration. Below we discuss how stress responses can be detected and provide examples of how stressors are already influencing natural populations.

Evolutionary Responses Detected Through Traits

Populations have the potential to evolve and thereby shift phenotypes over short periods of time. Impacts of stressful environmental conditions on populations can be detected through phenotypic shifts, such as increases in tolerance levels, changes in the timing of life history traits including flowering and reproduction, or changes in morphology. These phenotypic shifts can provide direct evidence of rapid responses to stressful environments and there are many examples in the literature. These include the many cases of rapid evolution of pesticide resistance in a variety of insects and mites to a range of chemical classes such as cyclodienes, carbamates, formamidines, organophosphates, and pyrethroids. Resistance is often first detected from the failure of a pesticide to control a pest species and this is usually validated by experimentally comparing tolerance levels of putative-resistant and sensitive populations. Resistance has also evolved in organisms not targeted by pesticides; for example, natural populations of the vinegar fly *D. melanogaster* are resistant to insecticides such as dichloro diphenyl trichloroethane (DDT) even though they have never specifically been targeted for control by these pesticides (Catania et al., 2004).

Evolutionary responses to pollutants have been less widely documented than responses to pesticides. Nevertheless, there are now well-studied cases of plant species evolving in response to waste from mining operations. Plant populations growing close to smelters commonly show a much higher level of resistance to heavy metals than other populations. The evolution of pollution tolerance has also been demonstrated in aquatic fauna, including crayfish, worms, and midges. However not all plants or animals successfully evolve in response to pollutants: levels of biodiversity are often much lower in polluted compared to unpolluted areas, suggesting that many species are unable to adapt.

Pollution stressors can indirectly influence the evolution of traits. There is the classic case of melanism in the peppered moth evolving due to increased pollution levels in England in the 1800 s. Although this species of moth is usually a light color, a darker

melanic form increased in frequency in some polluted areas during this time. The increase in this form was not a direct consequence of pollution but a response to predation by birds; pollution caused the trees which these moths reside on to darken and the melanic form was less likely to be predated upon than the previously camouflaged lighter form. A recent example is the decreasing frequency of grey body colour morphs (and concomitant increase in the brown morphs) in tawny owls as a consequence of decreasing snow cover that provides camouflage for the grey morphs (Karell et al., 2011). These examples highlight evolutionary responses arising as a consequence of changes in biotic interactions due to an environmental stress rather than its more direct effects.

Phenotypic evidence is accumulating on organism responses to recent climate change. Average global surface temperatures have risen 0.8 °C in the past century and more than 0.2 °C per decade over the past 30 years, and several studies that span decades are linking these changes to shifts in the timing of life history traits and geographical shifts in species ranges. A variety of birds, butterflies, and alpine herbs in the Northern Hemisphere have altered their geographic boundaries; a meta-analysis on 99 different species found significant range shifts, averaging 6.1 km per decade away from the equator. Additionally, many birds are now first laying eggs earlier and also becoming smaller in size.

To test whether these patterns reflect evolutionary shifts rather than just phenotypic variants of the same genotype (phenotypic plasticity), a genetic basis needs to be established through controlled breeding experiments or family studies (Hoffmann and Sgrò, 2011). Changes in the timing of diapause induction in the pitcher plant mosquito is an example of adaptive evolution in response to longer growing seasons induced by recent climate change (Bradshaw and Holzapfel, 2006). Parent–offspring comparisons have shown the timing of diapause induction in the pitcher plant mosquito has a heritable genetic basis and this trait has also been shown to cline with latitude along eastern North America. When southern and northern populations are exposed to mid-latitude lengths, they enter diapause either too late (southern) or too early (northern) and experience between a 74% and 88% decline in fitness, indicating that diapause timing is an adapted phenotypic response. Over the last 30 years, this latitudinal cline has shifted, with populations from the north shifting toward a more southern shorter day length form as growing seasons have become longer due to warmer temperatures. In contrast, shifts in the breeding time of birds often appear to represent a plastic response rather than an evolved genetic response.

The rigorous experimental approach needed to demonstrate a genetic basis for a phenotypic shift cannot be readily carried out for many organisms, particularly when they have long generation times. For this reason some of the recent attention on detecting evolutionary changes under stress has moved to the genetic and genomic levels.

Evolutionary Responses Detected Through Allele Changes

Underlying evolutionary changes are allele frequency changes – alleles that are at a selective advantage in particular environments are favored and increase in frequency. As evolutionary responses to stress directly involve changes in allele frequencies, detecting changes at this level is potentially the most direct way to measure and predict the biological consequences of stressors in populations. Initial studies used neutral markers to compare levels of genetic diversity between polluted and nonpolluted populations was one of the first ways DNA markers were used to assess the genetic impacts of stress. However, these markers do not reflect adaptive changes unless they are closely linked to a gene under selection. Genetic markers based on loci coding for proteins (allozymes markers) have been used in some studies, but these can only be applied to well-preserved specimens, which limits their application in longitudinal comparisons of specimens that are often poorly preserved.

One example where changes in allozyme markers were successfully linked to climate change is the alcohol dehydrogenase enzyme (Adh) in *D. melanogaster* (Umina et al., 2005). In the 1980s, the allele frequencies of the *Adh* gene (Adh^F and Adh^S) were found to cline with latitude across the continents of Asia, Australasia, and North America. This association with latitude has been implicated with thermal tolerance where flies with the Adh^S allele are more likely to survive heat shock than flies with the Adh^F allele. The rapid formation of these clinal patterns across continents highlights strong climatic selection on these genes. To determine whether recent changes in climate have influenced the clinal patterns in this marker since the 1980s, the Australian east coast cline was reinvestigated in 2000 and 2002. The slope of the latitudinal association had not changed over the 20 year study period; however, a shift equivalent to 4° in latitude was detected in the height of the graph, with the southern high latitude populations now having the genetic constitution of the more northerly populations. Frequencies of the chromosome inversion polymorphism (*In(3R)P*) in *D. melanogaster* have also changed drastically in the last 20 years (**Figure 2**). Furthermore, changes in chromosome arrangement frequencies of *D. robusta* from North America have been linked to shifts in minimum temperature since the 1970s. Similar parallel shifts in latitude association in numerous inversion polymorphism analyzed simultaneously have also been detected in populations of *D. subobscura* across three separate continents. These studies reflect the power of latitudinal markers to act as sensitive indicators of climatic change.

Ideally, shifts in allele frequencies in genes specific to particular environmental stressors could be used to track genetic responses to stress. Progress has been made in the area of pesticide resistance. Microarray technology has led to the discovery that a single chromosome P450 gene, Cyp6g1, confers resistance to DDT in *D. melanogaster*. Cyp6g1 was found to be over-expressed in *D. melanogaster* lines from natural populations that exhibit resistance due to the insertion of a transposable element in the promoter region that regulates expression of the gene (Catania et al., 2004). Examination of the patterns of molecular variation around this gene showed a sharp reduction in the level of molecular variation in this area of the genome indicative that it had undergone recent selection (selective sweep). Under a selective sweep, variation decreases in the genomic region around the candidate gene, as alleles at adjacent loci spread with the new allele favored by selection. Associations between insecticide resistance

and specific gene changes have been identified now in many insects including moths and mosquitoes, and they are being increasingly used to track changes in resistance in natural populations and to inform management actions.

Concluding Remarks

Ongoing research on model and non-model organisms is leading to the identification of genes and genetic processes linked to evolutionary shifts in response to climatic and chemical stressors. As more genomes are being sequenced, it is becoming possible to extend this search to a wide range of organisms, particularly sensitive species that respond differently to environmental stressors. Furthermore, the ability to extract DNA data from museum specimens or specimens that can be resurrected such as in the small crustacean Daphnia from lake beds is providing opportunities to collect historic data. Both phenotypic and genotypic data on model organisms in natural and laboratory-based environments provide evidence for rapid evolutionary responses to stress. It remains to be seen if sensitive species and those with restricted distributions can also show rapid evolutionary adaptation. There is a huge potential for genetic markers emerging from genomic studies to reveal current and past effects of stress on natural populations and to indicate the potential of populations and species to adapt in the future.

Glossary

Extrinsic factors In this article it refers to factors not attributed to the individual such as for example, intra- and inter-specific competition, predatoion, parasitism, and ecological opportunity.
Individual diet specialization Where the population niche consists of subsets of specialized individuals that compromise the population niche.
Intrinsic factors In this article it refers to factors attributed to the individual such as for example, sex, size, age, or morphology.
Ontogeny The development or course of development especially of an individual organism.
Optimal foraging theory A mathematical theory used to model foragers' decision-making in choosing among multiple available resources, assuming selection has favored a benefit-maximizing strategy.
Polymorphism Heritable variation among individuals within a population, for a focal trait or gene.
Sexual dimorphism The condition where the two sexes of the same species exhibit different characteristics beyond the differences in their sexual organs.

Introduction

Energy acquisition has been important in ecological and evolutionary theory to predict the survival and fitness of individuals and species. Energy acquisition is affected by prey density and behavior, as well as an individual's ability to detect, capture, and consume the prey (Fig. 1). These foraging abilities are shaped by both morphological and behavioral traits, which generally reflect genetic and environmental influences. To the extent that morphological or behavioral variation leads to different rates of energy income, these phenotypic traits will be subject to natural selection. Evolution of foraging traits will then influence the structure of ecological communities through changing predator–prey dynamics. Consequently, a major goal in evolution and ecology research has been to understand the mechanisms that determine patterns of resource use. In particular, researchers have tried to explain why species are generalists (using a diverse set of resources) or specialists, and why they use particular subsets of available resources. The resulting "niche theory" was a major focus of ecology from the 1960s through the 1980s, during which period ecologists tended to view the niche as a property of a species or a population as a whole. However, to understand niche evolution we must think of the niche instead as a property of individuals, based on heritable variation in foraging traits. Many animal populations with generalized diets actually consist of individuals specializing on a small subset of the population's diet. In some cases such diet variation among individuals may exceed differences between distinct species. Within-population diet variation can be related to phenotypic variation, including sexual dimorphism, ontogenetic niches, or related to morphological or behavioral variation in the population.

Defining Food Specialization

The term "specialization" is used in a variety of ways that require some initial clarification. A species or individual may be considered "specialized" (an adjective) if it uses a narrower diet than some reference group. For example, a specialized species might use fewer prey than are available in the environment, or than another species uses. An individual may be specialized if it uses fewer prey than its conspecifics (individually or as a group). Alternatively, the adjective has been used to indicate a species that uses a unique set of prey (not necessarily less diverse) compared to related species. Specialization can also be a verb, the evolutionary process of becoming more specialized. In this case we are comparing the focal group to its evolutionary progenitor. Finally, a specialization can also be a noun and refer to a phenotypic trait that confers a derived ability to perform some ecological task, for example, hypertrophied pharyngeal jaws are a specialization for molluscivory. In the context of individual food specialization, these three views correspond to asking whether or not an individual has a narrower niche than its population,

☆*Change History*: October 2017. Richard Svanbäck and Daniel I Bolnick updated the text and further reading to this entire article, especially a whole section on extrinsic factors have been added.

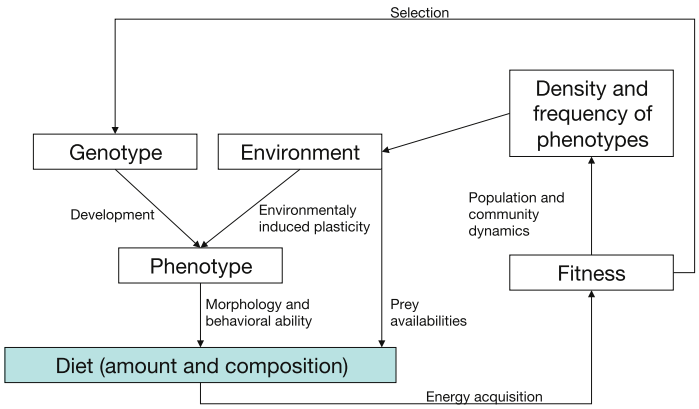

Fig. 1 Possible scenarios for how individual diets are determined and how it will feed back on ecological and evolutionary dynamics.

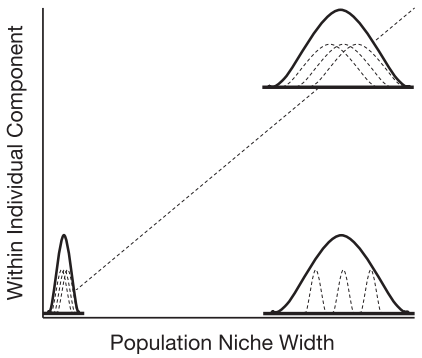

Fig. 2 Individual diet specialization is part of a continuum from where the within-individual component (WIC) equals that of the total population niche width (TNW) (on the hatched diagonal) to where WIC is a small part of TNW (close to the *x*-axis). The three schematic diagrams represent how individuals (*hatched curves*) can subdivide the population's niche (*thick curve*). The two diagrams on the hatched diagonal represent cases where individual diet specialization is low, that is, WIC is a large part of TNW whereas the diagram at the bottom right represents a case where there is a high degree of individual specialization.

describing the process of becoming more specialized and finally, the morphological or behavioral traits underlying food specialization among individuals.

When adopting the relativistic definition of specialization, it is possible to measure the degree of specialization (how much narrower a niche is than its reference). Consider a food resource distribution (niche distribution) that can be described by a single continuous variable such as prey size. The total niche width (TNW) of the population is simply the variance in size of all the prey captured. The total niche width can be partitioned into two components; the within-individual component (WIC) and the between-individual component (BIC) so that TNW = WIC + BIC. WIC is the average variance of prey sizes found within individuals' diets, whereas BIC is the variation between individuals. Individual specialization occurs when individuals niche widths (WIC) are much smaller than their population as a whole (TNW), or equivalently when BIC is a large proportion of TNW such that BIC/TNW is large. An increase in BIC could occur in a number of different ways. For example, BIC can be large if individuals of different age- or size-classes use different diets, or if males and females use different diets. Furthermore, an increase in BIC, could also be due to phenotypic variation among individuals (morphological or behavioral). Thus, individual food specialization is part of a continuum from where the within-individual component equals the total niche width (WIC/TNW = 1), that is, no individual specialization, to where WIC is only a small part of TNW, that is, great individual specialization (**Fig. 2**).

Causes of Diet Specialization

Why does an individual forager use a given set of resources? This is a problem often addressed with optimal foraging theory. Although optimal foraging theory has not always been successful in generating qualitative predictions of foraging behavior it can serve as a rough tool to understand what makes an individual choose its resources. According to optimal foraging theory, an individual is expected to choose its diet from among available resources to maximize its expected fitness. This might be achieved by maximizing energy income per unit time, or by some balance between energy income and another goal such as risk avoidance. The diet of an individual then depends on a variety of factors such as the energetic content of different prey, handling times, search

efficiencies, resource abundances and risk such as predation. All these factors are a combination of the resources traits (e.g., size, caloric content, abundance and defensive traits) and the forager's phenotype (e.g., search or handling behavior, morphology, physiology, and experience). Consequently, an individual's preferences for alternative resources will reflect a complex interaction between resource traits and the forager's phenotype.

Given a shared environment, why would different conspecific individuals specialize on different prey types? The most proximate answer is that individuals will use different resources if they have different resource use efficiencies. Different resource use efficiencies may reflect variable morphological, behavioral or physiological capacities to detect, capture, or handle alternative resources. This poses a second question: why does phenotypic variation result in efficiency variation? Without trade-offs constraining efficiencies on alternative resources, phenotypic variation would not produce efficiency variation. By trade-offs, we mean that an individual adopting one strategy that increases efficiency on one prey type will lose the ability to efficiently use alternative prey. In situations with trade-offs, a generalist forager may be unable to perform either strategy as well as the respective specialist and may therefore be selected against. Such trade-offs are known to occur in many aspects of foraging including search efficiency, handling time efficiency (prey capture and digestion), and prey recognition. Thus, trade-offs remain one of most plausible mechanisms for limiting an individual's niche breadth. Consequently, food specialization within a population can occur as a result of particular age- or sex-based characteristics or by individual level variations in phenotype. Phenotypic variation is often associated with discrete polymorphisms with distinct modes along a quantitative axis such as beak depth. However, this variation may also be simple unimodal quantitative variation, or may have a complex behavioral or biomechanical basis that is not effectively summarized by a single quantitative axis.

Not all diet variation need to be related to variation in efficiencies. Even individuals with equal efficiencies can nevertheless have different diets reflecting variation in social status, mating strategy or territories. For example competitive dominant individuals may defend and monopolize preferred resources, and suboptimal individuals will be forced to rely on lower quality resources. In this case, diet variation arises because individuals differ in their ability to achieve their optimal diet. Such interference competition is facilitated when the optimal resource is patchily distributed and can be defended by territories. Individual specialization in several mammal species is caused by territoriality in patchy environments. For example, individuals of both bears and pine martens whose territories abut streams have more fish in their diets compared to neighbors whose territories do not include streams. However, territorial foragers with similar resource use efficiencies may also end up with similar diets due to homogeneously distributed resources, so that each territory contain the full resource spectrum in the same proportions. Furthermore, coarse-grained environmental heterogeneity may sometimes also create differences among individual diets not related to foraging efficiencies. An example of that is the moose in the boreal forest region are severely limited in their movement in winter due to deep snow. Individuals will forage intensely in small patches of often homogeneous vegetation, while another will forage on very different vegetation. The next winter, a given individual may or may not find itself in a similar patch.

Although most of the examples of food specialization are probably due to maximization of energy intake, other food constituents can also be important in developing specialization. For example, the muskox in the Canadian arctic spends more time foraging for protein-rich arctic vetches on low productivity upland tundra than in the energy rich sedge meadows in the valleys, where in relatively little time they can gorge themselves on what is not a limiting resource in summer. Such food specialization is probably due to lack of essential nutrients in the most energy rich food source. Thus, organisms may forage to maximize metrics other than energy. Morever, it is plausible that individual foraging differences might arise from among-individual differences in optimization goals, but this possibility has not been widely tested.

However, most cases of individual diet specialization are not due to territoriality or lack of essential nutrients, but could instead be related to intrinsic (properties attributed to the individual, e.g., sexual differences, ontogenetic niche shifts, or phenotypic variation) or extrinsic (properties not attributed to the individual, intra- and inter-specific competition, predation, parasitism, and ecological oportunity) factors. We will here briefly describe causes and consequences of diet specialization related to intrinsic and extrinsic factors.

Intrinsic Factors

Sexual dimorphism

Sexual dimorphism in trophic structures is a common phenomenon in most animal phyla, and has attracted considerable interest from evolutionary biologists. In most animals, males and females differ in size, sometimes substantially. The usual cause cited for sexual dimorphism in animals is sexual selection acting through female choice and/or male-male competition.

Natural selection acting on the fitness advantages of reduced resource competition between the sexes, however, is also an important alternative evolutionary scenario that can produce sexual dimorphisms. This alternative idea is that sexual differences in body size or morphology may evolve due to ecological causes—that is, the ecological benefit of the sexes occupying different ecological niches, which reduces inter-sexual food competition and expand the species' overall feeding niche. Adaptation to different diets may also be due to sex specific nutritional requirements, as for example females may have additional dietary components compared to males that directly relates to nutrients needed for the production of eggs. However, sexual selection and natural selection for sexual dimorphisms are not incompatible, for example, it may well be that the direction of dimorphism in body size is determined by sexual selection, but that the degree to which the sexes diverge is either constrained or amplified by ecological factors.

Ontogeny

Intraspecific resource partitioning due to ontogenetic niche shifts occurs in many species. This is probably most obvious when age groups live in different habitats and use different types of food. Examples of such ontogenetic niche shifts include particle-feeding amphibian larvae that turn into carnivorous adult amphibians, immature stages of aquatic insects that turn into adult terrestrial insects, planktonic marine invertebrate larvae that settle down to be sessile adults. Other species live in the same general habitat but use distinct food types depending on size or age class, as for example, fish where the young are gape-limited planktivores or herbivores and the adults are predators. There might also be large ontogenetic changes in diet within the same general food type as for example for predators that start to feed on small prey species but as they grow they can and will include larger prey types in their diet.

Differences in diet over the ontogeny of an animal can have different reasons. Search and handling efficiencies can change as animals grow and gape-limitation eases. Other animals change their diet with growth because predation risk declines with size, allowing them to use previously risky habitats. Still other species exhibit a fundamental change in habitat use as a result of life history changes or dispersal (e.g., marine invertebrates with planktonic larvae that settle to become sessile adults).

Morphological and behavioral variation

Morphological variation within a species may reflect adaptive genetic variation or phenotypic plasticity, whereby individuals are able to modulate their morphology in response to foraging conditions. Food specialization in relation to morphology is thought to be a response to competitive pressures within a population favoring niche partitioning among conspecifics, and hence niche expansion. Diet–morphology relationships are mainly due to trade-offs in either search or handling time efficiencies where adaptations to maximize foraging intake have long been recognized to be dependent on specific habitats or prey types. Morphological specialization is thus presumed to lead to an increase in foraging efficiency in the habitat to which they are adapted but on the other hand, it is likely to constrain their efficiency in alternate habitats. For example, the beak size in birds can be related to feeding efficiencies on different sized seeds. Larger beak sizes are better adapted at large seed sizes but they loose their efficiency on smaller seed sizes. Smaller beak sizes on the other hand are more efficient on smaller seed sizes. In fish, species (or individuals) that are specialized for living in open water and searching for widely dispersed prey have fusiform bodies that minimize drag and allow for efficient cruising. In contrast, fish that are adapted for searching for prey in structurally complex habitats have a deep and laterally compressed body and extended fins and are well suited for slow and precise maneuverability.

Behavioral variation can also influence feeding performance and thus diet use of individuals. Behavioral variation can arise from morphological variation in the sense that morphology may determine an individual's ability to carry out a specific prey-capture behavior. However, behavioral variation may also arise from variation in cognitive ability, perception, risk aversion, which may all have a genetic and/or environmental basis. In particular, early experience may lead to learned behaviors that influence prey use. For instance, individuals that are initially exposed to different prey acquire divergent search images that influence later foraging abilities. For example, sea otters (*Enhydra lutris*) show extensive among-individual variation in prey preferences. These differences are maintained through cultural transmission, as mothers teach their offspring how to forage. In *Pieris* butterflies, individuals form a new search image for a single flower type at the start of each day, and specialize on that flower for the rest of the day. Individuals that feed on multiple flower types form less effective search images and thus forage less efficiently.

Extrinsic Factors

Intraspecific competition

Increased intraspecific competition can lead to increased or decreased among individual diet variation, depending on the context. It is generally thought that intraspecific competition will favor diversification. In fact, several correlational studies have shown a positive relationship between intraspecific competition and among individual diet variation, alternatively that reduced resource abundance lead to increased among individual diet variation. This positive effect of intraspecific competition on diet divergence has also been shown in experimental studies. Yet, other studies have found that among individual diet variation is lower at higher levels of intraspecific competition. In general, competition has been shown to be diversifying in species with small effects on their resources and non-diversifying in species with large effects on their resources. Increased density of consumers might besides increase resource competition as described above also increase interference competition. Although not as thoroughly investigated as resource competition, interference competition can lead to diet variation among individuals when individuals defend territories with different resources.

Interspecific competition

In 1965, Van Valen proposed the "niche variation hypothesis," which suggests that "populations with wider niches are more variable than populations with narrower niches." Van Valen suggested this hypothesis in an attempt to explain the observation that bird populations inhabiting oceanic islands tend to be more morphologically variable than their mainland counterparts. Van Valen suggested that island birds evolve to use a wider diversity of resources when they are released from selection imposed by interspecific competitors. Similarly, theory on character displacement and character release relies on the assumption that a population's niche width is limited by a competitor species, and when released from competion, the population can diversify by increased among individual diet variation. The only experimental study so far on how interspecific competition affects among

individual diet variation was conducted on threespined sticklebacks (*Gasterostues aculeatus*). This study showed that among individual diet variation in sticklebacks increased as predicted, when were they released from competition with juvenile cut-throat trout (*Oncorhynchus clarki*). On the other hand, sticklebacks showed reduced among individual diet variation as a consequence of expanded individual niche widths (and constant population niche width) when they were released from competition with prickly sculpin (*Cottus asper*). Some correlational studies have also been performed and found a negative effect of species richness on resource use divergence, as predicted by the niche variation hypothesis. Thus, studies on the effect of species richness on among individual diet variation have yielded conflicting results and more research has to be done to understand when interspecifc competition will increase and when it will decrease among individual diet variation.

Predation

Foraging in different habitats or on different prey types may come with differences in predation risk. As predation and predation risk can have strong influence on prey populations, it is expected to have large effects on among individual diet specialization. Among individual diet specialization can be affected by predation either via reduction in forager densitity or changes in forager behavior in reponse to predation risk. The reduction of the density of forager species by predation, which in turn will reduce the competition within the forager species can either increase of decrese among individual diet specialization. If among individual diet specialization increases with intraspecific competition, then predation will reduce diet specialization. The reduction of competitors by predation can also counter the effect of over-exploiting resources leading to an increase in diet specialization (see "Intraspecific competition" above). Refuge seeking is a common reponse in prey to predation risk. In this case, predation can close off niche space by driving forager individuals to a safer habitat, thus reducing among individual diet variation. However, forager individuals may differ in vulnerability or risk aversion and in this case predation risk might exaggerate among individual diet variation as less vulnerable or less risk-avers individuals can stay in the more profitable habitat whereas other individuals forage in the safer refuge habitat.

Parasites

It is well known that niche specialization may drive parasite infections, as variability in niche use can differentially expose individuals to prey species containing intermediate hosts. However, recent findings have shown that habitat or diet-specific parasites may also influence individual niche use. For example, manipulative parasites, parasites that alter aspects of phenotypic traits and behaviors of the host, can drive divergence in diet between paraitized and unparasitized host individuals. For example, cestode parasites modifies their behavior of intermediate fish hosts to use habitats that increase predation from the definitive host (fish eating birds). Parasites can also affect growth and competitive ability of infected hosts, potentially leading to divergence in niche use between parasitized and unparasitized host individuals. Lastly, parasites that are acquired by consuming a particular food type, may drive selection favoring foragers that avoid that prey type. Thus, parasitism could reduce individual specialization by driving the evolution of a narrower niche width. However, despite some evidence that parasites can drive among individual niche specialization, the potential role of parasites in trophic niche specialization remains unclear, and further research is needed.

Ecological opportunity

Both predation and interspecific competition can restrict populations from using specific resources or habitats. By ecological opportunity we mean other factors, that hinders niche divergence, such as patch size, and microhabitat/resource diversity. As larger patch sizes can hold more diverse prey populations habitat fragmentation may have large effects on among individual diet variation. For example, it has been shown that habitat fragmentation in eustarine tidal wetlands leads to lower resource diversity consequently decreasing among individual diet variation in the gray snapper (*Lutjanus griseus*), a predatory fish. Similarly, it has also been shown that among individual diet variation in the fruit bat, *Rousettus aegyptiacus*, was higher in spring when the number of plant species bearing fruits was also higher.

Measuring Diet Specialization

There are many different indices for calculating the degree of individual diet specialization. Most measures of niche breadth compare the frequency distribution of the individuals' resource use with that of the average population resource use. The total niche width of a population (TNW) can be broken down into the average variance of resources found within individuals' (within-individual component WIC), and the variance between individuals (between individual component) so that TNW = WIC + BIC. Assuming that variation in diet parameters can be expressed along a single continuous dimension x (e.g., prey size) and x_{ij} is the size if the jth prey item in individuals i's diet. Then,

$$\mathrm{TNW} = Var\left(x_{ij}\right)$$

$$\mathrm{WIC} = E\left[Var\left(x_j i\right)\right]$$

$$\mathrm{BIC} = Var\left[E\left(x_j i\right)\right]$$

The relative degree of individual specialization can be measured as the proportion of TNW that is explained by the within-individual variation, WIC/TNW, or its converse BIC/TNW. The latter is more intuitive, since it is larger in populations with greater diet variation, but the former has been used more frequently.

This index is, however, limited to continuous diet data. An alternative is to use the Shannon–Weaver index as a proxy for variance for discrete data such as the frequency with which individuals use a set of prey taxa. In this index n_{ij} represents the number (or mass, or volume) of diet items in individual i's diet that fall into category j. n_{ij} is then transformed into p_{ij}, which describes the proportion of the jth resource category in individual i's diet. Then

$$\mathrm{TNW_s} = -\sum_j q_j \ln\left(q_j\right)$$

$$\mathrm{WIC_s} = \sum_i p_i \left(-\sum_j p_{ij} \ln\left(p_{ij}\right)\right)$$

$$\mathrm{BIC_s} = \sum_i p_i \ln(p_i) - \left\{\sum_j q_j \left[-\sum_i \gamma_{ij} \ln\left(\gamma_{ij}\right)\right]\right\}$$

Subscript "s" in $\mathrm{WIC_s}$, $\mathrm{BIC_s}$, and $\mathrm{TNW_s}$ distinguishes this from the continuous index. The variable p_i, is the proportion of all resources used by the population that are used by individual i, q_i is the proportion of the jth resource category in the population's niche, and γ_{ij} is the proportion of the population's total use of resource j that was used by individual i, so that

$$p_{ij} = \frac{n_{ij}}{\sum_j n_{ij}}$$

$$p_i = \frac{\sum_j n_{ij}}{\sum_i \sum_j n_{ij}}$$

$$q_j = \frac{\sum_i n_{ij}}{\sum_i \sum_j n_{ij}}$$

$$\gamma_{ij} = \frac{n_{ij}}{\sum_i n_{ij}}$$

As before, $\mathrm{TNW_s} = \mathrm{BIC_s} + \mathrm{WIC_s}$ and the relative degree of individual specialization is also as before; $\mathrm{WIC_s/TNW_s}$. The Shannon–Weaver index has been widely used, but suffers serious disadvantages. First, the index increases both with the number of prey categories and/or with the evenness with which those categories are used, making its interpretation rather ambiguous. Second, the index can substantially over-estimate diet variation (low WIC/TNW) when the population as a whole relies heavily on a single prey taxon. In this case individuals whose diets largely match the population as a whole may have WIC = 0. The resulting WIC/TNW would thus be close to zero, falsely implying that there is pronounced diet variation.

The proportion similarity index (PS), is a distribution-overlap measures that provide discrete data alternatives to $\mathrm{WIC_s/TNW_s}$. This measures the mean pair wise overlap between each individual and the population where the diet overlap between an individual i and the population is

$$PS_i = 1 - 0.5\sum_j \left|p_{ij} - q_j\right| = \sum_j \min\left(p_{ij}, q_j\right)$$

where p_{ij} and q_j are the same as above. For individuals that consume resources in direct proportion to the population as a whole PS_i will equal 1. For an individual that specializes on a single diet item j, PS_i takes on the value q_j. The population-wide prevalence of individual specialization (IS) is then measured by the average of individuals' PS_i values.

These three indices all vary from values close to 1—indicating that all individuals have the same diet (may it be broad or narrow diet breadth)—to near 0, indicating strong individual specialization. All these indices yield very similar though not identical values when applied to the same data. But which index should one use? Although the indices are quantitatively very similar, each has particular advantages and disadvantages. Both WIC/TNW and $\mathrm{WIC_s/TNW_s}$ offers the attractive advantage of quantifying both relative specialization and population niche width. This can be used when testing hypotheses such as whether niche expansion during competitive release occurs by increased inter-individual variation (greater BIC), implying that higher TNW is associated with greater individual specialization (low WIC/TNW). Both WIC/TNW and $\mathrm{WIC_s/TNW_s}$ make assumptions about the resource distribution. The continuous version assumes that niches are normally distributed, whereas the Shannon–Weaver index assumes that resources are evenly distributed. The Shannon–Weaver-based index can also be biased to overestimate individual specialization due to its natural log of a proportion. Additional advantages of the two overlap indices are that they make no assumptions about the shapes of the resource distributions, and they yield estimates of specialization for each individual. The estimate of specialization for each individual further makes it possible to study the variation in specialization among individuals in a population so one can study the ecological or evolutionary (fitness) consequences of individual specialization.

It can also be important to characterize how the among individual diet variation is structured in the population, for example, the level of nestedness and clustering of the diets within the popoulation. Together with a measurement of individual

specialization, measuretments of nestedness and clustering can be useful to identify pattern of resource usage within the populations. A nested pattern of diet use indicates that the diet of selective individuals is a subset of less selective individuals. The degree of clustering in diet specialization can be estimated with network analysis. Network analysis of nestedness will then compare the overall density of connections in the network to the density of connections around individual nodes and can be used to analyze whether the network of diet use is totally random or if it is organized in clusters. Note that the clusters do not mean that individuals are clustered in space, but rather that individuals in the same cluster use the same subset of resources. Clustered diets would in this analysis represent discrete diet variation commonly refered to as discrete resource polymorphism, whereas totally randomly organized networks would represent more continuous diet variation. Indices of nestedness and clustering as well as the described indices of individual diet specialization can be calculated using the R-package RInSp (see "List of Relevant Website').

It is important that the niche axis or diet categories have been chosen appropriately when measuring diet specialization. For example, coarse-grained niche studies that pool functionally distinct resources may underestimate individual specialization. When resources that a forager distinguishes among are lumped together by an ecologist, individuals may appear more generalized than they really are. Conversely, high between-individual variation may not be biological significant if it is based on "snap-shot" sampling regimes. This risk can be minimized by several sampling schemes that allow one to establish the temporal consistency of diet variation. The most direct method is to follow individuals through time. Alternatively, a significant phenotype-diet correlation in a snapshot sample provides strong inferential support for consistent diet differentiation but does not guarantee that the quantitative measure is accurate. This is because it suggests that diet variation is due to functional morphology rather than random effects such as patchy prey distribution. Stable isotope ratios have been used to estimate the contribution of different prey to a forager's diet, as prey have characteristic isotope signatures. Isotope ratios in a forager's tissues turn over slowly, so isotope signatures thus represent a long-term average of prey use.

Why should we quantify individual specialization? The obvious answer to that question is that there are large-scale trends in diet variation that reveal more fundamental patterns about trade-offs, character release, and these effects of competition. These trends would not be detected if we simply tested whether diet variation was present or absent using a simple hypothesis testing approach. For example, one study showed experimentally that individual specialization in three-spine stickleback (*Gasterosteus aculeatus*) was stronger when competition was more intense. Furthermore, by quantifying individual specialization, we enable broad scale comparative studies where we can investigate similarities and differences between different taxonomic or geographic groups.

Implications of Diet Specialization

Why is it important to study individual diet specialization? Ecologically, studying individual level diet variation represents a more complete description of a biological system. Information on individual resource use is necessary if we want to make the transition from phenomenological models of population dynamics to mechanistic models in which the dynamics are predicted from the properties of its components (e.g., individual foraging decisions). Evolutionary, since variation is the raw material for evolution by natural selection, intraspecific niche variation thus represents an important target for natural selection. Furthermore, individual specialization, species specialization and similarly generalization are all affected by intra- and inter-specific competition, predation, and prey dynamics, so the topic of food specialization is at the interface of both ecological and evolutionary studies.

Intra- and inter-specific competition, types of social interactions, and the risk of predation or parasitism are factors generally used in describing a population's ecology, all of which can depend on an individual's resource use. Risk factors connected to diet are common because foraging individuals can be vulnerable to predators and parasites associated with a particular diet. Social and competitive interactions between individuals are strongest among individuals that use the same subset of resources especially if different resources are associated to different microhabitats. As a result, populations with large between-individual variation can be divided into subgroups that may compete within themselves but with low between-group competition. Consequently, censuses of total population size will not serve as a good proxy for the level of intraspecific competition. Instead, exploitative competition will be both density and frequency dependent.

Resource-specific ecological interactions mean that individuals within the same population can be subject to different selective pressures. Habitat and resource use affect an individual's energy income, mating options and exposure to risk. Niche variation among individuals is therefore likely to be a major source of variation in fitness and may play a central role in evolutionary diversification. In many models of evolutionary diversification, divergence is driven by disruptive selection because phenotypically average individuals (or generalists) experience disproportionately more intense competition than rare phenotypes (or specialists) with access to exclusive resources. When resource-specific fitness and individual specialization leads to frequency dependent interactions, individual specialization may lead to disruptive selection that will facilitate adaptive speciation. Whether such effects lead to trait evolution and speciation will depend on the heritability of the traits and the temporal consistency of the inter-individual variation.

Summary

Many generalized species are in fact composed of individual specialists that use a small subset of the population's resource use. The most proximate reason for why individuals will specialize on different resources is if they have different resource use efficiencies,

that is, there are efficiency trade-offs between different prey. Different resource use efficiencies may reflect variable morphological, behavioral or physiological capacities to handle alternative resources. Individual diet specialization can occur in a number of ways, they can be related to sexual dimorphism, ontogenetic niches, or related to morphological or behavioral variation in the population. However, not all diet variation needs to be related to variation in efficiencies, diet variation may also be related to variation in social status, mating strategy or territories. Studying diet variation is important both in ecology and evolution. Ecologically, diet variation is important when looking at predator–prey interactions, competitive interactions but also in population dynamical studies. In evolutionary studies, diets of an individual are equivalent to the energy acquisition of the individual and are thus strongly related to fitness. An individual with a relatively high rate of energy (high foraging rate) income will thus have a relatively higher fitness compared to the average individual. Thus, differential foraging rates on different prey types will have a big influence on both the ecological and evolutionary dynamics of populations.

Habitat Mapping

Vincent Lecours, University of Florida, Gainesville, FL, United States

Glossary

Abiotic Not living, nonbiological, without any life.
Geomatics Discipline dedicated to the acquisition, analysis, and management of spatially referenced data; includes the technologies and theories of remote sensing, cartography, spatial analysis, geostatistics and geographic information systems.
Habitat Space characterized by distinct environmental characteristics and that is associated with the presence of a particular species or community, or where a particular species or community could be found.
Spatial Autocorrelation (spatial dependence) Quantification of the tendency of spatially closer objects to be more similar than spatially distant objects.
Spatial heterogeneity (spatial nonstationarity) The level of variation of a property across space; whether a variable varies locally or globally.
Surrogate (proxy) A measurable characteristic of the environment that can substitute another one that is more challenging to measure or map.

Introduction

The use of habitat maps has become relatively ubiquitous in certain fields of ecology. Because species have a range of environmental preferences and requirements, habitat mapping approaches focus on the structure and quantity of potential habitats, either instead of, or in addition to, the distribution of biological populations at the time of sampling. The structure and spatial arrangement of habitats can be important predictors of species distribution, abundance, and richness. Habitat maps enable the interpretation of the nature, distribution, and extent of distinct types of environments, and allow predictions of species or communities distribution based on their habitat requirements or associations with the environment. Maps representing the actual or predicted spatial distribution of species and habitats have become key for data integration and synthesis to assist in the study of distribution patterns and ecological dynamics. When properly implemented at the relevant scales, habitat mapping provides accurate, quantitative and spatially explicit information that can inform decision-making. Habitat maps are among the best available spatial decision-support tools and are critical in contexts like conservation, the implementation of scientific management, the monitoring of environmental change, and the assessment of anthropogenic impacts on ecosystems.

The field of habitat mapping has evolved rapidly since the early 1990s (Fig. 1), following technological and methodological developments in geomatics, more specifically in Geographic Information Systems (GIS), spatial analysis methods and remote sensing technologies. Within a GIS environment, spatial analytical techniques are combined with different data to facilitate the

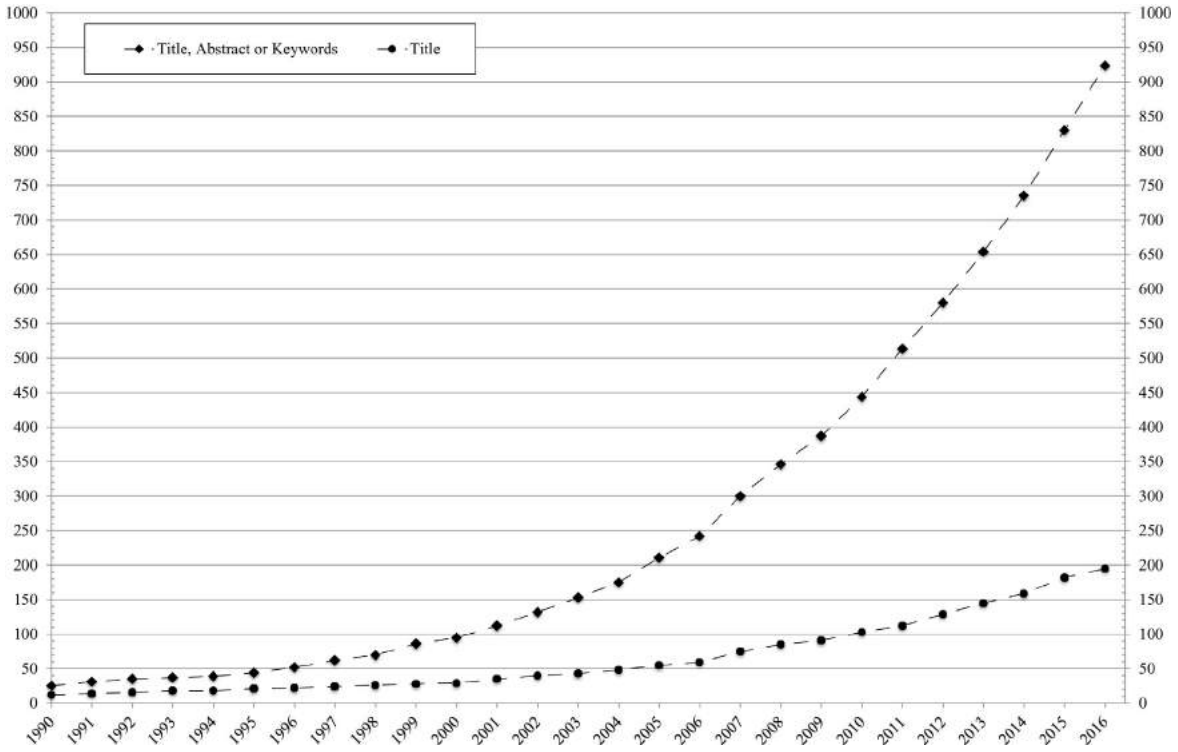

Fig. 1 Cumulative number of articles and reviews listed in the Scopus databased by the end of 2016 with the term "habitat map*" in their title ($n = 195$), or in their title, abstract or keywords ($n = 924$).

quantification and spatial representation of habitats, which provides a framework for mapping species/communities distribution and interpreting spatial patterns of biodiversity. The different approaches to habitat mapping thus generally involve the combination of various types of data (e.g., species occurrences, topographic and climatic variables) into a same geographic framework.

Definitions

Habitat

The concept of habitat has become increasingly used in ecology since the mid-1970s (Fig. 2). Many definitions of this concept have been proposed in the literature (Table 1), and many authors have called into question the ambiguous uses of the term. Some of the older definitions strictly define habitats as vegetation types, while others involve the condition that a species can survive and reproduce in the habitat, thus leaning towards the concept of ecological niche. A common element to many of those definitions is that of a multidimensional space associated with the presence of a species, the multiple dimensions representing characteristics of the physical environment. More recent definitions have generalized the scope of habitats by explicitly integrating the chemical environment—particularly relevant for aquatic and marine habitats—and by not requiring the presence of a species, thus delineating potential habitats that can be driven by different factors like vegetation types, substrate types, or altitude. The use of techniques from the spatial sciences and developments in spatial ecology have led to the recognition that habitats need to also be defined by their spatial and temporal components as opposed to only by environmental characteristics.

Mapping

Mapping, or cartography, is recognized to be as much an art as it is a science. Mapping as a science helps to define quantifiable spatial relationships (e.g., distance, relative position) among the different objects represented in maps. Maps display a selection of objects or phenomena that have been generalized, for instance by reduction, simplification or classification. The concern for the artistic component of mapping is now more about the efficiency of communicating information without jeopardizing simplicity than it is for purely artistic reasons—although maps need to be visually appealing to be effective means of communication. They are recognized to be a unique and powerful form of communication when properly drawn or produced. Good maps render the displayed information accessible to a wide variety of readers by putting the information into a common frame of reference, in this case, a geographic one, that can be read and understood by many. These characteristics of maps have made them very popular as

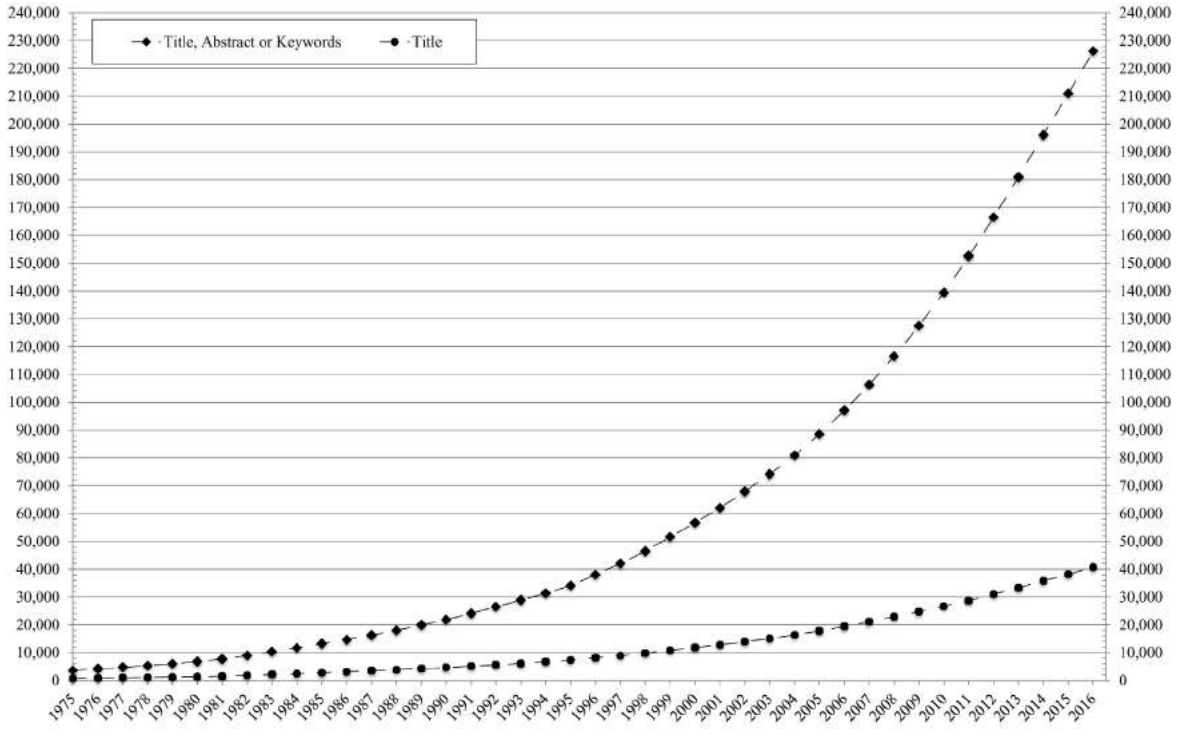

Fig. 2 Cumulative number of articles and reviews listed in the Scopus databased by the end of 2016 with the term "habitat" in their title ($n = 40{,}735$), or in their title, abstract or keywords ($n = 226{,}232$).

spatial decision-support tools in fields such as conservation and management as they facilitate communication between scientists and other stakeholders like land users or decision-makers.

The science of mapping has evolved dramatically in the last 50 years, particularly with the emergence of GIS, and digital and remotely sensed data. The increased ability to store more data in geodatabases and availability of user-friendly GIS have put mapping within the reach of scientists from a wide range of backgrounds and expertise. Developments in newer types of remote sensing (e.g., LiDAR, acoustic remote sensing) in recent decades has enabled the collection of spatial environmental data at an ever-increasing resolution, providing details on the environment in greater quantity and of better quality. These data have revolutionized habitat mapping and are invaluable for the scientific community to advance its understanding of various types of ecosystems.

Habitat Mapping

A simple etymological analysis of the term "habitat mapping" highlights the multidisciplinary and interdisciplinary nature of this field; habitat mapping integrates the ecological concept of habitat into a spatial framework for analysis and representation. Depending on contexts, habitat mapping can integrate theories and methods from the spatial sciences and ecology with those of fields such as geology, climatology, chemistry, oceanography, geomorphology, soil sciences, and many more. The adequate and simultaneous spatial representation of the different biological, physical, chemical and ecological elements of species and the environment make the accurate mapping of habitats challenging. Consequently, cartographic generalization techniques like classifications are commonly used to statistically regroup these characteristics into distinct classes organized such as the similarity inside each of them is maximized and the similarity between them is minimized.

Three broad categories of habitat maps are commonly recognized: single species habitat maps, community maps, and abiotic (or potential) habitat maps. The purpose of the map usually defines which of these types is produced, although habitat mapping is often data-driven and thus also depends on the available data. Single species habitat maps are regularly associated with the characterization of a species' fundamental niche. Community maps often link a particular combination of environmental variables with all the species forming a community. The interpretation of this type of habitat maps can be more intricate than for single species maps, as it requires a greater understanding of the biological and ecological interactions among the different species of the community. Multivariate statistics like multidimensional scaling or analysis of similarity (ANOSIM) can be used to regroup species into communities based on their similarity in spatial distribution and/or associations with the environment. Abiotic habitat maps, or maps of potential habitats, are based on the assumption that variations in biological communities follow changes in the abiotic environment. Such maps are often produced in areas with limited biological observations (e.g., the deep sea) to delineate broadly defined potential habitats.

Over broad areas, habitats are often delineated according to classification schemes, which can integrate different types of habitat maps. Classification schemes are often hierarchical, ranging from the delineation of the physical environment at a broad scale (e.g., physiographic provinces) to the delineation of finer-scale habitats. Abiotic habitat maps are thus used to define the broad levels of the schemes, while community maps and single community maps can be associated with lower levels of classification schemes (e.g., bogs, fens, seagrass meadows, soft substrate). An example of such classification scheme used for community habitat mapping is the European Nature Information System (EUNIS), which is based on six hierarchical levels that classify both the terrestrial and marine environments.

Surrogacy

Unlike broadly defined, well-known and easily mappable habitats (e.g., shallow-water coral reefs, croplands), many habitats are challenging to define. Due to the difficulties associated with sampling ecological data at sufficient spatial and temporal resolutions, habitat mapping practices often rely on the concept of surrogacy to understand species distribution and ecological processes. A surrogate, or proxy, is a measurable characteristic of the environment that can substitute another one that is more challenging to measure or map. For many habitat maps, the characteristic that is more difficult to measure or map is an element of biodiversity (e.g., presence, abundance). Surrogates can be sampled in situ at specific locations (e.g., soil content, water pH) or can be measured

continuously or near-continuously to provide broader coverage (e.g., vegetation indices, sea surface temperature). Several types of environmental variables, described below, were found useful for habitat mapping, with differing degrees of importance depending on species, locations, settings, and scales. While the next subsections introduce some of the potential surrogates of species and habitat distribution that have been used in habitat mapping, they do not make for a comprehensive review of all of them. Readers are invited to consult the list of recommended readings for more information.

Types of surrogates

Physical surrogates

The physical environment is arguably the most extensive and most used source of surrogates for habitat mapping. For example, temperature is often used for mapping habitats on land and in the oceans, as it has been associated with reproductive success, growth, and speciation rates, thus having the potential to drive or restrain species distribution. Geology, including the nature, size, and location of substrate, influences vegetation types and global biodiversity on land and is among the main drivers of benthic biodiversity in aquatic and marine environments. Topography and geomorphology, which respectively represent the arrangement of physical features and their shape, are also widely used in all types of environments. These two elements can be quantified using geomorphometry, or terrain analysis, which is the quantitative study of the terrain. Hundreds of algorithms from the geomorphometry literature enable the derivation of terrain attributes from digital terrain models representing elevation or depth. Many user-friendly GIS tools facilitate the derivation of these attributes without requiring prior knowledge of the algorithms behind them. Terrain attributes have been used extensively in ecology and habitat mapping. They have become particularly relevant for marine habitat mapping where bathymetric data (i.e., depth values) are often the only available environmental data. The derivation of terrain attributes thus provides a greater number of potential surrogates to be tested against biological data. Among the most popular terrain attributes, slope, rugosity and topographic position indices are often tested as surrogates as they together quantify terrain complexity. Terrains that are more complex are known to shelter a higher level of biodiversity than less complex ones. Aspect, which measures the orientation of the slope, can act as a surrogate of sun exposure in terrestrial habitat mapping or food supply in marine habitat mapping, and curvature can be used in relation to water flow on land and of sedimentation and current patterns underwater.

A few potential physical surrogates are only relevant for marine habitat mapping, and to a lesser extent aquatic habitat mapping. For instance, current patterns and other hydrodynamics conditions are excellent mediums of transport for elements essential for many marine species, including food and oxygen, and are therefore relevant to test for surrogacy when data is available. Hydrostatic pressure is another potential surrogate only applicable to marine studies as the physiology of many marine organisms is pressure-dependent. Pressure affects proteins, biological membranes and rates of enzymatic catalysis, thus having the potential to restrict habitat for particular species.

Chemical surrogates

Potential surrogates originating from the chemical environment are underused in habitat mapping, likely due to the difficulty to obtain continuous coverage of the relevant variables using remote sensing. Chemical surrogates are particularly relevant for habitat mapping of vegetation as plant growth and survival are dependent on particular pedological characteristics (e.g., soil pH, nutrients availability). In aquatic and marine environments, oxygen concentration is a potential driver of species distribution as some species have a low tolerance for hypoxic conditions. Many skeleton-forming organisms like corals also require specific chemical conditions to grow or survive, particularly in terms of phosphate, calcium carbonate, or salinity.

Biological and ecological surrogates

These types of surrogates are particularly relevant for species or communities associated with the presence of a habitat-forming species (e.g., vegetation, corals); ecological interactions like predation or commensalism can lead to the definition of surrogate for a species based on the nature of the relationship and the presence or absence of the other species. Chlorophyll α concentration at the surface of the ocean can also be used as a surrogate of primary production to determine the estimated nutritional resources available to different organisms and thus defining areas as suitable habitat. Knowledge of specific behaviors (e.g., feeding, growth, reproduction strategies) may help in the delineation of habitats when these behaviors are spatially varying, for instance when patterns of larvae dispersal can be assessed or nurseries identified.

Spatial and temporal surrogates

When expressed as ecogeographical data (i.e., spatial ecological data, or ecological data with a geographic component), potential surrogates have a spatial dimension defined by their latitude, longitude, and elevation (or depth). These spatial variables can themselves be used as surrogates as they sometimes are found to drive species and habitat distributions. For instance, latitude and altitude are known to drive patterns of vegetation distribution globally. A derivative of these components of location is geographical distance, which can be important in defining habitats. For instance, distance from the coast, distance from tree cover, and distance from a reef can be used to characterize transitional habitats or to quantify the influence of a specific habitat type on its surroundings (e.g., edge effect). The third dimension is also important. In some contexts, small changes in elevation or depth can better explain changes in habitat types than larger changes in latitude and longitude. The fourth dimension, time, is rarely used in habitat mapping but can be critical in some contexts. For instance, if there is a seasonal pattern in habitat selection for migratory species, an area may

be a suitable habitat for only a few months of the year. Time can be used as a surrogate of species distribution to capture the varying habitat suitability in temporally explicit habitat maps.

Direct and indirect surrogates

Once an environmental variable is identified as being a surrogate of a particular species or habitat distribution, one needs to be careful with the interpretation of that relationship as it is not necessarily a causal-effect link: it may be an indirect surrogate, as opposed to a direct surrogate. Topography is one of the most common indirect surrogates. On land, topography is often found to drive species and habitat distribution. However, topography influences gradients in moisture, energy, and nutrients across the landscape. These gradients are often the true drivers of species and habitat distribution (i.e., the direct surrogates) while topography is an indirect surrogate. The situation is similar underwater. Topography is often identified as a driver of the distribution of suspension-feeders, but is likely an indirect surrogate since topography influences circulation patterns and accelerates currents that bring food to these organisms and rid them of sediments. The hydrodynamic conditions are thus the direct surrogates of species and habitat distribution and topography is an indirect one.

Spatial variables such as latitude and longitude are often not direct drivers of habitat patterns as they reflect other driving gradients. For instance, the strongest environmental gradients in the oceans, such as temperature, pressure, sedimentation, food availability, and community structure (the direct surrogates), are all associated with changes in depth (the indirect surrogate).

Approaches

The very general approach to habitat mapping involves the spatial integration of different datasets representing potential surrogates and/or species or habitat distribution, most often within a geospatial environment. There are however three specific approaches to habitat mapping: the abiotic surrogate approach, the top-down (or unsupervised) approach, and the bottom-up (or supervised) approach. Each of them uses a different way to combine the different geospatial environmental datasets. In all cases, the available data are integrated into a habitat model. Different models are used with different approaches and types of maps. The choice of the methods is therefore adapted to the purpose and needs of the application.

Abiotic Habitat Mapping

Abiotic surrogate mapping does not consider biological data and produces maps of potential habitats. Maps created with abiotic surrogates allow the identification of broad environmental classes (e.g., geomorphic features) from which species' distribution can then be predicted; abiotic surrogate mapping is primarily based on the environmental attributes—or potential surrogates—deemed relevant for the distribution of the species or communities of interest. When there are no particular species or communities of interest, abiotic habitat mapping can be used in classification schemes. In general, this approach is used to map habitat features that can be resolved within the environmental data, thus not attempting to delineate attributes beyond what the habitat model is capable of resolving.

Habitat models used in the production of abiotic habitat maps are often unsupervised classification algorithms, more specifically statistical clustering techniques, from the remote sensing and digital image analysis literature (Table 2). The environmental data are used as input to the algorithm (Fig. 3), which usually performs a classification by regrouping individual pixels with others that share similar characteristics. If an object-based approach is preferred to a pixel-based approach, the algorithm first segments the dataset, meaning that the algorithm divides the data into distinct spatial units before classifying them. In some cases, segmentation can also be performed manually by expert interpretation, although this practice is dwindling because of the objectivity of algorithms as opposed to the subjectivity of expert interpretation. An expert validation and visual interpretation of the resulting units is however recommended. Like for pixel-based approaches, the different spatial units resulting from the segmentation are then regrouped with other units that share similar characteristics in order to be classified. The interpretation of these classes can be done based on existing knowledge of the area or by analyzing the characteristics of the environmental data within each class. Methods like multivariate ANOSIM, nonmetric multidimensional scaling, and percentage of similarity (SIMPER) can be used to investigate differences between classes and provide an estimation of the quality of the segmentation and classification.

Table 2 Examples of some specific techniques used in habitat mapping

Unsupervised classification algorithms	*Habitat suitability modeling techniques*	*Geostatistical techniques for multiscale analysis*
ISO cluster	Boosted regression trees	Bivariate scaling
K-means	Generalized additive model	Coarse-graining
Mahalanobis classifier	Generalized linear model	Lagging
Minimum distance	Maximum entropy	Scalewise variance
Nearest neighbor	Random forest	Spectral analysis

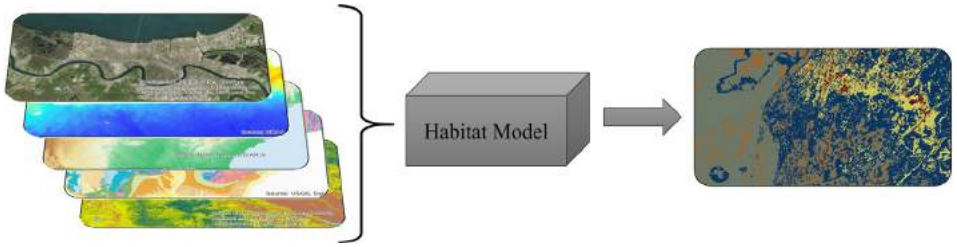

Fig. 3 In the abiotic habitat mapping approach, the environmental data (left) are used as inputs to the habitat model (center), which classifies the data to create a map of potential habitats (right).

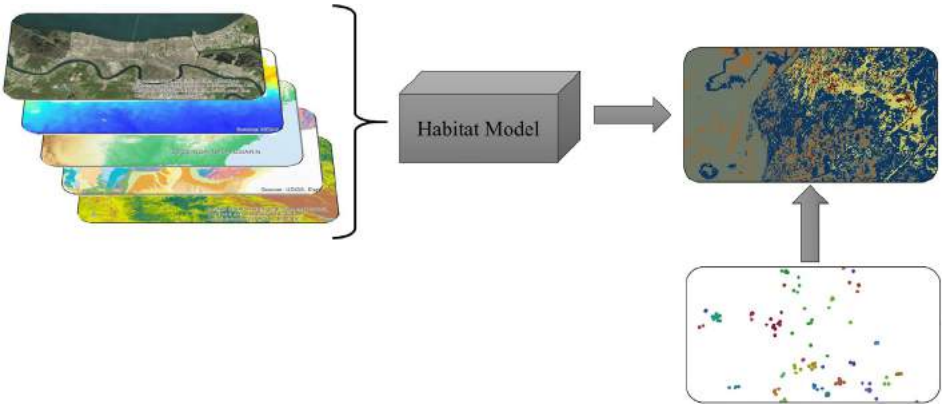

Fig. 4 In the top-down (unsupervised) approach to habitat mapping, the environmental data (left) are used as inputs to the habitat model (center), which classifies the data to create a map of potential habitats (right) that is then spatially compared with ground-truth data or biological observations to be interpreted and produce the final maps. Some of the classes resulting from the application of the habitat model may be further regrouped when compared with the sample data, thus creating a different but final habitat map.

Top-Down Approach

The top-down, or unsupervised approach is very similar to the abiotic surrogate approach: classification and, if needed, segmentation are performed, but the interpretation of the classes is informed by their spatial comparison with ground-truth data or biological observations (Fig. 4). When the ground-truth data are not of biological nature (e.g., sediment grain size), it then produces abiotic habitat maps (not to be confused with the abiotic surrogate approach to habitat mapping). If compared to biological observations, then single species habitat maps and community habitat maps are produced.

Maps produced using this approach can be validated and their accuracy measured with confusion matrices. Confusion matrices are built by spatially comparing the predicted habitat classes from the classification to the actual habitat classes provided by the ground-truth data or biological observations. A number of measures that quantify classification accuracy can be derived from a confusion matrix. The overall, producer and user accuracies, the kappa coefficient, the true/false positive/negative, and sensitivity and specificity are among the most commonly used measures of accuracy assessment.

Bottom-Up Approach

The bottom-up, or supervised approach, combines the ground-truth data or biological observations with the environmental data in the habitat model rather than after the model is applied, meaning that the segmentation of the environmental data into spatial units is informed and driven by the ground-truth data or biological observations (Fig. 5). Those data are usually divided between a training dataset and a validation dataset: model validation is critical in habitat mapping and is used to assess whether or not a model meets the performance requirements of its intended use. In its simplest form, the bottom-up approach to habitat mapping can be applied using simple statistics (e.g., correlations), multivariate statistics (e.g., linear discriminant function), and remote sensing algorithms for supervised classifications (e.g., maximum likelihood). With these techniques, the classification of the data is informed by the training samples, which are used to define the environmental characteristics, or signature, at their location. Then, the rest of the environmental data is classified according to this signature, and the validation samples are used to quantify the accuracy of the classification. The use of these techniques has however diminished in recent years because of the upwelling of habitat suitability models developed in ecology.

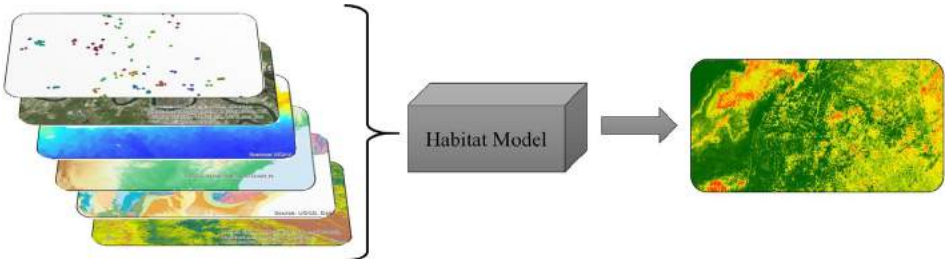

Fig. 5 In the bottom-up (supervised) approach to habitat mapping, the environmental data and the ground-truth or biological data (left) are used as inputs to the habitat model (center) to create the habitat map. In this example, the map represents habitat suitability.

Habitat suitability models, also called ecological niche models, species distribution models, resource selection functions or bioclimatic envelopes, have become the most common applications of the bottom-up approach to habitat mapping. These models can produce single species habitat maps or community maps by modeling the location of the species or community as a function of the environmental data. These models can then be used to predict the extent and location of the species or community distribution in areas where only environmental information is known, whether it is within the geographical area of the existing samples (i.e., interpolation), or outside the range of existing samples (i.e., extrapolation). While there are many types of habitat suitability modeling techniques operating on different frameworks (e.g., statistical, tree-based, machine learning), new models are frequently being introduced (Table 2). The wide availability of techniques and the lack of consensus on which one to use make the choice of modeling techniques challenging. The selection of the appropriate techniques depends on the availability and the spatial or temporal resolution of data in relation to the geographic extent of the study area. Models are often developed for a specific type of data, whether it was for use with presence-only data, presence/absence data, or abundance data. The criteria to consider in the selection of a model for a particular application are (1) species characteristics, (2) data availability, (3) spatial scale, (4) stability in time, and (5) the ecological underpinnings of the model.

Validation techniques specific to habitat suitability models have been developed. Models are expected to have some level of prediction error, and although ecological representativeness and model credibility should be considered, the validation of habitat suitability model usually focuses on the model's predictive performance. While the area under the curve (AUC) of a receiver operator characteristic (ROC) plot is the most commonly used performance measured, it has been highly criticized in the last decade.

Outcomes and Further Analyses

In general, two types of outcomes can result from the application of these approaches: habitat maps with classes represented as groups of pixels associated with a particular habitat type, or habitat maps in which each pixel represents a quantitative measurement such as the probability of occurrence, the relative likelihood of occurrence, or predicted abundance. If needed, the latter type can be categorized (e.g., 0%–25%, 25%–50%, 50%–75%, 75%–100%) to produce the former. The first type of outcome can also be simplified and transformed into vector data for esthetic purpose, although this may alter the accuracy of the displayed information.

Depending on their purpose, habitat maps are not always the final product of an analysis and can be used in further spatial analyses. For instance, they can be overlaid with other data to establish relationships between habitats and other spatial phenomena (e.g., human activities, the distribution of different species, municipal zoning). Habitat maps can also be used with other maps to assess temporal changes in habitat distribution, given that they were produced with the same methodology. They can also be used to analyze patterns in spatial and landscape ecology. Habitat-based approaches to estimate organism response to landscape heterogeneity have been used for decades in landscape ecology. The environmental heterogeneity represented in habitat maps is analyzed with spatial pattern metrics that quantify the spatial structure of the environment and delineate patch-based models of habitat type. The size of habitat patches can be an indicator of the spatial scale at which species use an environment when linked to species distribution and behavior.

Particular Considerations for Habitat Mapping

Scale

Species-environment relationships and ecological patterns and processes are scale-dependent, making habitats scale-dependent. A habitat occurring at a specific spatial or temporal scale may not occur at another one, and no single scale is suitable for the study of all habitats. The importance of scale became widely acknowledged in the 1980s and research on scale remains of utmost importance in many sciences. It is critical for the elements being mapped to be situated in context with the appropriate scales. Many types of scale are recognized in the literature. The types relevant for habitat mapping are spatial, temporal, thematic, management and social scales. Spatial and temporal scales commonly refer to the spatial and temporal characteristics of an object or process, including both

its resolution (i.e., the level of spatial detail or the length of the unit of time) and extent (area or range of time). These two types of scale can be further divided into three types: ecological (or intrinsic), observational, and analytical. The ecological scale is that at which a pattern of process occur, while the observational scale is that at which we measure this pattern or process. Consequently, the observational scale is often associated with the resolution and extent of environmental data. The analytical scale is the scale at which the data are analyzed, for instance in focal statistics used to measure terrain attributes. The analytical scale can also be related to the minimum mapping unit, which is characteristic of habitat maps used in a context of landscape ecology to determine the smallest area to be mapped as a discrete unit for the calculation of spatial pattern metrics. The thematic scale is linked to the level of organization at which objects of study are described (e.g., family vs. genus). Management and social scales are not directly related to the production of habitat maps but are important when the maps are used in some particular contexts. Management scale is related to spatial, temporal and thematic scales as management plans and actions can have a spatial, a temporal and a thematic component. Finally, the social scale is the scale at which people or industry use resources.

Scale has always been a challenge in both ecology and the spatial sciences, making it even more so in a discipline like habitat mapping that integrates them. Scale issues have been widely reviewed in the literature (see further readings). It is now widely recognized that species-habitat relationships are scale-dependent, that environmental characteristics may act as surrogates for species distribution as some scales but not at others, and that a spatial continuum-based approach should be used to identify the ranges of scales over which organisms associate with their habitat. The observed relationships between any two variables can vary across the different types of scales, and therefore understanding the effects of scale in habitat mapping is challenging but essential. Issues can arise when there is a mismatch between ecological, observational, and analytical scales as the appropriate detection of species-habitat relationships and ecological patterns and processes is dependent on the observational and analytical scales to encompass the ecological scales of the habitat being mapped. Producing habitat maps using unsuitable scales for the area or species being studied may affect map accuracy and model performance and reliability. Since habitat maps are used as spatial decision-support tools in some particular contexts (e.g., to inform management or conservation), the situation can be more complex as the appropriate matching of methodological (observational and analytical), ecological, social and management scales is needed to be effective. Much work remains to fully understand the underpinnings of attempting to match the many different types of scale to produce sound science, better inform decisions, and answer the needs of different stakeholders.

Habitat maps are often produced at one particular scale, namely the observational scale at which data were available, and thus regularly fail to capture multiscale environmental drivers of habitat and species distribution. However, recent years have seen the rise of methods for the adoption of a multiscale perspective in habitat mapping that would guide the choice of objective and nonarbitrary methods to select observational and analytical scales. The most relevant scales will vary depending on the study area, organisms considered, and environmental variables available. Some of the suggested approaches are truly "multiscale" and integrate data from multiple scales simultaneously in the habitat model, while others are "multiple scale approaches" that integrate data into a habitat model at multiple successive scales, giving the possibility to combine the multiple maps at different scales in further analyses. Geostatistics, or spatial statistics, put multiscale analysis on a sound mathematical basis (Table 2). Current limitations for a proper implementation of multiscale approaches are associated with data collection methods, which limit the resolution and extent of data, and the lack of availability of user-friendly tools to easily implement such analyses. Until such tools become available, scale information should always be explicitly stated as part of the metadata, and habitat mapping efforts should always be associated with a scale assessment.

Data and Map Quality

Another element that requires careful consideration in habitat mapping is data quality, which encompasses concepts of accuracy, precision, and uncertainty and can be of different types (e.g., spatial, thematic, and temporal). All data carry errors and uncertainty, and the parameters and structure of habitat modeling techniques themselves can introduce uncertainty in an analysis. Understanding data limitations is crucial when integrating them into a workflow as errors and uncertainty propagate throughout analyses and ultimately affect their outcomes. While research has been done on individual components of data quality (e.g., positional accuracy, uncertainty), there is still a general misunderstanding of how all the components integrate and add up together throughout the workflow and to influence habitat maps. While there are no readily available tools to assist in comprehensive data quality assessments, it is important that habitat map producers do not simply disregard it since it is an inherent part of any ecological analyses. Known limitations of data and methods should be acknowledged in the metadata associated with habitat mapping efforts, together with their potential impact on analyses. Such assessment should be made both at the data level before they are integrated into the analysis, and at the end of the workflow on the habitat maps. The assessment of the data before they are used in the habitat model may assist in deciding if the data should be at all integrated into the model. Measures of map accuracy (e.g., commission and omission errors) should always be reported. The need for maps of ignorance has been acknowledged in the literature; maps of ignorance spatially display errors and uncertainty that are associated with habitat maps. They can be provided as probabilistic outputs that account for model uncertainty, or by producing and combining multiple habitat maps with, when possible and appropriate, multiple habitat models. The comparison of the multiple maps may help identifying areas that are consistently classified as the same habitat type, thus indirectly providing a measure of confidence in the mapping outcome. Combining multiple maps can reduce uncertainty and help identify and understand data and ecological patterns where maps agree or disagree with each other. Ensemble techniques are promising methods for the implementation of these solutions.

Other Spatial Concepts

By its spatial and data-driven natures and the near ubiquitous use of GIS, remote sensing and spatial analysis in its workflow, habitat mapping and its practices are directly influenced by spatial concepts. Beyond the questions of scale, considering spatial properties of the data is vital in understanding ecological complexity in all types of habitats. The spatial attributes of measurements are thus essential to be considered when making habitat maps. Two of these attributes are spatial heterogeneity (spatial nonstationarity) and spatial autocorrelation (spatial dependence). They are properties of most ecogeographical data: spatial heterogeneity refers to the level of variation of a property across space, i.e., if an observed variable varies locally or globally, while spatial autocorrelation is the quantification of the tendency of spatially closer objects to be more similar than spatially distant objects. These two properties can affect the measurements of observed species-habitat relationships, particularly when regular statistical methods (e.g., those based on assumptions of independence between variables and identical distribution) are used. Spatially aware statistical methods (e.g., locally and geographically weighted methods) and techniques from geostatistics (e.g., factorial cokriging) should be adopted more consistently in habitat mapping to produce maps and measurements of species-habitat relationships that are sound and consider the spatial effects of the data.

Another concept from the geospatial literature from which habitat mapping practices would greatly benefit is the concept of fuzzy logic. Most habitat mapping efforts impose discrete boundaries to habitat types. However, it is well recognized that the natural environment rarely shows sharp transitions from a habitat type to another—except in the presence of anthropogenic disturbances. In order to improve spatial representation of habitats, there is a need to characterize these transition zones between habitat types. Theories from fuzzy logic demonstrate a lot of potential for application to habitat mapping. Instead of using a binary system in which a location either is a habitat type or is not, fuzzy logic quantifies the probability of that location to be any of the proposed habitat types, thus considering the possibility that the location could be of two or more types. An area having a relatively equal probability to be of two or more types can then be interpreted as being an area of transition between those particular habitat types. Some geostatistical methods have been developed to integrate the concept of fuzzy logic in analyses and should be used more often in habitat mapping.

Ecological Representativeness and Fitness for Use

Not all data are equally good at capturing the relevant information, and not all information is relevant for a particular species, habitat or area. Habitat maps are highly sensitive to the methods used to produce them and to the data selected, which includes their nature, quality and scale components. A critical evaluation of the data has to be performed before their inclusion into a habitat model. Rather than selecting data based on availability, the fitness for use of these data has to be assessed in terms of ecological, biological or environmental relevance (including scale), but also in terms of quality. An inappropriate selection of data can produce results that do not accurately represent the studied habitats. Requirements for the assessment of fitness for use is different based on the type of habitat map and approach used as it requires an intended purpose and specific application goals or questions. Abiotic habitat maps may not require data to be as much ecologically representative as data used for single species habitat maps, which should consider variables that are realistic for the focal species' life history and traits. The assessment of fitness for use may also guide the number of variables to be included in an analysis: too few variables can result in overly general habitat characterizations while too many variables can reduce the generalization and reproducibility of the approach. Fitness for use assessments also need to consider the scale of the data: it is as important to identify the relevant environmental factors as it is to identify the scales at which these factors drive species distributions. In addition, there is often a trade-off between spatial scale and data quality.

Conclusions

The application of geomatics-based habitat mapping to ecological questions is relatively recent and new developments and techniques are commonly introduced (e.g., object-based image analysis, ensemble mapping). In the near future, standards and protocols are likely to be updated to integrate new tools and methods that facilitate the implementation (1) of multiscale approaches that consider the spatial nature of data, (2) of error and uncertainty quantification in data and analyses, (3) of fuzzy logic techniques to study habitat edges and transitional habitats, and (4) of dynamic cartographic representations that provide a better multiscale, multi-temporal, and multidimensional representation of habitats. Assessments of fitness for use should always be performed, and complete metadata that explicitly state scale information, error and uncertainty quantification, and any other relevant information should always be associated with data and habitat maps. The availability of tools that streamline the workflow from data collection to analysis, in addition to data quality assessment, will be key in enabling scientists with a wide range of background and experience to produce habitat maps that are grounded on a sound statistical and spatially explicit basis. Finally, given their sensitivity to data and methods characteristics, habitat maps should be critically interpreted to try to understand not only the ecological patterns and processes that may have been captured by the habitat mapping, but also the cartographic patterns that are dependent on the procedures rather than the subject of the mapping.

Why Select or Prefer a Given Habitat?

Definition of Habitat and Habitat Patch

For most species, the environment is heterogeneous at various spatial and temporal scales (Fig. 1). A habitat can be defined by a given type of environment characterized by general physical features (e.g., type of vegetation, water, or soil structures). The habitat of a species can also be defined by the general characteristics of the areas used by individuals, which must be suitable enough for the species' activities. This definition results from the observed spatial distribution of individuals. Finally, at a finer scale, a habitat can also be defined by the portion of the environment devoted to a particular activity of individuals (e.g., breeding or foraging). Usually, the term `habitat' does not encompass conspecifics, that is, the social components of individuals' activities, contrary to the term `environment'. A habitat patch can be defined as a continuous and homogeneous portion of a habitat (Fig. 1).

Definition of Habitat or Patch Suitability and Quality

A habitat is suitable for a species when it contains all resources needed for a given activity in sufficient quantity (e.g., food when foraging, nest sites when breeding). Individuals can only live in suitable habitats; thus by definition, habitats where individuals are found to live or perform a given activity must be suitable. Habitat suitability can be difficult to define using other criteria than the observed repeated and long-term presence of individuals.

Suitable habitats and patches for a given species can differ by some intrinsic characteristics affecting individuals' fitness (e.g., available resource quantity and quality, level of competition for resources or predation). The quality of a habitat or patch is usually defined by the fitness (measured, e.g., by energy gains per time unit or reproductive output) that can be achieved by individuals in this habitat or patch: a habitat or patch in which individuals achieve high fitness is defined as a high-quality habitat or patch, relative to other habitats and patches. Within the framework of foraging and breeding habitat choice, the quality of habitats is usually evaluated in terms of energy intake rate and reproductive success, respectively.

Spatiotemporal Variability of Habitat Suitability and Quality Leads to Habitat Selection

In heterogeneous environments, natural selection will favor individuals capable of occupying the most favorable areas for activities linked to fitness, that is, survival and reproduction. Spatial and temporal environmental heterogeneity (Fig. 2) thus leads to selective pressures favoring behaviors that allow individuals to select high-quality habitats or patches, that is, the evolution of individual strategies of habitat choice, for any activity considered (e.g., foraging for food, searching for a sexual partner, finding shelter from predators, breeding).

Spatial heterogeneity and temporal predictability of habitat or patch quality are required conditions for habitat choice or preference to evolve (Fig. 2). In a homogeneous and equally exploited environment, there is no need for individuals to choose because the expected fitness will be equal in all habitats or patches. Moreover, if the environment is not predictable at the relevant timescale for the activity considered, a location cannot be chosen based on given characteristics since they could randomly change in the time between gathering information on those characteristics and individual decision, thus preventing individuals to achieve the expected fitness.

Habitat choice can have a major impact on fitness. Wrong decisions can lead to highly reduced survival, or complete breeding failure. Habitat or patch choice will be all the more critical as the temporal scale involved is long and individuals' movements are spatially constrained, for example, breeding compared to foraging habitat selection. The habitat used for breeding also determines the conditions to which breeders will be exposed during this period of life, sometimes representing most of an individual's lifetime. Selective pressures on habitat choice are thus strong.

Sources of Variation in Habitat Suitability and Quality

Spatial and temporal heterogeneity in habitat or patch suitability and quality can be due to many different factors linked to abiotic, biotic, and social characteristics. The physical characteristics of the environment that can affect fitness vary from climatic conditions (rain, wind, and temperature regimes), soil nature (e.g., for species that dig burrows), stability of the substratum (e.g., when breeding on a slope or in a tree), level of salinity (for marine species), etc., depending on the species considered. Biotic sources of environmental variation include the availability of biotic resources (e.g., food and nest-building materials), which may

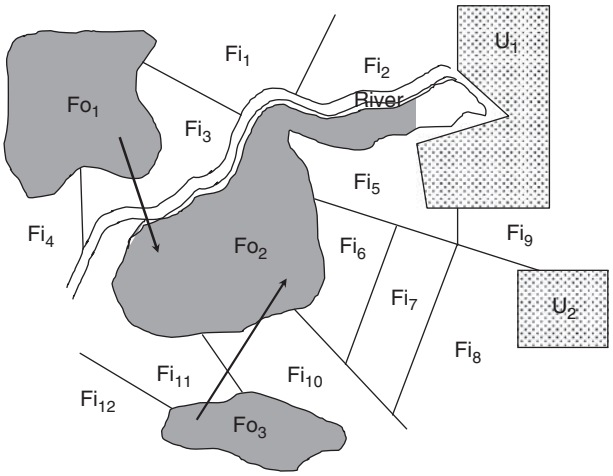

Fig. 1 An illustration of environmental spatial heterogeneity defining habitats and habitat patches. In this schematic farmland landscape, portions of the environment are constituted by a river, fields (delimited by straight lines), forests (gray zones), and urban areas (dashed zones), which have very different general physical characteristics and define four different habitats. Within each habitat type, several continuous and homogeneous subareas can be found and define habitat patches: Fo_1 to Fo_3 (forest), Fi_1 to Fi_{12} (fields), U_1 and U_2 (urban areas). Patches of the same habitat can vary in quality; for instance, different types of crops may generate different amounts of food or breeding sites availability in different fields.

be required in sufficient quantity as well as quality (e.g., required nutrients may only be available in specific food items); predators and parasites are often spatially heterogeneous biotic factors.

Finally, social components can play a major role. The density of conspecifics or heterospecifics exploiting the same resources can vary drastically in time and space, and competitors' presence may reduce the fitness of a given individual directly (e.g., when resources are limited) or indirectly (e.g., via the attraction of common predators). Because conspecifics also have to select and secure resources, their distribution among habitats and patches will affect the relative quality of potentially available resources. Conspecific decisions affect fitness gains expected by individuals choosing a particular habitat or patch (i.e., a frequency-dependent process). Conversely, conspecifics' or heterospecifics' presence can also have positive fitness effects, for example, when individuals interact with each other to capture preys, deter predators, build nests, etc., so that when conspecific density decreases below a certain value, individuals' fitness decreases (Allee effect). Conspecifics' presence can also be beneficial by providing information about habitat or patch quality. Both conspecifics' quantity and quality may vary and thus affect breeding habitat quality. In particular, the relatedness between individuals can affect local habitat quality, through kin competition or cooperation.

In many cases, individuals will require several different critical resources simultaneously. All the fundamental ecological requirements for a given activity thus have to be accounted for. For instance, a breeding patch may provide large amounts of food, but lack breeding sites, and thus will not be used. The different factors affecting fitness are also likely to interact with each other. Furthermore, spatiotemporal variations of important factors likely show different patterns at different scales, generating tradeoffs between factors, since the values of the different factors that maximize individual fitness may not occur in the same locations at the same time. These tradeoffs may themselves differ in time and space.

Scales of Variation in Habitat Suitability and Quality

The importance of a given factor for habitat choice varies with its spatiotemporal variability. Local habitat quality can vary at different scales, both spatially (e.g., between and within habitat patches) and temporally (**Fig. 2**). Detecting spatial heterogeneity and temporal predictability is tightly linked with the scale considered. The environment may be homogeneous at a given spatial or temporal scale (e.g., within patches or hours), but heterogeneous at another scale (e.g., among patches or years). Habitat selection can involve a cascade of nested scales: individuals can first choose among habitat types, then a general area within a habitat type, and then within this area, a patch that may comprise several sites. The relevant spatial and temporal scales at which habitat choice needs to be investigated thus have to be identified. These scales are constrained by habitat heterogeneity itself, but also by the ability of individuals to detect heterogeneity. Individuals may choose between habitats only if they are aware of habitat or patch quality variation. The scales at which an individual perceives spatial heterogeneity (depending, e.g., on its movement ability) constrain habitat selection and define the upper scales of possible habitat choice. Only environmental factors affecting fitness and varying in time and space at the scales individuals can explore are therefore relevant to habitat choice.

Definition of Selection/Choice/Preference

Because of environmental heterogeneity, individuals face alternatives with different fitness outcomes. When confronted with multiple alternative situations, individuals eventually select one of them, and are said to perform a choice or prefer one option

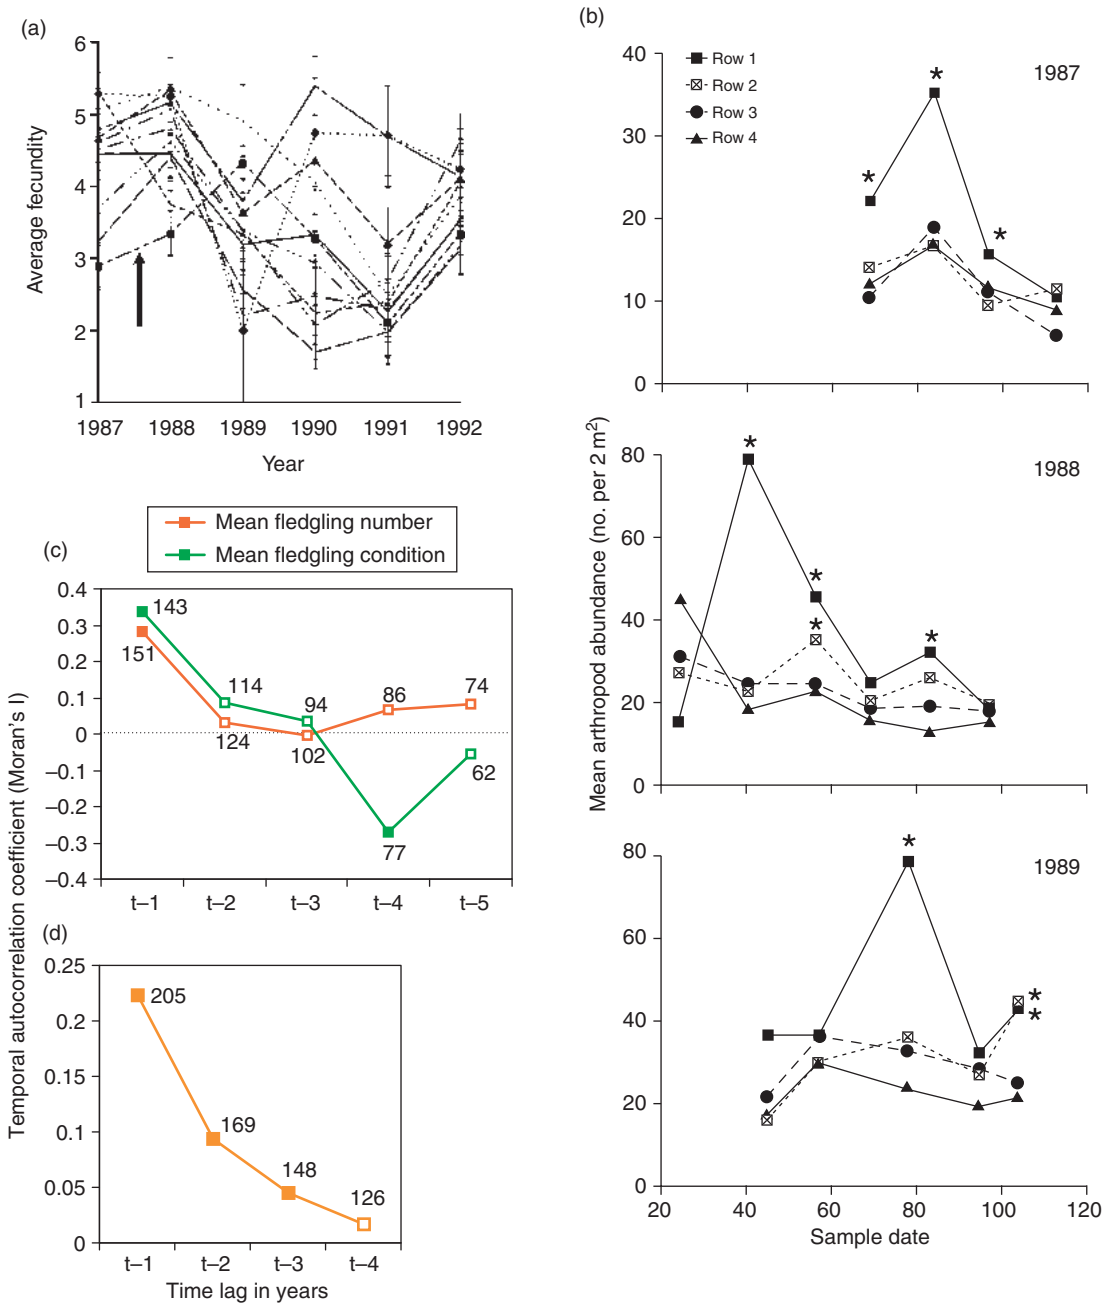

Fig. 2 Illustration of the spatiotemporal variation of habitat quality from several field studies. (a) Mean fecundity (number of young fledged per reproductive event ±1 SE) of collared flycatchers (*Ficedula albicollis*) in a series of 11 forest patches over 6 years. The relative quality of a patch differs between years: for example, the patch indicated by an arrow has the lowest mean fecundity in the first year, but the second highest fecundity 2 years later. (b) Mean prey abundance per 2 m^2 leaf surface in a flooded vegetation along shores that constitutes breeding habitat of prothonotary warblers (*Protonotaria citrea*) over 3 years, according to the localization of breeding site within patch. Sites are located in rows parallel to shoreline, with row 1 closest to, and row 4 farthest from, the shore (stars indicate significant differences). (c) Temporal autocorrelation of mean fledgling number and condition as measures of patch quality in collared flycatchers in a series of 20 forest patches over 20 years (closed symbols: significant coefficients). The autocorrelation fades after a time lag of 1 year. (d) Conversely, the temporal autocorrelation of patch reproductive success (mean number of fledged young per nest) for black-legged kittiwakes (*Rissa tridactyla*) stays significant for 3 years. (d) Data from Danchin, E., Boulinier, T., Massot, M., 1998. Conspecific reproductive success and breeding habitat selection: Implications for the study of coloniality. Ecology 79, 2415–2428.

when the probability to choose this option is significantly higher than expected by chance, and is affected by the variation in the expected fitness among potential alternatives. In the classic expression `habitat selection' (synonym of `habitat choice'), the term `selection' describes a process of individual choice using some decision rule (despite implying no conscious mechanism), which includes the processes of information acquisition about the quality of alternative habitats or patches, and information use to select the alternative expected to maximize fitness.

Because of competition, all individuals may however not be able to settle in the highest-quality, preferred habitat or patch, that is, the realized choice may not reflect individual's preference. This may be because individuals are prevented from choosing a habitat or patch by dominant competitors despite attempting to do so, or because individuals evaluate competition intensity beforehand and choose not to use these best habitats or patches. Furthermore, individuals may use different strategies than optimal habitat or patch choice, that is, choose a suboptimal patch but compensate for the decrease in fitness using other strategies. For instance, individuals may choose to exploit different food sources, or adopt strategies limiting risks, rather than changing patch.

Which Habitats and Which Constraints for Different Choices?

Foraging Habitat Selection

The issue of finding and exploiting food is crucial. In heterogeneous environments, foraging habitat patches differ in quality depending on the availability of food resources and their intrinsic quality (e.g., nutritive value), but also on the costs associated to exploit these resources, involving access to food items in terms of energy, time, and injury risk when competing, risk of being preyed upon, of getting scrounged by con- or heterospecific competitors, etc. Spatial and temporal scales involved in foraging habitat selection can vary (e.g., from a few seconds up to days in large predators), but in most species, foraging habitat choices are made by individuals a large number of times over their entire lives. Decisions linked with foraging habitat selection include the choice of patches where to start foraging and duration of patch exploitation following progressive resource depletion over time, thus decision to depart to another foraging patch (**Fig. 3**).

Theoretical models have been built and tested empirically to investigate which conditions affect these two types of decisions. Classical optimal foraging theory addresses the patch-time allocation that maximizes an individual's fitness by referring to the marginal value theorem (**Fig. 4**), which states that the optimal strategy is to leave a foraging patch when the instantaneous fitness gain rate from the current patch falls below the average gain rate that can be achieved in the environment. The model predicts that individuals will stay longer (1) in a more profitable patch, (2) as the distance between patches (and thus travel time) increases, and (3) when the environment as a whole is less profitable (**Fig. 4**). The marginal value theorem has been a useful tool but has however been criticized on the grounds that it makes simplified assumptions, in particular that foragers are optimal and have a complete knowledge of resource abundance and distribution in the environment, which is unrealistic. Linking the optimality predictions of the model with proximate mechanisms of patch departure decisions involved is necessary. Simple mechanistic rules for patch-leaving decisions have therefore been proposed and tested experimentally (**Fig. 5**):

(a) *Incremental rule*. The probability to stay in the current patch decreases with unsuccessful search time spent in the patch, but increases each time a resource is found; individuals will find more resources items, and thus stay longer, in rich patches.
(b) *Decremental rule*. The probability to stay decreases each time a resource is found; individuals will thus stay shorter in high-quality patches.
(c) *Giving-up-time rule*. The tendency to stay decreases with unsuccessful search time spent on the patch, but each time a resource item is found, the tendency to stay is reset to a maximum level; individuals leave after a fixed unsuccessful search time (giving-up time).
(d) *Fixed-number rule*. The individual leaves the patch after a given, fixed number of resource items have been found.
(e) *Fixed-time rule*. The individual forages for a fixed period of time in each patch and leaves the patch independently of the number of resource items found.

Which decision rule will be adaptive depends on (1) the spatial distribution of resource items in the environment, which conditions the information about patch quality that can be derived from finding a resource item, and (2) the individual's *a priori* knowledge about the environment (**Table 1**).

Breeding Habitat Selection

Individuals will also have to make a series of habitat choices for breeding. As for foraging, breeding requires availability of high-quality food resources necessary for offspring development, but also many other resources affecting breeding success, in particular the presence of mates and availability of safe breeding sites (**Fig. 6**). In some species, decisions made during the course of breeding are sequential in time and space, and made independently based on different criteria. In other species, all resources have to be secured simultaneously, which may generate tradeoffs between optimal choices for each resource. In many species, the number of breeding attempts is limited over an individual's lifetime, because breeding involves longer timescales than foraging (up to several years), and/or is a seasonal activity implying yearly timescales. Thus constraints associated with breeding habitat selection often

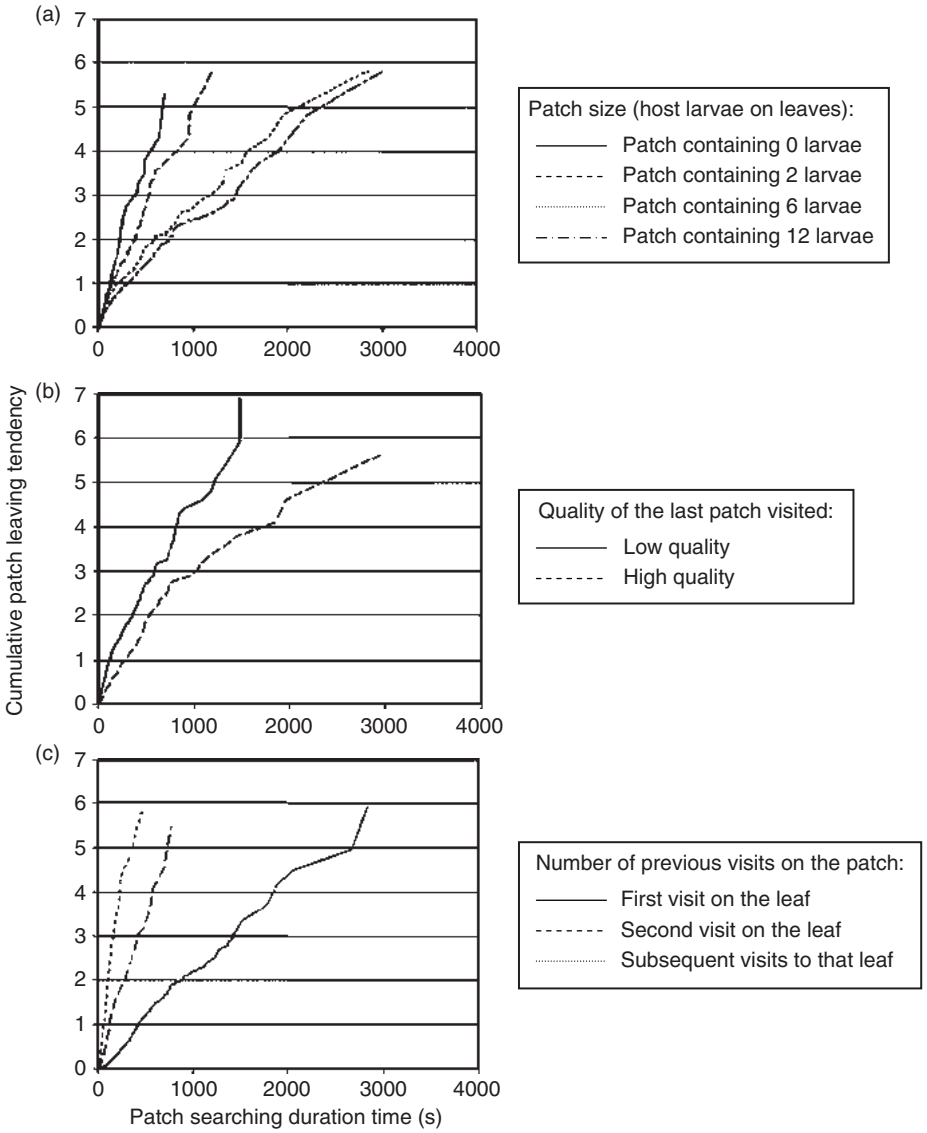

Fig. 3 Foraging decisions in an insect parasitoid, *Aphidius rhopalosiphi*. Females of this parasitic wasp lay eggs in grain aphids *Sitobion avenae*, which are spatially distributed in discrete patches. Parasitic wasps have to adjust their searching time within a given host patch and allocate their foraging time among the different patches available in the habitat, to maximize their fitness. These decisions have to be based upon information on patch quality, obtained through both host encounter rate in the patch and previous searching experience by the wasp on the same or other patches. Patch-leaving decisions in this species depend on (a) host patch size, (b) quality of the last patch visited, and (c) previous experience in the current patch. Females spent more time in a patch when it contains more resources, when they just visited a high-quality patch, and during their first visit in the patch. From Outreman, Y., Le Ralec, A., Wajnberg, E., Pierre, J.-S., 2005. Effects of within- and among-patch experiences on the patch-leaving decision rules in an insect parasitoid. Behavioral Ecology and Sociobiology 58, 208–217.

differ from foraging habitat selection. Habitat choice may vary depending on the type of breeding site and species breeding ecology, and can occur at variable spatial scales, both in absolute values (from millimeters for some parasites to hundred of kilometers for large vertebrates), and relative values, depending in particular on the spatial range used by a given species.

Other Habitat Selection Behaviors

Individuals have to choose a habitat or patch in many other situations. In species where mating occurs in a different place than the remaining of breeding activity (e.g., lekking species), individuals have to select an optimal displaying habitat or patch, and within the patch, an optimal site, for example, close to a dominant male, or within a light spot in low-light-intensity environments. For instance, if visual signals are used in mate choice, the environment chosen to display can affect mating success because signal appearance depends on the joint effect of ambient light and individual's reflectance spectra (Fig. 7). Similarly, individuals may

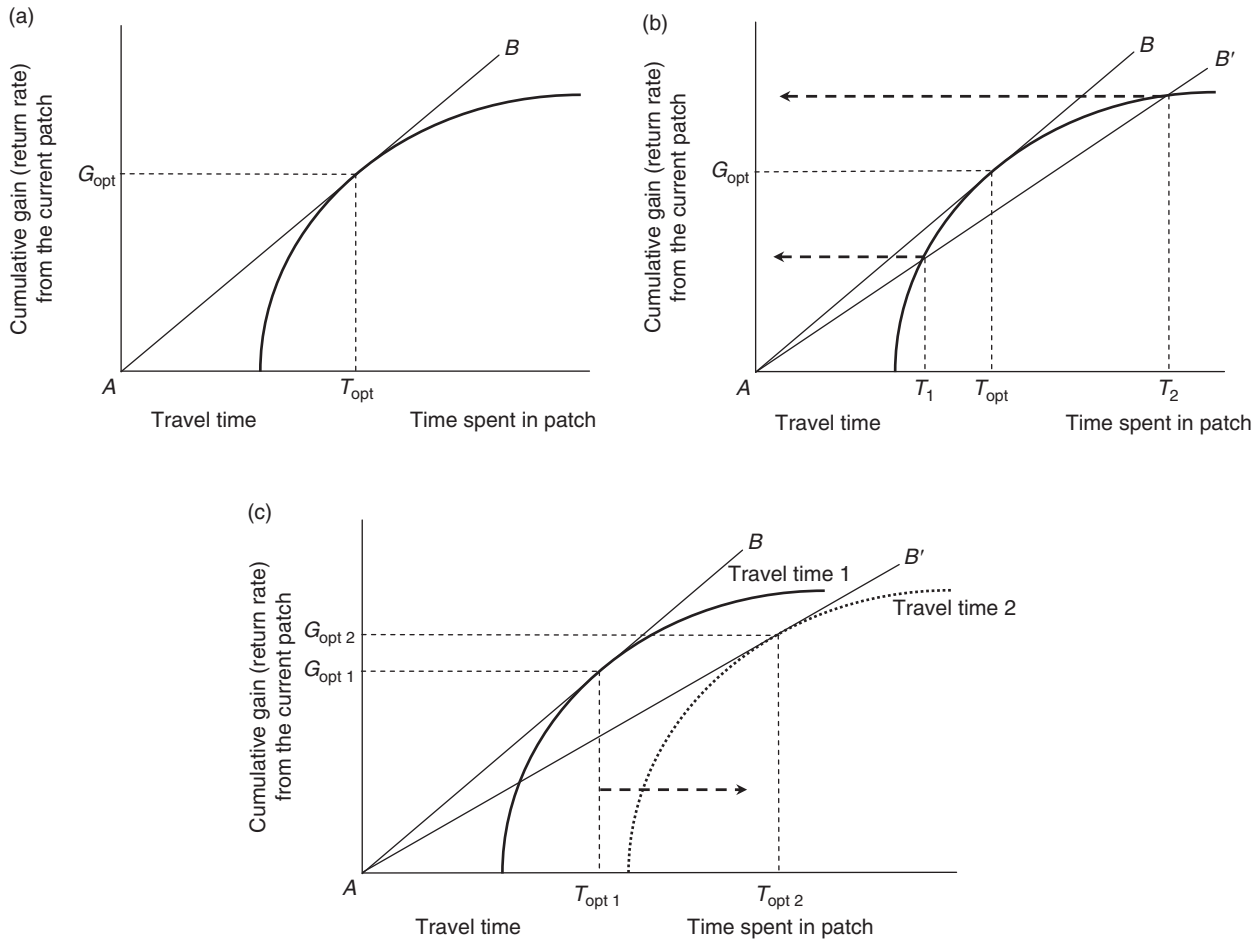

Fig. 4 The marginal value theorem yields the `giving-up time' when an individual should leave its current foraging patch. (a) As an individual forages, its cumulative fitness gain gradually slows down as food becomes scarcer in the patch and food items take longer to find. An individual should aim at maximizing the net rate of fitness (or energy) gain, including time during which it cannot feed because it travels between patches. The rate of fitness gain corresponds to line *A–B*. The steepest slope line (gain/time), which maximizes the rate of energy gain, corresponds to the tangent line to the gain curve. When time on the patch reaches the point of contact between line *A–B* and the gain curve (T_{opt}), the individual should leave the patch. (b) An individual that leaves too early (T_1) will gain less energy per unit of time relative to the maximum (line *A–B′*). Similarly, there is no benefit in staying too long (T_2) as food items are running out. (c) When an individual should stop exploiting its current patch and leave will depend on the travel time between patches, even though the gain curve once on the patch does not change. When travel time is long, individuals should leave the patch after spending more time (T_{opt2}). Adapted from Charnov, E.L., 1976. Optimal foraging: The marginal value theorem. Theoretical Population Biology 9, 129–136.

have to choose among alternative resting habitats or patches. In this case, the main resource is a safe site from predators or a site allowing individuals to optimize energy expenditure (e.g., against cold or rain).

Migration can be considered as an extreme form of habitat selection, when individuals change habitat because resource availability is seasonal while individuals' requirements remain unchanged. However, migration behavior is a fixed habitat selection process, individuals changing habitat similarly year after year. During migration, individuals will choose stopover areas, but this choice can be considered as classical foraging habitat choice, constraints of which include energy requirements and costs of long-distance flights.

Differences between Choices: Spatiotemporal Scales Involved, Tradeoffs

Habitat selection shows fundamental differences depending on the activity considered, in particular in spatiotemporal scales involved. Estimating a foraging patch quality may take only up the time to try to find a food item (**Fig. 5**). The equivalent rule for assessing a breeding patch quality implies attempting to breed to obtain information on expected breeding success in this patch, thus spending time and energy for one breeding attempt there, which may represent a significant portion of life span. In other words, foraging decisions are more dynamic than breeding habitat decisions. Breeding habitat choice may occur only once in life, when individuals decide whether to stay on or leave the natal site (natal site fidelity vs. dispersal). In mobile iteroparous species,

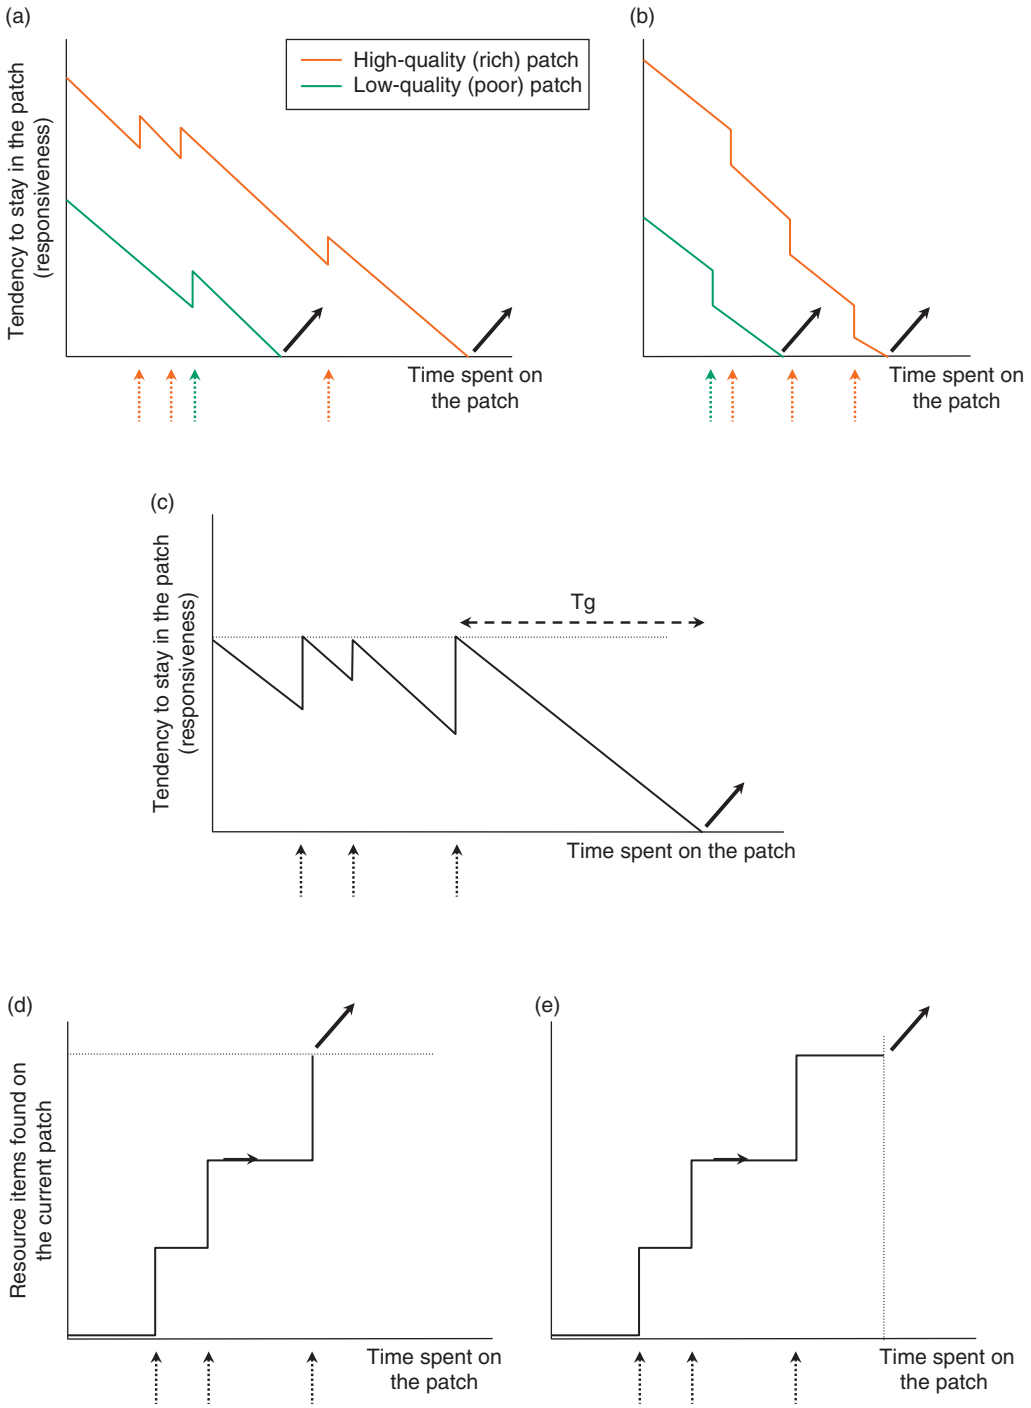

Fig. 5 Patch-departure decision rules in discrete foraging environments. When resources are not distributed evenly but are aggregated in patches whose size is not *a priori* known, individuals can adopt several simple rules for deciding when to stop exploiting their current patch and leave for another patch (black arrows). Dashed arrows indicate when resources items are found by individuals. The probability to stay in the current patch, also called responsiveness, is shown depending on time spent in the patch. When the probability to stay in the current patch drops below a critical threshold, the individual leaves the patch. (a) Incremental rule; (b) decremental rule; (c) giving-up-time rule (giving-up time: Tg); (d) fixed-number rule; (e) fixed-time rule. (a, b) Adapted from Waage, J.K., 1979. Foraging for patchily distributed hosts by the parasitoid. Nemeritis canescens. Journal of Animal Ecology 48, 353–371; and Van Alphen, J.J.M., Bernstein, C., Driessen, G., 2003. Princeton, NJ: Princeton University Press. (d, e) From Iwasa, Y., Higashi, M., Yamamura, N., 1981. Prey distribution as a factor determining the choice of optimal foraging strategy. American Naturalist 117, 710–723.

Table 1 An overview of the different rules for patch-departure decisions in the context of foraging habitat selection, and the conditions in which each rule is likely to be selected for in terms of type of environmental variation in patch quality (i.e., spatial distribution of resource items) and individuals' knowledge on the environment. All proximate rules assume that individuals cannot *a priori* assess patch quality upon entering the patch

Patch-departure decision rule	*Conditions in which the rule will be selected for*
Ultimate mechanism	
Marginal value theorem	
Leave patch if when the instantaneous intake rate from the current patch falls below the mean intake rate in the environment	
Proximate mechanisms	
Incremental rule	
Initial probability to stay on patch depending on its quality (size); probability to stay decreases linearly with unsuccessful time on patch; each resource item found adds an increment to the current level of probability to stay; leave patch when threshold probability is met	High variability of patch quality (aggregated spatial distribution of resource items) Limited individual knowledge about patch size
Decremental rule	
Initial probability to stay on patch depending on its quality (size); probability to stay decreases linearly with unsuccessful time on patch; each resource item found subtracts a decrement to the current level of probability to stay; leave patch when threshold probability is met	Low variability of patch quality (evenly dispersed spatial distribution of resource items) Good individual knowledge about patch size
Giving-up time rule	
Leave patch if time since last resource item found exceeds a given threshold	High variability of patch quality (aggregated spatial distribution)
Fixed-number rule	
Leave patch when a fixed number of resource items has been found	Low variability of patch quality (constant number of resource items per patch)
Fixed-time rule	
Search patch for a fixed period of time and leave patch independent of the number of resources items found	Poisson distribution of number of resource items per patch

individuals can change breeding sites between breeding events (breeding dispersal), but in many species, once the breeding place has been selected, individuals remain on that place for the whole breeding season.

Selecting a habitat or patch often implies different habitat requirements for different activities, and may thus follow different decision rules. However, different types of habitat selection may strongly interact and therefore be traded off against one another, for instance, in species searching for food and reproductive sites simultaneously. Even when selecting a breeding and foraging location are distinct activities during the life cycle, selecting a breeding habitat constrains foraging during the whole breeding period, especially in species spatially constrained during reproduction, for example, sessile and territorially breeding species. Furthermore, breeding habitat choice is often strongly linked with mate choice, which implies that constraints linked to sexual selection also influence breeding habitat choice, while they are unlikely to influence foraging habitat choice.

How Select a Habitat?

The Use of Information

To choose between alternative habitats or patches, individuals have to assess the relative quality of (i.e., the expected fitness for) each alternative. Choosing a habitat or patch thus implies gathering and using *a priori* information on environmental variability, and this information may be critical. Due to the strong selective pressures on habitat selection, the use by individuals of any kind of information allowing them to improve their choice should be favored. Therefore, the existence of information-based habitat choice behaviors may be expected. This raises the questions of which type of information should be used, and how individuals sample the environment and acquire information. In theory, individuals should evaluate all characteristics affecting the success of the activity considered in each site. This could clearly become prohibitive in terms of time and energy when many factors influence this activity independently or at different moments. Therefore, individual strategies for choosing a habitat or patch based on cues integrating the effect of various factors on expected fitness, or that mix different information, may be especially favored.

What Defines Information, Its Value, Quality, and Reliability?

To be informative about habitat or patch quality, a cue should allow individuals to predict reliably their expected fitness in this habitat or patch and compare alternative patches. This depends on several factors:

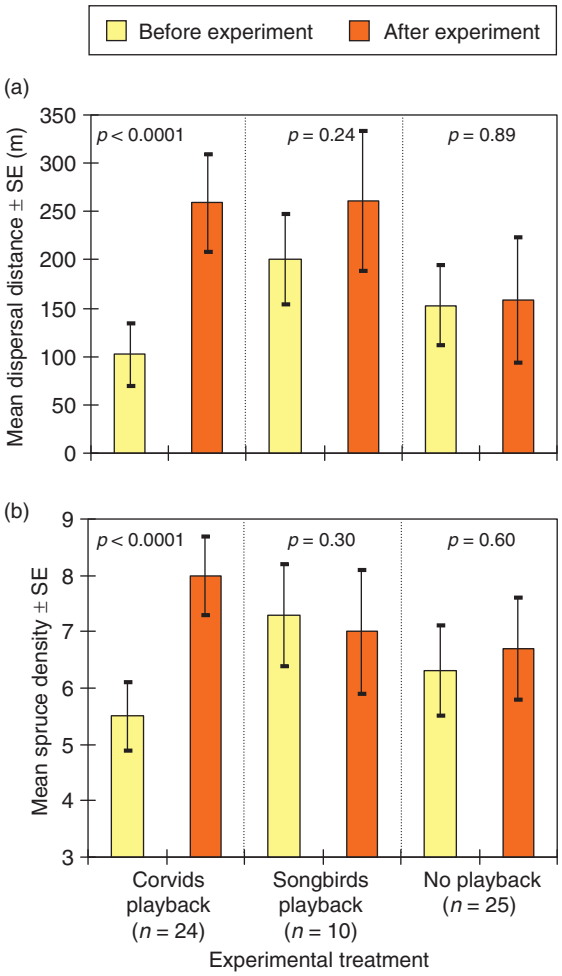

Fig. 6 An example of breeding habitat selection. Influence of the perceived nest predation risk on (a) dispersal distance and (b) nest site preferences in Siberian jays (*Perisoreus infaustus*). When exposed to nest predator playbacks (corvids) compared to control playbacks (songbirds) or no playback during breeding, individuals changed their breeding site choice in the following year. Data from Eggers, S., Griesser, M., Nystrand, M., Ekman, J., 2006. Predation risk induces changes in nest-site selection and clutch size in the Siberian jay. Proceedings of the Royal Society London Series B 273, 701–706.

1. Temporal predictability of habitat quality between the time of information gathering and use is one of these factors (**Fig. 8**); in seasonally breeding species, predicting environmental conditions from one year to the next may be easier than from the beginning to the end of the breeding season.
2. Degree of covariation between the cue and environmental variation is also important: an informative cue will in particular reflect environmental variation without time delay. Furthermore, the standard error of the cue measurement should be low compared to environmental variation; this will be the case when the cue is assessed on large samples.
3. Reliability of the cue as reflecting environmental variation is also one of the factors influencing information value. In particular, if the cue is linked to conspecifics' activity, they should not be able to affect it to provide false information; also, phenotype– or genotype–environment interactions should be limited.
4. Integrative power of the cue, which should be closely related to fitness, is another factor.
5. Easiness of cue assessment, that is, costs of acquiring or gathering information, which depend on (a) direct costs of sampling the environment (e.g., reduced survival due to predation or aggressive interactions) and (b) indirect costs (e.g., time lost in sampling and not used for other activities), is also factored in.

Subsequent costs may also be paid through competition between individuals using the same information and thus making the same choice. The costs (and thus the value of information) will depend on both species biology and spatiotemporal environmental variation of habitat quality, for example, individuals' mobility, length of the breeding period, and synchronization of breeding events among and within patches. In conclusion, the value of information will depend on the balance of information-gathering costs and benefits gained from its use.

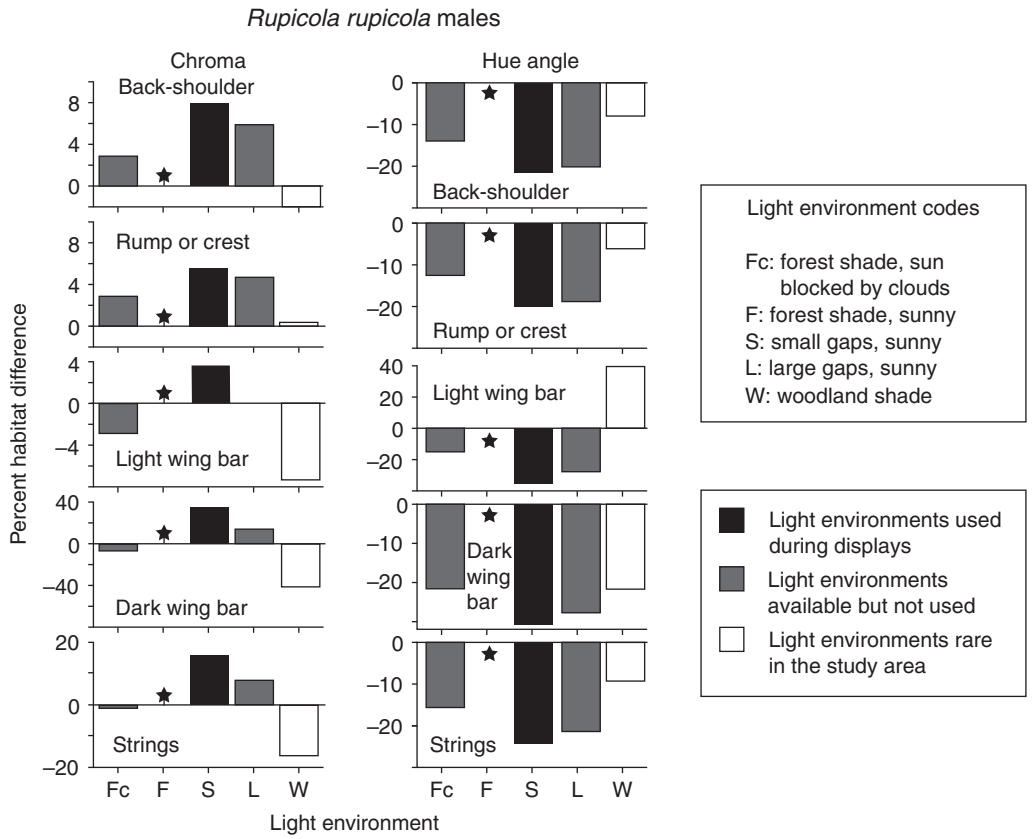

Fig. 7 Display site selection by a neotropical forest-dwelling, lekking bird species, the cock-of-the-rock *Rupicola rupicola*. Forests exhibit a mosaic of spectral environments arising from both vegetation cover and weather. Males display to females both in sunny forest shade (F) and small gaps (S), and these two spectral environments show the highest percentage difference (F taken as standard, indicated by a star) with respect to chroma and hue angle for each male color plumage element (shoulder, chest, wing, etc.). Cock-of-the-rock males therefore select for displaying the two light environments that illuminate different parts of their plumage and maximize the visual contrast during displays. From Endler, J.A., ThÅry, M., 1996. Interacting effects of lek placement, display behaviour, ambient light, and color patterns in three neotropical forest-dwelling birds. American Naturalist 148, 421–452.

Different Types of Information for Habitat Selection

Depending on species biology and activity considered, individuals can use many types of information, ranging from physical and biological habitat characteristics to conspecifics.

Nonsocial cues

Individuals may directly evaluate potential resources and constraints affecting success in a given activity (e.g., food availability, parasitism load, predator presence – **Fig. 6**). If success is mainly linked to one factor, then this strategy should prove efficient to assess habitat quality. However, when this factor is difficult to assess, when many factors affect success, or when information on some factors is not available at the time of information gathering, an alternative is to use indirect cues revealing the effect of important factors, for example, chemical compounds revealing the presence of predators. Individuals can use search images of suitable habitats acquired during development (imprinting) or later (learning).

Individuals may also use as information source their own experience and history, in particular their own performance in the activity considered in the habitat or patch, called personal information (and sometimes also private information, despite that other individuals can access it – **Fig. 9**). In the context of foraging, different strategies involve gathering information via direct environment sampling by individuals, using in particular trial-and-error tactics (stay after success, leave after failure). Differences in timescale between foraging and breeding decisions imply that trial-and-error strategies, which can be optimal in foraging, are unlikely to be selected for alone in breeding habitat choice, because they would imply settling at random to breed and using only the breeding success achieved to decide about future habitat choice. This might be very costly when the total number of breeding attempts is limited, and personal information in the case of breeding habitat selection will often be mixed with other sources of information. Philopatry, that is, fidelity to the natal site, can be considered as a form of personal information use: individuals choose a site whose quality has allowed their own growth and survival.

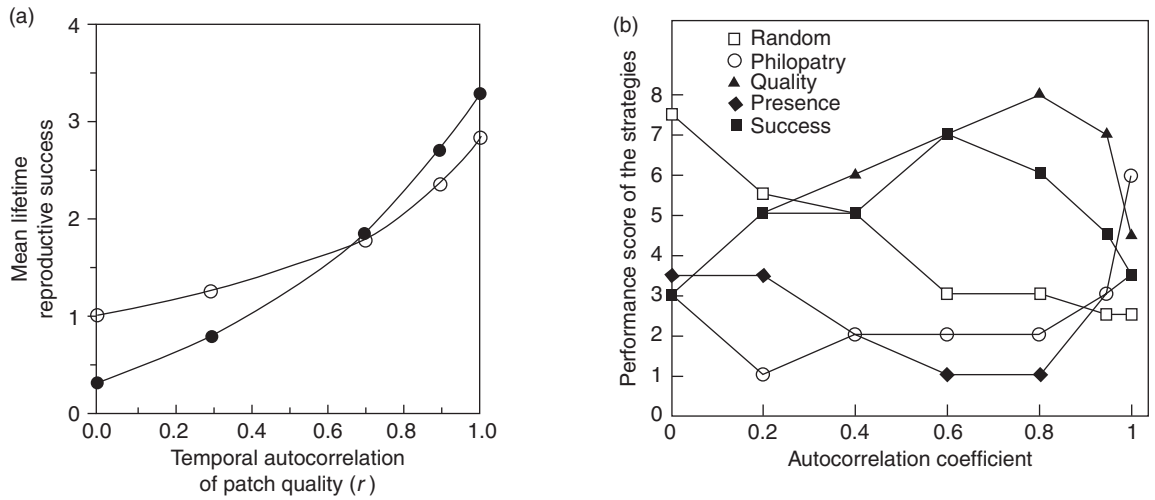

Fig. 8 The value of `public information', that is, the local reproductive success of conspecifics, for breeding habitat selection depending on environmental temporal predictability. In most seasonally breeding species, this cue will be available at the end of the breeding season, and can therefore only be used in the next year. It will thus be valuable only if the environment is autocorrelated from one year to the next. (a) In an optimality model, individuals choosing their breeding patch according to local reproductive success in the previous year (closed dots) achieve a higher lifetime reproductive success compared to individuals settling at random on a patch (open dots) only when the level of temporal autocorrelation of the environment is high. (b) Similarly, in a game theory model, strategies based on local reproductive success (`quality' and `success') are selected for only when the level of temporal autocorrelation of the environment is sufficiently high. (a) From Boulinier, T., Danchin, E., 1997. The use of conspecific reproductive success for breeding patch selection in territorial migratory species. Evolutionary Ecology 11, 505–517. (b) From Doligez, B., Cadet, C., Danchin, E., Boulinier, T., 2003. When to use public information for breeding habitat selection? The role of environmental predictability and density dependence. Animal Behaviour 66, 973–988.

Social cues

Conspecifics can also be used as a source of information about local habitat quality, that is, social information, because they share the same needs. Social information may be provided either intentionally through signals (communication), or inadvertently (inadvertent social information), when individuals monitor the behavior and performance of their conspecifics. When individuals use social information, they benefit in particular from environment sampling performed by others. Individuals can be expected to use social information more often for breeding than foraging habitat choice, and the importance of this information for breeding habitat choice has recently been emphasized (**Fig. 10**).

Conspecifics' presence on a habitat patch as an information source has received much attention (social attraction process). It can reveal good enough conditions for a local population to persist (**Fig. 10**). However, the mere presence of conspecifics may be misleading because the correlation between local density and habitat quality can prove weak in certain conditions. Conspecifics' activity and their success may better reveal habitat quality. Where conspecifics are the most successful can indicate where an individual is the most likely to be successful itself. Conspecific success integrates in a single parameter the effect of all components of environmental quality, including social interactions (**Fig. 10**). It can also be more precise than personal information when based on large samples (e.g., many conspecifics), and when phenotype–environment interactions are limited. The information derived from the performance of other individuals sharing ecological requirements has been called public information, in contrast to personal information.

The use of social information can be extended to heterospecifics, provided that they share the same needs (e.g., food or breeding sites), leading to interspecific social attraction or the use of heterospecific public information (**Fig. 10**). Because their characteristics will slightly differ from individuals of the focal species, they could even provide additional information compared to conspecifics.

Individuals are likely to combine and use several information sources, in order to refine their assessment of local habitat quality and adjust their future decisions, depending on which factors affect fitness and relative costs of gathering each information (**Fig. 11**).

Sampling the Environment and Gathering Information: Prospecting

Information gathering about relative habitat quality via prospecting behavior involves sequential visits of potential occupied or nonoccupied patches or sites by an individual that does not currently feed or breed there (called a prospector). Despite the major impact of prospecting on habitat choice, data on prospecting remain fragmentary. Prospectors on breeding patches are usually immature individuals before recruitment, and nonbreeding or unsuccessful adults, which are

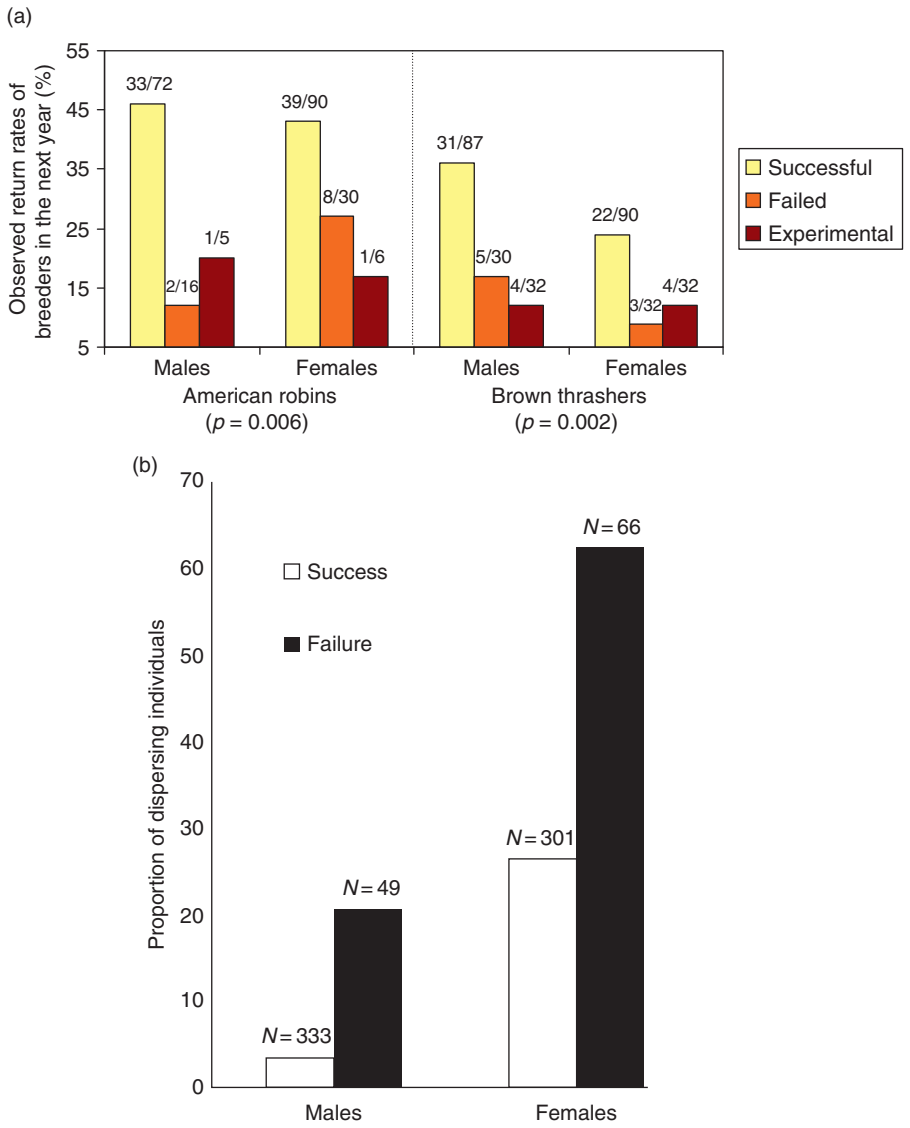

Fig. 9 Influence of personal information (individual's breeding success) in subsequent breeding habitat choice in (a) American robins (*Turdus migratorius*) and brown thrashers (*Toxostoma rufum*), and (b) collared flycatchers. Failed (naturally or experimentally) breeders are more likely to disperse to another patch in the following year compared to successful breeders. Individuals use their own reproductive performance as a cue to assess the current local breeding habitat quality and adjust their breeding patch choice in the next year. (a) Data from Haas, C.C., 1998. Effects of prior nesting success on site fidelity and breeding dispersal: An experimental approach. Auk 115, 929–936. likely to be looking for a breeding site for the following year. However, the links between prospecting, type of information gathered by prospectors, and subsequent habitat choice are still poorly investigated. Constraints acting on prospecting can however determine which types of information are available to individuals, and thus which habitat choice strategies can evolve. Prospecting may also shape the evolution of life-history traits such as age at first breeding when individuals have to prospect before settling for breeding.

Constraints on Habitat Selection

Habitat choice involves two important steps: (1) deciding whether to leave or stay on the current habitat or patch; (2) if individuals decide to leave, choosing where to settle next. These two sets of decisions may be based on different criteria, and be either independent or linked: individuals may decide to leave before having decided where to settle next; alternatively, they may

decide to leave because they have already chosen their next patch. Choices can occur on repeated occasions, and thus be increasingly shaped by personal experience, except for breeding habitat selection in sessile species. Habitat choice is thus a complex process constrained by many parameters linked to: (1) species characteristics, in particular cognitive (spatial and temporal memory) and movement capacities (maximal movement rate or distance, especially when individuals have to travel across unsuitable habitat – arrows in Fig. 1); (2) species life-history strategy and tradeoffs involved (investment in different activities, in particular prospecting vs. breeding; tradeoffs in choosing multiusage sites, in particular year-round territories); (3) individuals' characteristics and interindividual differences in the ability to exploit the environment (phenotype– or genotype–environment interactions), in habitat preferences (through imprinting or habitat training due, for example, to acquired parasite resistance), or in selective pressures (e.g., sexual selection depending on individual's sex); and (4) environment variation (e.g., temporal predictability, spatial variation patterns).

Testing the Existence of Habitat Selection Processes

Processes, that is, mechanisms, of habitat choice have to be distinguished from patterns of space use, that is, distribution of individuals in the environment resulting from individual decisions. Patterns of individuals' spatial distribution or variation in fitness are often used to infer habitat choice processes by individuals, because determining whether habitat selection occurs can be difficult. Empirical studies often analyze habitat choice processes by comparing site characteristics and patterns of site use in different types of habitats. Occupied sites are expected to be of higher quality than unoccupied or randomly picked up sites if habitat choice occurs. However, the same patterns can result from different processes, and from processes other than active habitat selection by individuals.

A widely used concept is the ideal free distribution (IFD), defined as the distribution of individuals among habitat patches expected under the assumptions that individuals (1) distribute themselves so as to optimize their fitness, (2) are free to move among habitat patches, that is, without any cost or constraint, and (3) have a perfect (ideal) and instantaneous knowledge of the relative quality of habitat patches and local density dependence function. At equilibrium, (1) mean individual fitness is equal on all patches because individuals are distributed among patches proportionally to the relative quality (availability of resources) of each patch and (2) individuals cannot increase their fitness by changing patch (Fig. 12).

More realistic refinements of the IFD model including (1) different forms of density dependence (e.g., nonmonotonic density-dependent functions such as Allee effects) and (2) interindividual differences in competitive ability (allowing some individuals to monopolize resources and thus achieve higher fitness than others: ideal despotic or dominant distribution (IDD)) have been proposed, but the IFD represents a null model describing the spatial distribution of individuals in the environment that maximizes fitness at the population scale given the distribution of patches, and to which distributions generated via different habitat choice processes incorporating constraints on information accessible to individuals (the ideal assumption) and their movements (the free assumption) can interestingly be compared (Fig. 13).

Inferring habitat choice solely from patterns of habitat use by individuals can be misleading because high densities may be observed on low-quality patches, for instance, because of constraints for individuals in obtaining reliable information about potential habitat patches quality. A direct investigation of habitat choice, aiming at identifying information cues and decision rules used by individuals and determining the extent to which habitat choice strategies affect fitness, is often more appropriate than

Fig. 10 Examples of the use of different types of social information for breeding habitat selection: (I and II) presence of conspecifics, (III) presence of heterospecifics sharing the same needs, (IV and V) local reproductive success of conspecifics. (I) Naive house wren males (*Troglodytes aedon*) preferred to settle in nest boxes of higher quality (as measured by previous breeding success in the box), but also close to the nearest occupied box. Black squares: boxes located $\leq$70 m from the nearest occupied box (open squares for $>$70 m). (II) Immigration rate of new breeders in a patch strongly positively increased with patch breeding density in the previous year, for both (a) experienced ($\geq$2 years old) and (b) naive (yearling) collared flycatchers. (III) The number of migrant passerine bird species and densities of migrant individuals were lower in patches where the density of heterospecific resident tit (*Parus*) species was decreased (REM) by removing individuals than in patches where it was increased (ADD) by releasing them. (IV) Immigration rate of collared flycatcher breeders was higher in patches where the mean number of fledglings had been increased locally (by adding nestlings – patches I) in the previous year compared to control (C1 and C2) patches (unchanged mean fledgling number), and higher in control patches compared to patches where the mean fledgling number had been decreased locally (by removing nestlings – patches D). (V) In the black-legged kittiwake, (a) prospecting and (b) nest attendance by failed breeders were higher on patches where local success was unchanged (black dots) than where it had been experimentally decreased by removing eggs (open dots), and, in the following year, (c) failed breeders were more likely to return to breed on the same patch in patches where success was unchanged (black bar) compared to decreased patches (open bar). Testing the effect of conspecific reproductive success on dispersal and recruitment decisions in a colonial bird: Design issues. Journal of Applied Statistics 29, 509–520.

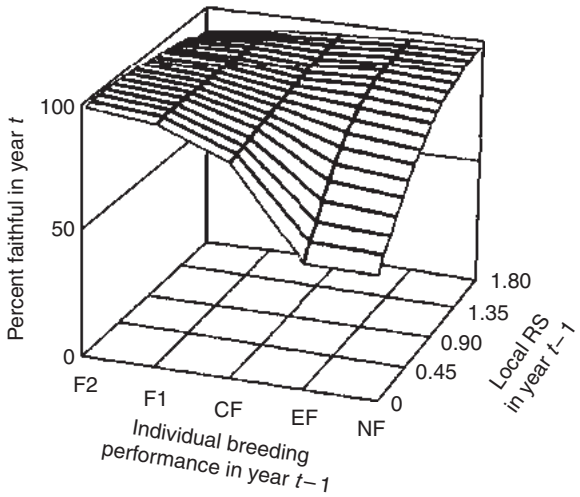

Fig. 11 Combining several sources of information for breeding habitat choice. In the black-legged kittiwake, the fidelity probability of breeders depended on both personal information (i.e., individual reproductive success) and public information (i.e., local reproductive success (RS) of conspecifics on the patch) in the previous year. Individual reproductive success decreases from F2 (high success) down to NF (nest failure: no eggs laid). Local reproductive success: average number of chicks fledged per nesting pair on the patch. Personal and public information significantly interacted. Successful individuals (F2 and F1) were always highly faithful to their breeding patch, while fidelity of early failed individuals (NF and EF) increased with local success. Thus, individuals used both personal and public information to decide whether to emigrate, but prioritize the different sources of information: public information was used only after breeding failure. From Danchin, E., Boulinier, T., Massot, M., 1998. Conspecific reproductive success and breeding habitat selection: Implications for the study of coloniality. Ecology 79, 2415–2428.

indirect inferences. Such an approach links proximate factors (elements of the environment used by individuals for choosing in a mechanistic way) and ultimate factors (evolutionary causes of individual choices, that is, linked to the relative fitness of individuals adopting different habitat choice strategies) involved in habitat choice.

Individual and Population Implications of Habitat Selection

Spatial Distribution of Individuals and Evolutionary Consequences

Habitat choice directly affects the distribution of individuals in the environment and their use of habitat patches through movement and dispersal. Individual habitat choice is thus linked to spatial aggregation patterns at the population level, and the choice of each individual may have important consequences for the rest of the population (Fig. 14). Different habitat selection decisions, in particular foraging and breeding, will affect the dynamics of individuals' distribution in the environment, but at different timescales: foraging habitat selection is linked to short-term use of the environment, while breeding habitat choice will be directly linked to long-term persistence of local populations via reproduction and exchanges of individuals (thus genes) between populations, that is, dispersal.

Habitat choice strategies based on different information sources may generate different individuals' distributions among patches and temporal dynamics (Fig. 14). In particular, social attraction (i.e., use of conspecifics' presence) will progressively strongly aggregate individuals on the highest-density patch, and the whole population may end up in a single patch, independently from the relative qualities of the different patches. The presence of individuals prevented from breeding because of the lack of available sites on highly occupied patches while breeding sites are available on other suitable patches can be explained by the use of social attraction for breeding habitat selection. Breeders will indeed aggregate on a fraction of suitable patches rather than colonizing empty patches, and on these occupied patches, only a fraction of the individuals manage to secure a breeding site, the rest remaining nonbreeders because of patch saturation. Constraints in habitat selection may therefore lead to the evolution of floating and queuing strategies.

Effect of habitat choice on population regulation

Simple habitat choice decision rules can also participate in site-dependent regulation of populations, through the sequential occupation of sites of decreasing quality (Fig. 14). When the population increases due to high fitness on good-quality patches, an increasing proportion of individuals start settling on patches of lower quality. Thus average fitness at the population scale decreases, which reduces the overall population growth rate, and may lead the population to start decreasing. This regulatory effect is obtained simply through the variation in the mean quality of chosen and occupied sites, even in the absence of local crowding effects (i.e., negative density dependence at the individual level), that is, no decrease in fitness is observed for individuals occupying the best sites: the population growth rate varies simply because of the variation in the mean quality of occupied sites.

Habitat choice and local population viability

Individual choices are constrained by the accessibility of reliable information, and the use of suboptimal information sources may increase individuals' spatial aggregation. In a metapopulation (i.e., a set of populations connected by dispersal), individuals' aggregation on some patches leaving others empty may increase the overall extinction probability of the metapopulation by increasing the probability of simultaneous extinction of all subpopulations. In addition, if individual fitness negatively depends on local density, aggregated distributions further increase local extinction probabilities. Mixed strategies of habitat choice, using a combination of cues, or condition-dependent habitat selection strategies, may minimize extinction probability.

Evolution of sociality and coloniality

Individual strategies based on conspecific cues have also been suggested to lead to the evolution of group living. By affecting spatial distribution of individuals in the environment and thus population structure, habitat selection can lead to selective pressures favoring the evolution of group living behaviors. The use of social information for habitat choice may have led to different forms of group living, such as coloniality, since individuals using conspecifics' presence or performance for breeding site choice settle on already-occupied patches and thus aggregate breeding sites. Furthermore, feeding or breeding close to conspecifics may favor the gathering of social information on habitat quality, thus individuals may actively seek spatial aggregation to gather social information.

Conservation Biology

Through effects on the spatiotemporal distribution of individuals in the environment and population extinction probability, habitat selection behaviors have strong implications for conservation biology.

Small and fragmented populations

Threatened populations are usually small and subdivided within fragmented habitats. Habitat choice behaviors are critical for conservation issues because: (1) habitat choice strategies affect individual exploratory and prospecting movements between isolated habitat patches, which can lead to increased mortality risk depending on the degree of fragmentation; (2) the distribution and movements of individuals among habitat patches directly affect the dynamics and viability of the small subpopulations and thus the metapopulation; (3) individuals may end up settling on low-quality habitat because of constraints on mobility and information gathering, or on sites of decaying quality because of human activity. The study of breeding habitat choice is thus critical for the monitoring and management of threatened, reintroduced, or reinforced populations. Knowledge of factors affecting habitat choice has direct implications in such situations, and may greatly influence the design and monitoring of protected areas as well as the assessment of subdivided populations' viability.

Environments under human influence

Human activities can alter habitat structure and quality, and in particular break the natural correlations among habitat components. Thus, naturally selected habitat choice strategies may become maladaptive in environments modified by human activity: individuals may be lured to unsuitable patches because cues no longer reveal habitat quality when some habitat characteristics affecting fitness deteriorated but do not affect the cues used by individuals to assess site quality. Such a mismatch defines an ecological trap. Because small and subdivided populations have often greatly decreased in size in the recent past, a large proportion of potentially suitable patches may be unoccupied, but may nevertheless need to be preserved to allow individuals to move. Such situations require managing habitat in terms of metareserves aiming at protecting a habitat type independently from the current occupation by the species of interest.

Fig. 12 The ideal free distribution. (a) Individuals start occupying the highest quality patch (patch A). As population density on patch A increases, fitness return decreases as a result of a negative density-dependence function (e.g., due to competition). When density on patch A reaches level D_1, expected fitness on patch A is equal to expected fitness on patch B, which is of lower quality but still empty. The next individuals to arrive should thus start occupying patch B, as well as continuing to occupy patch A. The same applies for patch C (level D_2 on patch B and D_3 on patch A), etc. At equilibrium (dashed line), individuals are distributed among patches (densities D_A, D_B, and D_C) so that their fitness is equal on all patches (F_e). (b) This mechanism can also operate in a closed population when local densities of individuals change as a result of demographic or environmental stochasticity. Unbalanced local densities will generate different fitness gains on different patches, due to the overexploitation of rich patches (patch A, case b1) or poor patches (patches B and C, case b2). In this case, some individuals should move to a less exploited patch, so that individual fitness as equilibrium is equal on all patches again (b3). Adapted from Fretwell, S.D., Lucas Jr., H.L., 1970. On territorial behaviour and other factors influencing habitat distribution in birds. Acta Biotheoretica 19, 16–36.

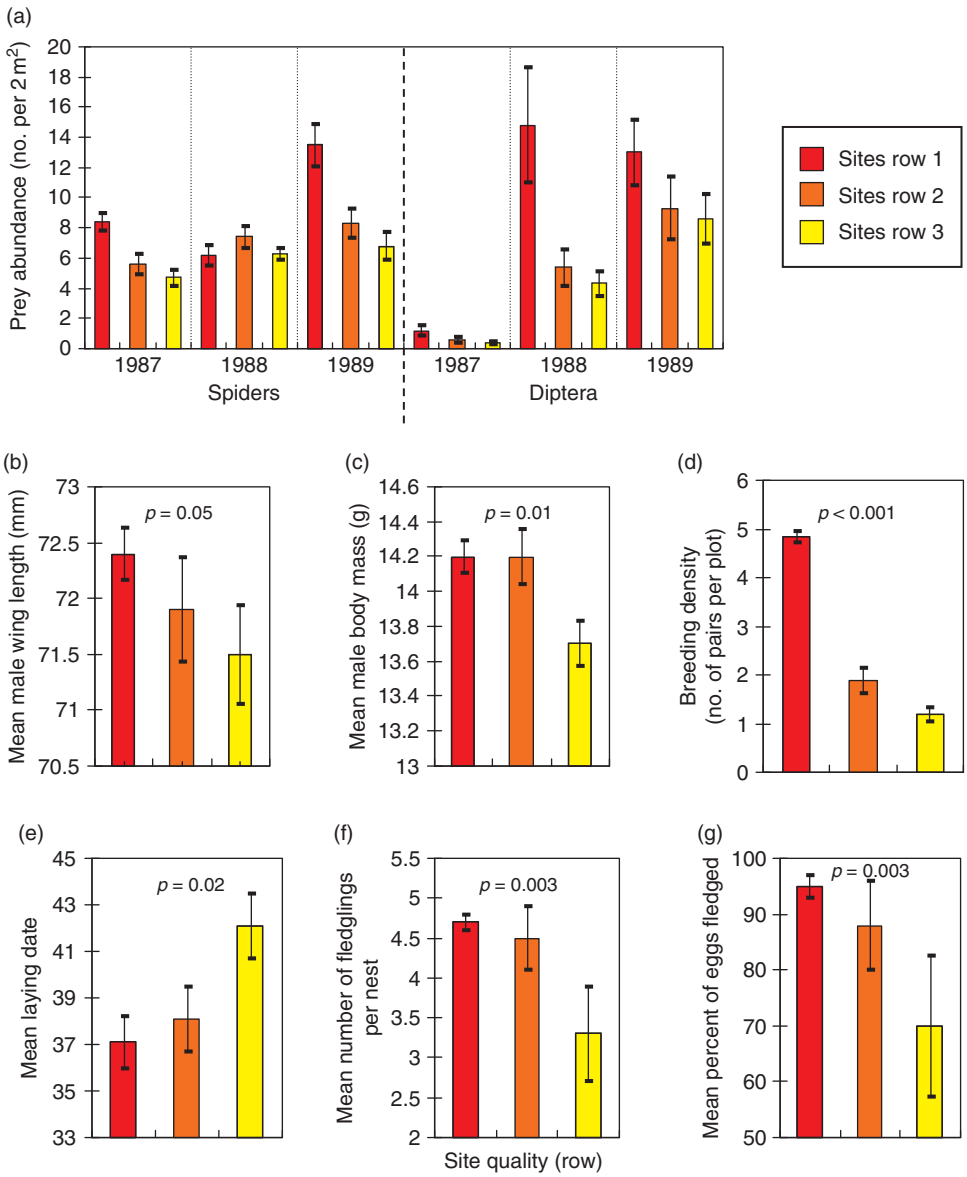

Fig. 13 Testing the predictions of the ideal free and ideal dominant distribution (IFD/IDD) models in a population of prothonotary warblers. Habitat and breeders characteristics were compared between sites of varying quality. Sites differed in their relative location with respect to shoreline, with increasing distance to the shore for increasing row level. (a) Prey abundance (thus intrinsic site quality) gradually decreased with increasing site row. Breeding male (b) wing length and (c) body mass (measuring male quality), and (d) breeding densities decreased with increasing row level, i.e., decreasing site quality (no differences in females). (e) Females initiated breeding earlier in high-quality (row 1) sites compared to low-quality (row 3) sites. Finally, breeding success measured by (f) mean fledgling number and (g) percentage of eggs that produced fledglings decreased with decreasing site quality. Thus the spatial distribution of prothonotary warblers in this population followed an IDD, with higher-quality males excluding lower-quality ones from the preferred, highest-quality areas, and thereby achieving higher reproductive success. Data from Petit, L.J., Petit, D.R., 1996. Factors governing habitat selection by prothonotary warblers: Field tests of the Fretwell–Lucas models. Ecological Monographs 66, 367–387.

Reintroduced populations

Finally, a thorough understanding of habitat choice behaviors is useful for increasing the efficiency of population reintroduction or reinforcement. The rearing conditions of individuals may affect their tendency to choose specific types of habitats, and habituation to a site can contribute to early individual settlement after release while a large mismatch between rearing and release habitats may result in individuals being unable to make optimal habitat choices. Social interactions can also be critical, such as attraction to active breeding conspecifics. Visual and/or sound decoys (e.g., mimicking successful conspecifics) can attract individuals to sites identified as suitable by managers. Decoys of predators can also be used to deter focal individuals from settling in areas identified as low quality. In other words, understanding the cues used by individuals for selecting a habitat patch allows manipulating these cues to alter individuals' choices.

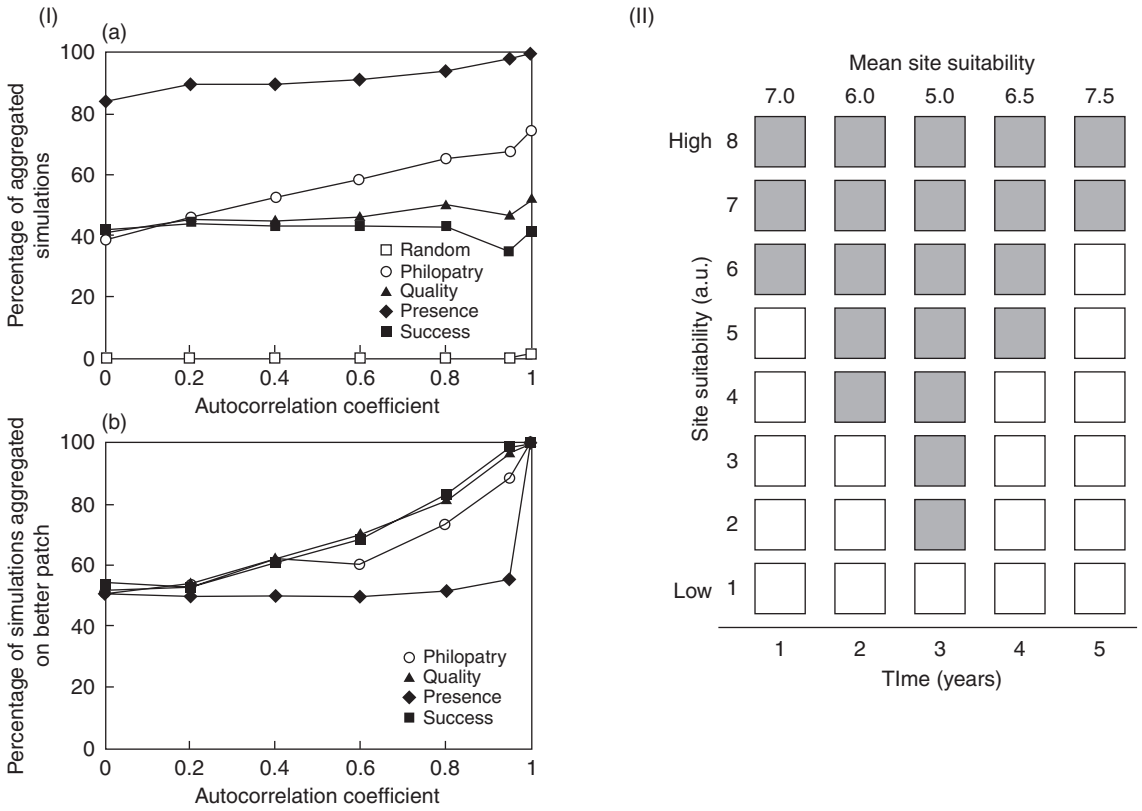

Fig. 14 An illustration of population consequences of individual habitat selection behavior. (I) Spatial aggregation of individuals. Strategies of breeding habitat selection based on different types of information lead to different levels of spatial aggregation of individuals among patches (a). In particular, the use of the presence of conspecifics generates spatial aggregation far above the IFD. (b) Individuals aggregate on the best patches as environmental predictability (and thus the value of information) increases. However, when breeding success is negatively density dependent, individuals using the presence of conspecifics pay a cost via decreased success, which limits the efficiency of this strategy. (II) Population regulation via site quality. A negative feedback can be created via individual habitat selection behavior. In small populations, individuals occupy the best patches, leading to a high growth rate (year 1). When population increases, individuals start settling on sites of decreasing quality, thus mean occupied site quality decreases (years 2 and 3). Consequently, population growth is slowed (year 4). As population declines again, mean quality of occupied sites, and thus population growth, increases again (year 5). (I) From Doligez, B., Cadet, C., Danchin, E., Boulinier, T., 2003. When to use public information for breeding habitat selection? The role of environmental predictability and density dependence. Animal Behaviour 66, 973–988. Herbivore-Predator Cycles

AC McCall, Denison University, Granville, OH, USA

Introduction

One of the most long-enduring and fascinating phenomena of terrestrial ecology is the origin and explanation of synchronous population cycles in herbivores and some of their predators. Often, these cycles are synchronized over large areas, sometimes reaching over 1500 km in their effective range. Charles Elton, one of the founders of the modern science of ecology, was one of the first workers to realize the importance of extreme population fluctuations in snowshoe hares and Canadian lynx and lemmings, early in the twentieth century. Since Elton, researchers have found similar cycles or regular fluctuations in such herbivores as lepidopterans, voles, mice, grouse, and geese. The cycles of these fluctuations vary with the particular taxon under study and the mechanisms underlying the fluctuations are not uniform (see **Table 1**). So far, ecologists cannot conclusively prove the origin and maintenance of many cycles, but progress has been made in identifying the individual mechanisms responsible for both the increases and decreases in population densities.

How Common are Cycles in Animal Populations?

Although they seem unusual and dramatic, cyclic dynamics in animal populations are not particularly uncommon. Approximately 30% of all animals display significant cycles in population size, which is substantially greater than the 5% expected by chance alone. These cycles typically occur in disturbed temperate and boreal biomes, while cycles in tropical insects are much less common. Mammals and fish are the two major taxa that have the highest proportion of cyclic populations (0.33 and 0.43, respectively). It is likely that as more data are collected, examples of either separate populations or whole species that exhibit cyclic population dynamics may become more prevalent than we had realized. Latitudinal gradients in propensity to cycle are common, but are only statistically detectable in mammalian taxa.

Cycles in Relation to Lotka–Volterra Models

In the now-classic standard Lotka–Volterra model of population regulation by predators, the end dynamic is cyclical for both the consumer and the consumed. In particular, herbivores tend to increase in density until brought under control by a specialized predator whose population is dependent on herbivore density. This model gives us hints as to what forces may be responsible for the cycles we actually observe in nature. In particular, predation by specialists or other trophic interactions such as parasite infection could be important, especially if there is a significant lag between the prey density growth and predator density growth.

Factors Involved in the Regulation of Populations

Broadly speaking, herbivore populations can be regulated by density-dependent mechanisms or affected by density-independent mechanisms. These factors are key in understanding how herbivore populations cycle. Density-independent factors affect population densities of the animal in question, but are not affected by changes in densities themselves so that there is no feedback in the system. These factors may include climatic variables, sunspots, or some types of human landscape-alteration. Any particular factor may act as a density-independent or density dependent mechanism given a certain set of circumstances. For example, a disease may be density dependent if higher host population densities increase its transmission rate, but density independent if it is not contagious or otherwise is unaffected by the host population.

Density-independent factors are rarely the sole determinants in causing cycles, but they are important in providing the arena in which density-dependent mechanisms play out. For example, density-independent factors may influence the amplitude of the

Table 1 Examples of herbivores with strong cyclic population dynamics

Herbivore	*Period (years)*	*Synchronous area (km)*	*Dominant process order*	*Mechanisms*
Voles	3–5	500	2	Predation
Snowshoe hare	9–11	1500	2	Predation
LBM	9–10	1000	2	Induced plant susceptibility, parasitoids

Cycle periods, maximum spatial extent of cycle synchrony, important mortality factors, and dominant order of population dynamics are presented.

This work is greatly influenced by Turchin P (2003) *Complex Population Dynamics: A Theoretical/Empirical Synthesis*. Princeton, NJ: Princeton University Press.

 doi:10.1016/B978-0-444-63768-0.00647-8

cycles. Researchers at one time believed that density-independent factors were relatively unimportant in either predicting or influencing the increases and decreases of cycles. We now know that these factors can be vital in exaggerating, dampening, or stabilizing the effects of density-dependent factors.

One density-independent factor that was invoked to explain some aspects of the hare–lynx cycles is the activity of sunspots. Since sunspot activity affects the entire planet, the effects may be responsible for the synchronization of hare population cycles across vast areas of high-latitude boreal forest. The sun goes through a 10-year cycle of solar activity with distinct and longer periods of high-amplitude cycles every 80–90 years, or what is known as the Gleissberg period. Although the relationship between sunspot activity and hare density drifts out of synchrony over many hundreds of years, they are forced back into synchrony at the onset of a new Gleissberg period of high sunspot activity.

Thus, it appears that sunspot activity by itself is not sufficient to cause or maintain the cycles we observe in herbivores, but may be necessary to force the population synchrony over large geographic areas. Several hypotheses have been put forth to explain the mechanism behind this forcing, but the researchers believe that sunspot activity seems to affect large-scale climatic variables such as precipitation, which can affect plant growth. Increased solar radiation can also affect the defensive compound concentrations in certain plants. Since the biochemical pathways for protection against UV radiation and antiherbivore chemical defense often use the same precursor or intermediate molecules, increased resource allocation to UV-protection during periods of high sunspot activity may cause concomitant decreases in antiherbivore protection. This would presumably allow hares to eat more food, reproduce more, and thus increase population density.

Latitudinal Gradients

Climate may also play an important role in moderating the strength of herbivore cycles. Some herbivore cycles are more pronounced at higher latitudes than at lower ones, although the strength of the relationship depends on the particular taxa under scrutiny. Many extrinsic factors vary with latitude, most importantly seasonality, strength and body size (Bergmann's rule). The strongest patterns in cycling along latitudinal gradients are found in Fennoscandian (Finland, Norway, Sweden, and the Kola Peninsula in Russia) voles and lemmings. Population cycles are very strong at high latitudes and lessen in strength as latitude decreases. In these systems, it is hypothesized, and supported with small-scale manipulative experiments, that the type of predators associated with latitude may help explain the dampening of cycles at lower latitudes. In particular, specialized predators are more abundant at higher latitudes than at lower latitudes, and generalist predators are more abundant at lower latitudes. Specialized predators that depend on voles to survive will decrease in population density, following the dynamics of the vole increase and decrease. Generalist predators, on the other hand, have the ability to switch from voles as the herbivores begin their population decline, thus moderating the decline itself. In other words, specialists destabilize vole populations and generalists stabilize them. Thus, latitude itself does not cause the cycles, but influences the predators that are probably drivers of cycles.

Density-Dependent Mechanisms

When ecologists speak of population regulation, they are often referring to density-dependent mechanisms. These mechanisms may be a product of the population itself, or a reaction to the population density. For example, a population of voles may increase exponentially until competitive intraspecific interactions cause either the birth rate to decrease or the death rate to increase, leading to a net decline in reproductive rate and subsequent decrease in population density. Alternatively, as the population of voles increases, the population may become more apparent to predators, causing an increase in herbivore consumption and subsequent changes in predator densities.

First- and Second-Order Dynamics

Feedback loops that may be characteristic of density-dependent mechanisms can be broken down into having first- or second-order dynamics. First-order dynamics occur over on a short timescale, with short lags (1–2 years) between the response of the herbivore population and the feedback mechanism. Second-order dynamics have pronounced time lags (3–5 years) between the mechanism and the effects on the herbivore population. Second-order dynamics can cause cycles, but may also result in more complex phenomena, such as chaotic (very dependent on initial conditions) and bounded fluctuations in population density. In general, ecologists believe that population cycles are caused by second-order or higher dynamics, since an appreciable time lag between the factor involved and the herbivore density is needed to produce periodicity in herbivore populations.

Some properties of herbivore populations themselves may cause negative feedback loops and thus may contribute to the maintenance of population cycles by causing or exacerbating the decline portions of the cycles. For example, increasing population densities may cause more competition for food or more aggression among conspecifics, leading to increased rates of mortality or decreased birth rates. Increased competition for shelter or mating sites may result in many individuals succumbing to prey or failing to recruit offspring into the next generation. These mechanisms, however, may not be sufficient to cause cycling, since there may be only short or even nonexistent time lags between consumption of food or space and subsequent reductions in herbivore densities. One prominent exception is the population cycles of Soay sheep populations on the St. Kilda archipelago off the coast of Scotland. This population goes through abrupt and somewhat regular fluctuations in number, and has been well documented for

over 30 years. There are no predators or significant parasites on these islands, so starvation and regrowth of forage are thought to be the main driver of the cycles. Some recent analyses also conclude that growth of forage and concomitant starvation is also affected by climatic variables such as the North Atlantic Oscillation (NOA).

For herbivores, like the Soay sheep, an obvious limiting factor in the growth and maintenance of populations is their food sources – plants. Population cycles of herbivores could be maintained if the plants that they feed on also undergo large fluctuations in their population densities. For example, defoliation of trees often reduces the quality and increases toughness of vegetation in following seasons. This phenomenon, coupled with the intrinsic rate of population growth of the herbivores, may result in a feedback loop in the population size of the herbivore. This feedback can be immediate or delayed, and thus characteristic of first- or second-order dynamics, depending on the particular system involved.

If plants were the sole determining factor in the cycling process, then herbivore densities should mirror closely the densities of their host plants with some time lag, and would thus have low-order dynamics (zero or first-order) This explanation, however, has not been supported by data since plant densities rarely undergo such drastic cycles as herbivores in any system. For example, the larch budmoth (*Zeiraphera diniana*) (LBM), which cycles approximately every 9 years, plant mortality is only around 1% after attack, and plant biomass is only reduced by 50% during the outbreaks. Thus, it seems unlikely that the drastic crashes in herbivore densities are due to a lack of food resource in this system.

Similarly, in a large data set of Fennoscandian voles, oscillations in population density are probably not caused by concomitant oscillations in plant abundance alone. Oscillations in these populations have characteristics of second-order dynamics with relatively long lags in response time. Again, if determining factor was available plant biomass for consumption, then there will be little time lag between the action of the herbivores and the decline in herbivore population densities.

Methods of Determining Patterns and Mechanisms

One of the problems inherent in studying population cycles is that cycles often take place over many years. For example, the snowshoe hare and lynx cycles have a period of roughly 10 years. Ecologists were only able to appreciate this phenomenon because of the careful records taken by Hudson Bay Company fur trappers. For most organisms, we do not have the long-term population data sets needed to observe cycles, so ecologists will likely discover more cycling populations as long-term data sets are established and evaluated in the future.

Cycles in population may, at first glance, seem easy to detect. For example, we can look at the snowshoe hare and lynx data and observe clear up and down portions of the graph in a repeating pattern (Fig. 1). But how do researchers detect if there is a regular pattern to the fluctuations? There must be enough detailed data from several years of observation to even begin the analysis. If the cycle has a period of 10 years, then at least 20 and perhaps 30 years of data are needed. After these data are collected, ecologists generally use time-series analysis to detect whether a true repeating pattern occurs. In practice, this usually takes the form of calculating the autocorrelation function (ACF), which measures the correlation in population density between pairs of years in the data. The ACF can tell you the most probable period of the population cycle, that is, whether a cycle takes 5, 7, or 9 years to complete.

More complex methods can also detect if the fluctuations are characteristic of first-, second-, or higher-order functions in the time series. A cycle with a period of t years does not necessarily mean that the only effect of this year's population will be felt t years in the future. Population densities in the intervening years will also have an impact on densities t years in the future.

Which years have the greatest impact on current populations are related to the order of the system dynamics, as mentioned above. How do we determine these orders if they are not evident by looking at graphs? Ecologists use partial ACFs (PACFs) or their

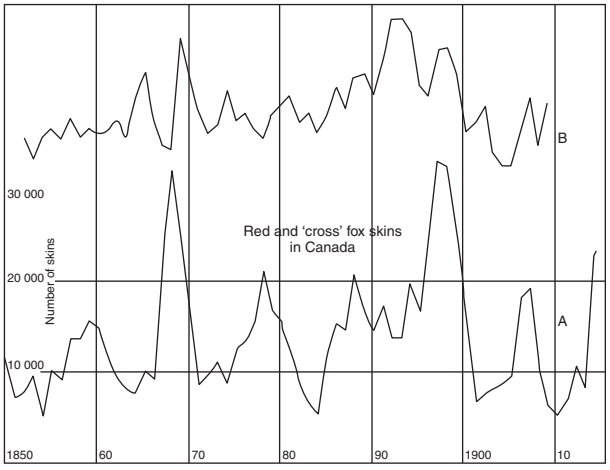

Fig. 1 Curve A shows the numbers of red fox and `cross' fox taken by the Hudson Bay Company in Canada each year. Curve B shows the same curve after a period of 10 years has been eliminated from it. The period remaining is one of about 3.5 years.

derivatives to determine the dominant process order of a density-dependent system. PACFs tell you where, in time, the greatest effects of population density occur. For example, systems with second-order dynamics usually have density-dependent lags of between 3 and 5 years, and systems with zero-order dynamics have almost instantaneous lags. It should be noted that although these analyses generally identify cycles of a certain period, there are many fluctuations around these periods in the actual data. Stochastic events are present in any ecological system and may perturb whatever periodic cycle we identify such that a population that has a general period of 3 years may have some periods of 4 years and others of 2.

These demanding forms of analysis have been used recently to help pinpoint actual mechanisms of population regulation in cycling populations. These methods are used to complement field manipulations, since field manipulations are rarely employed long-enough or at large-enough scales to replicate or change long-term dynamics.

Despite the difficulty of manipulations, such experiments have been executed, especially in the snowshoe hare–lynx systems in boreal Canada and the vole systems in Europe. Large-scale manipulations using exclosures or food additions have the twin advantages of being relatively realistic and having the ability to look in-depth at a single factor at a time over large areas.

Case Studies

Different ecosystems have different organisms, climates, primary productivity, and edaphic factors. Thus, it is not surprising that the strength of cycles, their periods, and the drivers behind the cycles vary with the particular plant–herbivore–predator system researchers examine. Since these idiosyncrasies are quite important, we will examine some of the major findings in the best-studied systems with the most-detailed records of herbivore abundance or density.

Snowshoe Hare

It is appropriate to begin with the well-known case of the snowshoe hare–lynx population cycles recorded in Canada and Alaska. These cycles were discovered by Elton while he was examining the hunting records from the Hudson Bay Company in Canada. He found that the hare and lynx pelt records as recorded by trappers exhibited strong periodic population fluctuations, and that the lynx populations seemed to track the hare densities, albeit with a significant time lag. The cycles are pronounced and occur over wide geographic areas; in 1997–99 hare population peaks were synchronous over large parts of Canada and Alaska. Since the cycles appear in the herbivore, the hares, and the predator, the lynx, the obvious causal mechanism seemed to be predation. So far, experimental data have supported this early hypothesis, with some caveats.

Although observing time-series data and making conclusions using models may give us insights into what causes the lynx–hare cycles, manipulative experiments are also necessary to determine what mechanisms are responsible for different parts of the cycles. Both the increases and decreases in herbivores may be caused by the same or different organisms. Although difficult to implement, some large-scale manipulations have helped ecologists examine individual portions of the hare–lynx cycles. The general strategy of these experiments is to try and change one major ecological factor in the hope that this manipulation will stop the cycles from occurring. These methods are very powerful, since a change in a single factor, such as food supply or predator abundance, may be shown to be responsible for the cycles.

Researchers have added food to hare populations in an effort to reverse the decline phases of a population cycle, with mixed results. When commercial-grade rabbit feed was added to large (1 km^2) experimental areas the amplitude of the cycles increased, but the cycles continued unabated. The increases in hare populations with food addition were not the result of increased fecundity by itself, but by immigration into the experimental areas from outside of the plots. Thus, food itself was not enough to `rescue' the populations from their decline phase. When more natural sources of food such as tree boughs were used to amend hare diets the same increase in population densities occurred during the increasing phase of the cycles, but this was again not enough to prevent the population crash portions of the cycles. Finally, even the addition of fertilizer to the extant vegetation cannot prevent the decline phases of cycles. On the other side of the cycles, the increases in population densities were also not significantly affected by food additions. Thus, it appears that food abundance is not solely responsible for either the increase or decrease portions of hare cycles.

In another large-scale manipulation with the hare–lynx system, researchers attempted to exclude large predators that were known to cause a great deal of mortality in hare populations. These included both lynx and coyotes, which caused very high proportions of all hare mortality in natural, unmanipulated populations. Hare populations in these exclosures did not show the marked decrease in survival rates seen in areas open to predators, but instead maintained relatively stable survival rates. Avian predators such as raptors did not seem to have a significant effect on survival rates, although it is important to realize that they still may be important in affecting certain parts of the cycle. Avian predators may, to some extent, be redundant with lynx and coyotes, replacing their numbers if they should decline.

Larch Budmoth

For lepidopterans subject to population cycles, two mechanisms have been proposed to explain the mechanism behind the pattern. Extrinsic factors, such as sunspots or weather, were popular explanations when these patterns were first discovered.

However there is little evidence that any such factors are as strictly periodic in their effects to produce the cyclical patterns we observe. Workers have come to accept the idea that negative feedback mechanisms involved with predators or parasitoids are probably responsible for most of the cyclical dynamics observed in lepidopterans. Although several lepidopteran systems exhibit relatively strong cyclical dynamics, the strongest exposition of the problem and the solution can be found in the larch budmoth.

The LBM system shows very regular population cycles in Europe. Since there are many long-term data sets for this organism, the population dynamics have received a great deal of scrutiny. Cycles generally have a period of 9 years, over large geographic areas. Based on time-series analysis, second-order or higher-order processes are likely to be causing the cycles, with declines in plant quality over many years of herbivory possibly being the mechanism. The decline in plant quality is hypothesized to occur as a result of LBM activity; this is sometimes termed induced susceptibility in plant tissues. Models employing declines in plant quality over several seasons as an exogenous factor and herbivore population growth dependent on plant material accurately mimic the observed dynamics in the system. Empirical evidence, however, suggests that other factors may be the main drivers of the cycles. During one LBM outbreak there was little decline in plant quality and the density of the larvae were quite low, relative to earlier outbreaks. However, the decline portion of the cycle still occurred, leading researchers to question the mechanism of induced susceptibility.

An alternative explanation for the production of cycles is the activity of specialized parasitoids. Many parasitoids prey upon LBM populations, although only two groups cause appreciable amounts of mortality. Simple models employing parasitoids and a time lag fit the observed dynamics significantly better than the plant quality models. There are, however, very few data regarding the exact proportion of budmoth larvae that are attacked successfully by parasitoids. A combined model that includes induced susceptibility in both plants and parasitoids actually explains the greatest amount of variation in the empirical data, suggesting that the mechanism may include the interaction between these two factors.

Owing to the lack of large-scale manipulations in this system, it is difficult to say conclusively what the true drivers of the LBM cycles are. It seems likely that many processes contribute to the effects that we see, with some redundancy in the factors. For example, population crashes still occur when plant quality stays relatively stable, so parasitoid activity may `take over' when plant quality does not decline.

Fennoscandian Voles

As mentioned above, Fennoscandian voles show dramatic population cycles over a wide geographic range with a pronounced decrease in cycle strength with decreasing latitude. Time-series analyses point to a significant second-order component in the system, again suggesting that delayed density-dependent time lags are in operation. In contrast to the previous systems, this example includes a suite of small mammals that cycle in partial synchrony: the field vole, *Microtus agrestis*, the sibling vole, *M. rossiaemeridionalis*, and the bank vole, *Clethrionomys glareolus*. The abrupt crashes in population densities that characterize the decline portion of the cycles occur despite seemingly adequate environmental conditions for survival and reproduction.

Time-series analysis again suggested that there is a significant lag dynamics, with an approximate order of 2. Thus, we are dealing with density-dependent lags that are of medium length (3–5 years). Model-fitting using specialist predators as the causal mechanism fit the dynamics of the actual populations quite well, and can mimic the declines in periodicity with increasing latitude given the correct model parameters.

In contrast to the LBM example, there are experimental data that support the time-series data and the mechanistic model results. Experimental removal of both avian predators and weasel predators eliminated the decline in population densities during two separate cycles. Elimination of weasels alone, however, did not preclude the population crashes, perhaps because weasels do not make up a majority of vole-eating predators in the study areas. Although these results are highly significant, they do not fully explain the cycles. They only are able to mechanistically account for the population crashes, but not the subsequent increases in population sizes as the next cycle begins. This may not be a large obstacle, as small herbivores have a high intrinsic rate of population growth, and the increases may be a case of standard exponential growth dynamics as described in Lotka–Volterra models.

General Conclusions

Cyclic population dynamics continue to fascinate ecologists, and as more long-term data are collected, more examples of population cycles are sure to be discovered. What broad conclusions can ecologists make regarding the forces responsible for the maintenance of these cycles, given the information we have at hand? First, it is apparent that cycles are usually not caused by a single factor at a single period of time. Indeed, this is the hallmark of many ecological phenomena, since science is largely the study of complex interactions among many factors. Many agents are probably responsible for the net effects ecologists have observed over time.

Given this caveat, if we examine the examples in **Table 1**, there seems to be a mechanistic bias toward trophic interactions, that is, predators or parasites of some kind seem to be involved in all of the examples listed. Secondly, the main drivers of the oscillations are second-order in nature, with significant time lags in density-dependent factors. This is not to say that first-order dynamics are unimportant; first-order dynamics are often needed to stabilize cycles, but they are not sufficient to cause cycles. In

general, population cycles in herbivores are rather common in nature and the cycles themselves tend to depend on significant time lags. These lags suggest that predation or other trophic processes may be operating, but only experimental manipulation over several population cycles can confirm the exact mechanism. Thus, as in most of ecological science, theories are rejected or supported based on many avenues of evidence. Since biological systems are so complex, we should expect that both the drivers of population regulation and the population trajectories themselves will be equally fascinating and multivaried.

Imprinting

T Slagsvold and BT Hansen, University of Oslo, Oslo, Norway

Introduction

The ability to learn is a naturally selected adaptation that enables an individual to adjust its behavior according to the current surroundings. Some of the most basic animal behaviors, such as recognizing conspecifics or knowing where to look for food, may be acquired through a learning process known as imprinting. A widely applicable definition of imprinting is that it is a learning process that restricts preferences to a specific class of objects. It implies some sensitive period when imprinting can occur. Usually, imprinting refers to the learning of social preferences that occurs relatively early in life, and that is stable once it is established in the individual. Under natural conditions, the social parents usually serve as stimulus objects for the developing young. A further characteristic of imprinting is that it occurs without any obvious reinforcement (this point has been widely debated). Although clearly a unique learning process, imprinting shares many characteristics with associative learning.

Two kinds of imprinting have been extensively studied. Filial imprinting concerns the development of a social preference of a young animal for its parent(s). Sexual imprinting is the process by which young animals learn the characteristics of future mates. Both kinds of imprinting may also function in individual and kin recognition. In a wider context, imprinting may determine the species recognition of many animals. Imprinting may even be of importance for establishing nonsocial ecological preferences, such as for food and habitat. The timing and duration of the learning process may differ between behaviors and species. Moreover, the kinds of behavior that may be affected by imprinting may vary with the life history and ecology of the species.

Filial Imprinting

Filial imprinting refers to the process where the social behavior of the young animal becomes limited to a particular object or class of objects, as a result of exposure to an object. In most cases studied, the stimulus object is the social mother, hence the young learn to recognize and attach to a parent through filial imprinting. The typical example is the young of ducks and geese, which instantly follow their mother. This is often called the following response. The chicks of these birds imprint on any individual present at hatching time, including a human, and will follow this individual as a mother figure. In fact, ducklings and goslings have also been shown to imprint on various inanimate objects in the laboratory. Generally, the attachment to the mother figure is very strong, and hence when a gosling is imprinted on a human, it will not change the attachment although it is given access to its true mother after only a day post hatch. Hence, a characteristic of this imprinting is that it is more or less irreversible. Cases of filial imprinting similar to those seen in birds are also found in mammals. For instance, a juvenile, single lamb will follow a human who provides milk from a bottle, also when the lamb is not hungry. The attachment may last well into adulthood.

At least two perceptual mechanisms are involved in the development of filial behavior, namely filial imprinting and predispositions. The latter refer to perceptual preferences that develop in young animals without any prior experience with the particular stimuli involved. The two mechanisms are neurally and behaviorally dissociable but are supposed to interact during the development of filial preferences, where the predisposition may bias the animal's responses. This bias may differ strongly among species, as observed in precocial birds. For instance, the bias may be relatively weak in a goose but strong in a wader.

Numerous experiments have shown that the young may imprint on a wide range of objects, and individuals that form an attachment to the wrong kind of object will certainly be disadvantaged under natural circumstances. However, in nature the adult present at this early stage of life will usually be the caring parent and so this imprinting method may work perfectly. In species with parental care, the benefits of filial imprinting are obvious because it helps an offspring to attach to its parent. If such a bonding does not take place, the parent may not start investing in that particular young and it will soon die. The following response of goslings and ducklings is adaptive because in these birds the nest is often placed at some distance from water and hence the mother has to lead the young to the water soon after hatching, often through various obstacles, like dense vegetation, where it is important that the young would follow closely. The strong attachment to the mother would also have other advantages, like avoiding dangerous sites and learning to recognize enemies, where the mother may give a specific call and the chicks would freeze and remain motionless until danger has passed. Attachment to the mother will, in many cases, also help the young to learn foraging behavior, to locate shelter, and to socialize with other members of their own species.

Typically, juveniles do not avoid any object initially but tend to approach and explore them. Imprinting on the caring parent would help them to avoid novel objects, and this acquired ability to discriminate may effectively bring the sensitive period for the filial imprinting to end. However, experiments have also shown that after having become familiar with an imprinting stimulus, the juvenile may begin to prefer stimuli slightly different from the initial one. This may have the effect of familiarizing the offspring with different aspects of the mother. It may be important to recognize a parent from many angles, which seems only possible if the juvenile builds up a composite picture of its parent's characteristics.

Apparently, the juvenile identifies as the caring parent the first object it meets that possesses some simple characteristics. Various tests have been made to study which imprinting stimuli are more important. In case of the geese studied by Konrad

 doi:10.1016/B978-0-444-63768-0.00017-2

Lorenz, most important was the movement of an object away from the chick. The effect was even stronger if the object produced some sound, although the sound did not need to be from a goose or bird; even the sound of a ticking clock could work. Furthermore, the model body did not need to be of an animal or covered by feathers but could be a simple box or a block of woods. However, more detailed studies have shown that young birds tend to show some innate preferences for certain features, such as color, shape, and size that may steer them toward the real mother figure rather than toward some arbitrary objects. Similarly, juvenile rhesus monkeys prefer a cloth surrogate mother to a wire surrogate mother. Such innate preferences are often referred to as predispositions. The variation among species in sensitivity to stimuli seems related to which stimuli are important in the wild. For instance, sound is very important in wood ducks. These birds nest in tree holes and the mother calls to induce the ducklings to leave the cavity. There also seems to be a change in relative importance of stimuli with time. For instance, in ducks, the following response is largely influenced by auditory cues from the mother soon after hatching whereas visual cues become important later on. Likewise, offspring of many species may show a preference for the more conspicuous signals, but if the signal is too startling, it may elicit fleeing rather than approach. The following response can also be enhanced with food rewards, which makes sense in species where the parent provides food or leads the young to a food resource.

Studies have also been made to identify the sensitive period for the filial imprinting, for instance, by quantifying the following response in ducks and geese to a proper mother model presented at various points in time. Some authors use the term `critical period' for the part of the sensitive period when the learning response is greatest. In precocial birds, like geese, where the chicks can run around and find food soon after hatching, the sensitive period for the filial imprinting is only the first one or two days post hatch. In fact, the young seem to learn the call of their mother already before hatching. However, the duration recoded for the sensitive period may be dependent on the method used, for example, whether the response is measured as the percentage of following responses after a single exposure, or by the percentage of birds following during the first exposure; the former measure may show a much more sharply defined period of sensitivity than the latter. One also has to take into account whether single individuals are tested, or a brood of young, because there may also be an effect of siblings (social effects, or imprinting on siblings). For instance, juveniles kept singly may remain responsive to moving objects much longer than juveniles kept in groups. Imprinting on sibs may help the juveniles to stay together.

The sensitive period for filial imprinting is much later in altricial birds than in precocial birds. Altricial young are blind and very helpless when hatching, which may limit their opportunity to imprint during their first days of life. Moreover, the necessity for very early imprinting on parents clearly differs between the two groups of birds. Precocial young move around and feed at least partly by themselves shortly after hatching, and may thus need immediate tuition in, say, feeding behavior. Moreover, this behavior may lead to many encounters with various adults apart from their mother. Altricial young, on the other hand, do not need to distinguish their parents from other birds until quite late in the nestling period since they receive food in their nest where there usually will not be any adults around except their parents.

Sexual Imprinting

Sexual imprinting is the process by which young animals learn a sexual preference for opposite sex conspecifics. The effects of this early learning process become manifest in adult mate choice. The social parents usually serve as templates for the young in the establishment of the mate preference. There is also some evidence that siblings may influence the development of mate recognition.

Most research on sexual imprinting has been performed with birds. Among birds, sexual imprinting has been documented in more than 100 species and seems to be the rule rather than the exception. Sexual imprinting has also been documented among mammals and fish. It is not limited to rapidly evolving species, or males only, as has been suggested. Most studies on sexual imprinting have been performed in a laboratory setting, particularly with zebra finches, mallards, and quail. However, the existing field studies show that sexual imprinting is also prevalent under natural conditions, and generally confirm the properties of the learning process as they have been documented in the laboratory.

Typical experiments demonstrating sexual imprinting involve some kind of manipulation of the parental phenotype. Interspecific cross-fostering is frequently used, that is, the experimenters let young of one species be reared by adults of another species. The result of this treatment is usually that cross-fostered individuals express a sexual preference for their foster species when tested in mate choice trials as adults **Fig. 1**. This is proof that mate choice is learned, since normally reared individuals do not express any preference for heterospecifics. Similarly, young raised by parents with an artificial ornament may learn a preference for this ornament.

Previously it was thought that sexual imprinting was confined to a short period early in life. However, a series of laboratory experiments on the zebra finch showed that this notion was incomplete, and redefined the understanding of the sensitive period and the irreversibility of sexual imprinting. They showed that birds raised by heterospecific foster parents develop a preference for their foster species if they also experience their first courtship with that foster species. However, if such cross-fostered birds are exposed to conspecifics during first courtship or breeding, they may shift their initial preference toward conspecifics. These findings have been corroborated by studies of the zebra finch forebrain where physical changes accompany the early experiences as well as the experiences during first courtship. It thus seems like sexual imprinting is accomplished in two separate stages.

Several studies have documented that interspecifically cross-fostered individuals in species that do show sexual imprinting may also have a sexual preference for conspecifics in spite of the experience of having been raised by heterospecifics. There are several

Fig. 1 A blue tit female paired to a great tit male, feeding young. Blue tits raised by great tits and great tits raised by blue tits imprint sexually on their foster species. Heterospecific couples may be formed between such interspecifically cross-fostered individuals. Photo copyright: Tore Slagsvold.

potential sources for such an own-species bias. First, the bias may be genetically encoded, that is, mate recognition may to some extent be inherited rather than learned. Second, an own-species bias may have arisen as a result of conspecifics initiating more courtship than do heterospecifics toward the interspecifically cross-fostered individuals. Hence, the behavior of the stimulus individuals in the experimental mate choice situation may influence and even constrain the mate choice of the cross-fostered individuals. Third, factors such as the amount of care received by the parents, or the number of siblings in the nest, may influence the degree of imprinting, and such factors may have differed between cross-fostered and control individuals. In sum, there are many potential sources of variation in the development of mate choice. These must be kept in mind when designing and drawing conclusions from experiments on imprinting.

Some studies have revealed that the recognition of same-sex individuals also may be influenced by imprinting. Interspecifically cross-fostered great tits and blue tits respond aggressively toward same-sex individuals of their heterospecific foster species during the breeding season, while normally reared controls of both species respond aggressively only toward conspecifics. This effect lasts for life (Fig. 2). It is not known whether the development of such rival recognition is different from sexual imprinting. However, the fact that the appearance of rivals also may be learned highlights the function of imprinting in the development of species recognition as a whole.

Species recognition is a prerequisite for adequate mate choice, and learning species-specific characteristics from social parents and/or siblings is reliable because social parents and offspring are usually of the same species. A notable exception is the case of interspecific brood parasites such as cuckoos and cowbirds, which leave their young to be reared in nests of heterospecifics. Initially, it was thought that recognition templates were genetically inherited in brood parasites. However, recent findings suggest that the early social environment affects choices of social partners and mates in some brood-parasitic species. The timing of learning may have been shifted to the postfledgling stage for species that do not associate with conspecifics earlier. It has been suggested that conspecific recognition in the obligately brood-parasitic brown-headed cowbird is initiated when a young brood parasite encounters an innate species-specific vocalization that triggers learning of additional aspects of the vocalizing individual's phenotype.

Is Sexual Imprinting Adaptive?

Individuals that fail in the very basic task of recognizing conspecifics are clearly disadvantaged – thus there is a strong selection pressure for optimal species recognition. Why may this ability be affected by a learning process? After all, the learned features seem categorical and quite straightforward (i.e., conspecific/heterospecific), so why is not this knowledge inherited rather than learned? Although the categories to be distinguished remain distinct, there is considerable variation within the categories. Species-typical properties might change over space and time, as might the environment. Inheriting species recognition is hence potentially disadvantageous, because a change in the gene frequencies of the inherited recognition will be much slower than learning the change in species appearance. A genetically inherited behavior thus gives less flexibility, and inflexible individuals may thus miss out on mating opportunities if they do not recognize a novel conspecific morph. Learning from parents or other tutors may enable the animal to track such changes when they appear, and hence to develop adequate preferences. An advantage of learning mate preferences through imprinting is thus that it offers some flexibility in the face of stochastic events. However, the flexibility offered by learning can also be costly. If an animal imprints on the wrong kind of stimulus object, it might end up courting heterospecifics. Erroneous species recognition may result in futile hybrid mating, or no mating at all. Also, forgetting and relearning of mate recognition in the course of an individual life span may be disadvantageous because repeated stimulus object choice could

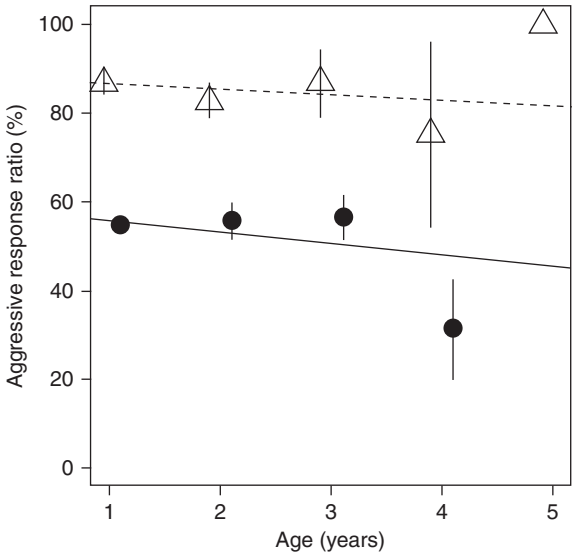

Fig. 2 Rival imprinting in blue tits persists with age. Aggressive response ratio (*y*-axis) is measured as the aggressive response toward blue tits divided by the sum of the aggressive responses toward blue tit and great tit intruders into the territory. Hence, a ratio of 50% means equal responses to great tits and blue tits, while a higher ratio means a stronger relative response toward blue tits than great tits. Control blue tits (triangles) respond mostly toward blue tit intruders into their territory, while blue tits cross-fostered to great tits (circles) respond aggressively toward both great tit and blue tit intruders, and this pattern persists throughout the life span of the respondents. Aggressive response is measured as the proportion of 5 min spent within 2 m of a caged intruder placed near the nest box of breeding respondents. All respondents were sequentially presented with individuals of both species. Symbols indicate arithmetic means ± SE. Reproduced from Hansen BT, Johannessen LE, and Slagsvold T (in press) Imprinted species recognition lasts for life in free-living great tits and blue tits. *Animal Behaviour* (doi:10.1016/j.anbehav.2007.07.023; available online 29 Oct. 2007), with permission from Elsevier.

introduce errors. Imprinting trades off the mixed blessings of flexibility. It limits the error potential of learning by optimizing the timing of the event relative to the presence of adequate stimulus objects. Further, imprinting minimizes the number of learning events and limits learning duration. Note, however, that there seem to be species differences in the degree of sexual imprintability, which indicates that the selection pressure favoring a somewhat flexible species recognition is not universal.

Sexual imprinting may also have a function in kin recognition. For instance, quails of both sexes develop a preference for the phenotype of distant relatives of the opposite sex. Kin recognition is advantageous for many reasons, not least optimization of mate choice with regard to inbreeding and outbreeding.

Evolutionary Consequences of Sexual Imprinting

Sexual imprinting promotes assortative mating, and may thereby restrict gene flow between populations. It may thus be instrumental in the establishment and maintenance of premating isolation between species or populations, which may result in speciation. If two populations diverge in some mate recognition trait, so will the populations' preferences for that trait. The tight link between the appearance of the trait and the preference for the trait may ensure premating isolation if the trait values of the two populations do not overlap.

It has also been suggested that sexual imprinting may be a driving force in the evolution of exaggerated traits by sexual selection. However, a preference in offspring for individuals that look exactly like their parents will not lead to directional selection for exaggeration of ornaments. Furthermore, frequency-dependent selection resulting from assortative mating will select against novel mates. How, then, may imprinted mate preferences drive sexual selection? To balance the costs and benefits along the inbreeding–outbreeding continuum, it may be advantageous to choose a mate who looks rather similar, but not identical, to one's own parents. In addition to facilitating inbreeding avoidance, this asymmetric mate preference may drive sexual selection, since deviations from the population mean are favored. Sexual imprinting may hence produce preferences for novel modifications of secondary sexual characters, and this process may in turn drive speciation.

Preferences for traits that deviate substantially from the population mean have been shown experimentally in several species. Moreover, theoretical models confirm that sexual imprinting and an asymmetric mate preference can lead to sexual selection. The exact mechanism for the development of an asymmetric mate preference has not been firmly established, but it could be a product of sexual imprinting itself, or sexual imprinting combined with a perceptual bias. Recent empirical evidence suggests that skewed mating preferences may be a result of a by-product of the learning process, called peak shift. If two stimuli are similar in appearance, and are differently reinforced in the responding individual, this process shifts the peak in response to increase the contrast between the stimuli. Zebra finches show natural sexual dimorphism in beak coloration, and it has been shown that males prefer females with a beak of a more extreme color than that of their social mothers. The preference is in the opposite direction of

the paternal beak color. It thus seems like sexual imprinting through peak shift can generate skewed sexual preferences for exaggerated phenotypes that have not been present at the time of learning.

Other Types of Imprinting

Several other behavior patterns seem to be acquired by an imprinting-like process. Most of these cases have been less studied than filial and sexual imprinting, particularly in a laboratory setting, and hence less is known about the details, for instance, of the timing and duration of the sensitive period, and the degree of stability of the learning in the individual.

The acquisition of some nonsocial ecological preferences seems to be influenced by early learning processes. Such ecological imprinting is illustrated by a recent study on great tits and blue tits. These tits inhabit the same woodland habitat, but differ in the ecological niche they utilize, the larger great tit foraging more on the ground and closer to the tree trunk than do blue tits. In an experiment where these tits were interspecifically cross-fostered, adults of these birds chose the ecological niche of their foster species rather than that of their genetic species, even though they possess species-typical adaptations for niche utilization (e.g., bill and feet morphology). There are indications from other species that food-type, habitat, and home area preferences also may be similarly affected. For instance, invertebrate cuttlefish have been shown to visually imprint on their preferred prey type. The development of homing behavior is another remarkable example. Salmons learn olfactory information as juveniles and use those odor memories as adults to home to their natal site for reproduction years later. This has been termed olfactory imprinting, and a similar mechanism for homing has been demonstrated in sea turtles and pigeons.

Parental recognition of the young may also be acquired by an imprinting-like process. This process is atypical in the sense that it occurs during adulthood rather than during the early stages of development. It is of course beneficial for parents to recognize their young so that they can direct care to their own kin. In birds, as in a colony of seabirds, vocalization may be particularly important in this regard. In goats, an olfactory imprinting mechanism may help mothers to recognize their own kin at a very early stage. Development of very early offspring recognition is necessary in herds of goats because kids may lose contact with their mother and may then try to approach other females. A few minutes of contact with a kid may be sufficient for the mother to imprint on it. During this period, the mother may learn the smell of the kid, and label it further by licking. Afterwards, she may only allow such labeled kids to suckle. The high arousal of a female giving birth may facilitate the imprinting on the young. In contrast, altricial birds associate the young hatching in their own nests as their own kin and hence do not need to recognize them individually until they leave the nest. However, there is a cost to the parents when following this simple rule of thumb, namely that the parental imprinting mechanism can be exploited by brood parasites, like cowbirds and cuckoos, dumping eggs into their nest. Parasitic eggs may be recognized and removed, but as soon as they hatch, the parasitic chicks are usually given full support by the foster parents.

Imprinting may also play a role in host choice in certain brood-parasitic species. Some brood-parasitic birds exploit hosts of a particular species, and the egg of the brood parasite has evolved to mimic the host egg. Hence, the brood parasite must recognize its optimal host species, and it has been suggested that they may have imprinted on the host only to such an extent that they prefer exploiting, but not mating with, the same kind of host that they grew up with.

Song learning and song preference learning in oscine birds, sometimes referred to as acoustical imprinting, have been studied in great detail, and possess some of the characteristics of imprinting. However, the sensitive period for song learning occurs later than in the classical cases of imprinting, and the time window for learning may be considerably extended. Also, tutor choice in song learning is often more diverse than is the case in filial and sexual imprinting. There may also be a greater degree of flexibility throughout life in song learning. Language acquisition in humans is an analogy to avian song learning.

Kin Selection

AS Griffin, University of Edinburgh, Edinburgh, UK

Natural selection is the process by which a trait can be favored because of its beneficial effects on fitness. Kin selection is an extension of natural selection theory that allows for the fact that a trait can be favored because of the beneficial effects on the fitness of relatives. The term itself was first coined by John Maynard Smith in 1964 although the idea that a gene could spread due to beneficial effects on relatives has been appreciated at least since the 1930s.

Kin Selection Optimizes Inclusive Fitness

Natural selection optimizes fitness. Understanding what kin selection optimizes was crucial to its emergence as one of the fundamental tenets of evolutionary theory. W. D. Hamilton was the first to explain this formally in terms of his theory of inclusive fitness in 1964. Hamilton pointed out that when we measure the fitness of a trait we must take into consideration the effect that trait has on the fitness of other individuals as well as the actor who performs the behavior. If a trait has a beneficial effect on carriers of the same gene, then that gene can spread by kin selection. Inclusive fitness therefore is made up of two components – direct fitness (from the production of offspring) and indirect fitness (from aiding the reproduction of relatives). Kin selection explains how a trait can spread by its effect on indirect fitness.

Kin Selection Explains Altruism

The gene-centered view of Hamilton's inclusive fitness theory solves Darwin's problem of how a gene that reduces the fitness of its carrier can evolve. One of the main aims of Hamilton's work was to explain altruistic behavior but in fact, the theory is much more general and applies to any social behavior (see **Table 1**). Examples of animals behaving altruistically toward one another are all around: animals feed one another, groom one another, build homes for one another, defend one another, babysit for one another, and even die for one another. If there is no direct fitness benefit to a helping behavior, then kin selection is the only explanation for the behavior. Crucially, the beneficiary of an altruistic act must have a higher probability of sharing genes in common with the altruist than a random member of the population. Helping relatives is simply the most common way in which this can be achieved.

The spread of a gene for altruism was formalized by Hamilton in what is known as Hamilton's rule. The rule states that a gene will be favored if the following condition is met:

$$rb > c$$

where r = relatedness between the actor of a behavior and the beneficiary, b = benefit to the recipient, and c = cost to the actor. The effect of the behavior to the actor's own lifetime reproductive success is $-c$ and this must be outweighed by the positive effect on the recipient rb.

Testing Kin Selection Theory

As well as being supported by a large body of mathematical theory, the parameters in Hamilton's rule are measurable and the theory is testable. However, it is also deceptively simple – in many cases this simple rule can hide a huge amount of complexity. For example, the term kin selection is used to refer to selection in two different situations: when the gene of interest is shared due to common ancestry alone or more broadly to any situation where the gene is shared. For example, in the latter case, the relatedness between two individuals who are known to carry the gene for an altruistic trait would be $r = 1$, regardless of kinship by co-ancestry.

Hamilton's rule clarifies the predictions of kin selection theory: traits will be more likely to spread if they maximize r and b and minimize c.

Table 1 Categories of social behaviors based on the effect on the fitness of the actor and the recipient

Effect on actor	*Effect on recipient*	
	+	−
+	Mutual benefit	Selfishness
−	Altruism	Spite

 doi:10.1016/B978-0-444-63768-0.00019-6

Maximizing Relatedness

There are two ways in which an appreciable relatedness between social partners can arise.

1. *Kin discrimination*. If, as is often the case, an animal is faced with a decision of who to help, potential beneficiaries may or may not be related. Kin discrimination refers to a process by which an altruist discriminates with respect to relatedness when deciding who to help. In long-tailed tits, in which case helpers have the choice of helping at several different nests in the territory, it has been shown that they preferentially provide help at the nests of relatives (see **Fig. 1**).
2. *Population viscosity*. This refers to a population structure where dispersal is limited from a natal patch. By chance, a potentially altruistic individual will be surrounded by relatives and so any altruistic act it performs will, by chance, benefit those who share the altruistic gene. This is the case in social insect colonies, which are typically founded by one or a few reproductive queens. Viscosity may account for the fact that there is no evidence for kin discrimination in eusocial insects. The costs of such a system are not worth the benefits as workers have not evolved in an environment where help is squandered on nonrelatives.

Although there is a wealth of evidence in support of kin selection theory, much of it is correlative. This is mainly because it is difficult to design experiments where relatedness and altruism can be manipulated. Recently, however, this has been made possible using microorganisms. In populations where relatedness between social interactants was higher, a higher level of cooperation was selected for (see **Fig. 2**).

Maximizing Benefit

One field where a great deal of work has been done on the ability of kin selection theory to explain altruistic behavior is in the study of cooperative breeding in birds and mammals. In such species, nonbreeding helpers remain in the natal territory to help raise offspring in subsequent breeding seasons rather than dispersing to reproduce. The question often asked is: do helpers at the nest preferentially give help to more related individuals? Cooperatively breeding species offer the opportunity to test this prediction of kin selection theory. In several species, such as the long-tailed tit and the Seychelles warbler, helpers were found to discriminate in favor of kin. However, in other species, such as the kookaburra and the meerkats, workers do not appear to discriminate in favor of kin. In such cases, other explanations for helping behavior are needed based on direct fitness benefits. However, it turns out that Hamilton's rule predicts this pattern. Further analyses have shown that the extent to which helpers discriminate depends on the amount of benefit provided by helping: if there is no benefit to help in terms of offspring raised then

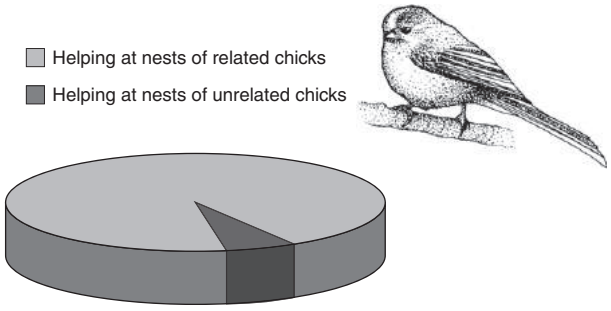

Fig. 1 The difference in the amount of help provided at the nests of relatives (94%) relative to nonrelatives (6%) in a cooperatively breeding bird, the long-tailed tit.

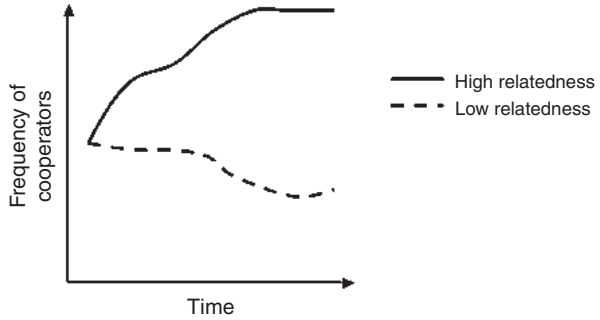

Fig. 2 Two populations of bacteria were maintained and the changes in frequency of an altruistic trait (production of a molecule involved in the scavenging of iron) was monitored across time. When there was high relatedness between cells the frequency of altruism increased, providing the first experimental support for the prediction that relatedness facilitates the evolution of altruism.

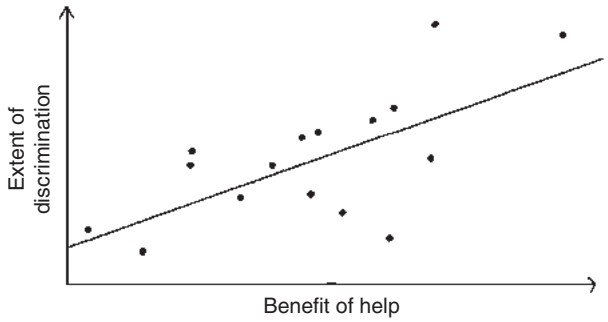

Fig. 3 Each circle represents a species of cooperatively breeding bird or mammal. For each species, the extent of kin discrimination was measured as the effect of kinship on the likelihood or the amount of help given by nonbreeding helpers. The extent of kin discrimination was correlated with the benefit of providing help which was measured as the proportion of offspring surviving to 1 year. As predicted by kin selection theory, when helpers were more helpful, they were also more choosy about which individuals they helped.

there is no incentive to discriminate (see **Fig. 3**). This provides an across-species test of Hamilton's rule – when b is higher, preferential helping of relatives is more likely to be favored.

Minimizing Cost

There is less empirical support for the prediction that cost, in terms of direct fitness, is minimized for the simple reason that it is a difficult parameter to measure. Whereas relatedness can be estimated using pedigree or genetics and benefit can be measured by counting offspring, the cost resulting from competition with relatives is more difficult to quantify. However, kin selection theory has been supported by a study which measured the cost of helping in terms of direct fitness in the hairy-faced hover wasp. In the hairy-faced hover wasp, there is a single dominant breeding female, and helpers that provide aid to the dominant, form a queue to reproduce. The queue is based on age: when the dominant female dies, the second oldest female takes over the breeding position. Cost in this example is easily measured in terms of queue length. Helpers help less when the queue to reproduce is shorter: a shorter queue means more to lose in terms of direct fitness and so selection does not favor investment in helping.

General Application of Kin Selection

The true power of kin selection theory is its generality: kin selection can help explain a huge range of social interactions and not just altruistic cooperation. The simplest cases are when interacting individuals are more closely related, they should be more likely to cooperate, show more selfish restraint, and show less aggression. A range of more subtle possibilities arise whenever there is the potential for cooperation or conflict between relatives. A few examples of these are:

- Individuals are expected to be more likely to give warning calls about the presence of predators, if they are in the presence of close relatives, as occurs in ground squirrels.
- In species where cannibalism occurs in response to food limitation, individuals should prefer to eat nonrelatives, as occurs in tiger salamanders and ladybirds.
- In social insects, such as wasps and bees, workers remove eggs laid by other workers, because they are more related to the queen's eggs, than the worker-laid eggs.
- In many insects, related males (brothers) compete with each other for mates (often their sisters), before these females disperse to lay eggs elsewhere. When this happens, mothers produce a female-biased offspring sex ratio, to reduce this competition between brothers.
- If the relatedness between the parasites infecting a host is high, they are expected to prudently exploit that host, causing less damage and mortality (virulence).

In other words, kin selection theory describes when individuals should behave altruistically and also when they should curtail their selfishness. Furthermore, kin selection theory also predicts the existence of spiteful behaviors, where an individual suffers a personal cost ($c>0$) in order to inflict harm upon a social partner ($b<0$) (**Table 1**). Such behaviors are favored when $rb>c$ is satisfied, which requires a negative relatedness ($r<0$) between spiteful actor and victim. Examples of spiteful behaviors include bacteria producing chemicals that kill nonrelatives, or wasp larvae preferentially attacking and killing individuals to whom they are less closely related.

Learning

DR Papaj, EC Snell-Rood, and JM Davis, University of Arizona, Tucson, AZ, USA

Introduction

Learning is ubiquitous among animals and plays an important role in all manner of ecological processes including competition, predation, mutualism, species coexistence, and population regulation. Learning has important consequences for evolutionary change, including biological diversification. Learning is also important to consider when assessing the effect of human activity on animal populations. Here we provide an overview of learning from an ecological and evolutionary perspective.

What Learning Is

The definition of learning has been the subject of long, unresolved debate, and no definition is universally accepted. However, most students of animal learning agree that learning involves a repeatable change in behavior with experience that persists for some time after experience ends (i.e., there is evidence of memory). Furthermore, with a few important exceptions, learned behavior changes gradually with continued experience to some asymptote; wanes if not continually reinforced; can often be undone by a new type of experience; and is more suited to the environment in some way (i.e., associated with higher fitness) than before learning took place.

Learning is just one form of behavioral plasticity. Learning is sometimes referred to as a form of phenotypic plasticity in which the phenotype is behavior. This is not imprecise, but can be somewhat misleading because behavior is itself a form of phenotypic plasticity. Behavior, like any form of phenotypic plasticity, can be described by a `reaction norm' that relates an animal's phenotype, in this case a set of morphologies generated by motor outputs, to particular environmental states. Learning in turn can be described as a mechanism by which the reaction norm representing a particular behavior is modified by experience with the environment. Learning is thus a mechanism of plasticity in behavior, which is itself a type of plasticity.

While learning is an important mechanism of behavioral plasticity, behavioral plasticity also results from motivational and maturation processes. For example, females from a given butterfly population may respond to the same host plant cue in different ways (e.g., laying eggs or not), depending on the number of eggs that are currently matured. The more number of eggs that are matured, the more likely the female will lay eggs in response to the host plant cue. Thus, a response to an environmental cue (a behavior) is different as a result of reproductive state, rather than learning. It can be difficult to distinguish changes in behavior due to motivation or maturation from learning.

Learning involves but is not equivalent to information gain. Learning is more than just information gain. Animals acquire much, if not most, information without use of memory. Any behavioral response to a sensory stimulus is indicative of information gain. For example, a tap on our knee results in a knee jerk reflex. No learning is involved in this reflex, yet information about a mechanical stimulus impinging upon the knee has been acquired by our nervous system and responded to.

The changes in physiological state discussed above can also be used as source of information that can change behavior without requiring memory. For example, a bird's increasing hunger may indicate that food resources are locally scarce. If the bird chooses nest sites on the basis of relative food availability, its choice may involve learning but could also involve an estimate of availability derived from patterns in hunger level.

The equation of learning with information gain may reflect a human bias. For example, we say that we `learn' what time it is or that we `learn' that it is raining this morning. This language is not inappropriate, since humans store so-called declarative knowledge (or, `knowledge of what' such as names and images of things or places) in a type of memory termed declarative memory. However, there is only limited evidence of declarative memory in nonhuman species. This form of memory is difficult to identify in nonhuman animals and its prevalence in animals is unknown.

Learning is not equivalent to synaptic plasticity. There is growing evidence that changes in the structural connections between neurons (termed synapses) mediate learning and memory in animals as different as vertebrates and insects. Nevertheless, an ecological and evolutionary perspective on learning need not and probably should not require *a priori* that a common mechanism underlie all examples of learning and memory. In fact, there is evidence of phenomena that resemble learning in every way, but which do not involve synaptic plasticity. For instance, feeding experience affects diet choice in locusts in a manner that resembles discrimination learning (a form of learning in which an animal learns to discriminate one food type from another). The effect of experience involves at least in part a taste-feedback mechanism in which the sensitivity of sensory receptors to nutrients in the hemolymph is adjusted. Conversely, synaptic plasticity simply means that synaptic function is not fixed with respect to inputs, and there are many kinds of synaptic plasticity unrelated to learning.

 doi:10.1016/B978-0-444-63768-0.00020-2

Who Learns

Learning has been found in every major group of animals in which it has been examined. Although not all animal phyla have been examined with respect to learning and, although no formal phylum-level phylogenetic analysis of learning has been made to date, existing evidence suggests that learning may be ancestral to the animal kingdom. Evidence of learning phenomena in protists affirms this position.

Learning has been ascribed to organisms other than animals and protists, including bacteria, slime molds, and plants. For sure, elements of learning are found across almost all taxonomic groups of living organisms. In unicellular organisms such as phage, networks of cell proteins appear to perform analogously to neural networks, possessing properties that make them capable of a cell-level associative memory. Empirical results suggest that metabolic responses in bacteria are tuned by repeated exposure to particular conditions in a fashion that resembles how behavioral responses are tuned in animals. Evidence of learned behavior in microbes may not be long in coming. Plants, like bacteria, have processes that resemble learning at the level of protein networks within cells, and physiological responses of plant cells consequently change with experience. A kind of memory occurs in plant cells in which information about environmental stress is stored until receipt of a complementary signal required for a developmental change. Although these processes are physiological in scope, the behavioral repertoire of plants is quite rich and learned behavior in plants conceivable.

Why Learn

Benefits of Learning

The basic advantage of learning is that it permits an individual to behave adaptively even in the face of environmental change. The environment must be unpredictable for learning to be of benefit, but not too unpredictable; what happens in the present must relate in some way to what happens in the future for learning to be useful. Straightforward though this benefit of learning is, the benefit of learning in particular contexts may not be so apparent. For instance, despite decades of study of the ontogeny and neuroethology of song learning in birds, the issue of why birds learn song (and the related issue of why animals such as insects and frogs do not) is still not settled.

Costs of Learning

Learning also has costs that arise from the time, materials, and energy necessary to acquire and store information. `Behavioral costs' arise from sampling a range of behaviors early in the learning process. For instance, birds take large amounts of time learning foraging skills and suffer energy losses from their mistakes; species that use a wider range of resources have more pronounced exploratory behavior during this period. Exploration may be costly in terms of time and energy, or in terms of increased risk of attack by natural enemies. `Tissue costs' of learning arise from the neural tissue necessary to acquire and store information. Since neural tissue is particularly energetically expensive to maintain, tissue costs can be considerable.

Costs of learning translate into various tradeoffs with learning ability. In *Drosophila* fruit flies, artificial selection for faster learning in adults resulted in reduced competitive ability by larvae. In *Pieris* butterflies, natural variation in learning ability is causally linked with delays in reproduction.

Learning in an Ecological Context

What Animals Learn

Evidence of learning in animals has been obtained with respect to foraging, territoriality, predator avoidance, dispersal, migration, thermoregulation, communication, mating behavior, parental care, kin recognition, and other social interactions. In these contexts, animals learn relevant features of their environment. Animals can learn the caloric content, nutrient profile, and handling time associated with food types, and the genetic and direct benefits offered by different mates. They learn the quality distribution of essential resources such as food, breeding sites, and mates. In other words, information about virtually every aspect of an animal's ecology may be acquired through learning. Of course, not every animal of every species or population is expected to learn all possible behavior in all ecological contexts. What, if anything, is learned should depend on the net value of learning to the individual. Two observations support this statement. First, animals frequently show biases in what stimuli they are prepared to learn. Second, animals that differ in their ecological requirement for a particular kind of learning differ in how much they invest in such learning.

Learning biases. Animals do not learn all environmental stimuli in all contexts equally well. A classic example of learning bias has been described for food aversion learning. Food aversion learning, best studied in birds, rodents, and insects, involves avoidance of food stimuli associated with a digestive malaise. The sensory properties of food aversion learning in rats are intriguing. Rats readily avoid a flavor associated with an illness but not sound or light. This is not because sounds and light are

generally more difficult to learn than flavors: rats more easily learn to associate sound and light with an electric shock (a rapidly acting punishment) than they do a flavor. This pattern most likely reflects an evolutionary history in which foods and their flavors are sometimes associated with delayed illness, favoring a learned aversion toward them, but such illnesses are very rarely associated with sound or light. Similar learning biases are known for song learning in birds. In playback experiments, for example, sparrows prefer to copy their own species-typical song over that of other sparrow species.

Patterns of investment in learning. What information animals learn should depend on the relative costs and benefits of learning that should in turn depend on a species' or population's particular ecological demands. Spatial learning is critical to navigation (including homing) in many animals, as well as to formation of territories and home ranges. Such learning necessarily entails acquiring, processing, and storing large amounts of information. As such, spatial memory can be expected to be very costly and, in fact, large areas in metabolically expensive brains (e.g., the hippocampus in birds and mammals) are devoted to it. Not surprisingly, in view of its high costs, some of the strongest evidence of species differences in learning occurs in relation to spatial learning. In birds and mammals, for example, spatial learning and associated areas of the brain, like the hippocampus, are better developed in species, populations, or sexes in which spatial learning is relatively important. Home range size, for example, is larger in meadow voles than pine voles and thus the former species has correspondingly better spatial memory and larger hippocampi. In meadow voles, the male's home range is much larger than the female's, a difference associated with superior spatial learning and larger hippocampi in males. Food-storing behavior is correlated with similar species differences in corvids. Nutcrackers, which depend strongly on food caches to survive the winter, have better spatial memory ability than scrub jays or pinyon jays, each of which depend less on caches. Significantly, nutcrackers are no better at learning nonspatial tasks than these other jay species.

When Animals Learn

Ethologists have long been aware that animals are not uniformly sensitive to experience throughout their lives. `Sensitive periods' are periods during development when experience has a particularly strong effect on later behavior. For example, it has been shown in birds from several taxonomic families that mate preference is based largely on the phenotypes individuals experience as fledglings, and that those preferences are only slightly altered later in life. Sensitive periods have been described in the ontogeny of behavior related to habitat, host, food, and mate preferences as well as communication (e.g., bird song) and homing.

The occurrence and timing of sensitive periods are shaped by selection such that an individual's behavior is influenced most by those experiences that most improve reproductive success. For example, young salmon (*Onchorhyncus* sp.) become particularly sensitive to experience with stream odors as their morphological transition from stream-dwelling forms (termed parr) to ocean-dwelling forms (termed smolt) is initiated. In this manner, salmon learn olfactory landmarks as they migrate toward the ocean that they can use later when they move back up those same streams to spawn. Similarly, some bird species have a sensitive period during the fledgling stage in which mate preferences are learned. The phenotype most frequently experienced during this period is that of the parent. Fledglings thus develop a preference for a phenotype that, by evidence of their own existence, represents a reproductively successful conspecific.

Sensitive periods can have important population and evolutionary consequences. Animals whose behavior is shaped early in development may not be able to adjust to environmental changes that occur within their lifetimes, even when adjustments would be beneficial. In a world in which environmental change has been accelerated greatly by human activity, the occurrence of a sensitive period may result in a potentially tragic kind of behavioral obsolescence. For example, in homing species such as sea turtles and salmon, individuals choose their spawning grounds based entirely on early experience, and typically do not alter those choices. Animals may consequently be `trapped' into reproducing in suboptimal habitats if those habitats are degraded within their lifetime by human activity.

How Animals Learn

How animals learn has long been the domain of psychology, where learning processes have been described with the objective of defining underlying cognitive mechanisms. More recently, psychologists have joined with ecologists to ask why animals learn in the way that they do. This functional approach to how animals learn is readily introduced with respect to the basic categories of nonassociative and associative learning. Nonassociative learning is exemplified by habituation, defined as the waning of a response to a stimulus upon repeated presentation of that stimulus. Habituation permits an animal to suppress wasteful neural processing of and behavioral responses to stimuli that are irrelevant to fitness. Associative learning entails pairing a stimulus with another stimulus (S–S), or with a motor response (S–R), in space and time such that the response to the first stimulus is altered as a consequence of the pairing. Associative learning enables animals to describe the correlative structure of information in their environment and to adopt behavior that takes advantage of that description. Animals learn by association to orient toward stimuli predicting fitness gains (e.g., acquisition of food or mates) and away from stimuli predicting fitness losses (e.g., effects of heat, toxins, or natural enemies).

The use, or not, of social learning offers another example of a functional approach to learning. Social learning, long known for vertebrates but recently described in insects and other invertebrates, is a form of learning that is facilitated by interactions with other individuals, usually of the same species. Social learning is diverse in terms of mechanisms. One form, local enhancement, occurs when an individual is attracted to a locale where another individual is present, and consequently learns something in that

locale. Another form, observational conditioning, occurs when an observer learns a stimulus–reward association by watching a demonstrator experience that association. For example, nectar-foraging bees might learn to prefer a certain floral color by watching other bees visit and extract nectar from flowers of that color. Acquisition of a fear of snakes in monkeys who watch conspecific respond fearfully to snakes has been categorized as observational conditioning. Imitation involves learning in which a pattern of behavior engaged in by an individual is copied. Song learning in birds is viewed by some as a special case of imitation. True imitation that involves imitation of a novel behavior, is rare in animals and difficult to document, but noteworthy because it allows for the rapid spread in a population of truly novel behavior. Chimpanzees learn to use tools to obtain food by imitating other, usually older individuals.

Social learning has costs and benefits that overlap partly, but not entirely with those of individual (asocial) learning. An animal might therefore adjust its use of social or asocial learning as the costs and benefits of each change. This appears to be the case, at least with respect to food-foraging behavior in birds. When a task associated with finding food is made more difficult in terms of individual learning, birds are more likely to rely on social learning.

Memory processes are similarly open to functional explanations. Forgetting is intuitively considered to reflect a constraint on the durability of memory. However, forgetting might be adaptive if it permits animals to discard obsolete information in a way that facilitates the acquisition, storage, and use of new, more relevant information. Forgetting of obsolete information may also reduce `operating costs' associated with maintaining memory.

A variety of learning processes described mainly in the laboratory may have functional significance in nature. Generalization, a ubiquitous phenomenon in which animals trained to a stimulus S+ respond also to stimuli that resemble S+ along some perceptual dimension, was once assumed to reflect a constraint on learning capacity. From an ecological perspective in which variability in the environment is viewed as a given with which all organisms contend, generalization seems functional. A forager that learns to search only for an S+ associated with a food reward and ignores related stimuli may overlook perfectly suitable food items. Generalization is thus a mechanism for coping with stochastic variation in environmental stimuli.

An adaptive argument can also be made for a phenomenon in learning studies known as blocking. Blocking occurs when an animal that first learns to respond to a stimulus (A+), and is then reinforced on A and a novel stimulus, B, presented together ([AB]+), subsequently fails to show an enhanced response to B alone. Learning of stimulus B has been `blocked' by coupling it with the previously learned stimulus A. Blocking illustrates a kind of economy in learning: for a stimulus to be learned, it must convey new information. Given a cost to storing information, blocking is functional because it minimizes the storing of redundant information.

Functional explanations like those above have been put forward for a variety of other phenomena including attentional shifts, latent inhibition, peak shift, and effects of local context on learning.

Learning and Evolutionary Change

Effects on Adaptive Evolution

Learning can influence evolutionary change in a number of ways. First, if the environment changes, learning may allow a population of individuals adapted to the old environment to persist until adaptations to the new environment evolve. This assertion implies that animals can learn to cope with challenges different than those the population evolved to meet. In fact, learning does often enable individuals to solve novel problems (as evidenced by numerous examples of animals learning to coexist with humans and even to flourish in novel urban environments). Once a population has a `foot in the door' in a new environment, its members may evolve to learn the new behavior faster or to express the behavior congenitally. Simultaneously, selection may favor morphology, physiology, or biochemistry that is suited to the new environment. These new morphological/physiological/biochemical traits must add something beyond what is afforded by the learned behavior and existing traits. Otherwise, learning can actually retard their modification. For example, if learning enables an animal to utilize a new resource perfectly well with its existing morphology, there may be little or no selection to alter that morphology.

Learning can also facilitate evolutionary change in morphological, physiological, or biochemical traits by promoting adaptive linkages among such traits. For example, a genetic variant in bill morphology in a population of birds may learn to exploit food types to which the bill is best suited, food types which are different than those exploited by individuals with different jaw morphology. The new diet will select for gut physiology appropriate to the diet. In this way, gut physiology and jaw morphology may evolve as correlated traits. Such correlated traits can greatly accelerate adaptation to the new resource and rapidly drive genetic differentiation within and among populations.

Effects on Diversification

By allowing individuals to behave adaptively given their particular phenotype, learning can permit a broader range of phenotypes and underlying genotypes to coexist in a population. For example, in one parasitoid wasp species, individuals of different size learn to use host species that they can handle most efficiently, generating a correlation between wasp size and

host preference. Wasps of all sizes may be more or less equally successful, permitting a broader range of phenotypes to coexist in the population. In time, the different phenotypes may experience selection on whatever traits promote fitness in their different host niches. The end result could be greater genetic differentiation within the wasp population than would occur in the absence of learning.

Learning can also promote genetic differentiation by restricting gene flow between populations or subpopulations. In the apple maggot fly, conditioning has been suggested to facilitate the formation of host races in sympatry on two alternative host fruit species, apple and hawthorn. Conditioning may facilitate host race formation in at least two ways: first, by biasing allocation of eggs by a female to its natal host fruit species, and second, by suppressing dispersal by adults from the natal host tree. Both effects can be considered examples of `natal habitat preference induction' and both may reduce gene flow between the two host types. A similar process may occur in the indigobird, an avian brood parasite. In indigobirds, females exclusively lay eggs in the nests of the host bird species they were reared by as nestlings. In addition, they learn to prefer the host species' male call. Because male indigobirds mimic the songs of their host species, matings are most likely to occur between birds that were reared by, and thus adapted to, a particular host. Such assortative mating can promote sympatric differentiation and even lead to the formation of host races.

Analogous effects of learning on diversification may occur at higher taxonomic levels. For example, filial imprinting in birds has been proposed to promote speciation in birds. Avian learning has been linked to diversification: rates of diversification of species lineages are correlated positively with that lineages' rates of innovation, which is mediated in part by learning. Moreover, in birds, innovative behavior can spread particularly rapidly through social learning. Interspecific correlations between social learning and innovation frequency suggest that learning interacts synergistically with innovation to promote diversification.

Learning and Species Interactions

Learning is important to consider in all manner of species interactions, including mutualism, competition, predation, and parasitism. In all cases, learning by one species in the interaction has the potential to shape the evolution of traits in the other species. For example, learning by predator species is thought to have played a role in the evolution of warning coloration in potential prey species. Warning coloration is coloration that serves to advertise the noxiousness of potential prey, to the mutual benefit of both prey and predator. It is typically highly conspicuous. One advantage of conspicuous coloration is that it is easier for the predator to detect from a distance. However, conspicuous coloration has two additional advantages. It is learned faster by predators and remembered longer, effects which should favor the evolution of conspicuous coloration.

A prey's conspicuous coloration and a predator's propensity to learn conspicuous colors could evolve in tandem, a prediction that remains to be tested. The possibility that learning in one species may be shaped by interactions with another species has been suggested for imprinting in avian brood parasites. Female brood parasites imprint to their hosts before fledging, a process which causes them later to be attracted to the nests of host species. However, the degree of sexual imprinting by females on their hosts is dictated by a tradeoff. Imprinting must be strong enough to allow females to be attracted to the nests of the host species and thus continue the brood parasitic cycle, but not so strong as to prevent females from mating with males of their own species. One strategy circumventing the mate-recognition problem, which appears to be implemented in cowbirds, is self-phenotype-matching wherein the maturing cowbird learns what it looks like and interacts selectively with individuals that resemble it. In effect, the parasitic lifestyle has led to self-phenotype-matching filling the role of imprinting in cowbirds.

Learning and Environmental Change of Human Origin

Human activity and population growth is causing rapid, radical changes in the habitats of many, if not most, species. In contrast to many forms of cue-based phenotypic plasticity, such as seasonal polyphenisms, learning can provide a wide range of beneficial responses to novel environments. Trial-and-error learning may result in `innovative' behaviors, which may facilitate adaptation to environments quite different from those in an animal's recent evolutionary history. For instance, some research suggests that animals can learn to recognize novel, invasive predators in genera or families other than those to which native predators belong. Such innovative behaviors may help certain species invade novel habitats: birds with larger brains tend to establish themselves better in novel environments.

Global climate change represents one of the more striking consequences of human activity. As with other environmental change, learning will likely play an important role in the ability of species to cope with global climate change. Some birds and mammals have already begun to adjust their timing of reproduction to accommodate changes in temperature and the availability of their prey; it has been suggested that learning is involved in this accommodation. The extent to which learning facilitates species' abilities to cope with global change remains an open area of study with important implications for evolution and conservation. Although learning may allow species to adjust to global change in some behavioral contexts, climate change may conceivably select against learning. As noted above, learning is likely to evolve only under conditions of moderate levels of unpredictable environmental variation. If weather becomes highly unpredictable, as suggested by some global change models, learning may not be useful in tracking variability in weather. The links between learning and how species adjust to human activity remain to be elucidated.

The Marginal Value Theorem in a Nutshell

Vincent Calcagno, Université Côte d'Azur, Sophia Antipolis, France

Glossary

Average rate of gain (E) Total gain acquired, per unit of time, over a large number of patch visits.
Gain function (F) Function giving the gains acquired by an individual after exploiting a patch for some time (t).
Giving-up density (GUD) Level of resource the individual lets in a patch upon leaving.
Functional response (h) Function giving the instantaneous rate of consumption as a function of the current resource level in a patch (n).
Marginal gain Additional gain obtained if staying a little longer in the current patch (time derivative of the gain function F).
Travel time (T) Average time needed to enter the next patch after leaving one.

History and Background

Optimal foraging theory has produced some very general and successful results, one of which is the marginal value theorem (MVT). Even today, 60 years after the seminal publication (Charnov, 1976; although one can trace it back to slightly earlier papers), the MVT remains one of the most cited theories in ecology. It has been repeatedly tested experimentally and confronted to data, in organisms are different as viruses, insects, plants, ungulates or humans. It is commonly considered as providing satisfactory predictions that resemble observed patterns, even though, of course, an abstract and general model cannot pretend to match many datasets exactly. Several reviews are available and these aspects will not be discussed in further detail here.

Sometimes referred to as the "patch model" in behavioral ecology textbooks (as opposed to the "prey model," another foundational result from optimal foraging theory), the theorem predicts how long an individual should keep exploiting a resource patch before leaving in search of another. Arguably, MVT is not the most informative name. First, marginal value is a general and earlier concept in optimization theory, largely employed in the economical sciences for instance. Second, while theorem puts emphasis on the calculations, the result is a rather straightforward consequence of the definition of an optimum. The defining feature of the MVT probably resides more in the modeling choices and hypotheses (the patch model), than in the use of marginal values or in the derivation itself. One can find strong analogies between the MVT and optimality models under variable-interval schedules in behavior and psychology (Staddon, 2001). However the two seemingly developed independently; the latter does not quite predate the original MVT papers, and cross references are almost inexistent. Also, albeit mathematically equivalent, assumptions regarding which quantities are fixed and which are flexible differ radically. Therefore the MVT is a genuine product of behavioral ecology in the early 1970s, at a time when the application of economical principles in ecology flourished. Let us have a closer look at the underlying biological model.

Model Assumptions

The model assumes that the environment of an individual consists in many patches: spatially discrete entities where the individual can perform a rewarding activity and thus acquire gains (**Fig. 1**). This has a clear virtue of conceptual clarity, and in practice patches range from an obvious property of biological systems (compartments such as cells, individuals, flowers or water ponds) to a useful simplification of more continuous landscapes. In that it follows the familiar strategy in ecology of binarizing habitat complexity, as does for instance metapopulation theory. An individual can be in one of two states: (i) in a patch performing the profitable activity (**Fig. 1**; *orange*) or (ii) outside patches, performing other activities (**Fig. 1**; *green*). The course of time is therefore characterized by an alternation of (i) phases ("exploitation," e.g., eating) and (ii) phases ("exploration," e.g., searching).

The MVT considers that individuals (through reasoning, learning, plasticity mechanisms, or natural selection screening many variants) can adjust the time of (i) periods, as they can decide to interrupt a visit and leave the current patch, thus starting a novel (ii) period. They therefore control how long to stay on any patch, and this is called the residence time. In contrast, they cannot act of the duration of (ii) periods. The latter are envisioned as unavoidable and incompressible; if anything, they should be as short as possible considering a variety of external constraints. An individual has to spend some time outside patches before finding a new patch, and this time constraint is classically called the travel time (T). It represents the average time it takes to enter a new patch after leaving one. The duration of these periods, though it needs not be constant and can vary randomly, is independent of the duration of (i) periods. For instance, there is no fixed duration for a (i)/(ii) cycle, and no correlation between the time spent in patches and the speed at which the next patch will be found. An individual can act on the number of patches visited per unit of time, but only by adjusting its residence times (by staying less on each patch, it visits more). A nice property of the MVT is that the

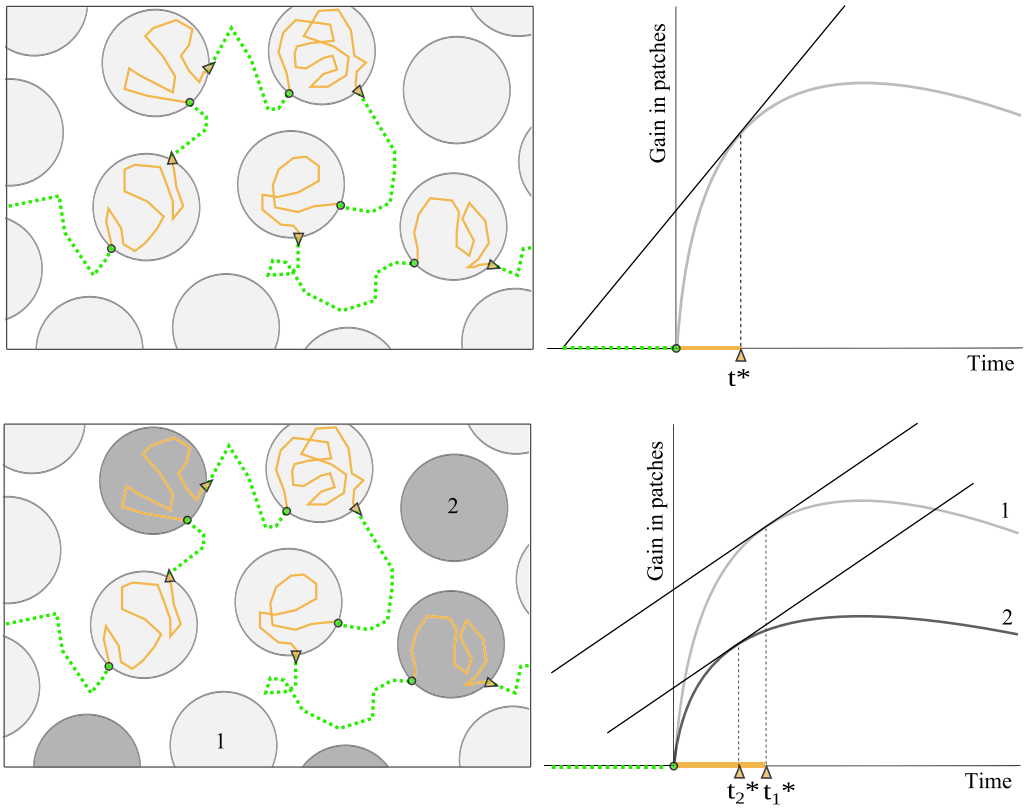

Fig. 1 Graphical interpretation of the MVT. *Top:* homogeneous habitat. *Left:* the habitat is composed of many patches (*gray disks*) among which the individual navigates (*dotted green lines*). When entering a patch (*green circles*), it spends some time exploiting it (*orange*) before deciding to leave in search of another (*triangles*). *Right:* while in patches the individual acquires gains as given by the gain function. If all patches have the same gain function, the individual maximizes its overall rate of gain by spending time t^* in each patch. This optimal residence time can be found by drawing the line tangent to the gain function starting from $(-T, 0)$, whose slope is E^*. *Bottom:* heterogeneous habitat. *Left:* two kinds of patches were assumed—good ones (1; *light gray*) and poor ones (2; *dark gray*). *Right:* having computed E^* from Eq. (1), optimal residence times are such that the gain functions have slope E^* in all patches. Here the individual should spend more time on good patches ($t_1^* > t_2^*$; that is, $\rho_{\text{INTRA}} > 0$). Modified from Charnov, E.L., 1976. Optimal foraging, the marginal value theorem. Theoretical Population Biology 9 (2), 129–136.

distribution of T does not matter, only the average does. The latter quantity is treated as a fixed parameter that depends both on the characteristics of the environment (e.g., the average distance between patches) and of individuals (e.g., their efficiency/speed at locating new patches and attaining them).

The process of gain acquisition during (i) sequences receives most attention. It is assumed that acquiring gains takes time, so that the total gains acquired during a patch visit of duration t are given by some gain function $F(t)$. Note that this gain function represents both the quality of a patch (Is it good or poor?) and of the individual (How efficient is it at extracting gains from the patch?). Quite universally, this function is considered to represent a law of diminishing returns, that is, the longer one stays in a patch, the less profitable it becomes to stay more. In mathematical terms, it means that F is an increasing function of time, but at a decreasing pace, that is, it should be concave at some point in time. It can otherwise have any shape. An important point is that F must represent net gains acquired, discounting potential associated costs. Therefore it may be negative for some time intervals (when the costs outweigh the gains acquired) and/or ultimately decreasing (if the rate of gain acquisition eventually drops below the costs of foraging in the patch).

Each patch can have its own gain function, and the environment of the individual is thus defined (besides the travel time) by the collection of gain functions encountered during consecutive patch visits. The simplest homogeneous case considers that all patches have one common gain function, but in general there will be a distribution such that a fraction p_i of patches will have gain function F_i. Importantly, this distribution is unaffected by what the individual does. In practical terms, it means either that all patches are visited only once (no revisits), or that revisits are sufficiently distant in time for patches to have restored their initial state by the next time they are visited. Recurrent patch revisits and less-than-perfect recovery of patch quality could be accommodated for in the MVT framework with limited changes, although this has not been much explored.

A second defining assumption is that individuals cumulate gains over time and seek to maximize the total gain accumulated (G) over the duration of an entire sequence (D). In practice, if the duration D is unaffected by what the individual does (for instance, if it is constant), this is equivalent to maximizing the average rate of gains over the period ($E = G/D$), and the MVT is classically presented as maximizing the latter. Maximizing this quantity implies that gains have the same value irrespective of when

they occur, and of what has already been accumulated during previous patch visits. For instance, it means that severe starvation does not occur in the short-term, so that an individual would never desperately need to find resource as soon as possible. Similarly, the total duration of the foraging sequence (D) should not be affected by patch leaving decisions, as would be the case if moving frequently between patches shortened average life expectancy (see also section "Going further and open questions").

In these conditions, the average rate of gain is the total of gains accumulated, divided by the total time elapsed ((i) and (ii) sequences). If there have been N patch visits (N large), the quantity an individual would seek to maximize is thus

$$E = G/D = \sum_{j=1}^{N} F_j(t_j) / \sum_{j=1}^{N} (T + t_j) = \frac{F_j(t_j)}{T + t_j}$$

where $< >$ represent averages over all patches visited.

The Classic MVT

Maximizing E implies that an individual should act in a way so that the residence time on patch i is t_i^*, as defined from the equation:

$$F_i'(t_i^*) = \frac{F_j\left(t_j^*\right)}{T + t_j^*} \tag{1}$$

These residence times are called optimal residence times, and the r.h.s. of the equation is therefore the optimal average rate of gain they permit to achieve (E^*). The equation defines a maximum as long as all gain functions have concave shape around the residence times t^*. Note that the maximum needs not be global: in particular, some of the patches (if there are too poor compared to the others) should be completely unexploited,[1] in which case their t^* must be set to 0 in Eq. (2). The equation holds even in the face of variability in travel times and the patch types, if the number of patch visits (N) is large enough. The exact meaning of large is not precise, but in practice it can be as low as 20–30. In other words, the total duration of the sequence (D) must be long enough for sufficiently many patches to be visited.

The use of "in a way so that the residence time on patch i is …" was purposely vague: the MVT, as many evolutionary predictions, does not pretend to specify how individuals should achieve the particular phenotype. The mechanisms brought up to achieve it will likely depend on the organisms studied, their evolutionary history and sensory and cognitive capacities. The ontogeny of t_i^* values, and the identification of rules-of-thumb that an individual could use in practice, are strictly speaking out of the scope of the MVT. For instance, an individual might compute its average rate of gain E and decide to leave a patch when the instantaneous rate of gain falls below E, or it might monitor the flow of time and leave when t^* has elapsed, or any other algorithm one can imagine. Any such algorithm may prove feasible or unrealistic depending on the study species, and clearly for many organisms the capacity to implement the optimal residence times may be a major constraint. We do not enter into these interesting considerations here, as they do not question the fact that t_i^* is an optimal strategy an organism would want to target.

In its simplest form, assuming that all patches identical, averages disappear and we get only one equation:

$$F'(t^*) = \frac{F(t^*)}{T + t^*}$$

This homogeneous MVT equation has the advantage of being easy to solve using an elegant graphical construct, which certainly contributed to the popularity of the MVT (Fig. 1). In a heterogeneous habitat, that is, when different patches visited do not all have the same gain function, the graphical construct cannot be used and one must solve Eq. (1) by other means.

So far the function $F(t)$ was not specified and can essentially have any shape. This is one strength of the MVT, allowing it to retain great generality and flexibility, as different situations will likely result in very different gain functions. We can obtain some general predictions at this level (Calcagno *et al.*, 2014a), but we may also want to be more specific and specify what F looks like, in order to obtain quantitative predictions or go further in the analyses. The simplest, and earliest, approach is to postulate some reasonable and convenient function, such as a Monod function or Holling disk equation. However, this has severe limitations in two ways: (i) in most cases we have no knowledge of the actual gain functions and similar functions are hard to tell apart from available data; and (ii), more importantly, some predictions thus obtained happen to be very dependent on the exact function chosen. To circumvent these limitations, a more recent approach was proposed that restricts the class of possible functions based on properties of the mechanisms at play, without going all the way to proposing specific functions. This is introduced briefly below.

The MVT for Resource Consumers

The gain function in a patch is usually assumed to be concave (saturating) because of resource depletion: as the individual consumes the resources initially present in the patch, patch profitability declines until virtually nothing is left to be consumed. This

[1]Quite simply, those patches are those for which $F(t^*)/t^*$ would be less than E^*.

emerges in a range of situations including predators feeding on prey populations or individuals, pollinators feeding on nectar, males fertilizing female eggs, or humans gathering fruit or catching fish. The particular case where gains represent the consumption of resources is of major interest in ecology. Processes of resource consumption are classically modeled by describing the dynamics of resource density through time, with the consumption rate at any time given by the so-called functional response of individuals (Fig. 2). By writing the initial density of resources in a patch as $n0$, the size (scale) of a patch as S, and given some functional response $h(n)$, the resource density in an exploited patch varies as $dn/dt = -h(n)/S$. We can thus deduce the gain function of an individual from the amount of resource consumed as:

$$F(t) = \gamma S(n0 - n(t)) = \gamma \int_0^t h(n(\tau))d\tau \quad (2)$$

with γ the energetic value of one resource unit (Calcagno *et al.*, 2014b).

Note that function h has not been specified. Just like in the classic MVT, $F(t)$ may thus have infinitely many different shapes, depending on h. However, some F functions one might consider in the classical MVT could not result from Eq. (2) and are thus not permitted, for they are incompatible with the proposed mechanism. As shown below, we get much more precise and easily interpretable predictions in the context of Eq. (2) than in the context of the general MVT, while retaining great generality.

What Questions Can Be Addressed?

The MVT can be used to predict several quantities of interest. First, it can tell what the average rate of gain (E^*) will be (or would be for an optimal individual) in a given habitat. This is important as the average rate of gain is very much a proxy of fitness, conditioning survival and/or reproduction. Second, it can tell us how the optimal residence times vary with environmental and patch characteristics. Optimal residence times are of special interest to behavioral ecologists and those interested in movement as they are closest to decision mechanisms and condition how frequently an individual moves over different patches in its habitat. Finally, the MVT can inform us on the level of patch exploitation, that is, for resource consumers, the amount of resource depletion: how much resource, if any, should be left in patches? The latter quantity, often called the giving-up density (GUD), can have intrinsic value (e.g., it may reflect the amount of pest suppression by a biological control agent) and is often more amenable to observation.

From these quantities, a broad range of questions can be addressed, which has sometimes generated some confusion in the literature. It is helpful to discriminate three intertwined, but slightly different, types of questions:

(1) What should be the relative exploitation of the different patches within a given habitat?
A typical question: should an individual stay longer on the best patches?
(2) What are the consequences of changing habitat characteristics, letting patches (i.e., gain functions) unchanged?
A typical question: should individuals stay longer on patches when those are longer to find?
(3) What are the consequences of changing the patches (i.e., the gain functions) in a habitat?
A typical question: should individuals stay longer on patches if patches contain more resources?

In the first case, we are comparing different patches in one given habitat: as a consequence E^* is a constant, which is a great simplification. We only need to understand the consequences of changing the gain function in one patch on the exploitation level

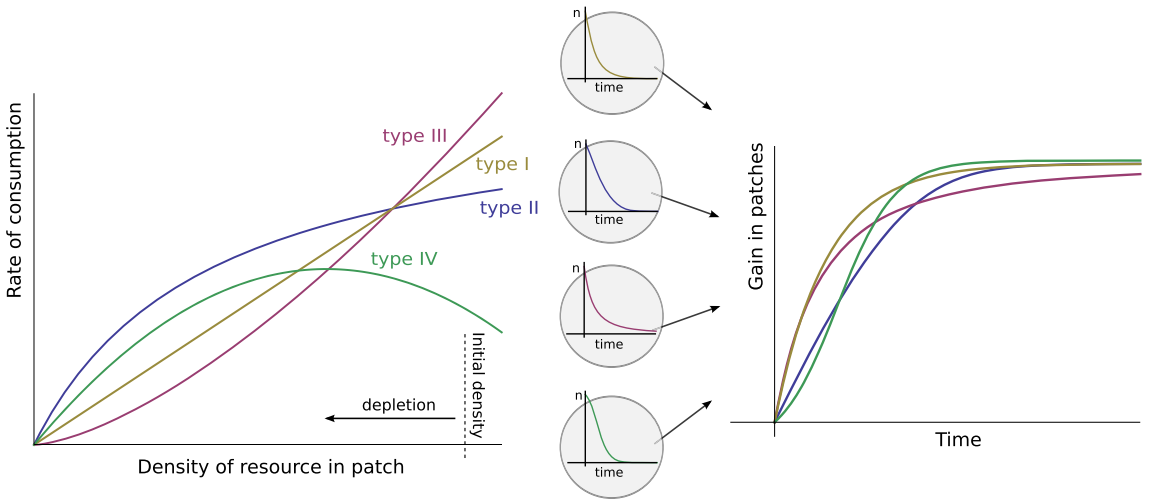

Fig. 2 From functional responses to the MVT. *Left*: the functional response (h) determines how the rate of consumption varies with the density of resource in a patch (n). *Middle*: As the individual exploits a patch, the resource level gradually drops from its initial level. *Right*: This in turn determines the gain function of the individual. Note that contrasted functional responses (*left*) can yield similar looking gain functions (*right*). Type IV functional responses (*green*) can yield sigmoid (initially accelerating) gain functions, as illustrated.

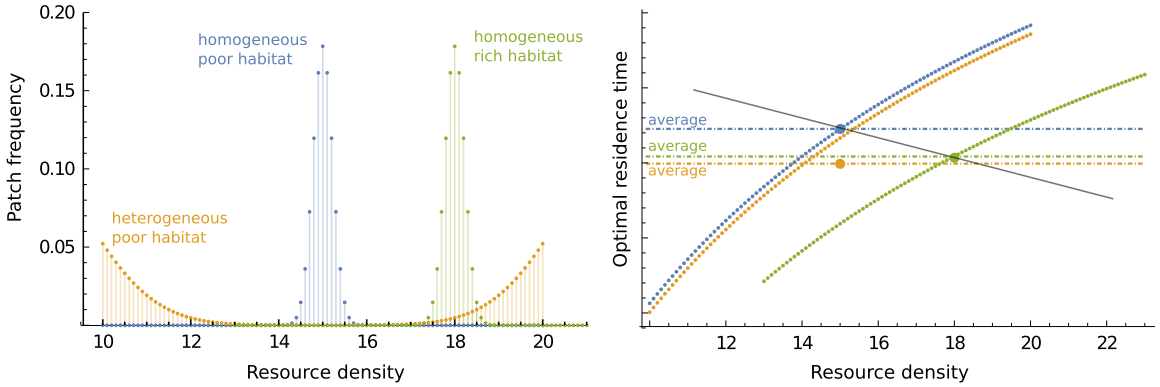

Fig. 3 An illustrative example of habitat modifications. *Top*: three habitats are considered that differ in resource distribution. *Blue* and *orange* habitats differ in the variance of patch resource density, with the same average (15). The *orange* habitat has patches with very contrasted resource densities, in the range 10–20, whereas the blue mostly has average patches. *Blue* and *green* habitats differ only in mean resource density (15 vs. 18). *Right*: An accelerating functional response was assumed and optimal residence times computed numerically. In all habitats an individual should spend more time on the best patches, that is, $\rho_{\text{INTRA}} > 0$ (**Table 2**). As predicted from **Table 2** for an accelerating functional response, increasing the mean resource density decreases the average residence time. The cross-habitat correlation of residence time and resource density is thus negative (*gray line*). The average residence time also decreases with increasing patch heterogeneity, keeping the mean constant (variance effect; see **Table 2**). Remark that in the heterogeneous (*orange*) habitat, contrary to the more homogeneous cases, the average residence time differs importantly from the residence time on the average patch.

of that patch, given some value of E^*. In the second case, the characteristics of the habitat, for instance the travel time (T), vary, and so E^* varies as well. However, since the gain functions stay unchanged, we only need to understand the consequences of changing E^* on the exploitation level in a patch, given its gain function. Clearly, in the third case, both effects must be taken into account simultaneously, as changing the gain functions in a habitat also impacts E^*. Two sorts of effects are particularly worth studying in this case: (i) the impact of the average quality of patches in the habitat (comparing good and poor habitats, that is, a 1st order effect); and (ii) the consequences of habitat heterogeneity (introducing variance in patch quality and comparing homogeneous and heterogeneous habitats; a 2nd order effect). **Fig. 3** provides an illustration of these two possibilities. Unsurprisingly, case (3) is not only the most interesting, but also the one for which predictions prove most challenging to obtain.

Below is an attempt to provide a comprehensive overview of MVT predictions, for the three types of questions, with emphasis on the third. Predictions from the classic MVT are first presented, before introducing the additional insights one can get in the case of resource consumers.

What Is Predicted by the MVT (and What Is Not)

Within a Given Habitat

As a direct consequence of Eq. **(1)**, patches in a given habitat should all be left at times such that the marginal rate of gain is the same (see **Fig. 1**): this "quitting rate" is invariant within a habitat.[2] It is a standard expectation from optimization and economics, with little specific to the MVT (it holds if the r.h.s. of Eq. **(1)** is replaced with any constant). In practice, it means that the marginal rate of gain of individuals when they leave patches can be used to infer the quality of the overall habitat. Since it is often challenging to measure the marginal rate of gain of individuals, for resource consumers people usually use the giving-up density as a surrogate.

As far as residence times are concerned, there is no unique prediction regarding their ordering with patch quality. Depending on what patch quality implies in terms of gain functions, the correlation between patch quality and residence time within a habitat (called ρ_{INTRA} henceforth) can have any sign (**Table 1**). Broadly speaking, when better gain functions get steeper, we expect a positive correlation, whereas when better gain functions get shallower, we expect a negative one. Distinguishing the two situations is sometimes tricky. The sign of ρ_{INTRA} also controls, if looking at a particular patch in the habitat, the sign of variation of the residence time on that patch if its quality were increased (keeping the rest of the habitat, and thus E^*, constant).

Changing the Habitat, but Not the Gain Functions

Provided the gain functions are left unchanged, MVT predictions are straightforward. Changes in the travel time (T) have unambiguous and intuitive impacts on the various quantities of interest, as summarized in **Table 1**. Remark that increasing T decreases the average rate of gain E^*, and it is obvious to see that any decrease in E^*, given a constant gain function for a patch,

[2]This of course only holds for patches effectively exploited ($t^* > 0$).

Table 1 Predictions of the classic MVT (from Eq. (1))

		E^*	t^*	GUD	ρ_{INTRA}
Travel time ↑		↓	↑	↓	NA
Patch quality	Mean ↑	↑	?	?	?
	Variance ↑	↑ or 0	?	?	

The first three *columns* show how each quantity of interest respond to changes in the environmental characteristics (*rows*) of a habitat. "?" indicates that no general conclusion can be reached (response depends on the specifics). For heterogeneous habitats, t^* and GUD should be intended as their spatial averages (over all patches). The last column shows how residence time correlates with patch characteristics within a habitat.

would similarly increase the optimal residence time on that patch. Therefore, a related prediction is that, looking only at one particular patch, any change in the rest of the habitat that increases E^* (e.g., an increase in the overall frequency of good patches) shortens the optimal residence time (and increase the GUD) on this particular patch. Those results are easily deduced from graphical arguments (play with the slope of the tangent lines in Fig. 1) and are probably the ones most often reported about the MVT, even though they only cover a fraction of the situations of interest.

Changing the Habitat Through the Gain Functions

Predictions were so far about changing one patch in a constant habitat (see section Within a given habitat), or changing the habitat for some constant patch (see section Changing the Habitat, but Not the Gain Functions). What happens in the general case, when an entire habitat is modified through the gain functions of its constituting patches? Predictions happen to be much scarcer (Table 1). Optimal residence times, in particular, can respond idiosyncratically to changes in patch quality depending on what exactly quality implies in terms of the gain functions (Calcagno *et al.*, 2014a). A couple of firm conclusions can nonetheless be established in all generality:

- Introducing variance in the gain functions (patch heterogeneity), keeping the average constant, generally increases the average rate of gain E^* (Table 1). In some special cases, fitness is unaffected by patch heterogeneity,[3] but this is not the general expectation. In biological terms, this prediction reflects the fact that an optimal forager is able to take advantage of patch heterogeneity, by disregarding the poorest patches and focusing on the best patches. Incidentally, it implies that knowledge of the average gain function over all patches is insufficient to predict neither the average rate of gain nor the optimal residence times. A forager that would not account for patch heterogeneity, devising its strategy from the average patch only, would achieve smaller fitness, and as a consequence over-exploit all patches, compared to a fully-informed optimal forager.
- If residence time correlates negatively with patch quality in a given habitat ($\rho_{\mathrm{INTRA}} < 0$), increasing the overall quality of patches in the habitat necessarily decreases all residence times (and thus average residence time). However, the reverse in not true (Calcagno *et al.*, 2014a). If residence time covaries positively with quality ($\rho_{\mathrm{INTRA}} > 0$), we cannot tell whether an increase in the quality of all patches would increase or decrease residence time. We can thus formulate this general expectation: it will be more common to observe a positive correlation between patch quality and residence time within habitats ($\rho_{\mathrm{INTRA}} > 0$), than a positive correlation between patch quality and residence time across different habitats.

From Table 1 it appears that frustratingly many answers are left unanswered in the classic MVT. Fortunately, much more precise predictions can be obtained in the context of resource consumers and Eq. (2), with patch quality intended as resource content (e.g., number of prey items).

Refining Predictions for Resource Consumers

Table 2 provides a synthetic overview of predictions regarding the effect of varying the resource distribution (mean and variance over patches) in a habitat, based on the mathematical analysis of Eqs. (1) and (2). Defining patch quality as resource content can mean two slightly different things. One may consider variation in the resource density ($n0$) of patches, or in their size (S). Both actions vary the total resource content, but since the rate of consumption is usually governed by resource density (rather than sheer quantity), they do not have the same implications. Predictions are thus given regarding the two possibilities. Of course, some organisms might respond to total resource amount irrespective of density and we would just treat n as the resource amount and forget about S. Also, some organisms respond to the fraction of resource items not-yet-attacked, for instance parasitoids that keep probing hosts already attacked, in which case one can take S to be the total amount of resource and n the fraction yet-to-be attacked. This framework thus encompasses all possible shapes of functional responses, and different types of consumption processes that have been studied separately.

It can be seen that predictions are clarified in several ways. Importantly, while some predictions remain uncertain if patch quality is intended as resource density (shaded cells), knowing, even qualitatively, the type of functional response suffices to lift all uncertainties.

[3]One such case is when patches differ in the energetic cost of reaching/entering them; Calcagno *et al.* (2014a).

Table 2 MVT predictions for resource consumers (Eq. (2)) regarding the effect of the distribution (mean and variance) of patch quality (resource density or size) of a habitat

		E^*	t^*	GUD	ρ_{INTRA}
Resource density (n)	Mean ↑	↑	↑ (II, IV) 0 (I) ↓ (III)	↑	+
	Variance ↑	↑	↓ (I, II, III) ↑ (IV)	↓ (I, II, III) ↑ (IV)	
Size (S)	Mean ↑	↑	↑	↑	+
	Variance ↑	0	0	0	

A major clarification is that there will invariably be a positive correlation between patch quality and residence time within habitats ($\rho_{\text{INTRA}} > 0$; Table 2). However this positive correlation within habitats does not imply that increasing patch quality in a habitat necessarily increases the average residence time. Indeed, an increase in the resource density of patches can have any effect on the residence time, and in particular it can decrease it. This illustrates the general expectation from the classic MVT on the links between within-habitat and cross-habitat correlations of residence time with patch quality (previous section). It turns out that the outcome of increasing the resource density of patches is entirely determined by the concavity of the functional response: with concave (type II or IV) functional responses, we would observe an increase of residence time, whereas with convex (type III) we would observe a decrease. Linear (type I) functional responses are the knife-edge case when patch quality has no impact on residence time (Table 2).

Variance in the resource density of patches can also have contrasted impacts of residence time and on the GUD (Table 2) but again, knowing the type of functional response removes uncertainty. In this case what matters is not the concavity of the response but its slope: increasing functional responses (type I, II or III) cause an increase of average residence time and average GUD with patch heterogeneity, whereas decreasing (type IV) responses cause a decrease of both. As the latter is probably not the most likely situation, we can safely state that greater variance in resource density would generally increase the average rate of movement in a habitat (Calcagno *et al.*, 2014b).

When patch quality is intended as patch size, predictions are much more straightforward: increasing patch quality invariably increases residence time and the GUD (Table 2). However, variance in patch size, unlike patch resource density, has no effect whatsoever on any quantity of interest: these are invariant to size heterogeneity. Patch size (at constant resource density) constitutes one of those special cases for which heterogeneity does not yield any fitness benefit for an optimal forager (see Table 1) and knowledge of the average patch size therefore suffices to determine the optimal strategy.

Overall, there is a fairly complete set of testable predictions regarding the consequences of altering the distribution of resources in a habitat, providing one knows the type of functional response. One often overlooked result is that individuals might decrease their residence time if patches are made better, even though they stay longer on the best patches within any habitat (see Fig. 3 for an illustrative example). This is predicted in the case of an accelerating functional response (Table 2), but not only (see next section about foraging costs).

It is also important to remark that in several cases, the mean and variance of the resource distribution have distinct effects. For instance, with type II functional responses, greater mean resource density increases the average residence time, while greater variance reduces it (Table 2). When the two effects operate simultaneously following habitat changes, their net outcome will therefore critically depend on the mean-variance scaling of the resource distribution. For instance, in Fig. 3, the green habitat is enriched (higher mean resource density) but as the variance stays constant, the variability (coefficient of variation) of the distribution is effectively reduced. From Table 2, decreasing the variability of resource density for a type-III functional response increases the average residence time. Therefore, in Fig. 3, a positive variance effect counteracted (but did not outweigh) the negative effect of average resource density. We can thus predict that the observed decrease in residence time would be even stronger if the habitats were strictly homogeneous (i.e., if all patches had exactly resource density 15 in the blue habitat, and resource density 18 in the green). In contrast, when shifting from the orange to the green habitat, the negative impact of increasing mean resource density was dominated by the positive variance effect (as the green habitat has much lower patch heterogeneity), and the net outcome was an increase in average residence time (Fig. 3). The bottom line is that predicting the consequences of patch enrichment in heterogeneous habitats requires paying attention to how enrichment is distributed over the different types of patches (Calcagno *et al.*, 2014b).

Going Further and Open Questions

For simplicity, foraging costs were not explicitly considered here, following a tradition of treating resource intake as gains. However, strictly speaking the MVT applies for net energy gains, discounting costs. We can easily assume the existence of some per-unit-of-time cost of moving between patches (μ) and of foraging in patches (ν). Obviously both cause a decrease in E^*, and the greater μ relative to ν, the longer residence times will be (as an individual will allocate more time in the compartments with lower cost). In fact, it is chiefly

the difference between μ and v that matters (Calcagno *et al.*, 2014b). All predictions reported above hold in the presence of costs, as long as μ is close to v. If this is not the case, there is only one change in **Table 2**: predictions regarding t^* and the GUD following an increase in mean patch quality must be shifted in some direction. When costs are greater between than within patches ($\mu > v$), predictions must be shifted in the direction of a decrease, whereas if costs are greater within patches, they must be shifted toward an increase. For instance, for a linear functional response we predict no effect of enrichment on the optimal residence time (0; **Table 2**). If $\mu > v$ we would predict a decrease ($\downarrow$), and if $v > \mu$, an increase ($\uparrow$). Quite unexpectedly, higher costs of traveling between patches thus expand the conditions under which decreased residence times are expected following patch enrichment.

Of course, foraging costs could be variable among patches, in which case further complications arise. For instance, the quitting rate would still be the same in all patches, but the GUD would not, as it would no longer be a reliable indicator of the rate of gain. For resource consumers, one can in principle still use Eq. **(2)** and the same mathematical techniques to obtain predictions regarding the consequences of patch variability in foraging costs, or in other aspects of the foraging process. One can for instance study the impact of resource quality (parameter γ) or of some parameters of the gain function,[4] such as attack rates and handling times. A comprehensive treatment of these aspects remains to be done.

More importantly, the MVT ignores the notion of risk. A foraging individual often faces the risk of being interrupted or even killed by a predator, and these risks typically vary over different parts of the habitat. This can strongly affect the foraging decisions and the optimal allocation of time. In addition, the total duration of the foraging session (D) would then depend on the residence times, violating one MVT assumption, and rendering the average rate of gain (E) an inadequate predictor of fitness. Marginal gains and optimization can still be used in the presence of such risks, and formalisms have been proposed in the optimal foraging theory to deal specifically with these aspects (Brown, 1988). However they remain quite distinct from the MVT and a better integration of the two frameworks would be valuable.

Introduction

Male–Female Differences

Males and females by definition are different. Male gametes are usually motile; female gametes are usually not. Yet most humans have the sense that males and females are distinct in ways other than mere gamete dimorphism. Sexual differences in human phenotypes, while moderate compared to some species, are undeniable, and consequently much has been made of battles between the sexes, of sexual dialectics, even of the possibility that men and women have different planets of origin. We are hardly unique in this regard. Any observant naturalist can list several species in addition to our own in which male-female differences are clear, if not extreme. Some of us can produce an even longer list of species in which external sex differences are inscrutable. Songbirds, for example, often lack external sexual differentiation. A large number of marine species, such as fucoid brown algae, sea urchins, polychaete worms and red snappers, all have separate sexes that are indistinct. Sexual differences in land plants too are often obscure. Botanists may assert that this is because both sexes coexist within each individual; but why should monoecy cause monomorphism? And if it does, why should sex in both cottonwoods and willows be apparent only upon close examination, whereas sex among marijuana plants, even for aficionados, is simple to diagnose? Invertebrate zoologists might now chime in with examples of physical uniformity among hermaphroditic barnacles, flatworms and freshwater snails, as well as among gonochoristic comb jellies, kinorhynchs and veneroid clams. What explanation can possibly exist for extreme sexual differentiation in some species, and for virtual monomorphism among others, especially those lacking gender? The answer to this question is mating system. That is, the circumstances in which reproduction occurs within individual species. It is here that sexual differences arise—or do not.

Historical Descriptions

Mating Systems in Plants, Fungi, and Protists

In current literature, mating systems are described in two distinct ways, and each description has different implications for how sexual differences may or may not appear. The first description of mating systems, one that is familiar to botanists and coevolutionary biologists, emphasizes the genetic relationships that exist between mating males and females. Selfing, partial selfing, random mating, positive assortative mating (inbreeding), and negative assortative mating (outbreeding), all are examples of mating systems described in terms of the genetic relationships that may arise among breeding pairs. This framework also serves to describe fungal and many protist mating systems in which, depending on the species, individuals may engage in selfing through homothallic fusion—the union of hyphae or gametes of like mating type; or outcrossing through heterothallic fusion—the union of hyphae or gametes of unlike mating type.

The diversity of floral traits in plants can be categorized, as Darwin noted, by the degree to which self-fertilization occurs or is prevented to various degrees by physical, temporal, or genetic separation of male and female elements (**Table 1**). Among species with "perfect" flowers, cleistogamous plants are entirely self-pollinating, whereas chasmogamous plants use pollen to fertilize ovules on different flowers, either within the same individual, as in geitonogamy, or on different plants, as facilitated by a wide range of mechanisms. For example, heterostyled or herkogamous plants show physical separation of the style and stamen, whereas dichogamous plants separate the development of male and female elements in time. Outcrossing may be further encouraged by genetic self-incompatibility systems that occur in either the sporophytic or gametophytic stages of the life cycle, or it is prevented entirely by separation of the sexes on different individuals with "imperfect" flowers, as in dioecy, or as in androdioecy, and gynodioecy, in which males or females may coexist with monoecious individuals, respectively. Because certain heritable traits tend to covary between the sexes within each breeding scheme, genetic correlations may arise that lead to, or prevent, the appearance of sex-specific phenotypes.

Mating Systems in Animals

A second description of mating systems, familiar to zoologists and behavioral ecologists, considers mating systems in terms of the number of mates acquired by males or by females. This scheme has historical precedence, but it can lead to inaccurate

Table 1 A classification of plant mating systems based on fertilization mode and flower morphology

General category	*Fertilization mode*	*Definition*	*Associated terminology*
Perfect flowers (monoecious)	Self-pollination	Pollen fertilize ovules on the same flower	Autogamy, cleistogamy
	Cross pollination	Pollen fertilize ovules on different flowers	Chasmogamy
	Heterostyly	Physical separation of style and stamen	Distyly, tristyly
	Dichogamy	Temporal separation of anther and stigma maturation	Protandry, protogyny
	Self-incompatibility	Pollen cannot fertilize ovules on the same plant	Sporophytic, gametophytic self-incompatibility
Imperfect flowers	Outcrossing	Flowers are sex specific or exist as combinations of perfect and imperfect flowers	Dioecy; androdioecy, gynodioecy

characterizations, such as the misconception that on average, males can be more promiscuous than females. In fact, when adjusted for the sex ratio, the average number of mates, and of matings, if individuals mate more than once, for males and for females, must be equivalent. A terminology that accommodates this fact describes mating systems in terms of the *variance* in mate numbers among members of each sex. According to this scheme, monogyny and polygyny are descriptions of the variance in mate numbers among males, which for these terms equals 0, or exceeds 0, respectively. In contrast, monandry and polyandry are descriptions of the variance in mate numbers among females, which also for these terms, equals 0, or exceeds 0, respectively (**Table 2**). Additional descriptors address the variance in male and female mate numbers relative to that of the other sex (**Table 2**). For example, monogamy describes the condition in which no variance in mate numbers exists for either sex, whereas polygamy describes the condition in which non-zero, but approximately equivalent variance in mate numbers exists for both sexes. Polygynandry describes the condition in which non-zero variance in mate numbers exists for both sexes, but is greater among males than among females, whereas polyandrogyny describes the condition in which non-zero variance in mate numbers exists for both sexes, but is greater among females than among males (**Table 2**).

Each of these groupings describe convergent states that may arise from different ancestral conditions because a wide range of circumstances appear to favor these basic categories. Moreover, the spatial and temporal distributions of matings, the degree to which females tend to mate once or multiple times, whether females tend to aggregate or remain solitary, and whether male and female associations are brief or prolonged, all contribute to the "special circumstances," as Darwin called them, that make competition for mates more or less severe. When these conditions are considered, additional descriptors may modify the basic categories of animal mating systems.

For example, "mass mating" or "persistent pairs" may describe mating system variants in which breeding pairs form synchronously within a population, but are either aggregated or dispersed in space. In contrast, "attendance polygyny" or "feeding site polygyny" may describe variants of polygynous mating systems in which the variance in male mating success depends on whether males guard and mate with individual females in sequence, or guard the food resources that females require to reproduce. Again, most descriptions of animal mating systems focus on males, because males tend to be more active in courtship or mate monopolization than females. However, females in some species seek mates more actively than males, thus "cursorial polyandrogyny," or "dominance polyandrogyny," may describe variants of polyandrous mating systems in which females move among their several individual male consorts, or defend territories containing small aggregations of nesting males. In general, the basic categories of animal mating systems (**Table 2**) are fundamental to sex differences in fitness variance, that is, to the strength of sexual selection - or to its absence as an evolutionary force.

A Case for Combining Terminologies

Although usually considered separately, novel insights are possible when the schemes for describing plant and animal mating systems are combined. In particular, genetic covariances that arise between male and female mating phenotypes, because of the circumstances that cause mate number to vary among individuals, can be incorporated into discussions of mating system evolution. Such considerations provide simple explanations for observed interspecific variation in reproductive traits, including differences within and among species in promiscuity or mate guarding, as well as tendencies within and among species to release gametes synchronously or over prolonged durations. A combined description of mating systems identifies the nature, as well as the rates, of possible "run-away" processes. These evolutionary feedback loops arise when particular mating associations or preferences, cause genetic variation underlying male and female traits, as well as selection acting on those traits, to covary.

In this light, apparent examples of sexual conflict between males and females can be explained simply as the result of a genetic correlation between coercive mating behavior in one sex and resistance to such coercion in the other. Similarly, female tendencies to seek multiple mates may have less to do with females attempting to enhance the genetic quality of their offspring, and more to do with a genetic correlation that inevitably arises between the sexes when both sexes tend to mate more than once. Such trait associations may even occur between species, leading to interspecific genetic correlations, mostly mutualistic but occasionally not, involving plants and their pollinators. Such considerations explain more of the observed variation in sexual dimorphism, floral

Table 2 A classification of mating systems based on male and female mate numbers

Mating system	*Definition*	*Variance in mate number*	
		Females	*Males*
Monogamy	All individuals in each sex have a single reproductive partner (a mate).	0	0
Polygyny	All females have a single mate; male mate numbers vary.	0	+ + + +
Polygynandry	Both sexes have variable mate numbers; mate numbers vary more among males than among females.	+	+ + +
Polygamy	Both sexes have variable mate numbers; mate numbers are equally variable within each sex.	+ +	+ +
Polyandrogyny	Both sexes have variable mate numbers; mate numbers vary more among females than among males.	+ + +	+
Polyandry	All males have a single mate; female mate numbers vary.	+ + + +	0

morphology and patterns of gamete release and fusion, than classification schemes based on sex differences in mate numbers, or reductions in heterozygosity, can provide.

Recent Emphases in Mating System Research

Plant Mating Systems

Evolutionary research on plant mating systems began with Darwin, who combined the classification of species by their floral morphology, with documentation of whether these traits allowed or prevented self-fertilization (**Table 1**). Since Darwin, the population genetic consequences of these phenotypes, as well as the genetic and evolutionary mechanisms by which selfing, self-incompatibility, dioecy and gynodioecy may arise and persist, have all been given detailed theoretical expression. Frequency-dependent selection appears to maintain selfing and outcrossing as alternative stable states in some species, whereas mixtures of these traits in other species seem to be constrained by the deleterious effects of inbreeding. The stability of selfing and outcrossing within a given species also appears to be influenced by frequency- and density-dependent processes associated with pollen transmission. Here, patterns of floral morphology are expected to correspond to the spatial density of conspecifics, as well as to the relative amount of pollen available for export to other flowers.

Wind pollinated plants appear to fit these theoretical predictions more clearly than animal pollinated species, but this relationship may simply reveal that "animal pollination" is too broad a category to capture the distinct, or at times overlapping activities, of avian, mammalian and arthropod pollinators. Moreover, plant genetic diversity is affected by the relative distances pollinators can travel, further complicating classification. Most analyses of plant mating systems make use of the increasing sophistication of molecular methods available to document how population genetic structure is influenced by observed patterns of selfing and outcrossing. These tools have also proven useful for exploring how the evolution of sexual phenotypes is influenced by stochastic processes and by environmental influences on gender expression. Molecular phylogenetic analyses reveal with increasing precision that mating systems are among the most evolutionary labile of all plant traits.

Animal Mating Systems

Evolutionary research on animal mating systems also began with Darwin, who again combined classification schemes, this time according to differences in mate numbers for members of each sex, as well as according to the social contexts in which mate numbers become variable. Much of animal mating system research still focuses on whether sexual selection occurs within the contexts of male–male competition or female mate choice. As molecular methods have improved, animal researchers too have verified with increasing precision the number of mates males and females may obtain, allowing (but not always leading to) increasingly explicit classification of mating systems according the variance in mate numbers for males and females. As with studies of plants, molecular phylogenies have revealed considerable diversity in mating system expression within monophyletic animal taxa, suggesting that regardless of the kingdom considered, mating systems are responsible for considerable evolutionary innovation.

Analysis of animal mating systems for most of the last century have emphasized sex differences in parental investment as the source of sexual selection. According to this view, female reproduction is limited by the availability of resources required for energetic investment in ova and young. Given that resource abundance may vary in space and in time, male reproduction is presumed to be limited, in turn, by the spatial distribution of resources required by females, and by the temporal distribution of sexually receptive females themselves. This insight, combined with observed sex differences in gametic investment, suggests that the intensity of male–male competition reveals the intensity of sexual selection.

Two measures have served as the primary metrics for determining how female spatiotemporal distributions may influence sexual selection intensity. The first measure, the operational sex ratio (OSR), was conceived as the ratio of potentially mature males to potentially receptive females, although researchers often focus on those individuals who are receptive at a particular time and place. When OSR $>$ 1, females are rare, and male competition for mates and sexual selection can appear to be intense, although this depends on the consistency of mating success among males throughout the breeding season. When OSR $<$ 1, females are

abundant, and male competition for mates and sexual selection can appear to have relaxed; but again, depending on the cause of the surplus in females and how males respond to it, such conditions may still allow disproportionate success to certain males.

The second measure, the environmental potential for polygamy (EPP), identifies the degree to which social and ecological conditions allow males to monopolize females. Although useful for visualizing when male-male competition might arise, standardized methods for quantifying female distributions, or the scale on which EPP could be measured have remained undefined. As a result, while serving as conceptual surrogates for the intensity of sexual selection, the uncertain relationships between OSR, EPP and selection intensity itself, within, as well as among species, makes these measures unreliable for estimating sexual selection.

Researchers emphasizing sexual differences in parental investment as the source of mating system variation have encountered further difficulties in putting its assumptions to empirical tests. In particular, a sex difference in relative parental investment has proven extremely difficult to compare within and among species. Not only are the amounts of energy, cost and risk associated with relative parental investment difficult to quantify, but the correlation between sex differences in parental investment and sexual dimorphism itself is often poor, particularly in species with reversed sex roles. Measures of sexual selection intensity based on the predictions of parental investment theory, including comparisons of maximum potential reproductive rates among males and females, require laboratory conditions that are rarely encountered in nature. Other estimates, which emphasize how mating behavior may enhance or diminish the future fitness of individuals, require assumptions about who is breeding and who is not, that may underestimate the actual variance in mating success within the population; or they may be impossible to directly test at all.

Combining Methods for Mating System Analysis

Covariance Methods

The most obvious way to understand how selection acts within a mating system is to measure selection itself. Sexual selection gradients and parental tables isolate the statistical relationship between male and female trait values and fertilization success relative to other components of selection. Bateman gradients, named for this author's classic work with fruit flies, measure how the mating success for each sex correlates with offspring numbers. These gradients measure the selection that acts on every sexually-selected trait, thereby revealing the final common path between sexually-selected traits and fitness. Only when the gradient is zero, does it indicate that sexual selection is negligible and that selection in other contexts may prevail. Sex-specific gradients also provide a quantitative measure of "sexual conflict," measured as the sex difference in sign of this covariance. When the sign of this covariance is negative, additional matings will enhance the fitness of members of one sex, but diminish the fitness of members of the other sex. This approach provides a simple statistical explanation for apparent eagerness to mate in one sex and apparent choosiness before mating in the other, that is unrelated to sex differences in parental investment.

When a genetic basis for particular traits is associated with fitness, the covariance approach also provides a means for predicting evolutionary trajectories when genetic correlations become established by the cooccurrence of particular male–female relationships, such as when stigmas that are available for pollination appear synchronously with stamen dehiscence in wind-pollinated plants. However, direct estimates of selection also have their weaknesses. This approach assumes that the researcher has correctly identified and measured the trait that is under selection. Estimates of selection intensity can be erroneous if the actual target of selection is unmeasured, or if it is correlated in some unknown way with other traits that directly or indirectly influence fitness.

Parentage Data and the Zero Class

Both plant and animal mating systems increasingly use molecular parentage data. These assignments provide the easiest avenue for a combined approach to mating system analysis. Identification of genetic parentage reveals the degree to which progeny have arisen through inbreeding or outcrossing, and they establish whether males and females mate within or outside of their social pair bonds. To understand whether and to what degree the sexes may become distinct within a species, and to understand if a sex difference in selection intensity could be responsible for phenotypic divergence among related species, it is necessary to measure the variance in relative fitness for males and females within, as well as among taxa. This method illustrates when and why sexual selection can be strong enough to overwhelm the effects of natural selection and therefore, how it can produce the sex-specific phenotypes researchers find so compelling (Box 1). However, parentage data from plants and animals suffer from a common problem; they are both obtained from the fraction of their respective populations that are *successful* in producing progeny. The fraction of the population in plants and in animals that is *unsuccessful* in producing offspring typically goes unidentified in most analyses that assign parentage to experimental populations.

Why do such omissions matter? A focus on successfully reproducing individuals fails to capture the largest fraction of the variance in fitness that exists for a total population. To measure the total variance in fitness for a population, one must measure the average variance in fitness within the successfully reproducing individuals, as well as the variance in the average fitness between the successful reproducers and those individuals who fail to reproduce at all (Box 1). The latter component of the total variance in fitness is usually the larger of these two components. Thus, estimates of fitness that exclude nonbreeding individuals tend to *overestimate* the average fitness and *underestimate* the variance in fitness of the portion of the population that actually is measured. Moreover, the larger the fraction of the population that fails to reproduce and therefore goes unmeasured, the more severe this

Box 1 Measuring the sex difference in the variance in relative fitness

The Mean and Variance in Offspring Numbers

Consider a hypothetical population, say of albatrosses or penguins, consisting of 20 individuals and a sex ratio equal to 1. If, in a given breeding season, a single ovum from each of the 10 females in the population is fertilized by a different male, the total number of offspring, $N_{\mathbf{O}total}$, equals (1 ovum) $\times$ (10 females) $=$ 10. Because each mating pair produces 1 offspring, the total offspring produced by all females, $N_{\mathbf{O}♀}$, equals the total offspring produced by all males, $N_{\mathbf{O}♂} = 10$. Because there are 10 females and 10 males in our population, the average offspring per female, $\mathbf{O}_♀$, equals $N_{\mathbf{O}total}/N_♀ = 1$, which equals the average offspring per male, $\mathbf{O}_♂$, evaluated similarly as $N_{\mathbf{O}total}/N_♂ = 1$. Also, because each individual in the population produces the same number of offspring ($=1$), no variance in offspring numbers can exist for either sex. Thus, if $V_{\mathbf{O}♀}$ and $V_{\mathbf{O}♂}$ equal the variance in offspring numbers for females and for males, respectively, $V_{\mathbf{O}♀} = V_{\mathbf{O}♂} = 0$. This example shows that when the number of fertilized ova each female produces is 1, or even when it is larger, when each female is mated once by a different male, and the sex ratio equals 1, the mean and the variance in fitness for each sex are identical.

This example provides a simple explanation for why wind pollinated plants, marine species with external fertilization, and even hermaphroditic organisms, all tend to show little sexual dimorphism. In each of these cases, population sex ratios equal or are nearly equal to 1, pollen or sperm are either so widespread or so restricted in their distribution that individual males and individual females each have similar probabilities of reproduction, and members of each sex tend to contribute approximately equally to the next generation. In the case of hermaphrodites, both sexes are represented within every individual, thus reproduction by one sex usually allows reproduction by the other; and unless some hermaphrodites emphasize, or are forced to reproduce as only one sex (as occurs in certain flatworms and barnacles), the population-wide variance in fitness through male and female functions, are approximately equivalent. When such conditions apply, neither sex is likely to become distinct from the other, except as is specifically required for the production or ova or sperm.

Now consider a case in which 1 of the 10 males secures 2 mates instead of just 1. The total offspring produced by our population, $N_{\mathbf{O}total} = 10$, remains unchanged. Similarly, because $N_♂ = N_♀ = 10$, the average offspring per male, $\mathbf{O}_♂ = N_{\mathbf{O}total}/N_♂ = 1$, equals the average offspring per female, $\mathbf{O}_♀ = N_{\mathbf{O}total}/N_♀ = 1$. Because each female still secures 1 mate with whom she produces a single brood, the variance in offspring numbers for females, $V_{\mathbf{O}♀} = 0$. However, because 1 male has 2 mates, 1 male must be excluded from mating. When this happens, the variance in offspring numbers for males, $V_{\mathbf{O}♂}$, must increase.

If parentage data were available for our population, we could estimate the magnitude of the increase in $V_{\mathbf{O}♂}$ simply by calculating the statistical variance in offspring numbers for males. This quantity equals the average of the squared number of offspring produced by each male, minus the square of the average number of offspring produced by each male, or $(\Sigma o_{i♂}^2)/N_♂ - \mathbf{O}_♂^2$, where $o_{i♂}$ = the number of offspring produced by the i-th male, $N_♂$ = the total number of males, and $\mathbf{O}_♂$ = the average number of offspring per male as defined above. Note that the variance in the number of offspring per female, $V_{\mathbf{O}♀}$, can be calculated in the same way by substituting $o_{i♀}$, $N_♀$ and $\mathbf{O}_♀$ for females into the above expression, where $o_{i♀}$ = the number of offspring produced by the i-th female, $N_♀$ = the total number of females, and $\mathbf{O}_♀$ = the average number of offspring per female as defined above. When such data are available, this is indeed the simplest approach. However, as is more often the case, when parentage data are lacking, an equally accurate and in some ways more informative approach, involves partitioning the variance in offspring numbers, within and among the classes of mating and non-mating individuals. In the example above, only males were variable in their numbers of mates, but in many species, both sexes may vary in mate numbers, and in sex role reversed species, including certain sea spiders, giant water bugs and pipefish, females are consistently more variable in mate numbers than males. Although they are seldom used for this purpose, the data necessary to calculate the mean and variance in mate numbers for males, and the mean and variance in offspring numbers for females, are often available in standard life history analyses. This quantitative approach allows us to measure the fitness variance within each sex, which is proportional to the intensity of selection. The sex-difference in selection intensity, in turn, estimates the degree to which the sexes will diverge in phenotype.

The Mean and Variance in Mate Numbers

We begin by identifying the classes of mating males and their population frequencies. Here, we represent the proportion of the male population in each mating class as p_j, where j represents the number of females in the j-th mating class of males. There are three such classes: males who do not mate, p_0 [$=1/10$ males $= 0.1$], males who mate once, p_1 [$=8/10$ males $= 0.8$] and males who mate twice, p_2 [$= 1/10$ males $= 0.1$]. The sum of all male mating classes, $\Sigma p_j = (0.1 + 0.8 + 0.1) = 1$. Next, we use these values to identify the average offspring produced by males in each j-th mating class, $O_{♂j}$, as well as the average offspring produced by all males across all mating classes, $\mathbf{O}_♂$ [$= \Sigma p_j O_{♂j}$ where $O_{♂j} = (\Sigma o_{i♂})/N_♂$]. The average offspring that males in each mating class produce, $O_{♂j}$, equals the average offspring per female, $\mathbf{O}_♀$, as defined above, multiplied by the number of mates, j, that males in each j-th mating class obtains, or $O_{♂j} = j(\mathbf{O}_♀)$.

Clearly, the average number of offspring produced by males who do not mate, $O_{♂0}$, equals $(0)(1) = 0$. The average number of offspring for males who mate once, $O_{♂1}$, equals $(1)(1) = 1$, and for males who mate twice, $O_{♂2}$ equals $(2)(1) = 2$. The average number of offspring produced by all males, across all mating classes, $\mathbf{O}_♂$, is equal to the number of offspring produced by the average female, $\mathbf{O}_♀$, multiplied by the number of females mated by males in each j-th mating class [$= j(\mathbf{O}_♀)$], then, each quantity is multiplied by the fraction of the males belonging to that j-th mating class, p_j, and summed over all j mating classes, so that,

$$\mathbf{O}_♂ = \Sigma\, p_j\, j\, (\mathbf{O}_♀) \tag{2}$$

Using the values in our example above, we can see that $\Sigma p_j\ j = 1$ and that $\mathbf{O}_♂ = \mathbf{O}_♀ = 1$. Thus, although females are distributed unevenly among the 10 males, relative to females, as well as to the initial case in which all 10 males have equal mate numbers, the average number of offspring produced by all males in this example, again equals 1.

The distribution of females across all classes of mating males is equal to the population sex ratio, which we can call R. This value can be calculated as the number of females mated by males in each mating class, j, multiplied by the fraction of the males in each mating class, p_j, and summed over all classes of males, or, $R = \Sigma j p_j = 1$. Because the distribution of all females with all males equals the average number mates per male, R also equals $N_♀/N_♂ = 1$. That is, R is the reciprocal of OSR ($= N_♂/N_♀$); but whereas OSR measures the apparent intensity of male-male competition, R measures a slightly more useful quantity for estimating how selection works; R measures the population-wide average in the number of mates per male (in sex role reversed species, $1/R = R_O$ measures the analogous quantity). By substitution, we can see that the average offspring per male, $\mathbf{O}_♂$, equals the average mates per male, R, multiplied by the average offspring per female, $\mathbf{O}_♀$, or $\mathbf{O}_♂ = R\mathbf{O}_♀ = 1$. Furthermore, although the distribution of females is now uneven among males, the average mates per male, R, the average offspring per female, $\mathbf{O}_♀$, and the average offspring per male, $\mathbf{O}_♂$, all remain unchanged relative to our initial example.

We can now express the total variance in offspring numbers for males, $V_{\mathbf{O}♂}$, in terms of the average number of mates per male and the average number of offspring per female. As in an analysis of variance (ANOVA) problem, the total variance in male fitness can be partitioned into two components: (1) the average variance in offspring numbers for males within the classes of males who sire offspring, and, (2) the variance in the average number of offspring sired by all the classes of males.

The first component of variance in male offspring numbers is calculated in three steps. First, for each mating class of males, the variance in female offspring numbers, $V_{\mathbf{O}♀}$, is multiplied by the number of mates obtained by males in each j-th mating class ($= jV_{\mathbf{O}♀}$). Next, this product is multiplied by the proportion of males in the population, p_j, that belongs to each j-th mating class [$= p_j(jV_{\mathbf{O}♀})$]. Lastly, these products are summed over all j mating classes. Thus, the variance in offspring numbers within the classes of mating males equals,

$$V_{\mathbf{O}♂(\text{within})} = \Sigma p_j\left(jV_{\mathbf{O}♀}\right) \tag{3}$$

In this example, because all females produce exactly 1 offspring, there is no variance in offspring numbers for females, $V_{\mathbf{O}♀} = 0$, and consequently, the variance in offspring numbers within the classes of mating males is also zero ($V_{\mathbf{O}♂(\text{within})} = 0$). We will return to this point below.

The second component of variance in male offspring numbers equals the variance in the average number of offspring sired by males among these same categories. This quantity is calculated in four steps. First, for each j-th mating class of males, we calculate the difference between the average number of offspring per male, $\mathbf{O}_♂$, and the average number of offspring produced by that mating class, $O_{♂j}$ ($= [\mathbf{O}_♂ - O_{♂j}]$). Secondly, we square each difference [$= (\mathbf{O}_♂ - O_{♂j})^2$]. Third, we multiply each squared difference by the fraction of males belonging to each mating class, p_j [$= p_j(\mathbf{O}_♂ - O_{♂j})^2$], and fourth, we sum across all classes to obtain,

$$V_{\mathbf{O}♂(\text{among})} = \Sigma p_j\left(\mathbf{O}_♂ - O_{♂j}\right)^2 \tag{4}$$

Substituting in the values from above we have, $V_{\mathbf{O}♂(\text{among})} = 0.2$.

The total variance in offspring numbers among males is the sum of the within and among male components in offspring numbers, or,

$$V_{\mathbf{O}♂} = \Sigma p_j\left(jV_{\mathbf{O}♀}\right) + \Sigma p_j\left(\mathbf{O}_♂ - O_{♂j}\right)^2 \tag{5}$$

Because there is no variance in offspring numbers for females, $V_{\mathbf{O}♀} = 0$, the first term in Eq. (5) drops out. However, if $V_{\mathbf{O}♀}$ were nonzero, $V_{\mathbf{O}♂(\text{within})}$ would equal this quantity because the variance if fitness within the class of breeding males will always equals the variance in fitness within the class of breeding females. Thus, in this example, $V_{\mathbf{O}♂(\text{among})} = V_{\mathbf{O}♂}$, and we can easily see that the variance in fitness among males goes from 0 to 0.2 when a single male mates with 2 females instead of 1. Note too that the increase in fitness variance comes entirely from the among-male component of total fitness variance. Now, if 1 male mates with all 10 of the females, the mean and variance in offspring numbers for females remains unchanged ($\mathbf{O}_♀ = 1$; $V_{\mathbf{O}♀} = 0$), and there is no change in either the sex ratio, $R = 1$, or the average number of offspring per male, $\mathbf{O}_♂ = 1$. But, because 1 male mates 10 times, 9 males do not mate at all. Thus, $p_{♂0} = 9/10 = 0.9$, $p_{♂1}$ through $p_{♂9} = 0$ and $p_{♂10} = 1/10 = 0.1$. When these values are substituted into Eq. (5), we see that $V_{\mathbf{O}♂}$ now increases to 9, a 45-fold increase in the variance in male fitness!

This exercise shows three relationships. First, when the sex ratio equals 1, both sexes must have equal, average fitnesses. Secondly, when some individuals are excluded from mating, the variance in offspring numbers within that sex will increase. This is the source of sexual selection. Exclusion of some individuals from mating means that only the traits of the individuals who do mate will be represented in the next generation. Third, if the fraction of individuals excluded from mating is larger in one sex than it is in the other, a sex difference in the variance in offspring numbers appears. Because fitness variance is proportional to selection intensity, the magnitude of this sex difference in fitness variance determines the actual intensity of sexual selection. The larger the sex difference in fitness is, the more the sexes will diverge in phenotype.

The Opportunity for Sexual Selection

The above examples consider the absolute mean and variance in fitness for males and females, but selection is a relative process, and to account for this fact, certain adjustments are necessary. When the variance in absolute fitness, $V_{\mathbf{W}}$, is divided by the squared average fitness, $\mathbf{W}^2$, we obtain $V_{\mathbf{W}}/\mathbf{W}^2$, a quantity known as the variance in relative fitness, $V_{\boldsymbol{w}}$, or as $\boldsymbol{I}$, the opportunity for selection. The opportunity for selection provides a dimensionless, empirical estimate of selection's maximum strength that is comparable within and among species. When paternity can be assured, $\boldsymbol{I}$ can be calculated from estimates of mating success alone.

This approach is especially useful for understanding the strength of selection within each sex. Here, the value of $\boldsymbol{I}$ is expressed as the ratio of the variance in offspring numbers, $V_{\mathbf{O}}$, to the squared average in offspring numbers, $\mathbf{O}^2$, among the members of each

sex. Thus, $\boldsymbol{I}_{\sigma} = V_{\mathbf{O}\sigma}/\mathbf{O}_{\sigma}^2$ and $\boldsymbol{I}_{\varphi} = V_{\mathbf{O}\varphi}/\mathbf{O}_{\varphi}^2$. Because each offspring has a mother and a father, the opportunity for selection on males, $\boldsymbol{I}_{\sigma}$, and the opportunity for selection on females, $\boldsymbol{I}_{\varphi}$, are linked through the sex ratio and mean fitness, which must be equal for both sexes. However, when the sex ratio equals 1, the sex difference in the variance in relative fitness, $\Delta\boldsymbol{I} = (\boldsymbol{I}_{\sigma} - \boldsymbol{I}_{\varphi})$. This value may be greater for males, greater for females or zero. Its value determines whether and to what degree the sexes will diverge in character because fitness variance is proportional to selection intensity.

How can we express these relationships for a natural population? Rewriting Eq. (5), which expresses the total variance if male fitness, partitioned into within- and among-male components, we substitute values from Eqs. (3) and (4) and rearrange terms. We have,

$$V_{\mathbf{O}\sigma} = RV_{\mathbf{O}\varphi} + \mathbf{O}_{\varphi}{}^2 V_{\text{mates}} \tag{6}$$

When $R = 1$, Eq. (6) shows that the variance in fitness for males, $V_{\mathbf{O}\sigma}$, equals the variance in fitness for females, $V_{\mathbf{O}\varphi}$ (which $= 0$), plus the quantity, $\mathbf{O}_{\varphi}^2 V_{\text{mates}}$. This latter term equals the average female fitness squared, $\mathbf{O}_{\varphi}^2$, multiplied by the variance in mate numbers among males, V_{mates} $[=\Sigma p_j(R - j)^2]$. For the above example, $\mathbf{O}_{\varphi}^2 V_{\text{mates}} = 9$. This shows that the sex difference in fitness variance is due to the fitness effects of a sex difference in the variance in mate numbers, V_{mates}. In this case, variance in mate numbers exists among males, but not among females. Now recall that $\boldsymbol{I} = V_{\mathbf{W}}/\mathbf{W}^2$. We can obtain an analogous expression for the variance in relative fitness for males in terms of offspring numbers by dividing Eq. (6) by $[R\mathbf{O}_{\varphi}]^2$; that is, by the squared average offspring number for males.

When we do this, we obtain,

$$\boldsymbol{I}_{\sigma} = (1/R)(\boldsymbol{I}_{\varphi}) + \boldsymbol{I}_{\text{mates}} \tag{7}$$

Or, $\boldsymbol{I}_{\sigma} = (R_O)(\boldsymbol{I}_{\varphi}) + \boldsymbol{I}_{\text{mates}}$ because R equals 1/OSR $(= 1/R_{\text{O}})$. Thus, the opportunity for selection on males, $\boldsymbol{I}_{\sigma}$, equals the opportunity for selection on females, adjusted by the sex ratio, $(1/R)(\boldsymbol{I}_{\varphi})$, plus the opportunity for selection arising from differences in mate numbers among males, $\boldsymbol{I}_{\text{mates}}$. This expression, like Eq. (6), shows the relationship between male and female fitness. However, because this relationship is now standardized by the square of mean fitness, it provides estimates of relative fitness; that is, of selection opportunities for each sex. These expressions show that the sex ratio is only part of the total opportunity for selection. When the sex ratio equals 1 $(R = 1/R_{\text{O}} = 1)$, subtracting $\boldsymbol{I}_{\varphi}$ from both sides of Eq. (7) yields, $\boldsymbol{I}_{\sigma} - \boldsymbol{I}_{\varphi} = \boldsymbol{I}_{\text{mates}}$ $(= \Delta\boldsymbol{I})$. This relationship shows that the sex difference in the opportunity for selection, that is, the opportunity for sexual selection, is indeed due to differences in mate numbers between the sexes.

Inserting the values from our example into this latter equation, we see that when males and females have equal mate numbers, $\boldsymbol{I}_{\text{mates}} = 0$. When males vary in mate numbers, $\boldsymbol{I}_{\varphi}$ still equals 0, so all of the opportunity for selection on males is due to sexual selection or, $\boldsymbol{I}_{\sigma} = \boldsymbol{I}_{\text{mates}}$. If $V_{\mathbf{O}\varphi}$ becomes nonzero, either because females vary in their mate numbers, or because females vary in their offspring numbers, or for both reasons, $\boldsymbol{I}_{\varphi}$ will increase and $\boldsymbol{I}_{mates}$ will be eroded to a degree determined by the relative magnitudes of $\boldsymbol{I}_{\sigma}$ and $\boldsymbol{I}_{\varphi}$. If $\boldsymbol{I}_{mates} < 0$, the sex roles will reverse because sexual selection acts on females. However, erosion of $\boldsymbol{I}_{mates}$ may become negligible if the variance in mate numbers among individuals in one sex becomes large and in the other sex remains small. When this occurs, sexual selection on one sex can overwhelm the effects of natural selection acting on the other sex, leading to apparent cases of sexual exploitation. However, such situations are unlikely to last for long. Mating systems with strong sexual selection tend to be invaded by alternative mating strategies that reduce the variance in mate numbers within the sex in which it is large. Such invasions shut down strong sexual selection, and illustrate why sexual conflict is always self-limiting. The important empirical points are: (1) $\boldsymbol{I}_{mates}$ explains much about why sex differences exist, and (2) $\boldsymbol{I}_{mates}$ can be estimated for any population in which the mean and variance in offspring numbers among females, and the mean and variance in mate numbers among males are known.

error will be. This difficulty is part of the reason why estimates of OSR and potential reproductive rates (PRR) provide biased estimates of how selection operates within mating systems; they tend to focus only on the activities of successfully breeding individuals. To accurately measure their contribution to the total fitness variance, the identity and frequency of non-reproducing individuals must be clearly established.

All Individuals Have a Mother and a Father

How can experimenters account for the "zero class" of individuals in any given population, when they only obtain genotypes from the individuals they can actually collect? The answer is to recall three principles in reproductive biology that extend from R.A. Fisher's statement, "All individuals have a mother and a father." The first principle is that all offspring genotypes must be accurately assigned to both parents. If a sample of progeny and adults are genotyped from a population, it is certainly possible that every offspring collected and genotyped can be assigned explicitly to parents within the genotyped adults. However, it is more likely that some of the progeny can be assigned to only one parent, usually their mother, or they cannot be assigned to any of the genotyped adults at all. Although considerable work may have gone into identifying these individuals, and while they certainly can be used to answer other questions that parentage data can address, they must be excluded from the sample to account for the zero class. By focusing only on offspring whose parentage can be explicitly assigned to both parents, the experimenter is able to identify only the progeny produced within the population in question.

Next, in addition to the adults whose progeny can be identified, there are some genotyped adults within the population that can be shown to have failed to produce any offspring at all. These adults can be presumed to belong to the population in question because there were collected there. Moreover, if only the progeny that can be unambiguously assigned to both parents comprise the offspring produced within the population, and if the assignable adults comprise the breeding parents, the genotyped adults who have no assignable offspring, must comprise the fraction of the population that was unable to breed. They may have produced offspring in another nearby population, but the researcher is unable to account for these progeny. Therefore, the individuals without any assignable progeny within the focal population must constitute the zero class. The breeding and nonbreeding fractions of the adult population and the progeny they produced, within the focal population alone, are thus established.

A second principle possible from Fisher's statement provides a check on the accuracy of this parentage assignment. If all individuals have a mother and a father, the average number of progeny produced by males and by females must be equal. After parentage is assigned using the method described above, it is possible to calculate the mean and 95% confidence limits on the number of offspring produced by males and females. If parentage assignment has accurately captured both the breeding and the nonbreeding fractions of the population, there should be no significant difference in the average number of progeny assigned to each sex. If a significant difference exists, the accuracy of the parentage assignment is likely incorrect and should be reexamined.

A third outcome of Fisher's statement provides an additional means for examining total adult fitness in samples that appear to contain only the genotypes of individuals who successfully produce offspring. If all individuals have a mother and a father, and if equal fitnesses are found between males and females within the populations, then over time, the sex ratio of such populations is expected to equilibrate at unity. If the numbers of successfully and unsuccessfully reproduced individuals are added up within each sex, the resulting ratio of males to females, also should nearly equal 1. Again, a significant deviation of this ratio from unity could indicate that the parentage assignment is incorrect, or it could indicate that the population is in the process of reaching an equal sex ratio after some displacement. In this situation, examination of the population in the next generation is expected to yield a value closer to unity.

A Sex Difference in the Variance in Relative Fitness

Once the mean and variance in fitness can be identified for both sexes, it is possible to examine the sex difference in the variance in relative fitness ($=\Delta I$; Box 1) within the population. This value can be compared directly because the variance in fitness is proportional to the strength of selection operating within each sex. The statistical variance in fitness can be standardized by the squared average fitness to yield the opportunity for selection, I, for each sex ($=I_{\male}$ and $I_{\female}$; note that $I_{\male} - I_{\female} = \Delta I$). The value of I for each sex compares the fitness of breeding parents with that of all individuals of that sex within the population before breeding occurs, thus it measures the maximum intensity of selection as a result of an episode of selection (Box 1). While the average fitness for each sex must be equivalent, the variance in fitness can differ and the opportunity for selection will be stronger within the sex with the larger fitness variance. It is for this reason that the sexes are expected to diverge in character. When $I_{\male} > I_{\female}$, sexual selection will modify males; when $I_{\female} > I_{\male}$, sexual selection will modify females; when $I_{\male} = I_{\female}$, either sexual selection is nonexistent, or sexual selection operates with equal intensity in both sexes, causing both sexes to become modified relative to their ancestral state.

The Spatiotemporal Distributions of Matings and Fertilizations

The insight of Emlen and Oring has guided conceptual understanding of animal mating systems for nearly half a century. However, as mentioned, their proposed metrics for measuring the process of mating system evolution have proven unreliable for measuring selection on mating systems. Two related approaches for estimating the opportunity for selection within mating systems are available using data on the spatial and temporal distributions, of breeding adults and of fertilizations.

The Mean Crowding of Sexual Receptivity in Space and Time

The first method requires estimates of the spatial and temporal crowding of sexually receptive individuals. If males defend territories or resources where matings occur, the mean spatial crowding of receptive females is measured as the number of other receptive females the average female experiences when she becomes receptive, or $m^* = m + [(V_m/m) - 1]$, where, m equals the average number of receptive females per resource patch, and V_m is the variance around that average. When receptive females are maximally dispersed in space, m^* approaches zero. When receptive females tend to be aggregated on particular patches, the value of m^* increases.

If the breeding season can be divided into intervals, whose length equals the average duration of female receptivity, the mean temporal crowding of matings equals the number of other receptive females the average receptive female experiences with she becomes sexually receptive, or $t^* = t + [(V_t/t) - 1]$, where, t equals the average number of receptive females per interval and V_t equals the variance around that average. When female receptivity is maximally asynchronous within the breeding season, t^* approaches zero. When female receptivities overlap within fewer intervals, the value of t^* increases.

The opportunity for sexual selection, I_{mates} (also written as $\boldsymbol{I}_s$ or $\Delta\boldsymbol{I}$) measures the ability of particular males to secure more than one mate, at the expense of the mating success of other males (Box 1). Both m^* and t^* have been shown to estimate I_{mates}, but do so in different ways. The relationship between m^* and I_{mates} is proportional because when females are maximally crowded in space, one or a few males could defend and mate with all of the females in the population. In contrast, the relationship of between t^* and I_{mates} is reciprocal because when females are maximally crowded in time, the ability of one or a few males to mate with multiple females is reduced. The combined effects of m^* and t^* generate a surface that estimates the maximal selection intensity possible from empirical estimates of female spatial and temporal distributions.

The Total Variance in Fertilization Success in Space and in Time

The second method requires construction of a matrix, whose rows represent individual males, and whose columns represent intervals during the breeding season in which females may become receptive. This scheme works in species with separate sexes, as well as in monoecious, hermaphroditic and heterothallic species, as long as each individual and its gender or mating type can be identified. The cells of the matrix may contain zeros or larger numbers, identifying the number of mates or fertilizations that the individual within each row obtains within each interval of the breeding season. If multiple males inseminate or pollinate the same female, these numbers may also represent the fraction of the total fertilizations with a given female that a particular male obtains. This provision offers a specific means for estimating the strength of post-mating sexual selection within animals as well as plants, and provides a means for accommodating plant, animal, fungal, or other mating systems in which multiple fertilizations by different parents may occur within families.

The more precise parentage data are, the more detailed such analyses can be, and fractions of clutches instead of individual matings can be substituted into the matrix. This approach is especially powerful if parentage data are known, but even without it, the framework provides crucial information on whether or not particular individuals contribute disproportionately to fertilizations, and how such biases affect selection acting on sexual phenotypes. This approach captures the spatial and temporal elements of mating system variation in terms of total selection intensities, and avoids the statistical difficulties encountered when using estimates of EPP and OSR.

The matrix described above includes the total variance in fertilization success among the individuals the rows represent. Moreover, as in an ANOVA problem, the total variance in fertilizations can be partitioned into the within- and among-individual components, providing a means for evaluating individual fertilization success in space and time. Although the rows may represent males or females, depending on the structure of the breeding system, for simplicity, let us suppose that the rows represent males, and that these males obtain all of the fertilizations possible with each female they secure as a mate, making mating success and fertilization success equivalent. Then, as in ANOVA, we can identify two components of the variance in mating success; the component arising within each of the males representing the rows; that is, the variance in mating success that arises in space, and the component arising among all males, across all of the columns in which females become receptive; that is, the variance in male fitness that arises in time.

First note that within each interval (column) of the breeding season, the total number of receptive females present, divided by the total number of males in the population (all of the rows), equals the interval sex ratio; that is, the average number of females mated by each male at that time. Notice too that the average of the squared number of females mated by males within each interval, minus the squared interval sex ratio, equals the variance in mates per male, obtained for each interval. These two quantities provide the mean and variance in male mating success, estimated across the breeding season intervals in which females are receptive (see Box 1).

Remember that ANOVA problems partition population variance into within- and among-group components. In general, the within-group component equals the average of the variances estimated for each group, whereas the among-group component equals the variance of the averages estimated for each group. If the "groups" we are considering are the males in this population who vary in their mating success, and if the analysis we seek is to partition to total variance in mate number, in time, into within- and among-male components (again, mates or fertilizations can be distinguished as described above), then the within-male component of the total variance in mate numbers, in time, equals the average of the variances in mating success for the males, across all of the intervals in which females are present. Similarly, the among-male component of the total variance in mating success in time, equals the variance of the average male mating success, across all of the intervals in which females are present.

But this is only part of the problem we want to solve. We also seek to partition the total variance in fertilizations, in space, into within and among-male components. To do this, note that within each row of the matrix, the total number of receptive females who mate with that male, divided by the total number of intervals containing at least one female, equals the average number of mates for each male, estimated across all of the intervals containing receptive females; or, the average number of females mated by each male, over the entire breeding season. Notice too that the average of the squared number of females mated by each male, estimated across the intervals containing receptive females, minus the squared average number of mates for each male, estimated across the intervals containing receptive females, equals the variance in mate number, across the breeding season, for each male. These two quantities provide the mean and variance in male mating success, estimated within the male rows, across the breeding season intervals in which females are receptive.

Again, recall that ANOVA problems partition population variance into within- and among-group components. Because the "groups" we are considering are the males in this population, and now, the analysis we seek is to partition to total variance in mate

number, in space, into within- and among-male components, then the within-male component of the total variance in mate numbers, in space, equals the average of the variances in mating success, across all intervals in which females are present, for the average male. Similarly, the among-male component of the total variance in mating success, in space, equals the variance of the average mating success that the average male has, across all intervals in which females are present.

The separate estimates of the variance in mate numbers among males, in time and in space, can then be algebraically combined so that the total variance in male mating success is partitioned into three components. These variance components, when divided by the squared average mate numbers for males, yield estimates of the opportunity for sexual selection (Box 1) that arises among males in three contexts, due to the availability of mates in time and space. Specifically, the total opportunity for selection on males, I_{mates}, evaluated in this way equals,

$$I_{mates} = I_{sex\ ratio} + \left[{}^{*}I_{mates(t)} - {}^{*}I_{males(k)}\right] \quad (1)$$

in which, (a) $I_{sex\ ratio}$, is the opportunity for sexual selection caused by temporal variation in the sex ratio. This value is similar to the OSR, but unlike OSR does not overestimate the intensity of sexual selection within the intervals in which females are abundant; (b) ${}^{*}I_{mates(t)}$, is the weighted opportunity for sexual selection caused by temporal variation in the availability of females. This value varies in magnitude depending on whether female receptivity is synchronous or asynchronous, and is weighted by the number of females that appear in each interval, with larger numbers of females per interval contributing the largest effects. Lastly, (c) ${}^{*}I_{males(k)}$, is the weighted opportunity for sexual selection caused by variation in the availability of females for mating by the spatially distinct males. Note that ${}^{*}I_{males(k)}$ decreases the value of ${}^{*}I_{mates(t)}$ because ${}^{*}I_{males(k)}$ estimates the variance in mate number for individual males. Overall, increases in the variance in relative fitness within males tend to decrease the variance in relative fitness that occurs among males due to the temporal availability of females.

Concluding Remarks

As information on mating systems accumulates across all species, it is increasingly clear that typological approaches, while necessary for documenting the existing variation, cannot explain how mating system diversity arises, is modified, and persists or changes over evolutionary time. Increasing spatial mobility within species, either by individuals themselves or as mediated by pollinators or the environment, appears to increase the spatial and temporal scales at which matings and gamete transfers can occur, evidently favoring increased outcrossing and ultimate the separation of the sexes entirely. Expanding familiarity with the range of this variation in all species can lead to better metrics for documenting the sources and intensity of selection that shape mating systems evolution. The time has come to end taxonomic parochialism in mating system research and embrace its unifying principles.

Optimal Foraging Theory

DW Stephens, University of Minnesota, St. Paul, MN, USA

Foundations

Foraging is a fundamental aspect of animal behavior that has implications for predator–prey interactions, competition, and studies of animal cognitive abilities. Animal foraging may be as dramatic as a lion stalking a gazelle, or as mundane as a barnacle filtering plankton from seawater. Foraging theory seeks to bring order to this diversity, by recognizing and analyzing the common problems faced by foraging animals. Foraging theory, or optimal foraging theory as it was originally known, has its origins in seminal papers by Schoener, Charnov, Parker, MacArthur, and Pianka, and Pulliam and Emlen published in the 1960s and 1970s respectively. Taken together, these papers produced a remarkably cohesive body of theory based on two common foraging problems: patch exploitation and prey selection.

Basic Models

Both of these basic models assume that a forager encounters items (prey or patches) one at a time, according to some well-behaved process (often a Poisson process). For example, if a forager encounters and consumes prey items that take h time units to handle and provide e calories of energetic benefit when consumed, then Holling's disk equation gives the rate of energy intake:

$$\frac{e}{1/\lambda + b} = \frac{\lambda e}{1 + \lambda h} \quad [1]$$

where λ gives the encounter rate, so that $1/\lambda$ is the expected time between encounters with prey items. The form of the equation on the left hand side shows how Holling's disk equation is simply the expected energetic gains per encounter divided by the expected time (search time plus handling time) per encounter. One can generalize this basic structure to include multiple prey types or to situations where the forager encounters patches instead of prey items. Both models find the foraging behavior that maximizes the rate of energy intake as given by Holling's disk equation, but the models focus on different aspects of foraging behavior. The following sections outline the prey and patch models.

The prey model

As described above, this model assumes that we can associate an energy value e_i, a handling time h_i, and an encounter rate λ_i with each prey type. The model solves for the attack probability p_i for each prey type that maximizes the rate of energy intake. The model makes three predictions: (1) A forager should always take or always ignore a given prey type. Foraging models call this the zero–one rule because it follows from the mathematical observation that the rate-maximizing attack probabilities can only be zero or one. (2) Prey types should be ranked by their profitabilities, which we define to be quotients of the form e_i/h_i. That is, the prey type with the highest energy to handling time quotient is the `best' type (rank 1), and the next highest is rank 2 and so on. (3) One can determine the set of prey that maximizes intake rate by working through the possible `diets' in rank order. That is, first considering a diet by rank 1 prey only, then a diet of rank 1 and 2. Obviously, one can use Holling's disk equation to calculate the rate of energy intake for each of these diets. We can show mathematically that if, for example, a diet consisting of types 1–3 yields an intake that is smaller than the profitability of the fourth ranked prey type e_4/h_4, then adding this fourth ranked type will increase the intake rate. Therefore, to find the rate-maximizing diet, we simply add prey types to the diet in rank order until this is no longer true.

This result focuses our attention on the properties of the `best' or first ranked prey item. Obviously, a forager should always attack this best item upon encounter, and the properties of this type determine whether the forager should attack the second best item. Specifically, if the best type is abundant (has a high encounter), then a `best-type-only' diet may make sense. If, however, the best type is rare, then it typically makes sense to add the second best type to the diet. Notice that the abundance of the second best type is not important in this reasoning! Some investigators find this result counterintuitive, because they can imagine situations in which superabundant but mediocre prey items attract a forager's attention.

The patch model

The patch model assumes that a forager encounters patches rather than prey items. While we characterize a prey item by its available energy and handling time, we characterize a patch by its gain function. A gain function, $g(t)$, gives the relationship between the time spent exploiting a patch (t) and the energy gains extracted from a patch (g). We assume that a forager can extract energy from a patch at a fairly high rate initially, but this rate declines as the forager spends more time in the patch simply because the forager's exploitation depletes the patch. So, we typically draw gain functions as increasing curves that bend down. The patch

 doi:10.1016/B978-0-444-63768-0.00026-3

models solve for the patch residence time (t) that maximizes intake rate. For a situation with only one patch type, one can easily show that the rate-maximizing patch residence time, say t^*, satisfies

$$g'(t^*) = \frac{g(t^*)}{1/\lambda + t^*} \quad [2]$$

Where $g'(t^*)$ represents the derivative of the gain function with respect to patch residence time. Modelers call this condition the marginal-value theorem because marginal rate is a synonym for derivative. The condition tells us that at the rate-maximizing residence time, the instantaneous (or marginal) rate of intake equals the overall rate of intake. Algebraically, this marginal-value condition can be difficult to solve, but it has a very simple graphical solution (Fig. 1). The model predicts that in poor habitats (low overall rate of intake) foragers should spend more time in patches extracting more from each patch; while in rich habitats the model predicts that foragers should `skim the cream' from each patch – spend less time and extract less.

Opportunity costs

Notice that although these models seem to address quite different aspects of foraging behavior, they are logically similar. The marginal rate of intake in the patch model plays a role that is very similar to the profitability of lower ranked types in the diet model's inclusion algorithm. Both models maximize the long-term rate of energy intake, and the central properties of both models

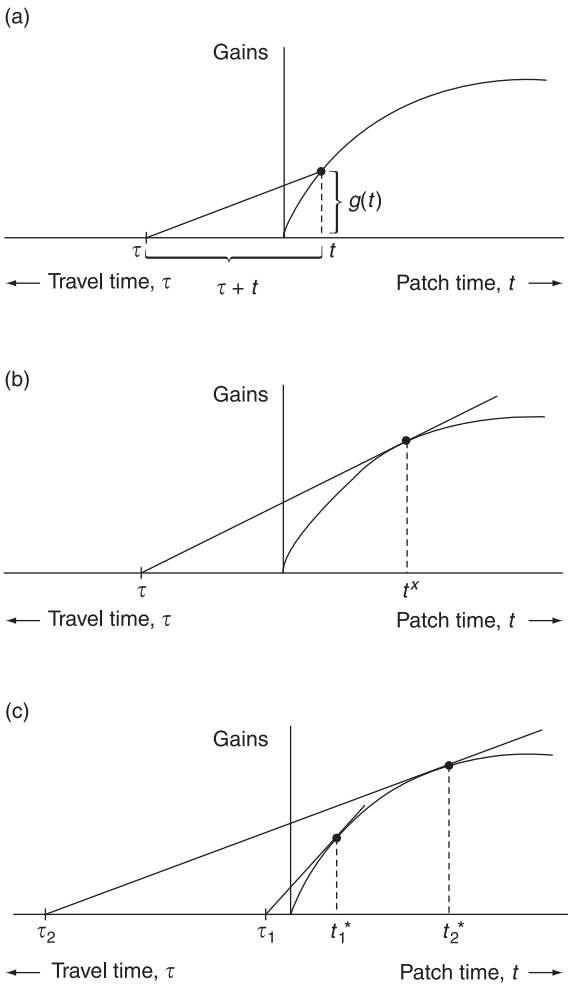

Fig. 1 The figure shows the graphical solution of the classical optimal patch exploitation model (the marginal-value theorem). The right hand side of all three panels shows a curve that gives the relationship between time spent exploiting a patch (patch time) and the resources extracted from the patch (gains). This curve is the function $g(t)$. The left hand side of each panel shows travel time (τ) increasing to the left. (a) shows a given travel time (τ) and an arbitrary chosen patch time (t). If we consider a slanting line from τ on the travel time axis to the point [t, $g(t)$] on the right side, we see that the slope of this line $g(t)/(\tau + t)$ is the rate of gain associated with patch time t. Clearly, the patch time shown in (a) is not the best, because we can increase this slope (the rate intake) by choosing a larger patch time. (b) shows that the optimal patch time corresponds to the case where the slanting `rate line' just touches (is tangent to) the gain function. (c) uses this solution to show the main prediction of the patch model, when travel times are long, say τ_2, then this tangent point just corresponds to a long patch time (t_2), but if travel times are short (e.g., τ_1) then we predict a short patch time (t_1).

stem from opportunity costs. For example, it can never be a mistake to attack the highest ranked item in the prey model, but it can be a mistake to attack the lower ranked items because in doing so, a forager might miss an opportunity to attack a higher ranked item. The role of opportunity costs is even clearer in the patch model. The model predicts that foragers should `skim the cream' from patches in rich habitats, because when a forager spends too much time in patches in a rich habitat, it loses opportunity to exploit fresh patches elsewhere.

Experimentalists and field workers have tested these models many times. Data broadly support many of their qualitative predictions. For example, virtually all patch-use studies support the prediction that foragers should spend more time exploiting patches in poor habitats. In addition, the claim that the abundance of high-quality prey types shapes animal selectivitiy is also well supported. Yet, the zero–one rule almost never holds. Each investigator in this area has a different interpretation of the empirical results. Some are encouraged by the pattern of qualitative agreement, while others emphasize the quantitative failures. In modern foraging theory, these models play a role like that of the Lotka–Volterra models in population ecology. They may not apply to any given situation, but modelers and students of foraging need to understand them so that they can use them as starting points for new models, and recognize their predictions within more complex situations. Literally hundreds of studies have used these models as building blocks. The work of Pirolli and Card on `information foraging' provides an especially novel example. These workers have used ideas from patch exploitation theory to analyze how computer users interact with websites and databases.

Most investigators recognize the patch and prey as the historical foundation of foraging theory, but as the theory has developed over the last 20 years, these same investigators have come to recognize two more ideas as basic building blocks of foraging theory: the ideal free distribution and dynamic optimization.

The ideal free distribution

Classical foraging theory, as represented by the patch and prey models, focused on the actions of solitary forager. The ideal free distribution provides a framework for extending foraging theory to cases in which animals forage in groups. The ideal free distribution considers how animals in a group should distribute themselves between two feeding sites. The foragers in this model are `ideal' in the sense they can immediately recognize the quality of sites and they share the resources at a site equally,that is, if $n$ individuals occupy a site, each obtains $1/n$th of the available food. The foragers are `free' because they can move freely between sites without cost. If site one produces food at rate r_1, then the n_1 individuals present there can expect to obtain food at rate r_1/n_1; similarly individuals at site two can expect to obtain r_2/n_2. The ideal free distribution holds that a stable distribution of individuals among sites can only occur when the intake rates in the two sites are approximately equal, because if intake rates differ in the two sites, then individuals at the lower-rate site can do better by moving to the higher-rate site. Data supports the ideal free model's predictions surprisingly well, even though the assumptions (e.g., equal sharing) are seldom satisfied. Although one can criticize the ideal free model at many levels, its focus on the economics of leaving and joining is fundamental to social foraging models.

Dynamic optimization

Dynamic optimization is not a model like the patch or prey model, instead it is a technique for modeling foraging and life-history problems. The patch model is a single-variable maximization problem like those studied by calculus students (e.g., find the height of tin can that maximizes volume). Dynamic optimization allows us to solve for an optimal trajectory or function, rather than a single variable. Consider the problem of foraging in the presence of predators. Typically, rich feeding sites are also the riskiest, while poor feeding sites are safer. As a rule, larger animals experience a lower risk of predation than small ones. So a small animal choosing the poorer but safer feeding site is also choosing a smaller future body size that could increase its risk of predation in the future. In situations like this, we cannot consider the best action at time 1 without also understanding the implications for time 2 and so on. Two pairs of workers (Marc Mangel and Colin Clark, and Alasdair Houston and John McNamara) have pioneered the application of dynamic models to foraging and behavioral ecology. Investigators have applied dynamic optimization to the study of predator avoidance and food storage (e.g., caching) with notable success, and dynamic models clearly represent a step forward in sophistication. The downside is that it can be difficult to solve dynamic optimization problems, and we must often resort to numerical techniques.

Where Is Foraging Theory Now?

Foraging theory has had a colorful intellectual history with vehement detractors (e.g., a paper with the title ``10 reasons why optimal foraging theory is a complete waste of time''), and zealous proponents. While the basic models and techniques outlined above represent basic building blocks of modern foraging studies, they are no longer the definitive core of `foraging theory.' Research that draws on this tradition is now so diverse that an outsider may find it difficult to recognize `foraging' as a single cohesive topic. This article recognizes three interconnected themes in contemporary foraging research. First, some investigators have focused on the neural, psychological, and physiological mechanisms underlying foraging behavior. Second, other investigators have generalized and extended traditional foraging models, developing a modern behavioral ecology of foraging that includes predator avoidance, social behavior, and food storage. Finally, a growing number of investigators considered the implications of foraging behavior for population and community level processes. The remainder of this article considers these three themes in turn.

Behavioral Mechanisms

Suppose we observe that foraging blue jays spend more time gleaning insects from clumps of foliage in poor habitats, as the patch model predicts. How do the jays achieve this? Do they learn the difference between rich and poor habitats? Does an internal clock trigger patch departures, or do jays use declining rates of prey capture to decide when to leave? Foraging theory, like the rest of behavioral ecology, emerged from a tradition of `mechanistic agnosticism', that ignores these types of questions. Natural selection, the argument goes, favors `outcomes' that might be achieved by any of several mechanisms, and one can study these behavioral outcomes and their fitness consequences without necessarily understanding the underlying mechanisms. The modern perspective holds that although one `can' study the fitness consequences of behavior without a complementary analysis of mechanisms, we achieve a richer and more complete understanding when we combine these approaches.

Many types and levels of mechanism influence foraging behavior. These include the physiological process of digestion and energy storage; the neural mechanisms of learning, memory, and sensation; and the psychological processes of learning, discrimination, and decision making. Each of these topics has something to add to the study of foraging. Readers should recognize that the interactions between the traditional models that follow from hypothesis about fitness consequences, and mechanistic analyses flow in two directions. Mechanistic approaches provide information about processes that can constrain foraging behavior, and we can use this information to refine traditional models. In the other direction, fitness-based models can inform mechanistic analyses by explaining the context and selective value of the behaviors controlled by a given mechanism. The following sections outline some key recent developments in this area.

Cognition and psychological phenomena

Many birds cache food items for later consumption. This raises basic questions about the fitness value of external food storage: how does food availability influence caching behavior (temporal patterns of abundance and dearth seem to be important); when is `external' storage superior to internal storage (e.g., as fat – predator avoidance may be important here). It also raises the question of how caching animals find and retrieve food items that they may have hidden weeks or even months ago. Studies of memory abilities of caching birds provide a textbook example of how to combine mechanistic and functional analysis. Evidence suggests that some caching birds have better spatial memories than related noncaching species. In addition to this, caching species tend to have larger hippocampuses in their brain (a structure implicated in memory), and some evidence suggests that the experience of caching food leads to an enlarged hippocampus. Finally, recent work by Clayton and Dickinson uses caching behavior to provide the first evidence of so-called episodic memory in a nonhuman species.

Neurobiology and neuroethology

Recent advances in neurobiology offer the promise of meaningful connections between neural mechanisms and naturally occurring foraging behavior. For example, worker honeybees undergo a well-defined progression from nurse to forager as they age. An impressive body of work now suggests that the worker's brain become modified for foraging as this sequence progresses. Particularly, the mushroom bodies (a structure crudely comparable to the vertebrate hippocampus) enlarge as the workers develop into foragers, and this structure appears to serve both the spatial abilities that foragers need to find and collect resources, and the abilities of foragers to form associations. The star-nosed mole provides an example of how foraging models can inform neurobiology. The `star' is a 22-lobed sensory structure covered with roughly 25 000 receptors and served by 100 000 nerve fibers, supported by a nearly literal `map' in the mole's brain. Why has this spectacular structure evolved and why don't other moles have such elaborate stars? The neurobiologist Kenneth Catania has turned to classical foraging models for insight. Behavioral studies suggest that the star and its associated neural machinery dramatically reduce the handling time associated with the small vertebrate prey that predominate in the mole's damp habitat.

Digestive physiology

Historically, students of foraging have paid little attention to the grimy fate of ingested food. Several recent studies have, however, shown that students of foraging must consider the `behavior' of the digestive system as part of an animal's overall foraging strategy. Internal physiological processes actively manage guts. Snakes provide a stunning example. A snake digesting a freshly caught meal dramatically upregulates its gut, increasing the weight of the intestinal mucosa, lengthening the microvilli, and increasing the overall metabolic rate by a factor of 40! All this happens over a very short timescale, and when the snake has finished digesting its meal, the process is reversed, downregulating the gut and associated metabolism. While the gut management of feast-or-famine foragers, like snakes, are obviously dramatic, studies with many types of animals document the flexible behavior of animal guts. Guts can be sensitive to the availability of food, as in the snake example, but they can also change in response to food types. For example, lengthening for a vegetarian diet and shortening for a carnivorous diet.

Modern Foraging Theory

While the basic foraging models provide insight into many foraging problems, they seldom provide a complete solution of any particular foraging problem. For example, they say nothing about tradeoffs with predator avoidance, or social interactions. In response, behavioral ecologists have extended and refined foraging theory in several directions. This section identifies three of these growing points in foraging theory.

Herbivory

Students of foraging have long recognized that the herbivores face different problems than carnivores. Recent work on herbivory shows two significant trends. First, students of herbivory have developed new intake rate models that are not based on Holling's disk equation. The best known of these is the Spalinger–Hobbs model. These `bite rate' models recognize that herbivores can often handle their food (i.e., chew it) while searching for the next `bite,' (a violation of the typical assumptions of the Holling approach). Whether constraints on chewing rate or constraints on food-discover limit, intake rate depends on the properties of the forager and the ecological situation. The second key trend in this area is the breakdown of barriers between applied students of herbivory (e.g., those who study domestic stock and insect pests) and behavioral ecologists interested in herbivory. These sort of barriers fall more slowly than one would hope, yet agricultural scientists offer many years of data and access to some impressive experimental systems and techniques, while behavioral ecologists offer comparisons to the natural setting and ideas about the evolutionary forces that have shaped the behavior of herbivores.

Foraging in the face of predation

Algae grow on top of rocks. Grazing snails would prefer to feed where the algae grow, but the exposed surfaces of rocks are also exposed to predation. Like grazing snails, many foragers face a fundamental tradeoff between obtaining food and avoiding predation. Indeed, the literature of `predator' effects is enormous and fast growing. Foragers may change where they feed, when they feed, or even the company they keep while feeding in the face of predation risk. This isn't news. Since the early days of foraging models, investigators have realized that a complete understanding of foraging would have to take predation into account. The problem is how to build quantitative models that account for foraging gains and mortality risk at the same time. The answer is a life-history approach. When we consider an animal's life history, we naturally think of current survival and future reproduction. Now the key problem is to specify how foraging behavior influences these two quantities. While there is, at present, no generally satisfactory way to specify universal relationships between foraging and life-history parameters, modelers recognize several important special cases. In one special case, for example, one can use the premise to simple maximization of survival probability to construct models that combine food acquisition and predator avoidance. Perhaps the most widely studied special case is Gilliam's 'μ over g' rule which minimizes the quotient of mortality rate (μ) divided by growth rate (g). Gilliam's rule applies to situation in which animals are not actively reproducing so that they allocate acquired resources to growth.

Social foraging

Many organisms forage and live in groups that range from loose aggregations to complex societies. The subtopic of `social foraging theory' pioneered by Giraldeau and Caraco takes a game theoretical approach to these problems. Group size models typically use a member–joiner paradigm that generalizes the approach taken in the ideal free distribution. In this approach, we plot the relationship between foraging gains (often, but not necessarily, measured as rate), and group size. The function typically increases to a maximum as new recruits contribute to the group's foraging efficiency and then declines as further recruits make excessive demands on the group's limited ability to detect and acquire new resources. Observations suggest that animal groups are typically larger than the rate-maximizing size. According to theory, this occurs because singletons can benefit from joining the group well beyond the rate-maximizing group size. The group size that is ultimately stable can depend on many factors such as the degree of relatedness between group members and the prospective joiners, that the degree to which current group member can limit joining. Models of within-group behavior have focused on the producer–scrounger framework. In this approach, some individuals (the producers) find food and others (the scroungers) parasitize their discoveries. Again, we need a game theoretical approach, because the scrounger tactic only makes sense if there are some producers. If group members can easily search for their own food and simultaneously `keep an eye out' for the discoveries of others, then we expect the group members should attempt to scrounge whenever the opportunity arises, since they lose nothing in doing so. If, however, watching for the discoveries of the other compromises your ability to find food on your own, this sets the stage for a more subtle balance between the producer and scrounger strategies.

Foraging Ecology

A key goal of early foraging models was to inform ecological theory, specifically population dynamics and community ecology. Early studies, however, tended to focus on the behavioral predictions of foraging models deferring studies of ecological implications for another day. This focus on behavior clearly frustrated some students of foraging ecology, but more recent work shows signs of fulfilling foraging theory's promise as an ecological tool. Within population dynamics, for example, the advent of individual-based models have given ecologists a tool with which they can study the population implications of foraging strategies, because one can specify the foraging strategies of the computational `individuals' within the model. Turner and colleagues have used this approach recently in a study of elk and bison populations within Yellowstone National Park making the prediction that the effects of fire on resource quality are keys to the winter survival of these two large grazers. Community ecologists have also begun to use ideas from foraging theory more frequently. For example, community ecologists have used an empirical technique derived from patch exploitation theory (Joel Brown's `giving-up density' procedure) to draw conclusions about species interactions and coexistence. Using this technique, Kotler and Blaustein found that one species of gerbil was more sensitive to the threat of

predation than the other, and this partially explains how the two species divide the available space; one uses more open habitat and the other uses habitat with dense cover. Perhaps the most exciting development in foraging ecology is the recognition of the indirect effects of predation. Ecologists have always recognized that predators (who are after all engaged in the business of foraging) affect populations by killing, but as foraging theory's models of predator avoidance tell us, predators influence prey behavior in a myriad of sublethal ways. These sublethal effects of predation can profoundly effect populations and communities. For example, changes in habitat use can influence plant communities, and this in turn can influence the other animals that depend on these habitats. While we are still in the early days of this research topic it is a very exciting patch for further exploitation.

The issues discussed in the article only represent a sampling of contemporary topics in foraging behavior. Other developments include models of energy storage (both external via caching, and internal via fat), studies of provisioning that recognize that animals must often balance the problems of feeding themselves and feeding their dependent offspring, and growing connections with conservation biology.

Conclusion

Over the last 20 years, the models of conventional foraging theory have provided a foundation for many new developments. These developments have produced an extremely diverse and vibrant body of inquiry. If there is a downside to this, it is that investigators have become so specialized that they may not recognize the commonalities between approaches. The challenge for the next 20 years is to keep the lines of communication open, so that we can recognize opportunities to understand better, the role foraging plays in behavior and ecology.

Orientation, Navigation and Search☆

Jochen Zeil, The Australian National University, Canberra, ACT, Australia

Orientation in Space

Probably the most fundamental requirement for a defined orientation relative to the world is imposed by vision and by the need to appropriately direct motor commands. There are only two "absolute" and reliable reference cues animals can use for their alignment with the world: one is the direction of gravity and the other is the division of the world into a celestial and a terrestrial hemisphere, separated by a visual horizon line, with light coming from above. Animals have evolved a number of sensor systems to determine "where is up": they use collections of heavy materials bedded on shearing sensors (statocysts or otholiths) which signal the direction of gravitational pull. Some water insects trap air bubbles in sensory hair fields which serve the same role. In terrestrial animals, the distribution and orientation of body mass relative to gravity can be measured by proprioceptors, in vertebrates by muscle spindles and stretch receptors in the joints and around internal organs and in insects, by mechanoreceptors in the head-thorax and thorax-abdomen joints. The second absolute reference is the fact that light comes from above. Insects and fish are known to use this property of the world to align their vertical body axis and/or their eyes. The compound eyes of especially flying insects are aided in this task by an additional visual system, the ocelli, which are an assembly of three lens eyes with huge visual fields on the top of the head. In dragonflies and flies, ocelli have been shown to be exquisite horizon sensors, in addition to "dorsal light sensors," which elicit compensatory roll and pitch movements of the head, whenever it is not aligned horizontally.

There are a number of other animal sensors that cannot by themselves assure proper alignment with the vertical, but are essential in controlling and maintaining orientation. Vertebrates, crustaceans and flies possess vestibular systems that are designed to sense the rotational acceleration (in the case of semi-circular canals in vertebrates and crustaceans) and the velocity (in the case of fly gyroscopes) of the body and the head. The principle of operation in semi-circular canals is the fact that liquid in tubes embedded in the head does not immediately follow the acceleration of the head due to inertia. There is a brief moment then, in which the liquid moves relative to the canal walls and this movement is being sensed by hair cell mechanoreceptors, which are sensitive to shearing forces. The relative motion is caused by acceleration only: during prolonged rotation at a constant velocity, the liquid comes to rest due to friction. The main function of these vestibular systems is to stabilize gaze around the three rotational axes, the yaw, pitch and roll axes, by sending the appropriate commands to the eye muscles in vertebrates and crustaceans, and to the neck muscles in flies, which then move the eyes or the head into the opposite direction. The modified hindwings in flies, called halteres, are a special case of such inertial sensors: they consist of clubs on rigid stalks, which during flight rapidly oscillate up and down in anti-phase to the wings. Any rotation of the flying insect creates an inertial force which resists the change of orientation of the plane in which the halteres oscillate. This Coriolis force (which is also operating on the large gyral ocean and air current systems on earth) is then sensed by fields of strain sensors at the base of the halteres and their output drives compensatory head movements of the fly. Because these inertial systems provide feed forward information (their effect does not feedback directly onto the sensor itself) with little delay, the reflex movements they elicit belong to the fastest biological sensor-action loops. However, the information they provide is dynamical, lacks an absolute reference and is unreliable at low accelerations and low angular velocities. Inertial sensors by themselves therefore cannot prevent slow drift from the absolute reference orientation. They thus need to operate in concert with other sensory systems, most notably the visual system and its high sensitivity to image motion (Fig. 1).

All visual animals exhibit a strong reflex which counteracts large-field image motion on the retina. Such large-field motion is produced by rotational movements of the eyes, the head or the body, which cause the retinal image to shift in the opposite direction. Animals respond to such un-intended rotations by eyes, head or body movements in the opposite direction. This so-called optomotor response, or optokinetic reflex, is part of a negative feedback loop, with the speed of image motion as input and a motor command as output which—within a certain range of speeds—reduces image motion to zero. As a result, the retinal image is said to be stabilized, which is not quite true, because there will always be some residual image motion experienced by an animal when it moves through the world, that is caused by the animal's translational movement. However, the retinal image is cleaned from the effects of rotations by the optomotor response (around all three rotational axes) and thus helps to stabilize gaze and to keep the

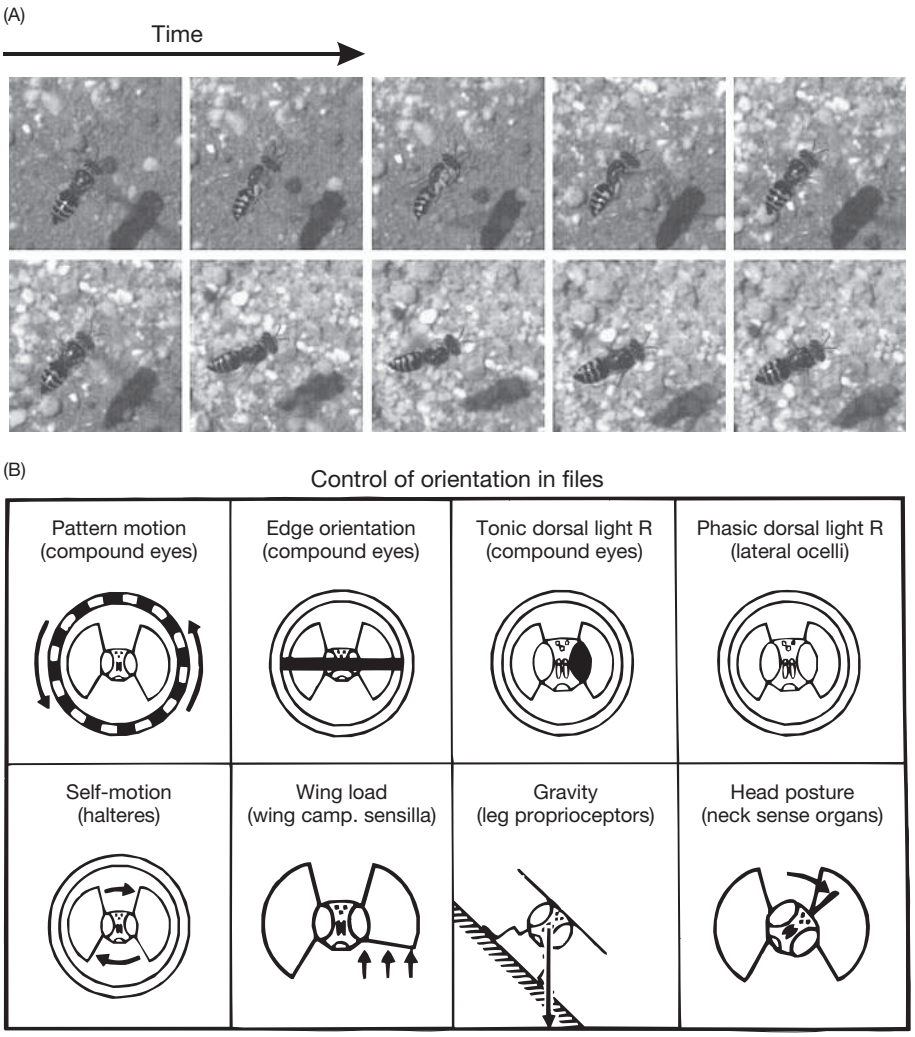

Fig. 1 Orientation in space. (A) Head stabilization in flight of a sand wasp (*Bembix* sp.). The sequence of high speed images shows the wasp as it executes a sideslip movement to the top left by rolling its body first to the left (top row) and then to the right as a breaking manoeuvre (bottom row). As the body rolls through nearly 180 degree, the head remains perfectly aligned with the horizontal. High speed video images were taken at 250 fps (from Zeil, J., Boeddeker, N. and Hemmi, J.M. (2008). Vision and the organization of behaviour. *Current Biology* **18**, R320–R323). (B) The different sensory inputs that contribute to head stabilization and orientation in flies (from Hengstenberg, R. (1993). Multisensory control in insect oculomotor systems. In: Miles, F.A. and Wallman, J. (eds.). Visual motion and its role in the stabilization of gaze, pp. 285–298. Amsterdam: Elsevier Science).

visual system aligned with the vertical. Although this sounds simple enough, there are some major computational problems animals have to solve, in order to achieve this optomotor stabilization: in flies, at least 60 large-field, motion sensitive neurons, many of them tuned to a particular rotational image motion component, are involved in the task of controlling the rotational movements of the fly's head!

Compass Direction and Distance Traveled

Even on their briefest journeys, like the 1 m or so excursions of fiddler crabs on their grazing trips away from their burrows, animals need to keep track of two kinds of information, if they are to eventually return home: their compass bearing and the distances they travel. This becomes even more important on longer forays, like the 600 m foraging excursions of desert ants or the many kilometers bees often cover when collecting nectar or water. The compass cues that are available on earth dependent on the scale at which animals move, a distant tree may suffice as a beacon for journeys of a few meters, a distant mountain can serve to provide compass direction for excursions of a few hundred meters, but movements beyond such "suburban" distances require compass information that is reliable and does not change over large distances of travel. The earth's magnetic field direction offers one such invariant cue, the celestial bodies sun, moon and stars, by virtue of their comparatively infinite distance, the other. The problem with celestial compass cues is that they change position as the earth rotates, and in order to use them for journeys that last longer than a few minutes, their movements need to be taken into account.

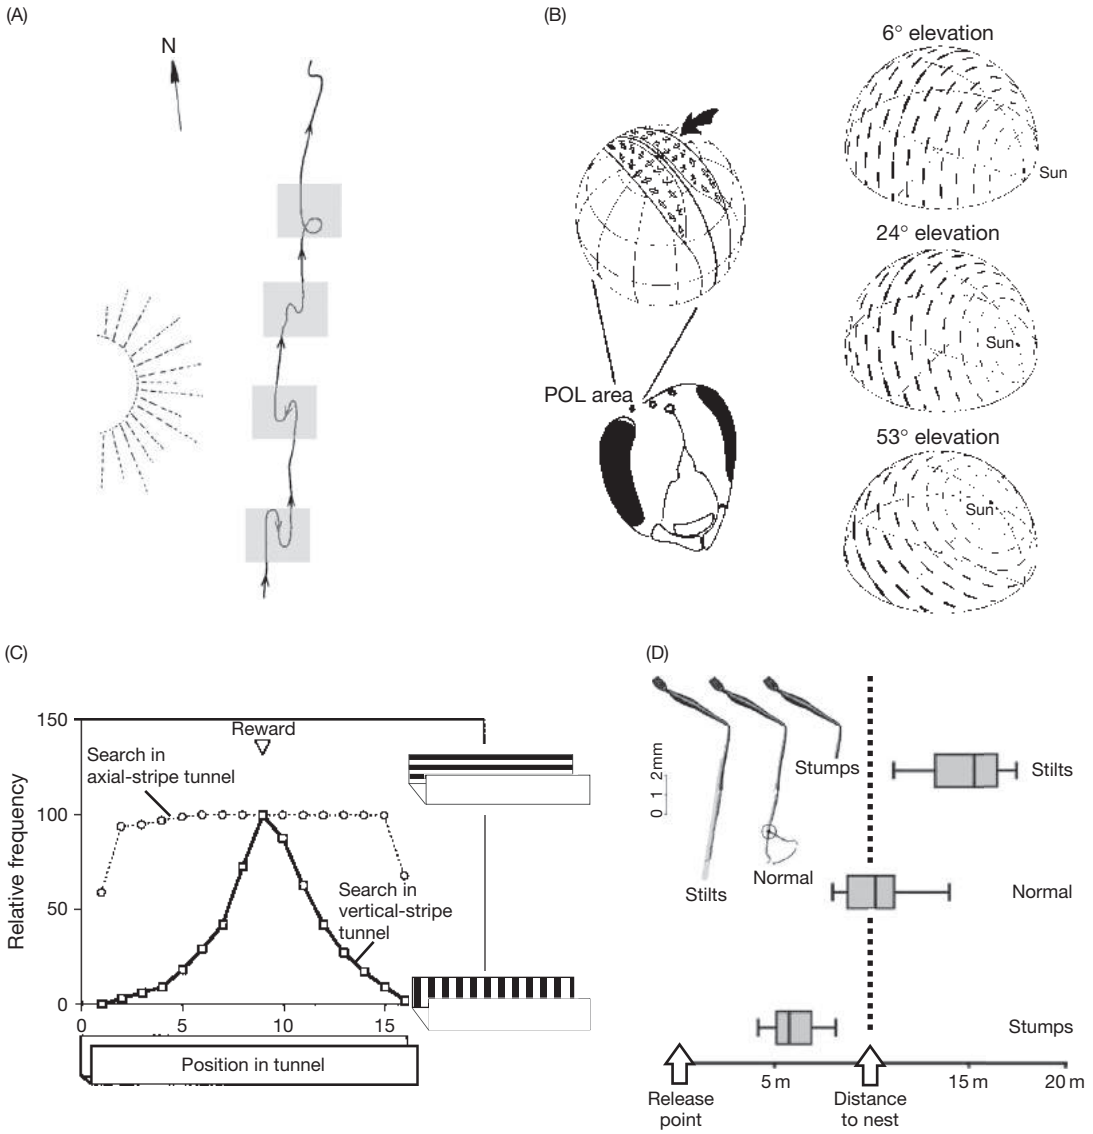

Fig. 2 Compass cues and odometry. (A) Insects are known to use the sun and the pattern of polarized skylight as a compass cue. *Left*: An experiment by Santschi (modified from Schöne, H. (1983). Orientierung im Raum. Stuttgart: Wissenschaftliche Verlagsbuchhandlung GmbH), in which he followed an ant on a straight path (line with *arrow* heads) and periodically screened off the sun on the left and reflected it back onto the animal with a mirror on the right during those parts of the ant's path that are marked with a gray patch. The ant always moves in such a way as to keep the sun to its left; making a u-turn whenever the apparent position of the sun has changed. (B) Many insects possess a specialized part of their eye, the dorsal rim, which carries photoreceptors that are particularly sensitive to the plane of polarization of light (*left*). Because the pattern of polarized skylight has an invariant structure with respect to the position of the sun, animals that are sensitive to the direction of polarization of light can infer the position of the sun from the direction of polarization of a few patches of blue sky: the sun must lie on the intersection of great circles perpendicular to the direction of polarization of these patches (modified from Wehner, R. (1982). Himmelsnavigation bei Insekten. Neurophysiologie und Verhalten. Neujahrsblatt der Naturforschenden Gesellschaft in Zürich **184**: 1–132). (C) Bees integrate optic flow to measure the distance they have to fly to a food source. Bees trained to find food about half-way into a small tunnel carrying pattern of vertical stripes at its walls, concentrate their search at a location where they had found the food source before. If the pattern in the tunnel is changed to horizontal stripes (which do not produce optic flow), the bees are unable to pinpoint a location in the tunnel and search throughout the tunnel (modified from Srinivasan, M.V., Zhang, S.W., Lehrer, M., Collett, T.S. (1996). Honeybee navigation en route to the goal: Visual flight control and odometry. *Journal of Experimental Biology* **199**, 237–244). (D) Desert ants (*Cataglyphis*) determine the distance they have walked by counting and measuring the size of their steps: when they walk on stilts on their home journey, they overestimate and when they walk on shortened legs, they underestimate home distance (modified from Wittlinger, M., Wehner, R. and Wolf, H. (2006). The ant odometer: Stepping on stilts and stumps. *Science* **312**, 1965–1967).

So, as far as compass cues are concerned, there are two kinds: cues that are static in relation to the world and those that are dynamic, but predictable. The static compass cues, in order of the scale over which they provide useful information, are landmark beacons, large oriented terrain features like edges of vegetation, mountain ranges, coastlines, and roads, and of course the polarity of the earth's magnetic field. The dynamic compass cues are all celestial: the sun, the moon, the stars, the pattern of polarized skylight and the distribution and spectral composition of skylight (Fig. 2A and B). Practically all mobile animals are known to use one or a

combination of these cues, when maintaining a straight course and those that derive compass information from the dynamic celestial cues do know about their movement across the sky. Bees, for instance, when communicating in the darkness of their hive to their nest mates the direction of a food source, can predict where the sun ought to be at that particular time of day and indicate the compass bearing of the food source relative to the sun.

When traveling, animals need in addition to a compass, also a way of measuring the distances they have moved. There is no direct way, in which this can be done, but animals could use a number of indirect measures of distance traveled: they could measure time, their energy consumption, they could count their steps, their fin- or wing-beats, or they could monitor the optic flow they experience, that is how much of the world has whizzed past their eyes. For insects, it is only in the last decade or so, that the sensory basis of odometry has been identified: bees integrate the image motion they experience during their foraging trips in order to judge (and communicate) the distance they have flown (Fig. 2C); while desert ants employ a step counter, which interestingly discards information on the three-dimensional topography of the ground they walk over, by only registering the horizontal component of the distance covered (Fig. 2D). Migrating birds, in turn, appear to come with instructions about how far to fly, that are based on the energy they would require to cover certain distances.

Animals that move over small and medium scales use these two navigational bits of information, compass direction and distance traveled, to determine a home vector, that is the direction and distance to the start of the journey (Fig. 3A). This process of path integration has been most thoroughly studied in desert ants, in bees, in crabs and in some small mammals, like hamsters and rats. Path integration thus seems to be a very old way of leaving an "Ariadne's Thread" behind throughout an excursion, that at the moment of return is being pulled taught and then defines a "beeline" home. The characteristic feature of path integration is that its result depends on the animal's own active movements. Passive drift or dislocations are not being registered. The navigational mechanism of path integration can therefore be identified by shifting an animal just before it heads home. If path integration is the only information an animal has about the location of its goal, like its nest, then after displacement it will move in the direction and the distance where it would find the goal, had it not been displaced (Fig. 3B). Path integration does not allow an animal to compensate for such passive displacements. Many details of the neural computations involved in this process are currently been unraveled, but one aspect of path integration has been well established: the process accumulates errors, because directions and distances cannot be measured with infinite accuracy, so that the information about the home position becomes less and less trustworthy, the longer the journey takes. There seem to be two solutions to this very basic problem. First, animals use visual, olfactory or even magnetic landmarks, which are the most robust way of pinpointing a goal. Landmarks in this context are any sensory cues that uniquely specify a location in space. Second, animals apply efficient search strategies to help them find the goal at the end of the home vector.

Position in Space

Probably one of the most fundamental abilities of animals is to know places. Many operate from nests and shelters, but also know and repeatedly visit other places of significance, especially places where they can find food and water. On a local scale, the most potent cue to the identity of a location in the world is its unique visual appearance. The fact that insects can utilize this property of the world in order to pinpoint their nest, was shown in the first half of last century in an elegant and simple series of experiments by Tinbergen and Kruyt (Fig. 3C): they displaced objects around the nest of a ground nesting wasp just a few tens of centimeters to the left or the right of the nest entrance, while the wasp was out foraging. The returning wasp searched not at its true location for her nest, but at a location defined by the displaced landmarks. These visual features, not the true geographical location, or olfactory cues, thus defined the goal location for this insect. Many experiments of a similar kind have been carried out since then, aimed at unraveling the detailed mechanisms underlying this ability of view-based homing in insects, but also in vertebrates. Homing insects behave as if they had stored snapshots of the world as viewed from the vicinity of the goal and upon returning then move to minimize the difference between these stored views and what they currently see. These stored views seem to contain the apparent sizes of salient objects, their shape and possibly also their color. However, insects also seem to use salient objects as beacons, not just as part of a panoramic scene and they can acquire information on the absolute distance between objects and the goal, not just on how large they ought to appear. View-based homing is so potent, because places in the natural world are uniquely defined by the view taken from them. The reason is that there are very few repetitive structures in nature that would make different places appear alike. On the other hand, the appearance of natural scenes change, because of changes in illumination and because objects are displaced by wind, water and by large animals. Ground-nesting insects, therefore, have to update their memory of the nest environment regularly, especially first thing every morning. To what extent our knowledge of view-based homing in insects can also explain the homing abilities of, for instance, birds which operate over distances of tens to hundreds of kilometers, is not entirely clear. It is only recently that the paths of birds at these scales can be accurately recorded. Like insects, birds visit the same food and nest sites over years—often after long migrations—and are attracted to and follow route landmarks. Both the pinpoint homing accuracy and the use of guiding landscape features, like roads, rivers or coastlines in the case of birds, are likely to be based on remembered views.

In barren landscapes, like featureless deserts, or the open and the deep ocean, view-based navigation fails. Yet, even there, animals are known to keep to idiosyncratic routes, to find tiny islands and to navigate on a global scale. One suggestion is that animals may have something akin to a global positioning system and the only cue they could access for that purpose would be the structure of the earth's magnetic field. By now, animals as diverse as bacteria, bees, lobsters, salamanders, fish, turtles and birds have

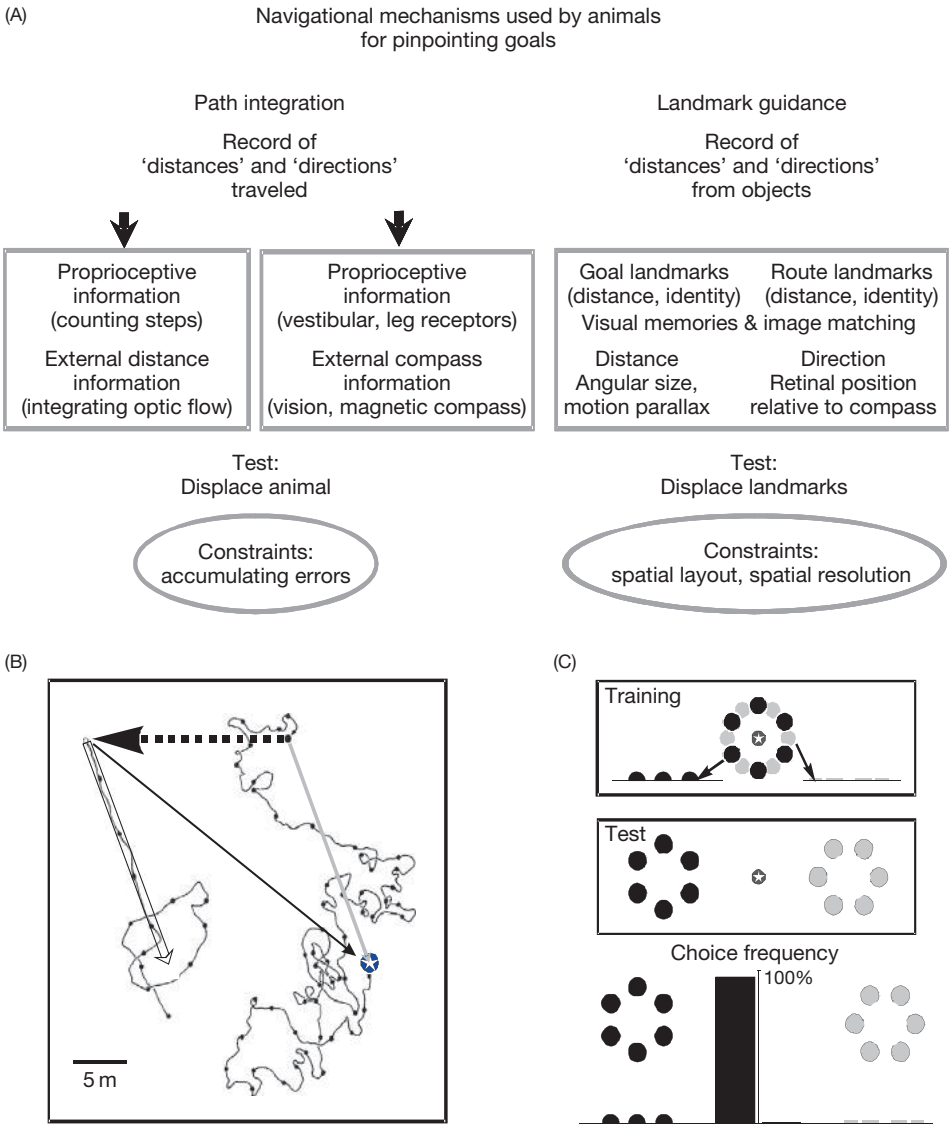

Fig. 3 Path integration and landmark guidance. (A) The two navigational mechanisms, the information required and examples of the cues animals are known to employ. (B) To test whether an animal employs path integration the animal is passively displaced before it heads home (*dashed arrow*). If the animal can compensate for the displacement (*thin black arrow*) it must have external (geocentric) information on its release site or on the nest location. An animal that relies exclusively on path integration information, like desert ants on featureless saltpans, runs into the direction and for the appropriate distance after displacement (*open arrow*) in which the nest would be, had it not been displaced (*gray arrow*). It then executes systematic search movements for the nest (see Fig. 8) (modified from Wehner, R. (1982). Himmelsnavigation bei Insekten. *Neurophysiologie und Verhalten. Neujahrsblatt der Naturforschenden Gesellschaft in Zürich* **184**: 1–132). (C) The demonstration that animals use the appearance of landmarks in order to pinpoint a location, like their nest, involves displacing the landmarks in the animal's absence and asking where it would search for the nest on its return. In many ground nesting insects, the nest location is defined by the surrounding landmark panorama, as this famous experiment by Tinbergen clearly demonstrates. The sand wasp *Philanthus* searches for her nest not at its true location (marked by a *star*), but in the centre of a ring of three-dimensional landmarks (*black*) rather than a ring of flat discs (*gray*) that both had surrounded the nest during training (modified from Collett, T.S., Zeil, J. (1997). Selection and use of landmarks by insects. In: Lehrer, M. (ed.) Orientation and communication in Arthropods, pp. 41–65. Basel: Birkhäuser Verlag).

been shown to be sensitive to at least some aspects of the magnetic field. Experiments with turtles in artificial magnetic fields that mimicked the situation in geographical locations that were hundreds of kilometers apart indicate that experienced animals actually recognized these locations by their magnetic field properties (although swimming on a tether in a backyard swimming pool) and moved in appropriate directions that would bring them back to their home grounds (Fig. 4). The magnetic field does not only vary along latitudes and longitudes across the earth, but also has local features, called magnetic anomalities, that could serve the same purpose as visual landmarks: something that uniquely specifies a place. Indeed, birds have been shown to change their behaviour in the vicinity of such "magnetic landmarks." Yet it is still unclear, whether any animal actually knows where it is at any point on earth

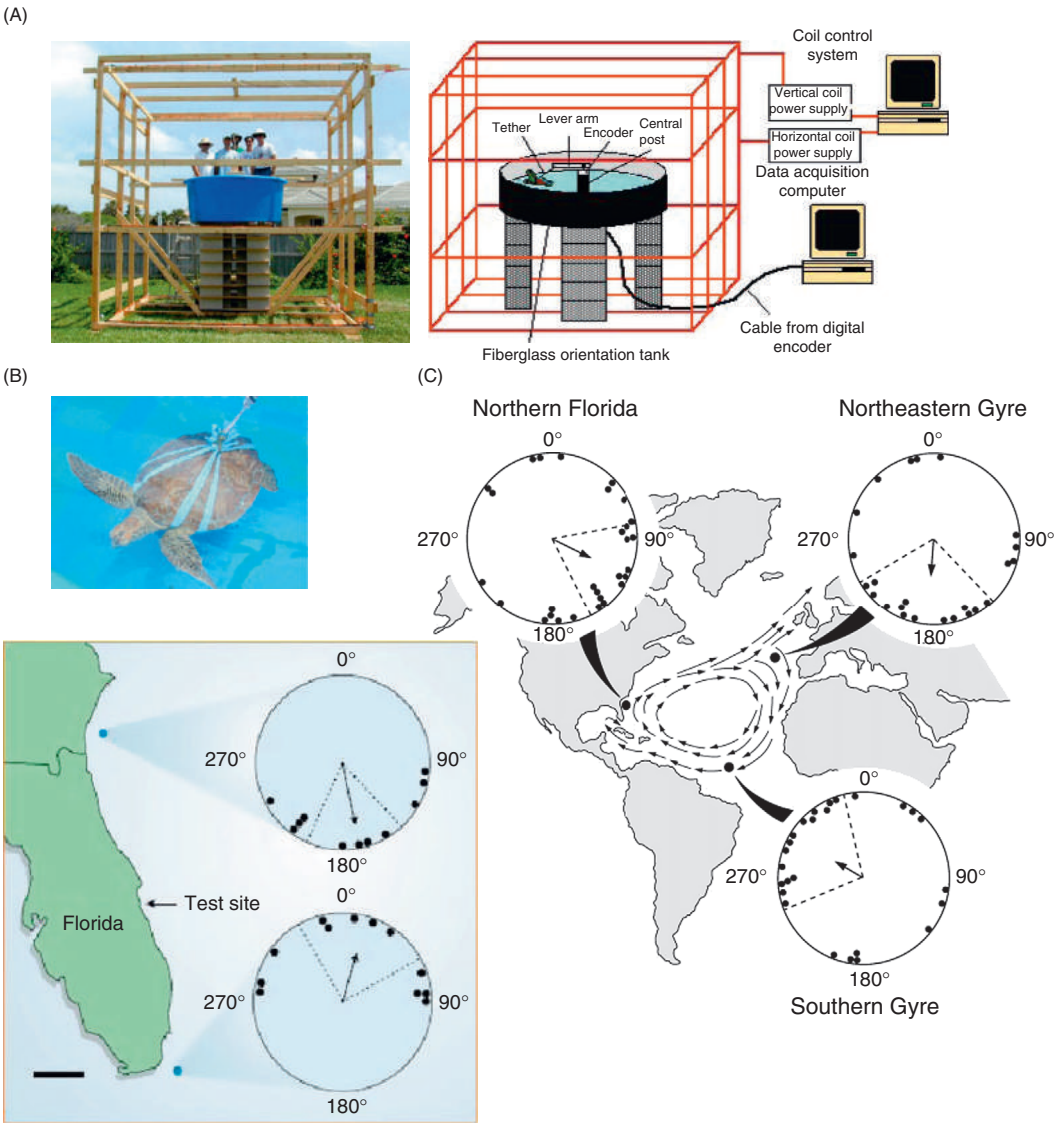

Fig. 4 Magnetic navigation. (A) The magnetic field properties of different locations on earth can be mimicked by sending appropriate currents through an arrangement of coils (from http:/www.unc.edu/depts/oceanweb/turtles, with kind permission of Kenneth Lohmann). (B) Adult turtles which are tethered in a large swimming pool and are subjected to a magnetic field characteristic of places several hundred kilometers north or south of their home ground (marked by stars), swim in directions that indicate that they perceive themselves to be north or south of their home grounds (from Lohmann, K.J., Lohmann, C.M.F., Ehrhart, L.M., Bagley, D.A., Swing, T. (2004). Geomagnetic map used in sea-turtle navigation. *Nature* **428**, 909–910). (C) Turtle hatchlings which are subjected in a similar way to magnetic fields that indicate different locations across the Atlantic ocean swim in directions that would keep them in the large Atlantic gyrus (from Lohmann, K.J., Cain, S.D., Dodge, S.A., Lohmann, C.M.F. (2001). Regional magnetic fields as navigational markers for sea turtles. *Science* **294**, 364–366).

by the particular property of the magnetic field that specifies that place, something that has been called the ability of "true navigation." The best evidence so far has been the behaviour of turtles and lobsters in artificially created magnetic fields that mimic the situation in specific places on earth (Fig. 4B and C). It is only very recently that the tools have become available that allow us to track animal movements over global scales. Knowing exactly where animals go, how they move and where they make navigational decisions is a prerequisite for understanding the knowledge base of their navigational abilities (Fig. 5).

Navigation: Compasses, Landmarks and Maps

Animals navigate across very different scales and the knowledge they require, the cues they have available and the mechanisms they employ differ depending on the task, the lifestyle, the habitat, the sensory limitations and the style of locomotion. Animals can also be expected to be very sensitive to the changing salience and reliability of navigational cues and adjust their reliance on these cues accordingly. Homing pigeons, for instance, follow roads and are attracted by large landscape features, like road intersections or

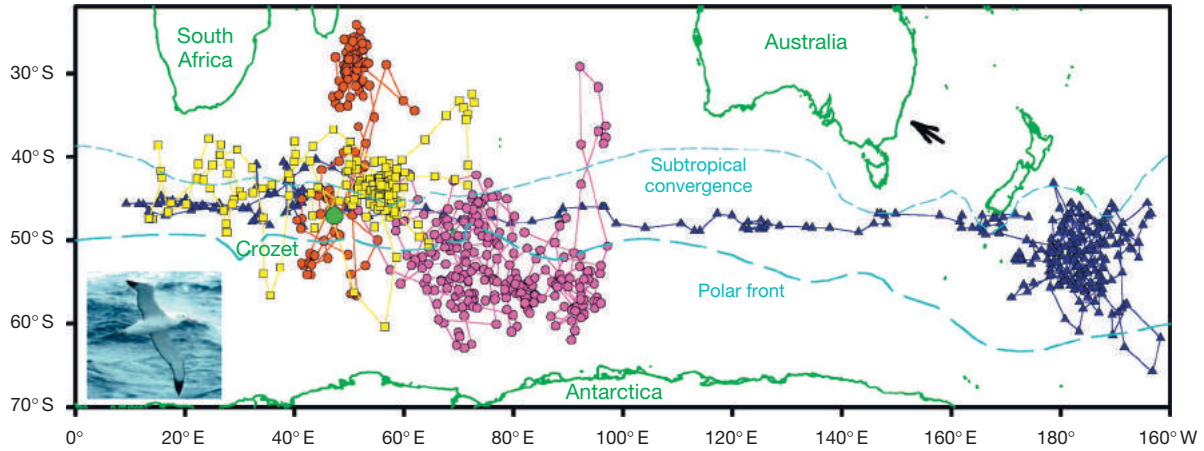

Fig. 5 Global navigation. Wandering albatrosses go on a year's sabbatical after breeding on Crozet Island. Two positions per 24 h cycle are shown for two male (*mauve dots* and *blue triangles*) and two female birds (*red dots* and *yellow squares*) as determined by light-intensity loggers. Each bird flies to its favorite wintering zones somewhere across the southern ocean (from Weimerskirch, H. and Wilson, R.P. (2000). Oceanic respite for wandering albatrosses. *Nature* **406**, 955–956).

bridges (Fig. 6A). Many insects use the sun as a compass on brief foraging trips, but switch to relying on the pattern of polarized sky light, or on landscape features, when the sun is not visible. Equally, some birds calibrate their magnetic compass using the twilight sky at the horizon; other birds calibrate their twilight and star compass with the aid of the magnetic field. Compass cue hierarchies thus differ in each specific case, possibly depending on the way experiments are being conducted, but also depending on the evolutionary history and the peculiarities of migratory behaviour.

The same flexible use of multiple navigational cues is also evident in the control of small- and medium-range movements by insects, in which information derived from path integration, from the visual scene and from olfaction interact. Honeybees, for instance, learn, remember and recall navigational instructions, when they encounter certain patterns, colors, or odors along a foraging route. Desert ants (*Cataglyphis*) can retrace their steps in complicated terrain, always detouring vegetation or artificial landmarks in the same direction on repeated trips (Fig. 6B). Wood ants (*Formica rufa*) are attracted by dominant landmarks as beacons and route guides, but can follow the same route even in the absence of such a landmark, indicating that they learned as well a sequence of other cues that defines their foraging path. The foragers of the Giant tropical ant (*Paraponera clavata*) ignore their own pheromone trails when they become more experienced with a route to a food source and rely themselves on route landmarks, while fresh recruits are guided by the trail.

These examples highlight several important aspects of animal navigation that are little or only partly understood: the organization of navigational memory, the saliency and reliability of navigational cues and the relative importance of genetically determined navigational instructions and of navigational learning. Large-scale migration routes in birds have been shown to be determined by genes that influence migratory direction, while the ability to pinpoint nest and food locations, has to involve learning and memory mechanisms. The close similarity of the complex behavioral organization of learning flights in phylogenetically distant species of nest-owning bees and wasps, however, suggests that the rules of how to learn about the visual scene around a goal have a genetic basis.

In recent years, a lively debate was concerned with the question, what kind of internal representation animals have of the different environments they navigate through. Is the knowledge they have similar to how we perceive the lay of the land, having been trained to read and interpret maps, which are basically bird eye views of the world? Or do animals know the world only as a set of paths and places they have traveled before, but without the ability to determine the shortest paths between these places? The debate revolves around the concept of a "cognitive map," the organization of the internal representation of space. In its hard definition, a cognitive map would mean that animals have a representation of the x–y–z coordinates of the landscape, much like a topographic map. In its softer definition, a cognitive map is any representation of the physical environment that allows an animal to navigate through it and to visit places of interest. One of the crucial experiments that were designed to test whether animals possess one or the other representation, involves training bees, for instance, to visit two locations that are some distance away from each other and then displacing them to a location half-way between the two training places, which is assumed to be unknown to them. The question then is whether the bees fly directly to one of the known places, which would indicate that they were able to judge, where the release location lies with respect to the training places. Such experiments and variants of it have so far not provided clear evidence, at least for bees, that they possess a topographic map-like representation of their environment. Similar experiments with dogs show that these animals do take short cuts between two places they know, possibly using path integration information. In contrast, insects seem to represent the environment they exploit as a set of instructions on how to reach and trap-line significant places from their nests and hives, but with no ability to take short-cuts between them. This question of how navigational knowledge in different animals is organized is still open and provides an inspiring and motivating challenge to scientists interested in the mechanisms of animal behaviour.

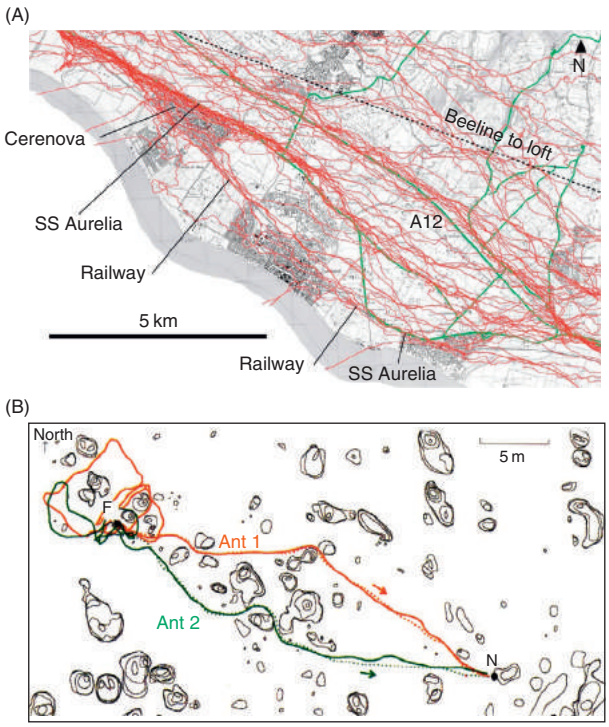

Fig. 6 Landmark guidance. (A) Homing pigeons are attracted to and are guided by large landmark features, like roads or large road crossings. Red lines show the GPS recorded paths of pigeons on their way back to the loft; *green lines* mark major highways (from Lipp, H.-P., Vyssotski, A.L., Wolfer, D.P., Renaudineau, S., Savini, M., Tröster, G. and Dell'Omo, G. (2004). Pigeon homing along highways and exits. *Current Biology* **14**, 1239–1249). (B) In terrain with vegetation, two desert ants (*Cataglyphis; green* and *red*) had returned from a feeder at (F) to their nest at (N) along the dotted paths. They were then picked up and returned to the feeder. After some search both ants practically retraced their steps (continuous *red* and *green lines*). Since *Cataglyphis* does not deposit pheromone trails, this experiment shows that they must remember route landmarks (from Wehner, R., Michel, B., Antonson, P. (1996). Visual navigation in insects: Coupling of egocentric and geocentric information. *Journal of Experimental Biology* **199**, 129–140).

Orientation by Olfaction: Trails, Flows and Plumes

Many animals are guided by olfaction. They are able to detect the gradient of molecule concentration to find the source that emits these molecules. However, homogeneous gradients are rare on earth, because molecules are transported by the media of air and water and therefore do not disperse in a homogeneous fashion. Rather, they are subject to diffusion and turbulence, processes that cause them to be very unequally and patchily distributed after a short distance of travel from the source. Animals have adapted to this pattern of molecule dispersal on earth and have acquired optimal strategies to detect the source of such turbulent plumes. The best way of doing so requires the following simple rules (Fig. 7): first, if a substance is detected, its most likely origin is from upwind or upstream. So first of all, move against the flow. Second, if you fail to detect it again, move across the flow direction in a zigzag fashion. Third, the moment the substance is detected again, move upstream or upwind. A recent theoretical study has shown that this is actually the only strategy that assures that an animal finds the source of a substance in turbulent media. Pinpointing the source of an odor is important for animals in a variety of tasks: to find food, like carcasses and flowers, to find mates, in which case very specific pheromones are being produced, and released into the medium, to detect predators and to find places that carry a specific olfactory signature, like a nest marked with pheromones or a river inlet. Some animals use odors to mark homes, territorial boundaries or in the case of ants, pheromone trails to a food source that serve to recruit and guide nest mates to such a significant place. It has even been suggested that locally varying blends of odors can be used like a map by animals, helping them to link places they visit by their distinct olfactory signatures.

Odors in the context of orientation and navigation have some interesting and unique properties: in the case of pheromone markers or trails, for instance, they carry information, not only about the sender, but also about time. Since molecules diffuse, depending on their volatility, their ambient concentration will decline with time and thus indicate the time elapsed after they were deposited. Olfactory trails and signposts are signals that do not require the sender to be present and they can be made very specific, compared to visual or sound signals. Chemical signals thus can help to avoid un-intended eavesdroppers. The problem with odors is that they are so affected by the movement characteristics of the medium. So, marking a nest entrance, for instance, will only help in homing, if returning animals are downwind from it. There is no signal to be detected from all other directions. For the same reason, it is also unclear at present—with the exception of rivers—how stable the distribution of natural odors are in the atmosphere

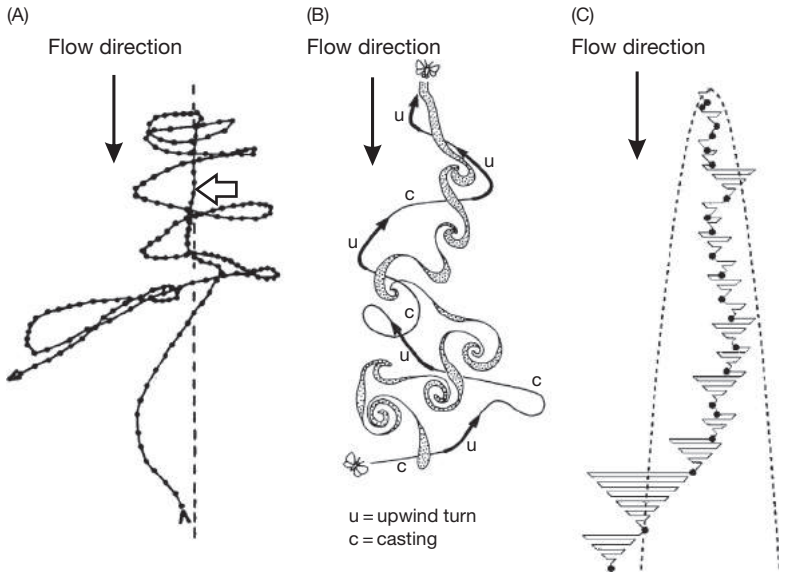

Fig. 7 Orientation in turbulent pheromone plumes. (A) A flight path of a moth silk moth male in a pheromone plume. The *open arrow* head marks the time when the pheromone release was switched off. Shortly afterwards, the insects starts casting, flying perpendicular to the wind direction. Moth positions are shown every 67 ms (modified from Baker, T.C. and Vogt, R.G. (1988). Measured behavioral latency in response to sex-pheromone loss in the large silk moth *Antheraea polyphemus*. *Journal of Experimental Biology* **137**, 29–38). (B) Principle of finding the source of a turbulent plume: if a molecule is encountered, move upwind or upstream (u); if no more molecules are encountered, move cross-wind or cross-stream (c) (modified from Kaissling, K.-E. and Kramer, E. (1990). Sensory basis of pheromone-mediated orientation in moths. *Verhandlungen der Deutschen Zoologischen Gesellschaft* **83**, 109–131). (C) The path generated by an optimal plume search algorithm. *Dashed line* encloses area of highest probability to encounter a patch of odor. *Dots mark* odor patch encounters (modified from Balkovsky, E., Shraiman, B.I. (2002). Olfactory search at high Reynolds number. *Proceedings of the National Academy of Sciences of the United States of America* **99**, 12589–12,593).

and in water, which is crucial for their utility as navigational aids, as directional compass cues and as cues for localization. This gap in our knowledge is mainly a technical challenge at the moment, because monitoring biologically relevant chemical cues over long periods of time and with sufficient spatial and temporal accuracy is currently impossible to achieve. Being able to monitor, track, map and modify olfactory information would be truly exciting, because many experiments with homing pigeons seem to suggest that they attend to olfactory information in one way or other when being released tens of kilometers away from their loft. These observations lead to the suggestion that birds may possess an olfactory map, knowing places and their relative locations by their unique olfactory signatures.

Search

There are limits to the navigational abilities of animals because they face sensory and computational constraints to what they can know and remember. In many situations animals have to search for a goal or for food. Faced with these limitations and with the unpredictable aspects of the world, animals have evolved very efficient search strategies. Depending on the type, location and distribution of targets, these strategies fall broadly into two categories: systematic and random search. Systematic search movements are being employed in situations, in which animals have some information on the location of a target, for instance, when ants have been following path integration information on their return to nest (Fig. 8A). When they do not find the nest entrance at the end of their home vector, ants begin searching for it by running along paths that describe ever increasing loops centred on the location where the search began. This systematic search pattern is driven by the fact that the most likely location of the nest from the perspective of the returning ant is at the end of its home vector. Given that this home vector is associated with some uncertainty as to the direction and to the distance at which the nest is to be found, the probability of finding the nest can be assumed to be distributed like a three-dimensional Gaussian around the end-point of the home vector (Fig. 8B). The probability would be highest close to that point and fall off with distance from it. At the beginning, then, search should be concentrated at that location, a process that decreases the probability that the nest is there and consequently increases the probability that it is located further away from the start-location of the search. As search loops increase, the probability of finding the nest further out decreases and the probability at the start-location becomes relatively higher again. The ant should thus repeatedly revisit this central location. An alternative to this strategy would be to search along a path spiraling out from the estimated nest location. However, if the perceptual horizon of an ant is limited, she is in danger of missing the nest and continuing on a spiral path would not allow her to correct that mistake. Interestingly, in ants which run off only part of their home vector, the subsequent search is not centred on the beginning of search,

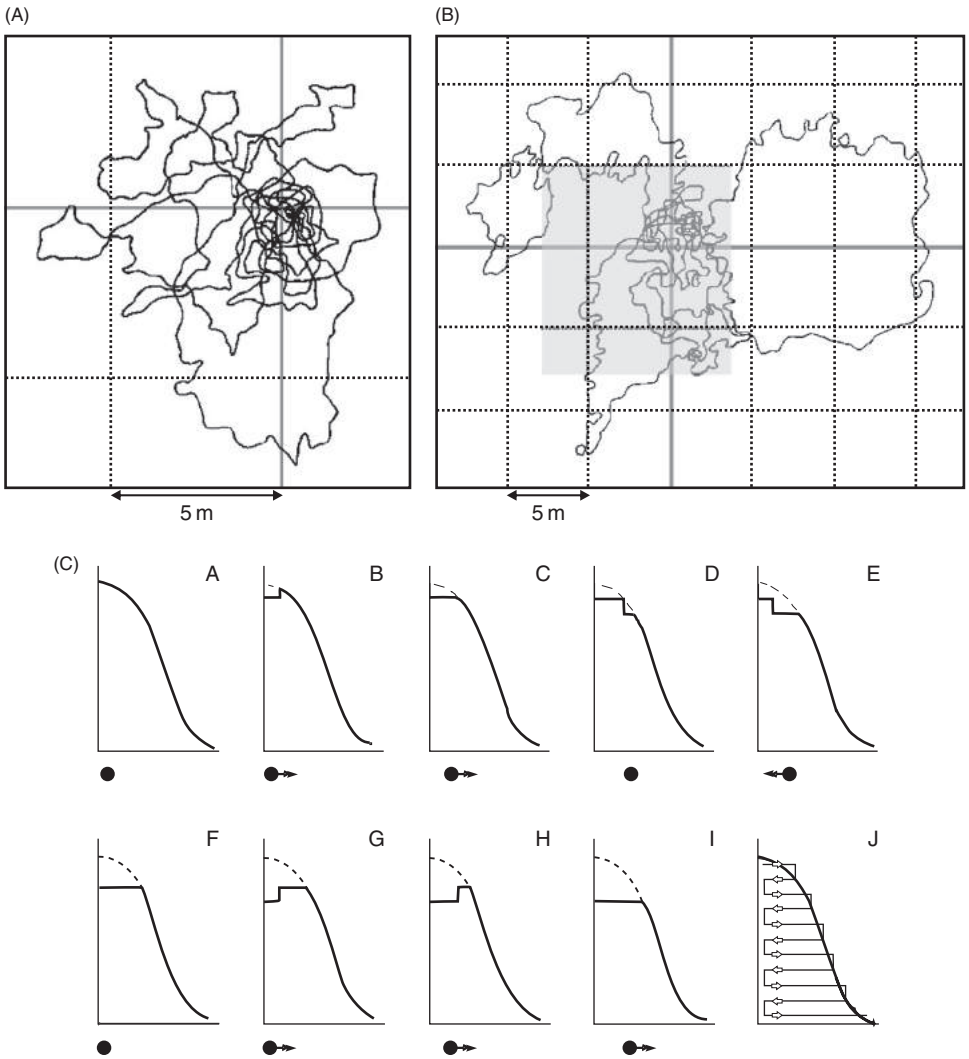

Fig. 8 Systematic search in desert ants. (A) and (B) The one hour long search path of a desert ant that had been displaced before running off its home vector (see Fig. 2B). The initial half hour path is shown in (A) and the subsequent path in (B). Note the different scales. The area shown in (A) is marked *gray* in (B). The ant searches in ever increasing loops, centred on the expected nest position at the intersection of the thick *gray* lines. (C) This systematic search pattern can be explained by considering that it is driven by the instantaneous probability distribution of finding the nest at the end of the home vector. The diagram shows the right part of a transect through a three-dimensional Gaussian distribution. Search is first concentrated at the centre of the distribution close to the end of the home vector (A) and consequently, the probability of finding the nest decreases there which causes more distant parts of the distribution to become relatively higher (B). If search loops lead the searching agent further away from the centre of the distribution, the probability of finding the nest decreases at these more peripheral parts of the distribution (D and E), leading to a relative increase of probability at the centre of the distribution, which attracts the searching agent back. Modified from Wehner, R. and Srinivasan, M.V. (1981). Searching behaviour of desert ants, genus *Cataglyphis* (Formicidae, Hymenoptera). *Journal of Comparative Physiology* **142**, 315–338.

but leads further and further away in the direction of the home vector. Such biased search movements are thus still informed by the direction of the home vector and reflect the probability of finding the nest in this direction, but with ever increasing uncertainty about both the distance and the direction at which it could be found relative to the beginning of search.

In contrast to situations—like the one described above—where animals have some information on the location of targets, many foraging situations are different: prey or food items are often randomly distributed and their location may be hard to predict. In such a case, random, rather than systematic, search strategies are being employed and have indeed been shown to be optimal for detecting randomly and sparsely distributed targets. The efficiency of random search movements is optimal, when the probability distribution of straight path lengths (between changes in movement direction) follows an inverse square power-law distribution. The foraging movements of so diverse animals as amoebas, bees, deer and wandering albatrosses, have all the characteristics of such optimized random search movements. They can also help animals to find favorable conditions—like places with preferred temperature or moisture—that are extended in space. In such cases, random search movements are modified by environmental cues, which for instance, trigger a decrease in the speed of movement and an increase in the size of turns whenever conditions become favorable. Both behavioral modifications tend to keep an animal within the range of favorable conditions.

The question of how animals orient in the world and what cues they have available to do so in an organized and systematic fashion can thus only be answered by understanding the specific ecology of information processing in each particular case. There are some universal constraints, like the ones imposed on vision, by its closed-feedback nature, and like the ones that are imposed by the physical properties of the world, like in the case of cues providing robust compass information, but how much a given animal is confronted with such constraints depends on the particular habitat of an animal, its style of locomotion, its active space and the tasks it has to solve. For most animals, we still know surprisingly little about these crucial aspects of their lives.

Parental Care

Per T Smiseth, University of Edinburgh, Edinburgh, United Kingdom

Glossary

Conflict resolution The outcome of familial conflict given how different family members influence the allocation of resources from parents to offspring.
Direct fitness The impact of an individual's actions on its own personal fitness. The benefits of parental care are assigned to the offspring's direct fitness whilst costs are assigned to the parent's direct fitness.
Forms of care Variation in how parents care for their offspring, ranging from the allocation of additional nutrients into the eggs to care for their offspring after they have become adults.
Indirect fitness The impact of an individual's actions on the fitness of a relative weighted by the coefficient of relatedness between them. Thus, the indirect benefit of care to the parent is found by multiplying the offspring's direct fitness by the coefficient of relatedness (usually 0.5), whilst the indirect cost of care to the offspring is found by multiplying the parent's direct fitness cost by the coefficient of relatedness.
Interference competition The negative effect that the density of competitors has on the amount of resources obtained by a focal individual.
Parental care Any parental trait that enhances the fitness of a parent's offspring and that seems likely to have originated and/or to be currently maintained for this function.
Patterns of care Variation in which parent provides care for the offspring, ranging from uniparental female and uniparental male care to biparental care.
Scramble competition Competition for access to shares of resources in a situation where the resource is accessible to all competitors.

Introduction

In virtually all birds and mammals, parents provide highly elaborate forms of care that enhance the offspring's fitness by neutralizing environmental hazards that otherwise are detrimental to offspring, including predation, cannibalistism by conspecifics, starvation, desiccation, extreme temperatures, and anoxia. For example, most songbirds build nests that conceal offspring from predators and protect them from extreme temperatures, place the nest in a safe habitat, incubate the eggs to supply a source of heat for the developing embryos, provision food to the nestlings after hatching, ensure nest sanitation to reduce the parasite burden, and ward off potential nest predators. Likewise, marsupial and eutherian mammals first nourish the developing embryo via a placenta, and then protect the young from predators and supply it with food in the form of milk after birth. In taxa outside the birds and mammals, parents often provide no care beyond supplying eggs with a small amount of nutrients. Yet, some reptiles, amphibians, fishes and invertebrates have evolved forms of post-fertilization care that match those of birds and mammals in terms of complexity. For example, females of the bromeliad crab *Metopaulias depressus* remove leaf litter and deposit snail shells into bromeliad pools to neutralize the low pH levels and boost the levels of calcium carbonate, defend the larvae from predators, and provision their larvae with food in the form of snails. Other species have evolved relatively simple forms of care, such as the treehopper *Publilia concava*, where females attend the eggs until hatching, thereby protecting them from ants and other egg predators.

The study of parental care and its evolution is a central topic in behavioral ecology (Clutton-Brock, 1991; Royle et al., 2012). As illustrated by the above examples, parental care is extremely diverse, varying both between and within species with respect to its form, magnitude and duration, as well as the extent to which it is provided by the female, the male, or both parents. Thus, an important aim in behavioral ecology is to understand the evolutionary origin and subsequent maintenance of this diversity in light of the benefits to the offspring and the costs to the parents. The costs and benefits of care may depend upon factors such as ecological conditions, life histories and mating systems (Clutton-Brock, 1991). Behavioral ecologists also take an interest in parental care because it often is associated with the emergence of family groups composed of one or two parents caring for one or several offspring. An important aim in behavioral ecology is to understand the mechanisms that mediate the resolution of conflict between family members over the allocation of parental care (Godfray, 1995; Mock and Parker, 1997).

Understanding the conditions promoting diversity in parental care is also of interest to behavioral ecologists because its evolution is closely linked with that of other important traits. For example, the emerging interest in parental care from the 1970s onwards was stimulated by Trivers's (1972) seminal paper in which he argued that the greater involvement in parental care by females makes them a limited resource to males, thereby leading to intense sexual selection in males. Although recent work has questioned this argument, the link between parental care and sexual selection remains an important topic in behavioral ecology (Kokko and Jennions, 2008). Furthermore, parental care plays an essential role in social evolution by providing a stepping stone from an ancestral solitary condition towards the advanced forms of eusociality seen in social insects, such as ants and bees. Thus, the study of parental care is fundamental to our understanding of the evolution of reproductive behaviors and complex sociality.

In this chapter, I start by providing a brief overview of the key terms used in the study of parental care and its evolution. I then describe diversity in how parents provide care for their offspring, and diversity in the extent to which female and male parents are involved in parental care for the offspring. Finally, I provide an overview of different forms of conflicts between family members over parental care and the mechanisms mediating the resolution of these conflicts.

What Is Parental Care?

Like any other field in behavioral ecology, the study of parental care and its evolution requires a clear terminology that facilitates comparisons between studies and translation between theoretical and empirical work. Unfortunately, the terminology in this field is described as 'diffuse and misleading' (Clutton-Brock, 1991), involving similar terms with distinct definitions in the literature. Furthermore, many terms have alternative definitions, and to make matters worse, the same definitions are sometimes applied to different terms (Smiseth et al., 2012). It is beyond the scope of this chapter to discuss the terminology in any great detail (for further details, see Clutton-Brock, 1991; Smiseth et al., 2012). Nevertheless, any student of parental care should be aware of the potential confusion caused by inconsistent use of terminology, and this section provides a brief overview of the six basic terms used in this field (Table 1).

The main distinction is between purely descriptive terms and terms used for the costs of care to parents. The use of three descriptive terms seems excessive but is a legacy of the history of the field. The terms *parental care* and *parental behavior* derive from behavioral ecology, and represent what Clutton-Brock (1991) referred to as 'broad-sense' and 'narrow-sense' definitions of parental care, respectively. The term *parental care* corresponds to the broad-sense definition and can be defined as any parental trait that enhances the fitness of a parent's offspring and that is likely to have evolved for this function (Table 1). Meanwhile, the term *parental behavior* corresponds to Clutton-Brock's narrow-sense definition that focuses specifically on behavioral traits. The term *parental effect* (or more specifically *maternal* or *paternal effect*) is defined as the causal effect of the parents phenotype on the offspring's phenotype over and above the effects of genes inherited from the parents. This term derives from quantitative genetics but is used increasingly by behavioral ecologists, often to describe prenatal influences of parents on their offspring. Adaptive parental effects can be divided

Table 1 Definition of different terms used in the study of parental care and its evolution (from Smiseth et al., 2012, with permission from Oxford University Press)

Term	*Definition*	*Currency*
Parental care	Any parental trait that enhances the fitness of a parent's offspring and that seems likely to have originated and/or to be currently maintained for this function	None (descriptive)
Parental behavior	Any parental behavior that seems likely to enhance the fitness of a parent's offspring	None (descriptive)
Parental effect (or maternal effect)	The causal effect of the parent's phenotype on the offspring's phenotype over and above direct effects due to genes inherited from the parent	None (descriptive)
Parental expenditure	Any expenditure of parental resources (including time and energy) on parental care of one or more offspring	Time and energy; benefits to offspring and costs to parents
Parental investment	Any investment by the parent in an individual offspring that increases the offspring's survival and reproductive success at the cost to the parent's ability to invest in other current or future offspring	Fitness; costs due to enhancing fitness of an individual offspring
Parent effort	The combined fitness costs that the parent incurs due to the production and care of all offspring in a given biologically relevant period, such as a breeding attempt	Fitness; combined costs due to production and care of offspring

between those that enhance the offspring's fitness and those that enhance the parent's fitness. Thus, the term parental effect is even more general than the term parental care as it includes both adaptive and non-adaptive parental effects and parental effects that may enhance or reduce offspring fitness.

The three remaining terms listed in Table 1 focus on the costs of care to parents and these differ with respect to the currency that is used to measure these costs. The term *parental expenditure* is used mainly by empiricists and quantifies costs in terms of the amount of time or energy spent on providing care. This term is also relevant for measuring the benefits of care to the offspring, which depend on the absolute amount of care provided by the parents. In contrast, *parental investment* and *parental effort* are important theoretical terms used in mathematical models. These two terms measure the fitness costs of care and differ with respect to whether these costs are measured in terms of enhancing the fitness of an individual offspring (parental investment) or producing and caring for all offspring in a given reproductive episode (parental effort). For example, models for how parents respond to their offspring's begging behavior are based on the term parental investment (Godfray, 1991). Unfortunately, it is often extremely difficult to measure fitness costs of parental care in the field because this requires information on levels of parental care and the future survival and reproduction of individual parents and their offspring.

There is an important distinction between energy and time costs and fitness costs. Given that it is challenging to estimate fitness costs in the field, it might be tempting for empiricists to use measures of parental expenditure as a proxy for parental investment or parental effort. Unfortunately, this practice is problematic because parental expenditure is measured in absolute terms (the amount of energy or time), while parental investment or parental effort should be measured in relative terms (the proportion of the total resource budget that is allocated to parental care). Given that the total resource budget is usually unknown for any species, it is not possible to estimate relative measures of costs from information of absolute measures of parental expenditure. This issue is particularly problematic when individuals differ with respect to parental quality or provide care under different ecological conditions. When this is the case, good quality parents, or parents providing care under benign conditions, may provide more care in absolute terms (i.e., expend more energy or time), yet pay a smaller cost in relative terms (i.e., allocate a smaller proportion of the total resource budget to care). In summary, readers are advised to be aware of the potential issues arising from the inconsistent use of terminology in this field.

Forms of Care

There is a great amount of diversity across animals with respect to how parents care for their offspring (Smiseth et al., 2012). The most basic, and presumably most widespread, form of care is for females to allocate additional nutrients into the eggs beyond what is required for successful fertilization. For example, females of the seed beetle *Stator limbatus* adjust egg size to match the environmental conditions as a means to enhance the larvae's survival after hatching. At the other extreme end, parents of some species provide care even after their offspring have reached adulthood. This form of care is extremely rare, but occurs in bonobos, where females support their adult male offspring during competitive interactions with rival males, thereby enhancing their son's social status and mating success. Between these two extremes, there are many other ways by which parents may enhance offspring fitness (Table 2). The precise ways by which parents enhance offspring fitness are often taxon-specific, and different schemes are often used to describe diversity in parental care in different taxa. Table 2 provides a general description of 11 basic forms of care observed across different animal taxa that are arranged in chronological order throughout the offspring's development (Smiseth et al., 2012).

Little is known about why different taxa or species have evolved specific forms of care. Potentially, this might reflect differences in the ecological conditions of a particular species and the specific hazards faced by the offspring. For example, selection might favor different forms of parental care when offspring are at a high of risk of predation versus a high risk of starvation. Furthermore, the evolution of different forms of care in different species may also reflect differences in life histories and the presence of pre-existing traits that selection can modify into parental care (Smiseth et al., 2012). For example, the risk of predation may only favor parental care if parents are capable of defending their offspring against predators and may originate from behaviors used by males or females to guard a territory or a partner. In some species, including most birds and mammals as well as some amphibians, fishes, arthropods and other invertebrates, parents provide elaborate and complex forms of care comprised of multiple components (see examples above). Relatively little is known about how such elaborate forms of care originate, but presumably they arise from relatively simple ancestral forms of care. For example, once egg attendance has evolved, it might evolve into offspring attendance by simply delaying the time of parental desertion, and additional components of care, such as food provisioning, might evolve once offspring attendance has evolved.

Patterns of Care

The extent to which females and males contribute towards parental care after laying or birth varies both between and within higher animal taxa (Maynard Smith, 1977; Kokko and Jennions, 2008). As a general rule, females tend to be more involved in care than males. For example, in the vast majority of mammals, females provide food in the form of milk and defend the young against predators after birth, while males make no contribution whatsoever. Likewise, in those arthropods that have some form of care for eggs or young, it is usually only the female that provides care. However, there are exceptions to this pattern. First, male-only care for

Table 2 Overview of different forms of parental care with examples (for further details, see Smiseth et al., 2012)

Form of care	*Description*	*Examples*
Provisioning of gametes	Deposition of energy and nutrients into eggs beyond the minimum required for successful fertilization. May include male nuptial gifts	Egg size in arthropods and birds enhances offspring growth and survival
Oviposition-site selection	Non-random choice of egg-laying site, including nest-site selection in nest-building animals. Excluding cases where oviposition-site selection increases female's own fitness	In the mosquito *Culiseta longiareolata*, females avoid ovipositing eggs in pool that contain larval predators
Nest building and burrowing	Concealment of eggs beneath substrate, building nest or burrowing in soil or excavating in wood. Nests may be built from materials found in environment (e.g., mud, plant material), processed plant material (e.g., paper) or materials produced parents (e.g., silk, mucus)	Many birds have a complex nest architecture where the outer layer conceals nest from predators and protects against wind and rain, while the inner layer insulates against extreme temperatures
Egg attendance	Remaining with the eggs at a fixed location, usually the oviposition site. Often associated with behaviors directed towards specific threats, such as egg guarding (directed at predators or oophagic conspecifics), egg fanning (to prevent hypoxia), egg cleaning (directed at fungal pathogens)	In the harvestman *Iporangaia pustulosa*, male egg attendance increases egg survival
Egg brooding	Carrying eggs after laying either externally (e.g., parent's back) or internally (e.g., specialized pouches or parent's mouth)	Male giant waterbugs carry eggs on their backs. In marsupial frogs of the genus *Gastrotheca*, females carry eggs within specialized brood pouches
Ovoviviparity and viviparity	Retention of eggs with the female reproductive tract, either (ovoviviparity) or until after hatching (viviparity). Viviparity may be associated with matrotrophy, where the embryo is provisioned with nutrients from sources other than yolk	Viviparity has evolved repeatedly in several invertebrate phyla as well as in fishes and squamate reptiles
Offspring attendance	Remaining with the young after hatching at a fixed location or escorting the offspring as they move around. Often associated with behaviors directed towards specific threats such as guarding (predators), and antimicrobial secretions (microbial pathogens)	The benefit of offspring attendance is demonstrated in a parental removal experiment in the lace bug *Gargaphia solani*
Offspring brooding	Carrying offspring after hatching or birth either externally (e.g., on the parent's back) or internally (e.g., in specialized pouches or parent's mouth)	Brooding of offspring in the female's stomach in gastric-brooding frogs
Food provisioning	Provisioning of food after hatching or birth. Mass provisioning occurs where food is provided before hatching, while progressive provisioning occurs where parents repeatedly provide food after hatching or birth. Progressive provisioning may be based on food found in the environment (e.g., arthropods) or specialized food produced by parents (e.g., milk, trophic eggs). Most extreme version is matriphagy, where hatched offspring consume their parent	In the caecilian *Boulengerula taitanus*, larvae feed on modified skin produced by female. In the freshwater leech *Helebdella stagnalis*, females provision food for their young
Care after nutritional independence	Assisting offspring after nutritional independence	In American red squirrels, offspring may inherit a cache of cones from their female parent
Care for mature offspring	Assisting offspring after sexual maturity	In bonobos, female parents assist mature sons during competitive interactions with rival males

eggs is relatively common among both fishes and amphibians. For example, in sticklebacks, males provide care by building nests and fanning the eggs to supply additional oxygen, and in African bullfrogs, males dig channels to adjacent pools to prevent the pool with their tadpoles from drying out. Second, both parents cooperate to provide care for their joint offspring in the vast majority of bird species. On top of these broad patterns, there is also variation in male and female involvement in care within each taxon. Thus, although patterns of care show a strong phylogenetic signal, they can undergo evolutionary change under the appropriate conditions.

Uniparental Female or Male Care

Why is it that in those species where only one parent provides care after laying or birth, this is usually the female? The fundamental difference between the two sexes is the difference in gametes size, termed anisogamy: females produce the larger gametes (eggs) while males produce the smaller ones (sperm). Thus, one potential explanation for the predominance of female-only care is that it is somehow a consequence of anisogamy. For example, Trivers (1972) argued that females should be under selection to provide additional care after birth to safeguard their higher initial investment into the zygote. However, this argument is logically flawed as it suggests that parents base decisions on current investment on their past investment; this sort of argument is known as the 'Concorde fallacy'. Instead, we should expect selection to favor parents that base their decisions on how much to invest in their offspring on the expected future returns on that investment. A formal theoretical model by Kokko and Jennions (2008) suggests that anisogamy alone is not sufficient to promote the evolution of sex role divergence and uniparental female care. The reason for this is that female-

only care leads to a male-biased operational sex ratio (OSR), which in turn promotes the evolution of male care because it becomes more difficult for males to find a mate. In this model, anisogamy alone is associated with the evolution of egalitarian sex roles and biparental care (see below). However, a more recent model by Fromhage and Jennions (2016) suggests that biparental care is evolutionarily stable only when there are synergistic effects due to both sexes being involved in care (see below), and that it otherwise will be replaced by uniparental female or male care due to genetic drift or small differences in the costs or benefits of care.

Why then is female-only care more common than male-only care? The theoretical model by Kokko and Jennions (2008) suggests that uniparental female care is favored only when there is strong sperm competition and/or strong sexual selection acting on males. The reason for this is that sperm competition reduces the coefficient of relatedness between male parents and the offspring in a given brood, thereby lowering the benefits of care to males. Meanwhile, strong sexual selection causes disparity in reproductive success among males, with successful males not providing care because they have more to gain from attracting additional mates and unsuccessful males not providing care because they have failed to sire any offspring. The more recent model by Fromhage and Jennions (2016) also predicts that strong sperm competition and/or strong sexual selection on males will favor female-only care. However, this model shows that anisogamy might lead to female-only care due to positive feedback between parental care and sexual selection. If the greater initial investment in the gamete by females is associated with greater investment among males in competition for mates, then the associated increase in mortality among males makes parental care more costly to males, thereby generating positive feedback between parental care and competition for mates.

Why does male-only care evolve in some taxa? As uniparental male care is much more rare than uniparental female care, the conditions under which male care is favored have attracted considerable attention from empiricists. As stated above, males may have lower benefits of care due to sperm competition and higher costs of care due to the trade-off between care and attraction of additional mates (Kokko and Jennions, 2008; Fromhage and Jennions, 2016). The evolution of male parental care may therefore be associated with the evolution of paternity assurance traits, such as mate guarding and frequent copulation, ensuring that the benefits of care may be almost as high for males as for females (Trivers, 1972). For example, in the ferocious water bug, *Abedus herberti*, males achieve a very high paternity for the eggs oviposited on their back by copulating frequently with the female. Furthermore, male care may evolve in species where caring males can continue to attract additional mates, thereby removing the trade-off between parental care and acquisition of additional mates (Kokko and Jennions, 2008; Fromhage and Jennions, 2016). In some species, caring males continue attracting additional females and there is even evidence that parental care may enhance the future mating opportunities of males due to their increased attractiveness to females. When this is the case, higher levels of male care might even be favored through sexual selection.

Biparental Care

Biparental care, which occurs when males and females cooperate to care for their joint offspring, is a rare pattern of care in most animal taxa (Royle et al., 2012). The exception is birds, where biparental care is found in about 90% of all species. Biparental care is rare because it is evolutionary stable under restricted conditions. First, for biparental care to evolve, two parents must improve offspring fitness beyond uniparental female or male care (Maynard Smith, 1977). Mate removal experiments on a wide range of species show two parents often can improve offspring fitness beyond uniparental care, suggesting that his condition is often met (Clutton-Brock, 1991; Harrison et al., 2009). Second, as suggested by a recent theoretical model, biparental care may only be evolutionarily stable if there are synergistic effects between male and female involvement in care (Fromhage and Jennions, 2016). Such synergy effects might occur when the two parents provide different forms of care that complement each other such that two parents are more than twice as efficient in providing care as a single parent. This condition is far more restrictive than the first one, and it may provide an explanation for why males and females often have distinct parental roles. Finally, biparental care is associated with sexual conflict between the two parents over the amount of care that each should provide, and the evolutionary stability of biparental care may depend critically on how this conflict is resolved (see Sexual Conflict below).

Conflict and Competition over Care

Parental care can be considered a form of altruism where the parent increases the fitness of its offspring at a cost to its own personal fitness. Given the overlapping interest in ensuring offspring recruitment into the population, we expect a high degree of cooperation among family members. Nevertheless, as with any other form of altruism and cooperation, parental care will be associated with conflict. Conflict in this context is defined as the divergence in the optimal levels of care between family members, and may not necessarily be expressed as behavioral squabbles or fights (Godfray, 1995; Mock and Parker, 1997). Familial conflict emerges as an inevitable consequence of two conditions: (1) a limited supply of resources, typically food provided by the parents, and (2) a relatedness asymmetry between family members. Relatedness asymmetries describe the probability that a focal individual shares a gene with another family member, which is usually determined by the coefficient of relatedness between them ($0 \leq r \leq 1$). For example, the probability that an individual shares a particular gene copy found in a focal offspring is obviously 1.0 for the focal offspring itself whilst it is 0.5 for its parents or its full siblings.

The nature of the conflicts that take place within a particular family group is contingent on its social structure, which in turn depends on whether it is comprised of one or two parents caring for one or multiple offspring. For example, when both parents care for multiple offspring, there may be three social dimensions of familial conflict (Mock and Parker, 1997; Fig. 1): (1) parent-

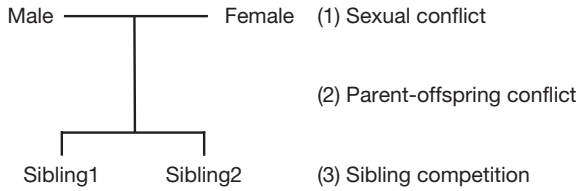

Fig. 1 Schematic diagram of the three different social dimensions of familial conflict: sexual conflict, parent-offspring conflict and sibling competition. All three social dimension of conflict are present in more complex family structures where both parents care for multiple offspring, whilst some social dimensions are absent from simpler family structures. For example, there is no sexual conflict if only one parent provides care and no sibling competition if there is a single offspring in the brood (redrawn from Mock, D. W. and Parker, G. A. (1997). *The evolution of sibling rivalry.* Oxford, UK: Oxford University Press).

offspring conflict; (2) sibling competition; and (3) sexual conflict. However, some of these social dimensions will be absent from simpler family structures. For example, there is no sexual conflict if only one parent provides care and no sibling competition if there is a single offspring in the brood.

Parent-Offspring Conflict

The first social dimension of familial conflict is parent-offspring conflict (Trivers, 1974). Trivers's theory of parent-offspring conflict introduced a major paradigm shift in how we think about the evolution of social interactions within families. Prior to Trivers, it was implicitly assumed that parent-offspring interactions were cooperative. Trivers showed that parents and offspring have overlapping but divergent interests with respect to the allocation of parental care. Fig. 2 illustrates parent-offspring conflict where the direct benefits of care are assigned to the offspring's fitness and the direct costs of care are assigned to the parent's fitness (Smiseth et al., 2012). Using kin selection theory, we can derive the indirect benefits to the parent and the indirect costs to the offspring by multiplying the direct benefits and costs by the relatedness coefficient ($r = 0.5$). Once we have the indirect benefit and indirect cost functions, we can identify the optimal levels of care to the parent (p_i^*) and its offspring (o_i^*). The conflict battleground is represented by the divergence in parental and offspring optima. The offspring's optimum exceeds the parent's optimum, suggesting that offspring are under selection to demand more resources than the parent is under selection to provide.

Trivers's theory of parent-offspring conflict met with initial criticism on the grounds that the theory was logically flawed (see Godfray, 1995). First, it was argued that any benefit gained as a more demanding offspring would be offset by a cost when producing demanding offspring as an adult. Second, it was argued that parents always win as they can control the allocation of resources. This criticism played an important role in the subsequent development of the field as it helped separate two key issues: (1) whether there is a conflict battleground and (2), if there is, how the conflict is resolved (Godfray, 1995). Theoretical models of the conflict battleground have shown that parent-offspring conflict can evolve when the perspective is shifted from that of an individual to that of a gene. Genes for conflicting behaviors in the offspring can spread in the population as long as they outcompete alternative non-conflicting alleles. Meanwhile, theoretical models for the resolution of parent-offspring conflict have shown that costly offspring begging behaviors can serve as a mechanism for resolving this conflict (Godfray, 1991). In the absence of any costs of begging, offspring are under selection to exaggerate their needs to acquire additional resources. However, such manipulative begging is not evolutionarily stable given that parents should ignore purely selfish offspring behaviors. In contrast, begging would be evolutionarily stable if offspring incur a cost from begging. Under such circumstances, the cost punishes offspring that misrepresent their true needs, and parents benefit from monitoring the offspring's begging behavior because they obtain honest information on their offspring's nutritional condition (Godfray, 1991).

The emergence of resolution models that made testable predictions stimulated empirical research on offspring begging in birds and other taxa. These studies find that, as predicted by theory (Godfray, 1991), begging reflects the offspring's nutritional state, and parents respond to offspring begging by adjusting their allocation of food (Kilner and Johnstone, 1997). There is also empirical evidence that offspring begging is costly in terms of attracting predators or slowing down growth or development (Kilner and Johnstone, 1997). Perhaps surprisingly, there is little empirical evidence for a conflict battleground, presumably reflecting that it is difficult to obtain empirical data on the shape of the benefit and cost functions of parental care that are needed to derive the parental and offspring optima (Fig. 2).

Sibling Competition

The second social dimension of conflict is sibling competition, defined as any offspring trait that promotes the fitness (survival or growth) of an individual offspring at the expense of the fitness of its siblings (Mock and Parker, 1997). Given that sibling competition occurs among close relatives, an important aim is to identify conditions that favor or constrain the evolution of selfish behavior towards close kin. Although relatedness constrains selfishness, sibling competition can evolve as long as there is a mismatch between the supply of resources from the parents and the total demand for resources by the offspring (Mock and Parker, 1997). Such a mismatch occurs because parents tend to overproduce offspring at the beginning of the breeding attempt (Mock and

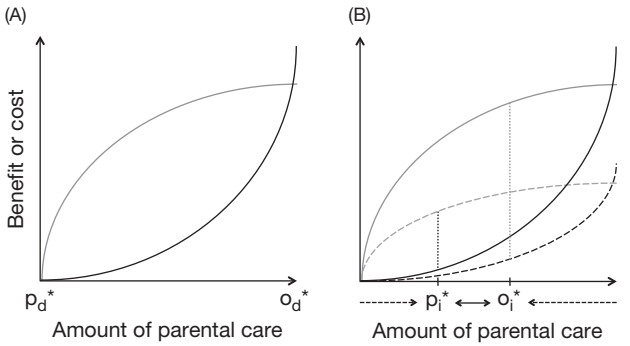

Fig. 2 Illustration of parent-offspring conflict, defined as the divergence between the optimal level of care for a parent and its offspring. The benefit of care to the offspring is assumed to increase at a decelerating rate, whilst the cost of care to the parent is assumed to increase at an accelerating rate. (A) The direct optima to the parent and the offspring when assigning the cost of care to the parent's fitness and the benefit of care to the offspring's fitness. The direct optima to the parent and the offspring, represented as P_d^* and O_d^*, are at the extreme ends (no care and maximum care, respectively). (B) The indirect optima to the parent and the offspring after assigning indirect benefits of care to the parent and the indirect costs of care to the offspring. The indirect benefits and costs can be found by multiplying the direct benefits and costs with the coefficient of relatedness between the parent and the offspring. The indirect optima to the parent and offspring are represented as P_i^* and O_i^*, respectively. The shift in the indirect optima illustrates that relatedness moderates conflict (dashed horizontal arrow), whilst the divergence in the indirect optima shows there nevertheless is a potential for conflict between close relatives (solid horizontal arrow).

Parker, 1997). Overproduction of offspring may be adaptive from the parents' point of view as it allows them to take advantage of favorable environmental conditions or to have an insurance against hatching failure of eggs and early mortality of hatchlings.

Sibling competition is common in species where parents provision their offspring with food, which may seem paradoxical given that parental food provisioning evolves to enhance the offspring's access to food and that there should be less sibling competition when there is better access to food. Parental care may nevertheless promote sibling competition because it is associated with interference among competing offspring. For example, in the burying beetle *Nicrophorus vespilloides*, larvae obtain food either by self-feeding directly from the carcass upon which they breed or by begging for food from the parent. In this species, there is interference when offspring compete by begging but not they compete by self-feeding. Sibling competition for parental resources can take many different forms, ranging from non-lethal scramble competition to lethal aggressive brood reduction (Mock and Parker, 1997). Diversity in the form of sibling competition may be driven by the extent to which an individual offspring can monopolize resources, which in turn is contingent on the size of resources, the existence of potential weaponry such as powerful beaks, and the presence of competitive asymmetries within the brood (Mock and Parker, 1997).

Theoretical models treat begging as a form of non-lethal scramble competition (Parker et al., 2002). However, unlike the honest signaling models of begging discussed above (Godfray, 1991), these models assume that it is the offspring (rather than the parents) that control the allocation of resources. Scramble competition models make the same predictions as honest signaling models; that is, begging reflects offspring nutritional state and parents respond to begging. Furthermore, scramble competition models also assume that begging is costly (Parker et al., 2002). Thus, distinguishing between honest signaling and scramble competition models of begging is a major challenge in this field. Nevertheless, there is empirical evidence that offspring adjust their begging behavior to the competitive environment in which they find themselves. For example, in many birds, individual nestlings adjust their begging behavior to the number of brood mates and/or to their competitive rank as determined by the hatching order. Thus, offspring begging is not simply a signal of the offspring's nutritional needs as suggested by honest signaling models.

A more extreme form of sibling competition is lethal aggressive brood reduction (Mock and Parker, 1997). This form of sibling competition has been studied in detail in great egrets. This species has a clutch size of 3–4 eggs, with a laying interval of 1–2 days between each egg. Females start incubation once the first egg is laid, leading to a pronounced age-based competitive hierarchy within the brood. Nestlings have powerful bills, reflecting the fish-catching lifestyle of the adults. The bills are used as weaponry during aggressive interactions between siblings. There are two types of feeding: indirect feeding where the parent deposits boluses of food on the nest floor and direct feeding where nestlings intercept boluses before they reach the nest floor. The nestlings do this by grabbing the parent's bill. The older chicks direct aggression towards their youngest chick, and the youngest chick get access to less food and have the lowest survival prospects within the brood (Fig. 3).

There is also scope for cooperation among siblings (Forbes, 2007). For example, in barn owls, siblings negotiate who is to get the next food item before the parents return with food as a means to reduce the amount of aggression within the brood. Meanwhile, in black-headed gulls, parents provide more food to the brood when nestlings synchronize their begging. Such cooperation does not preclude competition and a potential avenue for further work in this field is to investigate the balance between cooperation and competition among nestlings.

Sexual Conflict

The final social dimension of conflict is sexual conflict over parental care, which occurs because the benefits of care to the offspring depends on the combined amount of care by the two parents, while the costs of care to each parent depends on its personal

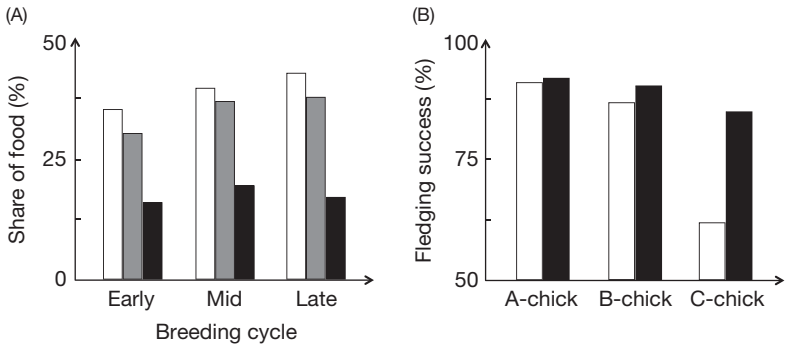

Fig. 3 Sibling competition by lethal brood reduction in the great egret. (A) The oldest A and B chicks (*white and gray bars*, respectively) receive the largest amount of food, whilst the youngest C chick (*black bars*) receives the smallest amount of food. (B) The A and B chicks have higher survival prospects, but the C chicks survival prospects improves if either the A or B chick dies first (*black bars*) (redrawn from Mock, D. W. and Parker, G. A. (1997). *The evolution of sibling rivalry*. Oxford, UK: Oxford University Press).

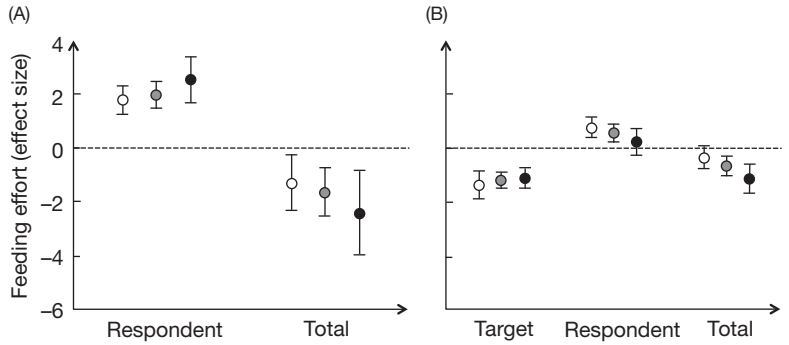

Fig. 4 A meta-analysis of published mate removal and handicapping experiments conducted on birds. (A) In removal experiments, the remaining parent (i.e., respondent) increases its level of care beyond the baseline (*dotted line*), but not such that it compensated completely for the removal of its partner (i.e., total). (B) In handicapping experiments, the handicapped parent (i.e., the target) reduces the amount of care it provides, its partner (i.e., respondent) increases the amount it provides but not such that it fully compensates for the reduction in the amount of care provided by the target (i.e., total). Females are represented by white circles, males by black circles, and both sexes by gray circles (redrawn from Harrison, F., Barta, Z., Cuthill, I. and Székely, T. (2009). How is sexual conflict over parental care resolved? A meta-analysis. *Journal of Evolutionary Biology* **22,** 1800–1812, with permission from John Wiley and Sons).

workload (Lessells, 2012). Owing to sexual conflict, each parent is under selection to reduce its own contribution and shift as much of the workload as possible over to its partner. Potentially, sexual conflict may undermine the evolutionary stability of biparental care and an important aim in behavioral ecology is therefore to identify mechanisms that allow biparental care to remain evolutionary stable despite sexual conflict.

Theoretical models suggest that sexual conflict over parental care can be resolved by three behavioral mechanisms: negotiation, matching and sealed-bid decisions (Lessells, 2012). Negotiation and matching occur when each parent adjusts its level of care in direct response to its partner's contribution. When there is negotiation, the focal parent responds to a reduction in amount of care provided by its partner by increasing its contribution, though only such that it compensates incompletely for the partner's reduction. In contrast, when there is matching, the focal parent responds by matching any increase or reduction in its partner's contribution. Finally, sealed-bid decisions occur when each parent makes an initial fixed decision about how much care to provide and that decision is independent of that of its partner. Experimental studies on birds and other taxa provide some support of all three mechanisms (Lessells, 2012). However, a meta-analysis of studies on birds found overall support for negotiation (Harrison et al., 2009; Fig. 4).

Less attention has been given to other mechanisms contributing towards the resolution of sexual conflict. For example, given that females control the production of eggs, females could potentially manipulate the behavior of caring males by adjusting clutch size, asynchronous hatching or maternal effects. Female manipulation is the outcome of any mechanism used by the female to influence the amount of care provided by her male partner in a way that increases the female's and/or offspring's fitness at the expense of the male's fitness (Paquet and Smiseth, 2016). Female birds deposit androgens such as testosterone in the eggs, thereby stimulating offspring begging, and this might provide females with a mechanism for increasing the male's contribution towards food provisioning. Currently, there is limited evidence that yolks androgens serve such a function, but further work is needed on the role of other mechanisms.

Familial Conflicts and their Resolution

An important aim in the study of familial conflict is to understand the mechanisms that mediate the resolution of such conflicts. This section highlights that each social dimension of conflict is associated with a specific mechanism of conflict resolution: (1) parent-offspring conflict with communication and honest signaling (Godfray, 1991, 1995); (2) sibling competition with scramble competition or aggression (Mock and Parker, 1997); and (3) sexual conflict with negotiation (Harrison et al., 2009; Lessells, 2012). Traditionally, the resolution of each conflict has been studied in isolation from each other. However, conflict resolution at one social dimension will impact on conflict resolution at other social dimensions. For example, the resolution of sexual conflict may determine the supply of food to the brood, which in turn may alter the level of sibling competition. Thus, an important future challenge is to understand interactions between conflict resolutions at different social dimension of conflict.

Acknowledgements

I thank past and present members of the burying beetle group at the University of Edinburgh and students attending the Evolution of Parental Care course at the University of Edinburgh for helping me develop my thoughts on parental care.

Sexual Selection and Sexual Conflict

Ulrika Candolin, University of Helsinki, Helsinki, Finland

Glossary

Effective population size, N_e The number of individuals in a population that contribute offspring to the next generation.

Mating system Describes the manner in which males and females associate during mating in an attempt to maximize their lifetime reproductive success. Animal mating systems are categorized according to the number of mates a given sex is able to monopolize (monogamy, polygamy, and promiscuity). Such categorizations can be based on social bonds (social mating system) or on genetic paternity and maternity of the resultant offspring (genetic mating system).

Operational sex ratio (OSR) The average ratio of fertilizable females to sexually active males at any given time.

Potential reproductive rate (PRR) The number of offspring that an individual can produce per unit time if unconstrained by mate availability. The rate is usually higher in males than females, as these produce many tiny sperm while females invest in larger ova and—more often than males—in time consuming parental care.

Sexually antagonistic co-evolution (SAC) A conflict between the evolutionary interests of the sexes that cause one sex to evolve traits that reduce the ability of the opposite sex to reproduce with other partners. The opposite sex can then evolve defense mechanisms against the manipulation, resulting in an "arms race." This can escalate and reduce female fecundity and, hence, population growth rate.

Transgenerational epigenetic effects Heritable alterations of gene expression without a change to the DNA sequence. Include DNA methylation, chromatin remodeling, histone modification, and non-coding RNA mechanisms.

Introduction

Many species possess conspicuous traits that appear to confer no advantage in the struggle for survival, such as colorful plumes and feathers, melodic songs, loud calls, and exaggerated structures like horns and antlers. The selection pressure behind these traits is usually sexual selection; in the competition for mates and fertilizations, organisms have evolved a variety of traits that increase either their attractiveness to the opposite sex, or their success in the competition among rivals for access to mates and fertilizations. How these traits evolve and why has intrigued scientists for decades and grown into a vivid field of research. In particular, the question of why females prefer males with cumbersome traits, which obviously reduce the probability of survival—the peacock's train being a classic example—has been difficult to solve and subjected to much research.

The foundation of the theory of sexual selection was laid by Charles Darwin. He realized that the competition for mates can result in traits that are of no advantage in the struggle for survival, but evolve because of the advantage they convey over rivals in the competition for mates. Since then, the field of sexual selection has grown rapidly and provided detailed knowledge of how and why sexual selection operates. The consequences of sexual selection for populations, on the other hand, are still poorly known and in need of more research.

In this article, I go through the mechanisms behind sexual selection—how and why does sexual selection operate—as well as the consequences of sexual selection for populations. I discuss both the benefits and costs of sexual selection, as well as the question of whether sexual selection enhances or depresses population viability. An inevitable part of sexual selection is a conflict of interest between the sexes, as the evolutionary interest of genetically different individuals always differ. This conflict can result in the evolution of traits that are beneficial to the individual but detrimental to the population. It can, hence, play a fundamental role in determining the effect of sexual selection on populations.

The Mechanisms of Sexual Selection

Intra- and Intersexual Selection

Sexual selection favors the evolution of traits that increase success in the competition for mates and fertilizations, i.e., of sexually selected traits. These traits can vary from flamboyant ornaments that attract the opposite sex, such as the peacock's train, to weapons used to combat rivals, such as the antlers of deer.

Sexual selection operates through two main pathways, intra- and intersexual selection. Intrasexual selection occurs when competition among members of the same sex for mates and fertilizations favors the evolution of traits that provide an advantage in this competition, like large antlers in male deer that are used in male–male competition for access to females. Intersexual selection occurs when members of one sex choose mates of the other sex based on some traits. When the preferences for these traits

 doi:10.1016/B978-0-12-409548-9.10886-3

are favored by selection, then the preferred traits may evolve and become exaggerated, like the train of the peacock (although strictly speaking intersexual selection is also competition within the sexes, but competition for being chosen and making the best choice). In most species, males are more competitive and females more choosy, but some degree of competitiveness and choosiness can occur in both sexes.

Pre- and Postcopulatory Sexual Selection

Sexual selection can be further divided into pre- and postcopulatory sexual selection. Precopulatory sexual selection takes place before mating and is the most obvious form of sexual selection. It was described already by Charles Darwin and was the focus of early sexual selection research. Postcopulatory sexual selection takes place after mating and received little attention until the publication of an influential paper by Geoff Parker in 1970 on sperm competition (Parker, 1970). Since then the field of postcopulatory sexual selection has grown rapidly and is today a highly active research field.

Precopulatory sexual selection can take many forms. It can be the competition for resources that are then used to attract mates —such as large territories—or the competition for direct access to mates—such as physical fights over mates, or ritualized displays of dominance. Similarly, mate choice can take many forms. It can be based on preferences for particular traits in the opposite sex—such as colorful ornaments—or take the form of resistance against mating attempts. The latter is common in species where the potential reproductive rate of males is much higher than that of females and males therefore attempt to copulate with unwilling females. A high potential reproductive rate reduces the cost of each mating attempt, which makes males less choosy.

Postcopulatory sexual selection includes sperm competition and cryptic female choice (Birkhead and Pizzari, 2002). Sperm competition arises when many males mate with a female, either because the female chooses to mate with multiple males or because multiple males overcome female resistance to mate (male harassment). It can favor the evolution of male traits that increase fertilization success, such as mate guarding, copulatory plugs that prevent female re-mating, or seminal proteins that influence female physiology. For instance, males of the fruit fly (*Drosophila melanogaster*) inseminate females with sperm that are embedded in a cocktail of seminal substances, which stimulate ovulation, deactivate sperm that are already stored in the reproductive tract of the female, and act as an anti-aphrodisiac, discouraging females from participating in future copulations (Chapman, 2001).

Cryptic female choice occurs when females have some control over which males' sperm fertilize the ova. It is "cryptic" in the sense that the choice takes place hidden within the reproductive tract of the female. Cryptic female choice is less investigated than sperm competition, and its prevalence is poorly known. An indication of the occurrence of cryptic female choice is complex female sperm storage organs that rapidly co-evolve with sperm and ejaculate traits. Cryptic choice has been documented in species such as fruit flies, stalk-eyed flies and feral fowls. Female feral fowls (*Gallus gallus domesticus*), for instance, have organs that can expel the ejaculates of lower-ranking males and, in so doing, increase the insemination success of higher ranking males (Pizzari and Birkhead, 2000; **Fig. 1**).

The Strength of Sexual Selection

The strength of sexual selection on traits used in mate competition and mate choice depends on the fitness costs and benefits of these traits. A common cost that constrains sexual selection is the expenditure of a limited pool of resources on competition and choice, as this reduces the availability of resources for other fitness enhancing traits. For instance, the allocation of time, energy and nutrients to mate competition and mate choice can reduce the amount available for feeding and growth. Other common costs are increased risk of predation and parasite infections. Mate searching, in particular, that increases activity can raise encounter rate with

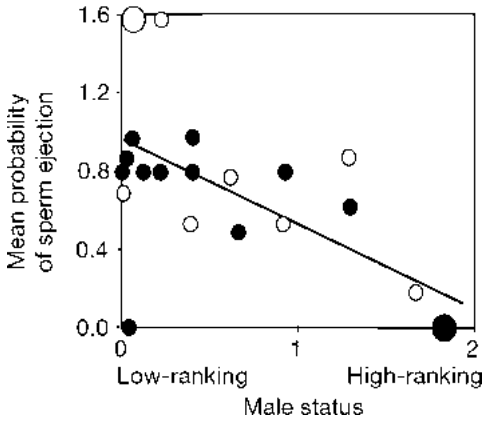

Fig. 1 An example of cryptic female choice; to increase the probability of ova being fertilized by sperm of high quality males, females feral fowls eject the sperm of low ranking males. Small data points represent one male, large data points, two males. Different colors refer to different years. Small data points represent one male, large datapoints, two males. Reproduced from Pizzari, T., & Birkhead, T. R. (2000). Female feral fowl eject sperm of subdominant males. *Nature 405*: 787–789, with permission from Elsevier.

predators or parasites, while ornaments and courtship behaviors can make individuals more conspicuous to these. An example is threespine stickleback males, who use a conspicuous red nuptial coloration to attract females and repel competing males, which increases their risk of predation from piscivorous fishes (Johnson and Candolin, 2017; **Fig. 2**).

The benefit of competition and mate choice, which favors the evolution of sexually selected traits, is improved fertilization success in relation to other individuals in the population. This benefit has to be larger than the costs, i.e., it has to increase lifetime fitness in terms of number of copies of the individual's genes that are transferred to subsequent generations. Relative mating success—not absolute mating success—is central, as relative success influences the representation of the genes of the individual in the next generation.

These costs and benefits of sexually selected traits depend in turn on a range of factors, both environmental and intrinsic to the individual. These are variation among individuals in the fitness benefits they can offer (if the variation is small, the benefit of mate choice is also small); mate encounter rate, which determines the possibility of choice; the operational sex ratio, which influences the strength of competition for mates; and life-history traits, such as number of lifetime reproductive opportunities, which in turn are determined by a range of factors, such as body condition, parental effort and age. For instance, the white plumage patches of collared flycatchers (*Ficedula albicollis*) show positive age-dependent expression, such that the size of the ornaments increases as individuals age (Evans *et al.*, 2011; **Fig. 3**). This increase in size could be a consequence of the cost of ornament expression decreasing when future reproductive opportunities decline towards the end of life, as this could allow individuals to increase their investment into the sexually selected trait as a terminal investment.

Sexual Conflict

A conflict of interest always arises when genetically different individuals attempt to maximize their fitness. This is because fitness is a relative measure, and the proportion of genes passed on to the next generation can only increase if that of other individuals decrease. In a mating context, a conflict of interest arises when the sexes have conflicting optimal fitness strategies (Arnqvist and Rowe, 2005). For instance, females may benefit if males increase their parenting effort, as this saves resources for investment into fecundity and future reproductive opportunities. Males, on the other hand, may benefit from leaving parental care to females, as this frees up time and energy for searching for new mates, to gain additional offspring. An example is males of the European starling (*Sturnus vulgaris*), who decrease their paternal effort when more nestboxes are available and the opportunity to attract additional mates is high (Smith, 1995).

Sexual conflict can be of two types: interlocus and intralocus. Interlocus sexual conflict occurs when one sex evolves traits that enhance its reproductive success at the expense of the fitness of its mating partners. The other sex may then evolve counter-adaptations, which are determined by other genes (loci), which leads to antagonistic coevolution between the sexes. For example, male fruit flies produce seminal proteins that reduce the probability that females will reproduce with other males. This has in turn induced females to evolve counteradaptations to resist their impact. Such sexually antagonistic coevolution can result in bizarre traits, such as the spines on the genitalia of male seed beetles, which harm females (Ronn *et al.*, 2007; **Fig. 4**). Other examples of traits that evolve through interlocus sexual conflict are mate guarding, physical harassment, and resistance against mating attempts.

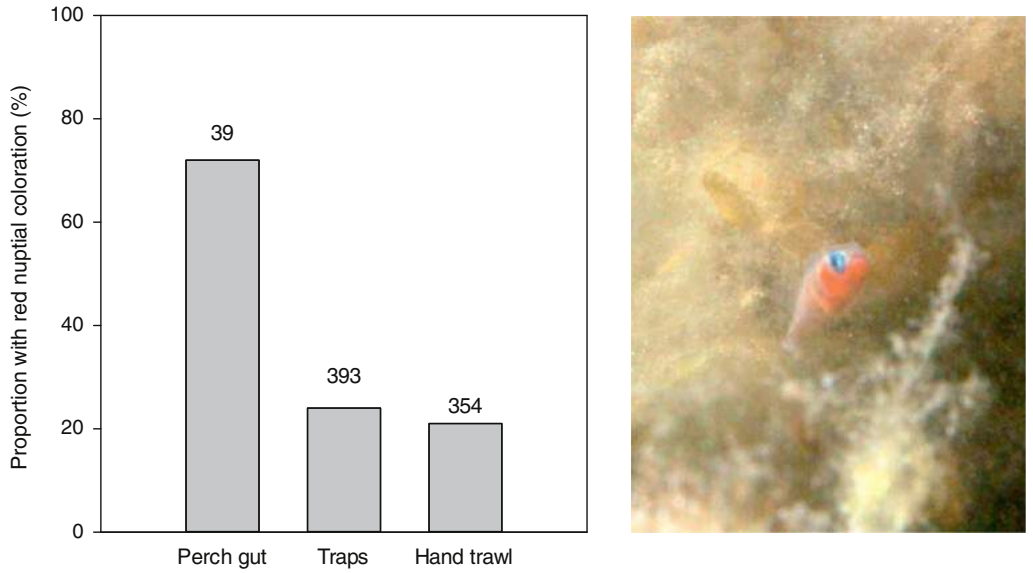

Fig. 2 The conspicuous *red* nuptial coloration of threespine stickleback males increases their predation risk. The proportion of *red* colored sticklebacks that are caught by a predator, the European perch (*Perca fluviatilis*), is higher than the proportion in the population. Reproduced from Johnson, S., & Candolin, U. (2017). Predation cost of a sexual signal in the threespine stickleback. *Behavioral Ecology*, *28*: 1160–1165, with permission from Elsevier.

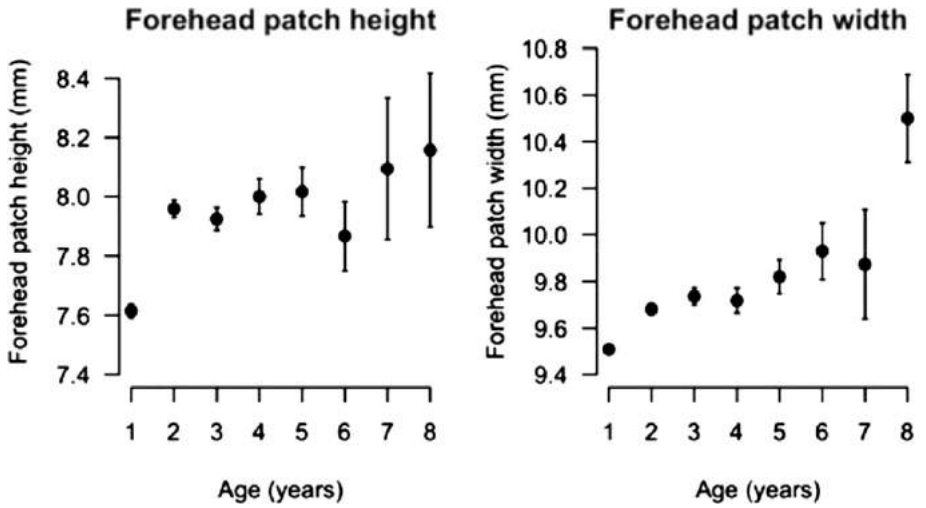

Fig. 3 The expression of a sexually selected trait, the *white* forehead patch size of the collared flycatcher, increases with age. This could be a consequence of reduced costs of expressing the trait in terms of loss of reproductive opportunities towards the end of the life, as reproductive opportunities then decrease. Reproduced from Evans, S. R., Gustafsson, L., & Sheldon, B. C. (2011). Divergent patterns of age-dependence in ornamental and reproductive traits in the collared flycatcher. *Evolution 65*: 1623–1636, with permission from Elsevier.

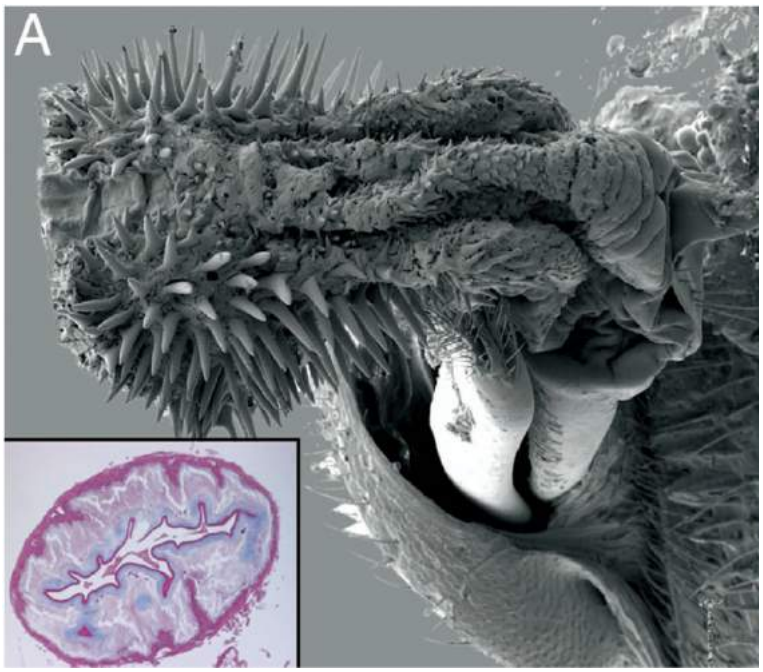

Fig. 4 Male seed beetles (*Coleoptera bruchidae*) have evolved spines on their genitalia that enhance stability during copulation, but cause harm to females. Females have in turn evolved resistance to these spines, through tougher copulatory ducts, which has led to sexually antagonistic coevolution (SAC) with males evolving more and more spines on their genitalia. Reproduced from Ronn, J., Katvala, M., & Arnqvist, G. (2007). Coevolution between harmful male genitalia and female resistance in seed beetles. *Proceedings of the National Academy of Sciences of the United States of America 104*: 10921–10925, with permission from NAS.

Intralocus sexual conflict occurs when the sexes have different optima for a trait that is expressed in both sexes and determined by the same genes, such as horn size or body coloration.

The conflict of interest is between individuals, between the male and the female attempting to reproduce. At the population level, the fitness of the sexes is equal when the sex ratio is equal, as each offspring belongs to both sexes. Thus, the variation in mating success is among individuals within each sex competing for mates. The variation is usually higher in males, as these typically have a higher potential reproductive rate, which, hence, are more competitive.

The Evolution of Sexually Selected Traits

Whether sexual selection results in the evolution of sexually selected traits depends on the strength of sexual selection, as well as on the heritability of the traits. The strength of sexual selection depends on the costs and benefits of sexually selected traits, as was discussed earlier in this article. The heritability of sexually selected traits depends in turn on the magnitude of variation among individuals in the traits, and the degree to which this variation is determined by genetic (i.e., allelic) and nongenetic mechanisms. If the variation among individuals in traits is genetically determined and in the direction of selection, then the traits may evolve through genetic changes. If, on the other hand, the variation is nongenetic and caused by phenotypic plasticity and environmental effects, then the traits might still evolve but through transgenerational effects, such as parental effects.

An increasing number of studies find nongenetic inheritance to contribute to evolution. An example is the loudness of an acoustic signal in a grasshopper (*Chorthippus biguttulus*), which is determined by the diet of the parents and, hence, inherited through parental effects (Franzke and Reinhold, 2013). The prevalence of nongenetic inheritance, and the persistence of the effects, are, however, poorly known. Transgenerational epigenetic effects (such as the methylation of DNA) might persists across many generations, as these alter gene expression, but how common epigenetic effects are in a sexual selection context, and for how many generations they can persist, are unknown.

Genetic and nongenetic inheritance may interact in influencing the evolution of sexually selected traits. This can complicate the prediction of evolutionary responses to sexual selection. Nongenetic inheritance may accelerate evolution by increasing the amount of heritable phenotypic variation that selection can act on, and by causing rapid changes in trait expression, as these may persist only from one generation to the next.

The heritability of sexually selected traits—whether genetic or nongenetic—is dependent on the magnitude of variation among individuals in the traits, as well as on correlations among the traits. Low variation and negative correlations can constrain evolution. For instance, in *Drosophila serrata*, female choice is based on male cuticular hydrocarbons (CHCs), but in populations with pleiotropic covariation among the traits, selection on several traits result in no evolutionary response (Hine *et al.*, 2014). This is probably because covariation among the traits reduces genetic variation in trait combinations in the direction of selection.

The Theory of Sexual Selection

The evolution of traits used in male–male competition for access to females is easily understood. A male that wins over other males in physical fights, or acquires a larger territory than other males, gains access to more females and have a higher mating success. The traits that ensures or correlates with this success, such as large body size or antlers, are then favored by sexual selection.

A more challenging question is the evolution of female mate preferences for traits that are harmful to survival, such as colorful ornaments that attract predators, or vigorous courtship displays that are energetically costly. This question occupied scientists during the early years of sexual selection research, and today we have a fairly good understanding of the factors that promote the evolution of female (or male) mate preferences. These mechanisms can be divided into two main groups; direct and indirect benefits of mate choice.

The direct benefits hypothesis states that females evolve preferences for traits that reflect some direct benefits of mating with the male, such as male parenting ability or fertilization success. By basing their mate choice on these traits, females improve their own reproductive success in terms of number of offspring produced. For example, females of the northern cardinal (*Cardinalis cardinalis*) use the brightness of the males' plumage to gain information on the proportion of the offspring feeding that the males would provide (Linville *et al.*, 1998; **Fig. 5**).

The indirect benefits hypothesis states that females evolve preferences for traits that reflect genetic benefits and, hence, improve offspring fitness, and thereby indirectly the fitness of the female. These models can be further divided into two groups: (1) good genes models that assume that offspring inherit genes that improve their survival, and (2) Fisherian runaway process that assumes that offspring inherit the attractiveness of their father and, hence, have a high mating success.

The Fisherian process includes self-reinforcing coevolution between the trait and the preference. Males evolve a trait that is preferred by females, and the trait and the preference then become genetically coupled. When the female preference increases in frequency in the population, exaggeration of the male trait yields an increasing advantage to the male and the trait evolves further, until the "runaway" evolution is stopped by opposing natural selection, i.e., by the costs of the trait. The degree to which Fisher's runaway process occurs in nature is poorly known, but it could commonly operate alongside other processes that drive the evolution of sexually selected traits.

Other mechanisms that can influence the evolution of mate preferences are the sensory drive mechanism and sexually antagonistic coevolution. The sensory drive model states that the presence of pre-existing sensory biases influence which traits females (or males) pay attention to and, hence, which traits will become exaggerated. For instance, females of a tropical fish—the swordtail characin (*Corynopoma riisei*)—feed on ants, which has favored the evolution of male ornaments with the shape of an ant (Kolm *et al.*, 2012). Although sensory drive can initiate the evolution of sexually selected traits and preferences, it is unlikely to drive the evolution alone. It needs to be coupled with direct or indirect benefits of choice for the sexually selected traits to persist in the population.

The sexually antagonistic coevolution model builds on the conflict of interest between the sexes, as discussed earlier. The sexes are caught in a perpetual sexual arms race where one sex attempts to overcome the resistance of the other sex, which then evolves

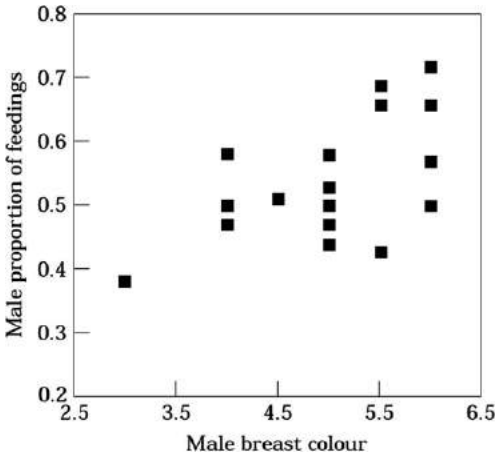

Fig. 5 The breast color of male northern cardinals reflects the proportion of the offspring feeding that the male will provide. Thus, the color can be used as an indicator of the direct benefit that the female would gain by mating with the male. Reproduced from Linville, S. U., Breitwisch, R., and Schilling, A. J. (1998). Plumage brightness as an indicator of parental care in northern cardinals. *Animal Behaviour 55*: 119–127, with permission from Elsevier.

stronger resistance, until the benefit of further escalation is outweighed by the cost. Antagonistic coevolution is assumed to operate alongside other processes and contribute to the evolution of sexually selected traits, but evidence for this is so far limited.

The Maintenance of Honesty

An intriguing question is how honest sexual signals of mate quality are ensured—i.e., what prevents individuals from deceptively increasing their signaling effort in order to attract more mates. A solution has been posed by the handicap principle; it postulates that sexually selected signals have to be costly so that poor quality individuals cannot express as costly signals as good quality individuals. This is analogous to the "big house and big cars" correlation, where individuals with much resources can invest in both, in the case of sexually selected signals, in both signals and other fitness enhancing traits. One mechanism that can ensure a positive correlation between viability and the expression of signals is condition-dependence of signals. For instance, the tail length of barn swallows (*Hirundo rustica*) indicates viability because long tails are costly in terms of energy and nutrient demands and, hence, only individuals in prime condition—who have a high viability—can sustain the cost (Møller, 1994).

Relation to Mating Systems

The strength of sexual selection is closely related to the mating system. In monogamous mating systems the number of mating opportunities is limited and the competition for mates is consequently less strong. Sexual selection is then weak and highly exaggerated traits are unlikely to evolve. In polygamous or promiscuous mating systems, on the other hand, competition for mates is stronger and exaggerated sexually selected traits are more likely to evolve. Exaggeration of male traits is particularly likely, as males usually have a higher potential mating rate than females. Male California sea lions (*Zalophus californianus*), for instance, can gather harems of 10–20 females on their territories, which results in fierce fighting among males for females. Such intense competition increases the strength of sexual selection on traits that improve success in male–male competition, such as large male size. Consequently, profound sexual size dimorphism has evolved, with males being three to four times heavier than females.

The mating strategy an animal adopts depends on the factors that determine the number of mates an individual can monopolize and fertilize, i.e., the mating skew. These factors can be demographic, social and ecological. For instance, the abundance and distributions of food can influence the number of females a male can provide for, and, hence, the intensity of competition for mates and fertilizations. Similarly, the need for male parental care can restrict the number of females a male can mate with and thereby the strength of sexual selection.

Alternative Mating Behaviors

When the competition for mates is intense, sexual selection may cause the evolution of alternative mating tactics. An individual with a low probability of gaining matings through the dominant mating tactic—such as fights or courtship—may adopt an alternative mating tactic, such as sneaking or forced copulations. For example, male guppies (*Poecilia reticulata*) that fail to gain matings through courtship may attempt forced copulations.

Such alternative tactics can be adopted throughout life, if the fertilizations success through them is higher than the success through the dominant tactic. For instance, males who are born at an unfavorable time of the year, and therefore suffer from small size throughout life, may remain as small sneaker males. On the other hand, if the males can grow in size with time, they may switch to the dominant tactic when reaching a critical size. If the lifetime fitness benefit of the two tactics is equal, then the tactics may become genetically fixed and persist throughout life, as both are then evolutionary stable.

Sexual selection can favor the adoption of an alternative tactic alongside the dominant tactic as a strategy to maximize fitness. For instance, stickleback males that have established a territory and successfully attracted females through courtship may, when given a chance, also capitalize on the courtship effort of neighboring males and sneak fertilize the eggs females lay in their nests (Candolin and Vlieger, 2013). Similarly, both males and females, of a range of species, engage in extra pair copulations in the pursuit of higher lifetime fitness. Sexual selection can then favor the evolution of traits that increases the success of such behaviors, such as a rapid switch to dull coloration when attempting to gain sneak fertilizations.

Population Consequences

The consequences that sexual selection has at the population level is debated. This is because sexual selection can both enhance and depress population viability, and whichever dominates depends on the characteristics of the species and the environmental conditions.

The good genes process predicts that populations benefit from sexual selection; individuals of high genetic quality—who are well adapted to prevailing conditions—are expected to have the highest mating success, which ensures that the population consists of individuals well suited to the environment. Similarly, the model of direct benefits of mate choice—according to which females enhance their lifetime reproductive success by being choosy—predicts that sexual selection can improve population viability as more offspring are born into the population.

The Fisherian runaway process, on the other hand, can result in reduced population viability. This is because the extravagant traits and expensive choice behaviors favored by the process can use up resources needed for population growth, or reduce survival by increasing predation or parasite infection risks. Similarly, the cost of sexual selection that ensures honest signaling of mate quality in both the good genes and the direct benefit models can reduce resources available for population growth, as well as increase mortality risk. An even more serious scenario arises when sexual conflict results in males evolving traits that harm females. These can drastically reduce female fecundity and, hence, population growth rate.

The degree to which the costs and benefits of sexually selected traits influence population viability depends on a range factors. In particular, any factor that alters female fecundity may alter population growth rate, as growth depends crucially on female fecundity. However, if only males suffer increased mortality because of the costs of sexually selected traits, and the surviving males can fertilize all females in the population, then the reproductive rate of the population need not decrease. On the contrary, increased male mortality could improve population growth rate if more resources are left to females to invest in fecundity. Similarly, if the use of resources in male–male competition has no influence on female fecundity, or the growth and survival of the offspring, then the cost of sexual selection may not reduce population growth rate. For instance, if males consume other food items, or inhabit different areas than the females and the offspring, then their use of resources may not influence population growth rate.

Antagonistic coevolution between the sexes, which results in males harming females and reducing their fecundity, can severely depress population viability. Little is known, however, about such effects in nature. Populations that suffer heavily from sexual conflict and male harm are not expected to be long-lived, as selection at the population level is expected to wipe out poorly performing populations. The frequency of harmful male traits could consequently be low in nature.

In general, the ultimate effect of sexual selection on population viability is poorly known. Sexual selection can be a strong force in driving the evolution of traits, but its influence on population viability, and the factors that determine its impact, need more investigations.

Sexual Selection and Speciation

While the influence of sexual selection on population viability and extinction risk is poorly known, its impact on hybridization and speciation is better understood. Sexual selection can be an important player in species divergence and convergence, given its power to drive changes in mate recognition traits. For example, the evolution of reproductive isolation between two frog species—*Pseudacris feriarum* and *P. nigrita*—is driven by sexual selection; by reinforcing differences in their acoustic signals and preferences—through reproductive character displacement—sexual selection acts against hybrids and promotes divergence (Lemmon and Lemmon, 2010).

Sexual selection may frequently interact with natural selection in driving species divergence or convergence. An example is sympatric species pairs of stickleback, which have diverged in parallel in both sexual and ecological trait in many lakes. Species that inhabit the benthic zone of lakes have evolved to base their mate choice mainly on body size, while species that inhabit the limnetic zone mainly use male nuptial coloration as a mate choice cue (Boughman *et al.*, 2005).

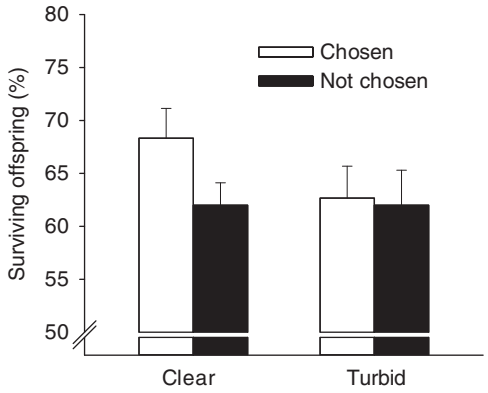

Fig. 6 Threespine stickleback females choosing between two courting males more often chose the male that sired offspring with low survival probability when the choice was made in turbid water rather than in clear water. Anthropogenic eutrophication can consequently cause maladaptive mate choices in the stickleback. Reproduced from Candolin, U., Tukiainen, I., & Bertell, E. (2016). Environmental change disrupts communication and sexual selection in a stickleback population. *Ecology 97*: 969–979, with permission from Elsevier.

Sexual Selection in Changing Environments

Environments are changing at an accelerating rate because of human activities. Whether species will be able to adjust to these changes can be influenced by sexual selection. Sexual selection can either facilitate or hinder adaptation to environmental change, depending on how it influences the number and quality of individuals reproducing in a population (Candolin and Heuschele, 2008).

If the change in the environment increases the costs of sexually selected traits, or, alternatively, decreases their benefits, then the survival or reproductive success of individuals may decrease. For instance, a shortage of food may increase the relative energetic cost of courtship activity, which can reduce survival, while a change in visibility may reduce the ability of females to evaluate ornamental traits and, hence, result in maladaptive matings. For example, female threespine stickleback that spawn in water that has become more turbid because of anthropogenic eutrophication are less able to evaluate the visual cues of males, such as their ornaments and courtship activity. This results in females increasingly spawning with males siring offspring with low survival probability (Candolin *et al.*, 2016; **Fig. 6**).

Correspondingly, if the costs of sexually selected traits decrease or their benefits increase in the altered environment, then sexual selection may improve the viability of the population. For instance, an increased variation among individuals in viability because of harsher conditions could increase the benefit of careful mate choice, which in turn could ensure that the individuals best adapted to the novel conditions have the highest reproductive success and, hence, accelerate adaptation. Moreover, if sexual selection had a negative effect on the population in the past environment, because of costs of sexually selected traits, then a relaxation of sexual selection in the altered environment could benefit the population. For instance, if antagonistic sexual selection reduced population growth rate in the past environment, a reduced ability of one of the sexes to manipulate the other sex in the altered environment could improve the growth rate of the population.

Sexual selection usually increases the mating skew, which decreases effective population size. This could increase the risk of extinction, as small populations have a higher probability of extinction than larger populations, because of higher demographic stochasticity and lower rate of adaptation. In support of this, populations introduced to island—which often involve only a few individuals—are less likely to establish themselves if sexual selection is strong rather than weak (Sorci *et al.*, 1998).

A factor that could limit the cost of sexually selected traits in altered environments, and prevent negative effects on the population, is condition-dependence of sexually selected traits. If individuals develop less exaggerated traits when conditions become harsher, then the cost could decrease and improve population viability. Currently, little is known about the impact that sexual selection has on the ability of species to adjust to rapid human-induced changes. It is clear, however, that sexual selection could play a major role given its influence on the reproductive success of individuals and their fitness.

Glossary

Direct fitness Passing on genes to the next generation by having offspring.
Eusociality Extreme sociality defined by reproductive division of labor, collective care for offspring, and overlapping generations.
Inclusive fitness The sum of an individual's direct and indirect fitness.
Indirect fitness The fitness advantage that results from helping related individuals. Because closely related individuals likely share genes, helping kin may increase the chances of passing shared genes to the next generation.
Kin selection A hypothesized evolutionary process that results in groups of closely related individuals.
Selfish herd A hypothesis devised by W.D. Hamilton in 1971, proposing that animals live in groups to gain selfish advantages, such as not being eaten, and compete for safer spatial positions within the herd.
Trait group selection A hypothesized evolutionary process that acts at the level of the group, selecting for traits that increase the fitness of all group members.

Introduction

All animals interact with others at some point in their lives. Interactions can take the form of mating, parental care, communal living, and collective care for offspring. A wide range of species, from bacteria to elephants, live most of their lives in a social group. Living in a group provides many benefits but can also incur substantial costs. Below we expand on some of the benefits and cost of living in groups and the evolutionary mechanisms that might have led to group living.

Why Live in a Group?

Groups can benefit from social living in many ways. These benefits include avoiding predators or harsh environmental conditions, obtaining large food items, building shelter, and sharing information (Fig. 1).

When living in groups, the chances of any single individual being attacked and eaten tends to be lower than if the animal was alone. This is due to the dilution effect (Fig. 2). The dilution effect refers to the decreased chance of any individual to be attacked by a predator because there are other individuals surrounding it that might become the targets of attack. In 1971, W.D. Hamilton developed the selfish herd hypothesis which states that individuals in a social group will compete for the safest location within the group. This is observed in schooling fish and herding ungulates, where the individuals in the periphery of the group are often the subordinate individuals and are at the highest risk for being attacked by prey. The more centrally located individuals hold higher dominance positions and are less likely to be attacked. The confusion effect suggests that predators attacking a group can be confused by the prey animals scattering and moving in random directions.

Along similar lines, the detection, or many eyes effect suggests that groups can detect predators faster than a single individual because when a vigilant individual spots a predator, it will communicate this information to other group members. In some species such as prairie dogs and meerkats, individuals will "take turns" in being the sentinels who alert other individuals of approaching predators while the group is foraging. Birds learn alarm calls of other species inhabiting the same community, which allows them to flee when hearing alarms produced by another species.

In addition to avoiding predation, social living can help obtain and defend resources. Social groups can locate and process food sources more easily than individuals. In primates, the search for fruiting trees relies on the knowledge of experienced group members to find trees that a single individual might not be able to detect or consume on its own before all the fruits rot. Furthermore, Ammie Kalan and others show that chimpanzees modify their calls to others depending on what food they have discovered and how big the tree is. Song birds communicate to their group both intra- and interspecifically about new food sources and novel ways to access certain foods. A classic example are the blue tits in the United Kingdom who discovered how to open milk containers and eat the fat-rich cream layer at the top of the bottle. Opened milk bottles spread across the country. The birds were watching each other and socially learning how to get the high-calorie reward.

Once a food source is obtained, groups can be better at defending their resources than individuals. Meerkat groups defend their foraging territories from neighboring groups, small song birds can mob large raptors, and social insects defend their nests (Fig. 3).

Fig. 2 Grooming: (left) a *Veromessor andrei* harvester ant grooming its nest mate. (Right) A troop of baboons in which a female is grooming a juvenile. Photos by Noa Pinter-Wollman.

Furthermore, groups can obtain resources that individuals cannot. Wild dogs hunt in packs because a single dog cannot take down a large ungulate, but a pack can. Once a large prey has been subdued, there is enough food for the entire group who can then defend their food from other animals. Social spiders attack and capture prey that a single spider could not obtain on its own, and leaf cutting ants engage in elaborate agriculture that turns leaves into fungus gardens, which are the ants' food, a process that requires extensive effort of many individuals. Ants also cooperatively carry large food items back to the colony. Fig. 4 depicts some of these social food collecting behaviors.

Living in groups can increase an individual's lifetime reproductive success. Being part of a group can ease finding a mate (Fig. 5). Cooperative breeding, that is, when group members help each other care for young, is an advantage of living in a group. Such cooperative care can allow the reproductive pair to produce more offspring throughout their lives because of the higher survival of the offspring, and because they can reproduce more often. Andy Russell and others found that in the presence of helpers, fairy wrens lay small eggs which require a smaller energetic investment than large eggs, presumably because the helpers will assist in rearing the chicks after they hatch. Laying smaller eggs increases the reproductive female's chances of surviving into the next breeding season and producing more offspring throughout her life. Communal sea birds nest in large colonies that lower the risk of predation and increase the probability of offspring maturing to adulthood. Elephants, primates, ungulates, dolphins, birds, and social arthropods, all provide examples in which group members tend and raise the young of others in their group.

In social groups, juvenile animals often disperse from their natal habitat. Such dispersal lowers the chance of inbreeding depression which results from the propagation of recessive traits which can decrease offspring viability. However, the high costs of

dispersal may keep young in their natal groups. Deborah Ciszek's work on the blind, hairless ground dwelling naked mole rat in Africa shows that dispersal is very costly. Within the nest a single reproductive female mates with one to three males, producing offspring that act as nonreproductive workers. These workers depend on the colony for thermoregulation and food, which are large

Fig. 6 Social interactions: (top) a pod of dolphins swimming together, (bottom left) a male and female African elephant (*Loxodonta africana*) interacting, (bottom right) *Pogonomyrmex barbatus* ants interacting near the entrance of their nest. Photos by Noa Pinter-Wollman.

tubers that animals reach by digging to them under ground. Dispersal is costly for these workers because they would have to excavate tunnels for protection and food searching on their own. Therefore, young tend to remain in their natal nest and help rear offspring. As a result, these mole rats are the only eusocial mammal on Earth.

Group living can be more efficient than living alone. For example, within a social insect colony, individuals are allocated to different tasks such as food gathering, taking care of offspring, and defending the nest. If individuals specialize on performing a certain task they might become efficient at performing it, similar to the division of labor in industrial factories. Dividing the labor allows individuals to become specialized on different jobs, and the group can accomplish more compared to a single individual that has to perform all the tasks. Which task is allocated to each individual can depend on their age, spatial position, needs of the colony, or morphological specialization.

When animals live in groups, certain tasks that would take a long time for a single individual are expedited. Collective shelter construction can range from a socially mating pair of birds digging out a cavity in a tree or constructing nests from twigs and grass, to hundreds or thousands of social insects constructing elaborate tunnel-chamber systems. A remarkable example of collective shelter building comes from social caterpillars, through research by Terrence Fitzgerald. Up to 200 madrone caterpillars will construct a single large nest from their own silk. This large, strong silk nest protects the caterpillars from predators and captures the warmth of the sun, providing protection from freezing temperatures. Termites are known for their enormous and complex nest structures which include a system of vents that maintain the temperature and gas composition within the nest. Dotting the African desert landscape, these structures jut out of the ground for miles. J. Scott Turner found that when the nest is damaged, termites know this immediately due to changes in carbon dioxide and humidity inside the nest. To repair the breach, workers use nest-building pheromones and vibrations to initiate nest building and repair, and immediately get to work carrying dirt in their mandibles. Without the work of many individuals, the construction of these elaborate and intricate structures would simply not be possible.

Group living allows animals to exploit potentially dangerous thermal landscapes. In large groups, animals can use collective thermoregulation to buffer brutal temperatures. Research from Caroline Gilbert and others explored huddling behavior in penguins. In the Antarctic, Emperor penguins huddle for up to 40% of their time to keep warm. The colder the temperatures became, the tighter the huddle is packed. When ambient temperatures dip to $-17^{\circ}C$, huddled penguins enjoyed temperatures as warm as $37.5^{\circ}C$. This protection from below freezing temperatures likely prevents body mass loss during blistering winters, as well as helping to successfully incubate eggs, which need an ideal temperature of $35^{\circ}C$. Honey bees are also excellent thermoregulators. Bernd Heinrich wrote extensively about his research on the honey bee's ability to maintain a constant internal hive temperature, even in subzero temperatures. During cold winter months, honey bees will form a cluster with the queen at the center, and shiver to keep warm. To ensure that everyone stays at a comfortable temperature, the workers will actually cycle through the cluster; as a bee becomes too warm in the middle, she moves toward the cooler surface, and when she is too cold, she begins to move inside again. During hot summer months, honey bees actively cool their colony by collecting water to spread on brood comb for evaporative cooling, and fanning to move hot air out of the colony, allowing cool air to move in. Chelsea Cook and Mike Breed found that honey bee fanning is an obligatory group-performed behavior; bees that are isolated will rarely fan, but they will begin to fan in small groups of just three bees. In Fig. 6, monarch butterflies cluster to keep warm during migration.

Why Not Live in a Group?

While there are many benefits to groups living, sociality also comes at a cost. When organisms live close together, they may compete over resources such as space, food, and mates. Further, a large group may help in avoiding predators, but predators may

Fig. 7 Access to mates: (top) Magellanic penguins (*Spheniscus magellanicus*) living in a colony and (bottom) Northern elephant seals (*Mirounga angustirostris*) in a rookery aggregate to gain access to mates. Photos by Noa Pinter-Wollman.

detect a group more easily than individuals, simply because of its size. If a predator can more easily detect the group, this may lead to more frequent attacks by more predators than any one individual experiences.

The increased competition for mates within a social group could decrease the chances that an individual reproduces. There could be lost breeding opportunities because of social hierarchies. Animals that fall on the lower end of the hierarchy may be beaten out of opportunities to breed. In extreme cases, individuals can become essentially sterile. In eusocial insects like ants, some wasps, and some bees, female workers rarely produce successful offspring. Even when eggs are laid, other workers actively police laying workers by eating their eggs.

Living in a group with many individuals can lead to the rapid spread of disease. This is especially true if the interactions between individuals are frequent and long lasting. Groups have developed collective methods to deal with the spread of disease. In mice, infected individuals decrease their interactions with other mice, which keeps a disease from spreading widely through the population. Bees exhibit a myriad of hygienic behaviors, including inducing a behavioral fever when sick or inspecting and discarding infected larvae. When bumble bees are infected with a conopid fly, or honeybees are infected with chalkbrood fungus or the *Nosema* microsporidian, they will regulate their temperature, essentially causing a fever for the hive that helps fight off the infection more effectively.

To decrease competition, individuals in social groups may kill other individuals. Craig Packer's work shows that female lions tend to aggregate and be more social than males who have only fleeing interactions with the females, which involve cofeeding and mating. When a new male joins the pride it may kill young cubs that were sired by another male. This infanticide causes the females to become reproductively active, as they are no longer nursing or caring for the cubs, and can then mate with the new male. If social groups remain stable and no new males join the pride, the rate of infanticide significantly drops. Competition over limiting food and water can become so intense that herbivorous insects resort to cannibalism. In migrating locusts, it was proposed by Sepidah Bazazi and others that the mass movements of hundreds of thousands of insects is initiated and perpetuated by biting behavior: when individuals get too close and touch, they begin biting each other, which forces them to move out of the way, but instead it leads to interacting more with other locusts, which leads to more biting. If movement does not happen quickly enough after being bitten, the animal may be eaten.

While there are many contraindications of being in groups, animals have adapted methods to mediate these issues. For example, to combat spreading disease, animals can groom each other (**Fig. 7**). Grooming not only solidify social bonds, it also plays a practical role of reducing potential pathogens from entering and spreading through the social group. We see grooming across animal taxa; from baboons to ants.

How Do Animal Groups Move?

One of the most striking behaviors animal groups engage in is collective movement. Moving groups include herding ungulates, schooling fish, and flocking birds. In these collectively moving groups, there is no leader, that is, no single animal is in charge of where the group is going. Marie Bourjade and other show that in herds of Przewalski horses certain individuals will prime the collective movement, but the actual decision to move is collectively agreed upon by a majority of individuals in the group. Building off of Karl von Frisch's pioneering work on the waggle dance, Tom Seeley has elucidated how honey bees choose new nest locations. In honey bee swarms looking for a new home, scouts will leave to find a suitable nesting place, then return to the swarm to signal the quality and location of the new found nests using an elaborate "waggle dance." More scouts will leave to examine the new potential nests, based on the advertised quality, and if they like it, they will return and add their "voice" to the other waggling scouts to recruit more bees to their preferred location. Once there are enough bees waggling to a particular site, that is, the swarm has reached a democratic consensus, it takes off. This is an example of quorum decision making, where a subset of individuals participates in making a decision about movement.

Individual animals within the group often base their movement decisions on very local information. This information includes what neighboring individuals are doing, for example, how far they are and in which direction they are moving, and the ecological context in which the behavior occurs. Both theoretical and empirical experiments from Iain Couzin and others show that using only local information, fish, for example, are repelled from each other only within very small distances. When the fish get farther away from each other, they attract. Speed and orientation within the group emerges from these simple rules which allow them to move away from predators without actually receiving direct information that a predator is there. While a fundamental assumption of these studies is that individuals tend to be behaviorally homogenous, it is becoming apparent that individuals vary in their behaviors and in how they respond to their neighbors. Such behavioral heterogeneity can lead to costs, for example, a group of both adults and juveniles will only be able to move at the speed of the youngest animals. In contrast, behavioral variation can expedite the response of a group to prey they capture, as seen in social spiders.

How Did Group Living Evolve?

Altruism and Cheaters

Group living requires cooperation. In some ways, however, cooperation goes against the idea of individuals working to maximize their own fitness. Altruism is defined as behaving in a way that increases the fitness of another individual at the expense of decreasing one's own fitness. Individuals who act selfishly maximize their own fitness, but groups of cooperators maximize the fitness of everyone in the group. However, in a group of cooperative individuals, selfish individuals can arise and take advantage of pro-social behavior of the altruistic individuals. The balance between altruistic individuals and cheaters is a strong force in the evolution of group living. Much theoretical work has attempted to explain why animals behave altruistically. One popular solution has been reciprocal altruism in which an individual will help another who will reciprocate and assist the helper at a different time. Interestingly there is no compelling empirical evidence for such reciprocal altruism. Other theories suggest that the cost of altruism to one's own fitness are not as great as they seem because the altruistic individual will benefit indirectly by being related to those it helps or because the group in which it lives will persist because of the altruistic behavior.

Kin Selection

Individuals can gain indirect fitness benefits by assisting with the production of closely related offspring. W.D. Hamilton hypothesized that individuals can give up their own direct fitness to enhance the fitness of another related individual. Why would animals ever forgo reproducing? When dispersal is very costly, closely related individuals will spatially cluster in groups. This means that group members share a high proportion of genes. For example, siblings share an average of 50% of their genes and offspring are 50% related to their parents. Depending on the relatedness of an individual to its group members, the costs and the benefits of assisting them, and environmental factors (such as difficulty of finding mates or a suitable territory), it may be advantageous to help parents rear one's siblings instead of dispersing and raising one's own offspring. If the genetic relatedness and the indirect benefits an individual gains when helping outweigh the costs of helping, sociality will emerge, this is known as "Hamilton's rule."

A critical component of kin selection is acting cooperatively with closely related individuals. How can one be certain that they are closely related to another individual? W.D. Hamilton proposed a hypothesis, popularized by Richard Dawkins as the "green beard" hypothesis, which postulates that individuals can perceive a shared allele through some phenotype (the hypothetical "green beard"). An empirical example of a "green beard" comes from Laurent Keller and Kenneth Ross on fire ants. In fire ant colonies, queens that are homozygous at a particular gene locus are killed by workers that are heterozygous in the same locus but heterozygous queens are allowed to live. The workers differentiate between the homozygous and heterozygous queens according to their smell, which is considered to be their "green beard."

Trait Group Selection

Trait group selection proposes that natural selection acts at the level of the group, in addition to the level of the individual. Thus, when one group does better than another, it will persist and the traits that allowed it to outperform other groups will be selected for. For example, groups that are more cooperative and collectively produce more offspring than others will outcompete groups that do not cooperate to increase the overall fitness gains. Work from Jonathan Pruitt and Charles Goodnight tests this hypothesis. In social spiders, the behavioral composition of a group is selected at the group level. The behavioral composition of a group determines its collective prey capture success and therefore the survival of the group. Certain behavioral compositions result in higher group survival in particular environments but not in others. Furthermore, groups' composition change over generations to fit the environments in which they are placed. In social animals where group living is critical for survival, group selection may have strong implications of which individuals persist through evolutionary time.

Overall, there are many levels upon which selection can act. While genetic and individual level selection are crucial, it is important to explore how group living may influence individual behavior, and how the survival of the individual depends on the survival of the group.

Applied Methods in Animal Behavior

Social behavior can be observed in both a natural setting, such as in the field, and in the lab where researchers can control for environmental influences. Scientists studying behavior have developed observational techniques that can be used in both a field and laboratory setting.

One of the foundational texts about these methods is Jeanne Altmann's 1974 paper "Observational Study of Behavior: Sampling Methods." In it, she outlines several, now common, methods by which to collect data that is suitable for both the field and the lab. One main question asked is what type of behavior is the researcher interested in studying. Importantly, care must be taken to avoid any influences the observer might have on the behavior of the animals and what Altmann calls "ad lib" sampling—where observations end up in field notes rather than structured observations that are taken at specific times, locations, situations, etc.

When designing a study of social behavior, one must establish whether the study will be based on experimental manipulations or observations.

Manipulative studies attempt to place the animal into a certain context to control the myriad of influences on the animal's behavior. These studies can take place both in the field and the lab. For example, providing primate groups with preferred food at particular locations to examine collective movement decisions; removing ant workers that engage in a certain task (such as nest maintenance or foraging) to examine task allocation processes; placing honey bees into a petri dish with a nonnestmate to evaluate aggression; and modifying the behavioral composition of social spider groups in the lab to determine how group composition influences collective behavior.

Social behavior can be studied by collecting data to characterize how the group as a whole behaves, or identifying a focal individual to keep track of during social interactions. Most sampling methods can be characterized as either a "state," or as an "event." States generally characterize the duration an animal is performing a behavior, while events are instances of behaviors. Group behaviors can be recorded as proportion of individuals performing a behavior in the group, for example, using scan sampling. Scan sampling is when the behavior of each group member is noted as an event at certain, predetermined, time intervals. Focal observations can be made when you have a single animal, while watching a group but focusing on one individual with that group, or while watching a group interact with another group. Characterizing focal individual (or individuals) behavior can be done in many ways, including counting all occurrences of one behavior, counting the order in which a behavior happens, or counting how long an animal spends performing a behavior. These simple experiments form the foundation of studying complex social behavior.

While Altmann and others provide an essential methodological framework to observing behavior, theoretical approaches have proven advantageous in developing hypotheses before and during experiments. Especially in social behavior, using mathematical models to predict how an animal will behave has given the field some of its most groundbreaking work. Here we discuss several important theoretical frameworks that contributed greatly to the study of social organization.

Theoretical Advances in Studying Social Behavior

Game theory has made a substantial impact on our understanding of social evolution. Game theory is essentially a mathematical puzzle, originally developed by economists, where during an interaction, one individual gains when another loses. The simplest model can be explored as a "zero sum" game, in which the sum of the exchange is zero (e.g., one animal benefits one food item and the other loses one food item). A popular application to animal behavior was led by George Price and John Maynard Smith who published "The Logic of Animal Conflict" in 1973, where game theory could be used to predict outcomes in animal interactions. The outcome is then translated into fitness and based on how individuals in a population will behave to enhance their fitness, the game theoretical model can help identify evolutionarily stable strategies (ESS). An ESS identifies a behavioral

strategy that will be selected by natural selection in a stable environment, Of course, environments are always changing, and therefore, ESSs are also shifting.

An example game theory test to explore cooperation is a game called the prisoner's dilemma. The thought experiment is as follows: two people are arrested for a crime. The two people cannot communicate. The police start to manipulate the criminals, stating that criminal #1 is going to give up information on criminal #2, and vice versa. The resulting potential outcomes could be:

(A) #1 gives up information on #2, but #2 keeps quiet. #2 goes to prison for 3 years, but #1 will be set free. The converse (#2 giving information but #1 staying silent, #2 goes free) is also true.

(B) If they both give up information on each other, they both go to prison for 2 years.

(C) If they both keep quiet, both will only go to prison for 1 year.

This experiment becomes especially interesting if the pair of actors in the situation know the outcome, and if they interact in similar ways over time. Examples of behaviors that can emerge from such repeated interactions include punishment from those who potentially suffered in the situation, or policing of individuals who do not cooperate, like when honey bee workers eat eggs laid by cheating sisters.

Payoff Matrix:

	Criminal #2 cooperate	*Criminal #2 defect*
Criminal #1 cooperate	Prison for 1 year	#1 Prison for 3 years #2 goes free
Criminal #1 defect	#1 goes free #2 prison for 3 years	Prison for 2 years

Optimal foraging theory is used to predict how animals will forage. The main predictors that go into optimal foraging are how much energy the food provides and how much energy the animal must use to collect the food. For example, Herring gulls will pick up mussels from the rocky coastline, fly into the air, and drop the mussels to crack the shells. Bigger mussels may yield more energy; however, the gull must then expend more energy to fly higher into the air to drop it a farther distance to crack it open. Living in a social group can make this relatively simple model more complicated. When a bumble bee is foraging, for example, is she cueing in on her own hunger, or the resources in her colony? Bumble bees use the amount of resources in the colony to make decisions about foraging versus their own satiation; if the colony needs food, a worker will collect more food, even if she has eaten recently. Social animals must collect different information and make decisions based on the balance of individual and group needs.

The organization of social groups has always fascinated and puzzled scientists. From herding antelope, schooling fish, and murmurating starlings, the ways in which animals organize themselves has been subject to many experiments. As discussed above, animal behaviorists have used the ideas of indirect and local information to explore how animals move as groups. In many complex systems, organization emerges from local behavioral rules and interactions. The study of these local rules has benefited from the use of Agent-Based-Modes (ABM). In these models, each individual is provided with a set of behavioral rules, such as which way to turn when it is a certain distance from another group member. Simulations are then run over many time steps and for various sets of parameters and situations. Comparing the simulation outputs for different parameters and with observed behaviors can guide experiments to test predictions generated by the models. For example, in an agent based model that was developed to examine local rules that lead to collective motion, Iain Cousin and colleagues in 2002 defined an attraction, repulsion, and orientation zones around a simulated agent. If another group member enters the repulsion zone of an agent, the agent will move away, if another group member enters the attraction zone, the agent will move toward the other individual, and if the other group member enters the orientation zone, the agent will orient in the same direction as its neighbor. By modifying the sizes of these zones, the researchers were able to reproduce movement patterns that can be seen in fish schools in different situations, producing predictions that can then be tested empirically. Manipulating the environment of fishes or using fish robots, whose behavior can be manipulated to test the response of school members, are some of the methods researchers can use to test the model assumptions and predictions.

In recent years, the use of social network theory has advanced substantially the way we study social behavior. A network framework allows the investigation of social interactions in the context of the group as a whole. Each individual is depicted as a node (shape) connected to other individuals with whom it interacts with an edge (line). Some network measures quantify the role of individuals, for example, how many others each individual interacts with (degree centrality), which individuals connect the most other individuals to one another (betweenness centrality), etc. Other network measures quantify medium scale structures, for example, identifying social cliques (modularity) and examining interactions with friends of friends (clustering coefficient and triads). Finally, at the group level, network measures can provide information, for example, on whether there are more connections in the group than one would expect at random (network density), or whether all group members tend to have similar interaction patterns or if some individuals tend to interact more than others (degree distribution). Social network analysis has allowed researchers to uncover what happens to the social interactions in a primate group when certain individuals are removed, revealing that older males take the role of policing (Flack *et al.*, 2006). Furthermore, a network approach has been used to identify individuals with high influence on social stability and whose removal would lead to social breakdown. Identifying such

individuals is important for preserving social structures of endangered species and when targeting individuals for vaccination, or when trying to prevent the spread of disease.

Overall, these applied theoretical methods allowed researchers to both develop and test hypotheses in social behavior.

Conclusion

Social behavior shapes individual, population, community, and ecosystem dynamics. The relationships between the benefits and costs associated with group living for each species and in any particular environment will determine whether sociality arises. There are still many open questions about why and how social behavior evolved across such a wide range of species, from bacteria to humans.

Thermoregulation in Animals: Some Fundamentals of Thermal Biology☆

Udo Gansloß**er and Gianna Jann,** Jena University, Jena, Germany and Greifswald University, Greifswald, Germany

Glossary

Allen's rule A biogeographical rule stating that, the farther away from the equator a species/subspecies occurs the fainter or lighter colored it should be.

Bergmann's rule A biogeographical rule stating that the farther from the equator a species/subspecies occurs the bigger in size it should be.

Brown adipose tissue (BAT) A specific form of storage tissue. Within cells of BAT lipids are not stored in one, large, microscopically translucent vacuole but in many small ones, which in light microscopy causes a brown stain of the endoplasma. BAT is used in nonshivering thermogenesis to produce extra heat, for example, while awaking from hibernation.

Ectothermy A physiological condition in which an organism's body temperature is not significantly different from ambient temperature. No thermoregulatory processes are employed.

Endothermy A regulatory condition in which an organism is capable of regulating its core body temperature significantly independent of external temperature.

Gloger's rule A biogeographical rule stating that the closer to the equator a species/subspecies occurs the large and more slender its body appendages (ear pinnae, tails, beaks, limbs) should be.

Heat shock proteins A family of proteins whose genes are activated by a heat shock factor. The proteins then are produced and act as molecular controllers of correct folding of other protein molecules.

Homeothermy A special case of ➔ endothermy. Homeothermous organisms regulate their body temperatures, by internal mechanisms of heat production and cooling, within a very narrow range, often within one degree centigrade.

Nonshivering thermogenesis (NST) A set of cellular/organ-physiological processes that allow heat production without muscular contraction (i.e., shivering). NST includes, among others, the action of ➔ UCPs, or the activation of ➔ BAT.

Thermoneutral zone (TNZ) A range of ambient temperatures, species/population-typical, within which range of outer temperature the organism needs the least energy in basal metabolism. If ambient temperature is below or above TNZ the animal needs more energy for basal metabolism per unit of body weight, for cooling, heat production, sweating etc.

Torpor A state of physiological inactivity to reduce energy expenditure. Can be daily (during cold nights in continental areas, or during noon heat in arid countries) or annually, for example, hibernation. Torpor can be triggered by active lowering of metabolic rate and thus body temperature or, especially in ectotherms, as a passive consequence of dropping ambient temperature.

Uncoupling proteins (UCPs) A family of proteins that, in low temperature, act on the mitochondrial membrane. They cause proton leakage and thus separate cellular dissimilatory processes from ATP synthesis, allowing extra heat production directly.

Heat exchange between animals and their environment is basically restricted to their body surface. Direction and intensity of this exchange are governed by the temperature difference between body surface and environment (the latter temperature being called ambient temperature Ta), and can be of three different types: radiation, conductancy or evaporation. Radiation is characterized by the two bodies not necessarily being in direct contact, it is being achieved simply by electromagnetic waves. Intensity of radiation in heat exchange depends on the difference between temperatures, and increases in the fourth power, thus heat radiation very rapidly increases with any small increase in temperature difference. Contrary to commonly expressed expectations radiation heat loss in animals seems not to be dependent on the color of their fur or plumage. Body color may, however influence heat gain. Conductance, contrary to radiation needs a direct contact between both bodies, and is not only dependent on the difference in temperature but also by the specific thermal conductancy constant of the tissue(s) in question. This thermal conductivity constant for most tissues is bigger than for air, but far less than for water; water has a conductivity about 23 times that of air, fat has a conductivity about 8 times that of air, and fur between 0.9 and 2.4 times that of air. In absolute terms and values for substances are expressed in J cm^{-1} s^{-1}°C^{-1}, and some values are:

Air: 0.23×10^{-3}
Fat: $1.47–2.09 \times 10^{-3}$
Epidermis: $1.59–2.09 \times 10^{-3}$

This is an update of U. Ganslosser, Thermoregulation in Animals, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 3550–3557.

 doi:10.1016/B978-0-12-409548-9.11170-4

Corium: $3.48–3.68 \times 10^{-3}$
Water: 6.28×10^{-4}

In terrestrial animals, conduction does not play a very important role for temperature exchange because it can only occur over the rather limited area of the feet or other body parts being in direct contact with the soil. This situation is totally different for aquatic animals. A specific form of conductance is called convection. This relates to temperature exchange between body surface and the immediately adjacent layer of air. The thicker this boundary layer, the less heat is transferred across it. The higher the density of this boundary layer, the larger the heat transfer. Should the boundary layer itself be in movement, then a turbulent movement leads to a higher convective coefficient than a laminar one. In general, however layers of still air (or fluid) have a much lower convective heat transfer. Thus erected plumages or furs, which lead to a still boundary layer, are almost twice as good for isolation as compressed ones.

The higher the wind speed, the thinner the boundary layer, thus the bigger the heat transfer. Heat transfer from a body surface to the environment is only possible as long as Ta is lower than the surface temperature. The only way to transfer heat from an animal into the environment under conditions of Ta being higher or similar to the temperature of the surface is by evaporation. A characteristic value for evaporative heat loss is called latent warmth. This is the amount of heat that is involved in transferring a substance from, for example, fluid to gaseous condition. Latent warmth is indirectly proportional to ambient temperature. Two examples from thermal biology: For evaporating 1 g of water at a Ta = 35 °C, you need 2413 J. An adult person normally loses about 1 L of water per 24 h via evaporation. For this, you lose about 2400 kJ of energy, which would be sufficient to freeze almost 5.8 L of boiling water! Evaporation thus is a very effective means of cooling, however water in many hot areas is a scarce resource, and behavioral adaptations to combine effective cooling and save water at the same time are much in need (see below). Most organisms are subject to changing ambient temperatures be they daily seasonal or unpredictable. Adaptation to these changes thus is one of the most important demands in physiological ecology. Basically there are two successful strategies as in other areas of physiological ecology: Conformers or regulators. Conformers in our case are organisms that have only a very limited capacity for internal heat production. They regulate their body temperature by staying in acceptable ambient temperatures. This rather limits their geographical and other ranges, but is energetically beneficial and can be kept with a reduced foraging activity. These so called ectotherms, sometimes also called poikilotherms, are typically invertebrates and so called lower vertebrates. Endotherms, on the contrary, are temperature regulators. They produce enough heat from their metabolism to keep their body temperature within a given range. This is however rather demanding on their nutritional needs, their food intake has to be 5–10-fold increased over that of ecotherms. Birds and mammals but also some reptiles, tuna fish, some insects (bees, moths) and even some flowers (Lotus, Philodendron) are endotherms. Among these, many species are indeed capable of regulating their temperature quite within a narrow range similar to humans, these are the homoiotherms. Many others, especially smaller species below 10 kg of body weight, are capable of reducing their body temperature daily, seasonally or spasmodically, in accordance with external conditions. These species are called heterotherms and shall be specifically discussed later.

In terms of temperature tolerance, eurythermal animals are those that can be active over a wide range of temperatures—many desert species are active at least between 8°C and almost 40°C.

Stenothermal species are active only over a small range of temperatures, and this also is the case for many ectothermal forms (e.g., polar fish can only exist between −2°C and +4°C, thus have a thermal tolerance of only about 6°C).

The range of temperatures at which we can find animals lies approximately between −5°C and slightly over +50°C (desert and hot springs insects reach about 48°C, hot-spring protists around 52°C). The hottest life forms may be hot springs bacteria at around 90°C.

Biochemical and Cell Biological Aspects

The so called Q10 value, the value that describes the change in reaction velocity at a temperature increase of +10°C, is normally regarded as being around 1.0, which means that an increase in 10°C would double the reaction velocity. This definitely in the case in most physical and inorganic chemical processes, however it is not necessarily true for organic chemistry or biochemistry. For biochemical (e.g., enzyme-modulated) and physiological processes Q10 often is between 2 and 3, in some cases (e.g., crustacean gill movements, thermal induction of insect diapause, or hemoglobin coagulation) for above 3.0. Another complication in this is the fact that Q10 is not independent of the temperature at which it is measured and an increase of Tb from 30 to 40°C might have a totally different value than an increase from 5 to 15°C. For an animal living over a temperature range of 30°C, this could mean differences in reaction velocities or decreases. Only very few obviously strongly selected processes in animals, such as the function of the biological clocks, seem to have Q10 around 1.0.

In species with rather narrow ranges of body temperature (endotherms and especially homeotherms), there is normally also a rather narrow "physiological comfort zone," called thermoneutral zone (TNZ). Within this range of ambient temperatures, oxygen consumption and basal metabolic rate (BMR) are lowest and curve function of metabolic parameters against ambient temperature forms a trough. Below TNZ, and above, the relationship between BMR/O_2 consumption and ambient temperature rises, mostly due to thermoregulatory processes.

Changes in biochemistry with temperature, and adaptive or regulatory processes, can be manyfold. Changes in effective concentration or activity of enzymes, for example, by phosphorylation, can lead to better activities at lower temperatures, changes

in compartmentalization of cells by mobilizing membrane—limited areas can change diffusion processes, production of cryoprotectants under hormonal control, changes of concentrations of ions altering pH, and many of these have also been found in animals such as cold-adapting insects.

These changes all can occur over a time span of already a few hours. Over a period of several days or weeks, different are found, such as an increase of mitochondrial protein content (i.e., increase of enzyme concentrations) in colder conditions or changes in isozymes. Thus in several cypriniform fish, the composition of myosin ATPase is changed by changing the light to heavy chain composition in the cold, which leads to a higher muscular activity. In trout, there are different forms of acetylcholinesterase at $+17^{\circ}$C versus $+2^{\circ}$C Tb, but at Tb of $+12^{\circ}$C both forms are present—giving these fish the possibility to migrate to both colder and warmer places. Over the long-term, evolutionary span of time, thermal stabilities of enzymes and other proteins can be altered genetically and it is often found that thermal stability is greater in eurytherms than in stenotherms. Enzymes from animals (species as well as populations) living at lower Tb seem to have a more open, less rigid, structure with fewer and weaker bonds, than these from a higher Tb!

Enzymes of animals from colder regions also have higher substrate turnover rates, and lower values for activation energy, etc. These fine-tuned biochemical changes even are found in sister species with almost identical DNA. Thus, in two species of gobiid fish (Genus *Gillichthys*) only four nucleotides may be different but isozymes can have different folding conformations.

Among the most temperature-sensitive tissues seems to be the nervous system. Neuronal functions, in terms of chemical and electrical conductivity, refractory periods etc. seem to depend strongly on temperature. Thus, action potentials, and the efficiency to create and forward them, greatly profit from increased temperature. But the optimum temperature here seems to be rather in a narrow range. Even slight increase of body temperature, for example, light fever can already cause severe impairment of neuronal functions.

Membranes in cells have a particularly high necessity to adapt to different temperatures because of their lipid structure. The proportion of short-chain and unsaturated fatty acids determines the viscosity of the biomembrane, and higher proportions of these can be found in cold-adapted animals. This even works the other way round: Lizards fed on a diet of highly polyunsaturated fatty acids afterward preferred temperatures of up to 5°C less than controls. Brain membranes of arctic fish have much higher proportions of polyunsaturated lipids and higher number unsaturated bonds per lipid chain. The activity of specific enzymes, cold desaturases, produces these changes in phenotypical adaption, and desaturase activity is increased up to 30-fold after transfer of the fish into the cold. To make matters more flexible for the animals and more confusing for the researchers, these changes are different from tissue to tissue. Biochemical changes can also help to produce body heat. In so called nonshivering thermogenesis (NST) biochemical pathways are operated that, for example, decouple the mitochondrial proton chain reaction from ATP synthesis thus leaving "only" heat as the product of catabolic metabolism. The best studied of these NST processes is in the brown body fat of mammals going into winter dormancy (see below).

An important biochemical process of temperature adaptation is mediated by "uncoupling proteins" (UCPs). Due to their action in mitochondrial synthesis, they cause proton leakage and generate heat directly. This process seems to occur in several plant species but also in birds and mammals (from bats through humans to cetaceans).

Leaving the adaptions to the cold there are also biochemical and cell biological processes to protect the animals from heat.

So called heat-shock proteins are being induced in production as soon as an animal comes into hot environment and these again are being produced at temperatures that depend on the normal range at which the population lives. In a commonly discussed model, this is started by a heat shock factor that starts to become active by trimerization and interacts with the promotor region of the heat-shock protein gene. Also, due to heat shock, ribosomes are detached from existing mRNAs, thus being available preferentially for translating the newly arriving heat-shock protein mRNA. Once heat-shock proteins are available, they seem to act as molecular chaperones controlling the correct folding of other proteins.

Inflammatory processes often are linked to increases in body temperature not only in endothermic species. Behavioral mechanisms of temperature regulation, by seeking warmer surroundings are often cooccurring with the development of inflammatory processes, allowing an increase in body temperature, hence fever. Experiments in rats do again demonstrate a high degree of variability in behavioral reactions with low doses of bacterial liposaccharides (LPS, inflammatory agents) causing warmth seeking, high doses however cold-seeking behavior. In snakes, an immunological challenge by injection of these LPS caused a change in shelter usage-corn snakes after injection of LPS spent more time in the open, instead of sheltering, compared to a control group of saline-injected conspecifics.

Physiological Adaptations and Regulatory Processes

Regulatory and Sensory Mechanisms

In order to regulate thermal conditions an animal first needs to become aware of possible thermal problems. The sensory and regulatory capabilities associated with this are best studied in mammals and reptiles. We find peripheral temperature receptors, as heat and cold sensors in the skin of an animal. These sensors are not evenly distributed. In mammals, the concentration of heat sensors is particularly high around the scrotal and inguinal area, whereas in and around the face there are mostly cold receptors. All peripheral temperature receptors studied so far are primary sensory cells. Color receptors often are branched into many small endings, with a high concentration of mitochondrial and glycogen particles. Thus we can infer a high metabolic activity.

Temperature sensors in mammals are mostly found at the boundary between corium and epidermis. Heat receptors in mammals seem mostly to be free nerve endings. Additionally to peripheral receptors there are sensors for temperature both in the central nervous system and in several other internal organs, such as the abdominal region and skeletal musculature.

Afferent nerve connections then connect sensory cells to the hypothalamus, however there are already some modifications and processing steps, at least with regard to heat receptors from the scrotal/inguinal area, within the spinal tract. In the hypothalamus we can find both thermosensitive and thermoresponsive neurons, and their input is then processed to influence both effector organs for heat dissipation or production, and to higher centers of thalamus and sensory cortex. Obviously the types of processing or reacting cells are different. Some seem to react proportionally, for example, increase firing rates proportionally to increase (or decrease) in temperatures others increase their firing rate when a certain set point is reached. Desert iguanas, for example, have set points of 36.4°C as the low set point for going into the sun again, and 41.7°C for going into shade. Whereas in normal cases, central thermoreceptors seem to take priority over the input from peripheral receptors.

In comparison to the important role of sensory and neural mechanisms the role of hormones in temperature regulation seem to be rather nonspecific, by increasing metabolic rate (e.g., thyroxine, adrenaline, or prostaglandins).

Excessive Heat, How to Cool and Conserve Energy

Heat production in endotherms is a function of basal metabolic rate (BMR) and as we know at least since the famous publications of M. Kleiber, this is dependent on a factor of body weight by the power of ¾ (or 0.75). If this were not so basal metabolic rate would directly increase proportional to the increase in body weight, then a ten ton elephant (at least some extinct species were as heavy as that) would need a skin temperature of >100°C to radiate his excessive metabolic heat, and a 1 kg rat would need 20 cm of fur length to insulate its body sufficiently.

Animals in hot areas would do well by reducing their BMR, because then metabolic heat contributes less to the amount of temperature they have to get rid of. Indeed, small desert rodents in many cases have BMR that reach barely 50%–75% of the expected values (as calculated from their body size). *Gerbillus nanus*, a small gerbil, only gets about 51%, the spiny mouse species, *Acomys russatus*, just 56% of their calculated values, for example.

Large species such as camels, are for better off in these respects. Not only are they capable of migration and other behavioral adaptations (see below), their large bodies also enable them to cope better from a physiological view point. Large bodies have relatively smaller surface areas, which means that they take up less heat from radiation. Large bodies also can store heat effectively. The larger an animal the more water (in its body fluids) does it contain, and these can store more heat. Camels, even under conditions of ad lib access to drinking water during the course of the day increase their body temperature from 36°C to about 39°C. Should they however not have enough water (thus must conserve water from evaporation), then their body temperature, over the course of the day, increases up to 41°C, and during the night they radiate heat again until their Tb is as low as 34°C. This span of 7°C helps a camel of 500 kg to conserve at least 5 L of water that would otherwise be necessary for evaporative cooling. The record in heat tolerance for large desert-living mammals is kept by Grant's gazelles, whose Tb can increase up to 46.5°C. However animals under these extreme conditions need some cooling system at least for their brains and other sensitive organs. In desert antelopes there is an effective cooling structure, a heat exchanger at the basis of their brain case. Here, the sinus cavernosus, a dilation of the nasal vene, is surrounded by an arteric rete mirabile in the Art. carotis. By means of this, "hot" blood from the heart is cooled down by cooler venous blood from the nose (where some evaporative cooling took place) before entering the temperature-sensitive brain.

Countercurrent heat exchanger are also found in ectotherms from hot environments. Thus, some desert reptiles (*Phrynosoma* spec, *Holbrookia* spec) operate heat exchanges between carotids and jugular veins while sun-basking. They only protrude their heads over the sand, and keep a temperature gradient between head and abdomen by a countercurrent system in their throat and neck areas.

Excessive secretion of saliva, and distributing it over the fur by grooming, is a widespread cooling mechanism not only in rodents but also in marsupials, for example, Red kangaroos. Nasal glands seem to contribute to evaporative cooling in Domestic dogs and probably other species of nonsweating mammals.

Heating, Isolation and Freeze Tolerance

In endothermal species the graphic curve describing relationships between heat production (or O_2 used for metabolism) and ambient temperature follows a characteristic trough form. Both with ambient temperatures below a so called lower critical temperature and above a so called higher critical temperature, O_2 consumption increases. The range of temperature between the lower and upper critical temperature values is called thermoneutral value for species or populations adapted to a certain environment.

As soon as an animal's ambient temperature falls below the lower critical point, heat has to be produced by physiological and biochemical means. One possibility we all know is shivering thermogenesis, caused by nonsynchronous contraction of skeletal muscles. The amount of heat produced by a given amount of muscular activity depends on body size, for example, 1 m V of muscular activity in a 390 g crow produces about 7.8 times as much heat than in a 14 g songbird. These differences are a consequence of the differing surface: volume ratio in larger versus smaller animals. At least in birds these phenomena are further complicated by different mechanisms of cold adaptation. On the one hand, electromyographic activity decreases with cold acclimation, on the other hand cold-adapted birds tend to have larger pectoral muscles in winter than in summer.

In mammals, there is also another mechanism of heat production called nonshivering thermogenesis (NST, see above). This biochemical decoupling of catabolic pathways from ATP production takes place under control of the sympathetic nervous system and the catechol-amines. It is particularly evident in muscles, liver and brown fat tissues. NST in small mammals often differs seasonally, and is higher in winter, especially in nonhibernating forms. Brown fat, which is characterized by having many small fat droplets per cell, and a high concentration of mitochondria, is particularly important for newborn mammals (even human beings have it perinatally) and small species. Capacity for NST is also depending on other ecological factors—desert living, and diurnal species have higher capacities than species from mesic environments or nocturnal habits.

Differences in thermal metabolism between active and resting animals are influenced by a complicated array of factors. The boundary layer is no longer undisturbed, increasing thermal conductance, wind passes over the moving body parts, more blood flows toward skin and muscles etc. Thus, there normally is no effective gain in heat production by just moving around—at least in small animals. Isolating morphological structures, such as thicker furs or plumages increasing the boundary layer, or thicker subcutaneous white fat tissue, also have to be considered, as well as regulatory changes in blood flow (triggered by hypothalamic activity, see above) toward skin and other peripheral organs. This is called regional heterothermy and it could be demonstrated in many species of temperate or cold-adapted ungulates (deer, Przewalski's horses) that this indeed, again depending on the season, significantly reduces heat loss.

Emperor penguins in Antarctic conditions also seem to be capable of changing surface blood flow, thermoimaging of penguins under clear sky demonstrated surface temperatures below ambient air temperature.

The perhaps most extreme and also most spectacular form of cold tolerance is found in ectotherms, mostly bony fish, living at or near freeze conditions in polar waters. In fact, living in very cold water can be achieved by different phenomena: we have to distinguish between animals that are freeze-tolerant (allowing the formation of ice crystals in their tissues), and those that are freeze-intolerant = freeze-avoiding—which means they can live in temperatures far below 0°C, but only if no ice is formed. Freeze-tolerant animals are mostly invertebrates (e.g., molluscs, insects), some specialized amphibians and reptiles also have this capacity. In invertebrates, this is achieved by several substances: ice-nucleating proteins control the formation of ice crystals in extracellular tissue fluid, by allowing the formation of very small icicles, whereas all the ions and soluble metabolites are concentrated intracellular. Cryoprotectant substances (sugars, polyolic alcohols) raise the osmotic concentration of body fluids, or bind to membranes to prevent ice crystals from forming there.

Freeze intolerance, on the other hand, if occurring under conditions of subzero temperatures has to be achieved by processes like supercooling. This, in animals again is achieved by adding substances, like glycerol, antifreeze proteins, and antifreeze glycoproteins, but also often by completely emptying one's gut in order to get rid of particles that could act as nucleators for ice formation. Cold-adapted invertebrates under these conditions can survive temperatures up to -60°C.

Size and Shape in Thermal Biology

As already discussed above, body surface to body volume ratios decrease with increasing body sizes. This leads to huge differences in mass-specific basal metabolic rates, 1 g tissue of a house mouse already having about a 10-fold higher BMR than 1 g tissue of a person. Also, small species consequently tend to have narrow TNZs, and increasing body size is, as Bergmann already formulated in his rule a common strategy for cold-adapted endotherms. In ectotherms, these correlations again are more complicated, because diffusional processes are much slower in the cold, thus insects, arachnids and other arthropods depending on O_2 diffusion into trachea or comparable structures can be larger in warm climate.

Another long-accepted rule of thermal biology has been formulated by Allen, also already in the 19th century: All body appendages of animals in the cold are smaller, thicker and rounder in shape than these of closely related taxa in warmer climates. Arid-adapted vertebrates often are small. This has to be discussed in connection with behavioral strategies see below. From a purely physiological point of view, a kangaroo rat (*Dipodomys* spec) would have to evaporate water of about 10% of its body weight per hour to keep its body temperature constant at a Ta of 43°C. Large and thin, sparsely furred ears (not the thickly furred ones of, e.g., a fennec), such as found in the Californian desert hares, *Lepus californicus* or *L. allerni*, which can reach up to 25% of their body surface areas, can help to radiate heat. Surprisingly on a typical day in the Californian desert sky radiation temperature is far below 20°C. As long as the hare is able to find a suitable micro-climate out of the direct sun, in the shade of a tree or other shelter, it is able by means of its "hot ears" (up to 38–40°C skin temperature have been found) to actually radiate heat back into the environment.

A comparative study of body size and degree of melanism in ant species from Africa, Australia and South America revealed similar correlations as predicted by these considerations: Species with larger body sizes were darker than smaller sized ones, color became lighter with increasing temperature but darkness again increased at the highest temperatures probably correlated to the high amount of UV-B.

Mammalian ear pinnae however, are not the only appendages allowing heat exchange. Horns, frills and antlers (be they of ungulates or dung beetles), large beaks of toucans and hornbills (*Ramphastidae*) also contribute significantly to heat flux. Hard bills, such as in ramphastids seem to have less possibility here than softer ones such as in toucans.

Torpor and Heterothermy

In temperature conformic ectotherms that are generally unable to increase their temperatures by internal means, torpor or hibernation in winter or aestivation in hot, dry summers (the latter being shown, e.g., by lungfish or desert snails), is superficially

similar to torpor in endotherms, however external energy sources are needed to end this state. In insects, a special form of arrested development called diapause, triggered by combination of hormonal, photoperiodic and nutritional factors, is a common strategy. Heterotherm animals are also characterized by changing their body temperatures and basal metabolism according to external conditions. A further distinction is often made between homeotherms that are capable of regulating their body temperatures with a very narrow range, and endotherms, species that are capable of regulating the body temperature at all, but not necessarily within a narrow range of only a few degrees centigrade.

Torpor is a condition which is characterized by a low body temperature and low BMR. In so far, it seems to be a variation of temperature conformity instead of regulation. However there is an important difference between heterothermy and ectothermy: heterotherms are capable of increasing body temperatures (mostly by increasing BMR) by their own, internal means whereas ectotherms need some external source of warmth or other energy for this waking up! Thermoregulation is never totally switched off during torpor, instead the setpoint for the onset of thermoregulatory activities is only temporarily lowered. Heterothermy has long been regarded as a primitive character of animals not yet ready for real homeothermy. It is a finely tuned adaptive strategy.

Torpor is further divided by the regularity and seasonality of its occurrence and triggering mechanisms. Long torpor, mostly in the form of hibernation, is often extended for several months and is characterized by a lowering of body temperatures under 10°C, and metabolic rate is about 5% of BMR during active phases. However even deep hibernating torpor in all species studied so far is interrupted by short periods of activity at normal body temperature, and these intervals are internally triggered.

Large mammals, such as bears, also go into torpor. However, this is only shallow torpor, with a reduction of their body temperatures by about 5°C, heart rates and metabolic rates are reduced by up to 30%. Nevertheless, hibernating bears can stay in their dens for several months, and their energy needs are covered by burning fat. Some other physiological adaptations, such as recycling urea into essential amino acids, and most probably also calcium storage and recycling, have been developed in these large carnivores as well. Large bears are not the only carnivores capable of larger torpor. Raccoons and Raccoon dogs at least in parts of their range also enter torpor for several weeks.

Short term torpor of several days or even daily torpor is much more widespread also among larger mammals: both American and European badgers have been shown to enter daily or short term torpors, with body temperatures of about 28°C. Daily or short term torpor in general reduces body temperatures to about 10–30°C, metabolic rates are reduced to values of about 30%. Most mammal species entering daily torpor are small and nocturnal such as small marsupials (dasyurids, petaurids and didelphids), mouse lemurs, hedgehogs, tenrecs, shrews, or bats. However, in almost all these taxa (except primates) we also find species exhibit deep torpor with body temperatures around 5°C and durations of 10 days to several months (marsupials: *Cercartetus nanus*, a burramyid, reaches values of 2% of its normal BMR for several weeks, European hedgehog: energy of about 4% normal rate, Tb around 5°C for at least 10 days, bats: Myotis -2°C– $+5$°C Tb, energy about 1% BMR etc.). Heterothermy among birds is different in several aspects: it mostly occurs during the night, Tb is lowered by about 5°C, it also occurs in rather large species such as Turkey vultures, but, and this is a phenomenon whose adaptive significance is still unclear, energetic demand is mostly higher than BMR! Only few species, such as some colibris, tend to reduce Tb to values below 18°C, some below 10°C, and only one species of bird, a night jar from North America, *Phalaenoptilus nuttallii*, goes into torpor for several days in consecution, and also reaches a Tb as low as 6°C. It is not yet totally clear, neither for birds nor mammals, which physiological mechanisms are responsible for reawakening. One hypothesis assumes that a combination of low blood pressure and accumulation of toxic metabolic products in the blood pressure to cleanse the blood from these waste products, another assumes a biological clock (maybe even the circadian on which is also being showed by lower body temperatures). In any case, the end of a torpor phase is achieved by active warming the velocity of which mostly depends on body size: small animals of about 10 g body weight can gain almost 1°C/min, species of about 1 kg only achieve 0.5°C/min and species over 10 kg are real slow walkers, with increases of about 0.1°C/min. This seems to be a constraint on the capability for deep torpor in large species.

Circadian and circannual changes in metabolic rates, circannual changes in body weight and weight of internal organs, changes in intestinal transport rates (especially peptide transport), and decreases of heart rate with decreasing subcutaneous (hence ambient) temperatures have been demonstrated in cold-adapted ungulates, for example, Red deer and chamois in the Alps.

Behavioral Adaptations

Social behavior can be an important component of temperature regulation. Many species hibernate or fall into torpor in larger groups, reducing the degree of heat loss and energetic demand for reheating. At least in the Alpine marmot it could be shown that, the closer related the members of such a hibernating group, the more synchronous their cyclic awakening rhythms.

Other behavioral strategies to cope with extreme temperatures depend on body size: Large species often migrate. At least in land-bound animals, such as mammals, energetic demands by locomotion are relatively lower in larger species, thus migrating mammals mostly are large ones. Swimming is the energetically easiest form of locomotion, thus seasonal migrations by aquatic vertebrates are quite common (chelonians, seals, sharks, cod…). Flying seems to be energetically the most demanding locomotion, however it is much easier to achieve high speed in flying than in walking. Gaining a certain distance for a small, flying bird thus is only about 1/10 as energetically costly than for a terrestrial mammals, thus even small birds (or bats) can migrate over long distances successfully. Smaller species of terrestrial endotherms, but also, for example, of reptiles, have different options. Many desert-living smaller mammals are totally nocturnal and it could be shown that even for rock-wallabies in northern Australia, rock clefts and crevices offer temperatures of at least xy°C lower and humidities at least yz% higher than outside. Another possibility, quite often found in

intermittent activity, retreating into burrows, rock crevices or other dark and cool places whenever one gets heated up too much. This strategy of intermittent activity bursts in an endotherm is well demonstrated by *Citellus leucurus*, a desert squirrel from the Southwestern United States. These animals use their bodies as heat-accumulators similar to camels, however, being small, they overheat much more quickly! As soon as their body temperature reaches dangerous values of around 43°C, they dash back into their burrows, or shady retreats, and closely press themselves on the ground or the walls. They rapidly lose heat by conductance thus and as soon as their body temperature return to safe values of about 38°C, within a few minutes they dash out again for the next foraging bout.

Intermittent activity bouts also are being used by desert reptiles. These animals additionally use changes in body orientation and body posture. Early in the mornings they start by directing their (mostly dark-colored) head and shoulder region toward the sun, and direct as much blood flow into these areas as possible. As soon as their blood has reached near critical temperature they turn away their body axes from the sun and later retreat into the shade. Again there are intermittent bursts of basking and seeking shade, and this helps them to keep their temperatures within acceptable ranges. Even nocturnal reptiles often have most of their activities during the first 3 h after sunset, thus also using a heat-storage strategy however in reverse to that of mammals.

Basking as a means of collecting heat from external sources is not limited to ectotherms. Hyraxes, a group of small Afrotherian mammals, living in rocky areas, also use this behavior to heat up in the mornings.

Withdrawing into a cooler, shady area beneath a tree, as being regularly seen by species in savannah areas, is the opposite, but similar type of behavioral regulatory adaptation. Australian koalas in hot conditions often hug cool trunks of large trees, hamadryas baboons sandbathe on hot days, Red kangaroos dig so called hip holes by scratching away the warm surface layer of earth, and lying down onto the then exposed cooler layers.

During sleeping periods, especially in REM sleep, thermoregulatory activities such as panting, shivering or sweating are discontinued, thus under conditions of severe heat or severe cold, most species do not fall into REM sleep at all whereas within the TNZ the amount of REM sleep significantly increases. Social mechanism such as huddling also correlate to ambient temperature. In many primate species there is an increase of social behavior, time spent socializing, and ambient temperature. Female vervet monkeys with more social partners had less hypothermia and reduced 24 h amplitudes of core body temperature.

Ontogeny of Thermal Reactions

The concept of ontogenetic niches also concerns different aspects of thermal biology. Not only the reduced body sizes of juvenile animals, but also different habitats, spending more time in shelters, or different diets can influence metabolic conditions and thus thermal biology.

Most endotherms need some time after completion of embryological development before really being able to thermoregulate. It is most obvious in species, both birds and mammals, that effective thermoregulation is achieved after some postnatal time span, particularly in species with altricial young. However, when comparing species of different degrees in precociality with respect to the onset of thermoregulation the postnatal period alone is not a good representation. Ideally we need to compare the time span between conception and onset of effective thermoregulation, because precocial species often have longer gestation periods than similar-sized altricial ones. Thus, postnatally a Virginia opossum needs about 85–95 days before achieving effective thermoregulation, a similar-sized porcupine about 3 days. However, taking into account the differences in gestation, the opossum needs 105 days from conception, the porcupine 115 days! Similar with small rodents: a gerbil takes 19 days, a spiny mouse only 7 days postnatally but taking into account gestation, the gerbil needs 39 days postconception, the spiny mouse 47 days.

It is also tempting to regard the nakedness of altricial young as a primitive character. But in reality this seems to be an effective and adaptive means to transfer heat from the parents to the offspring. And altriciality itself including the lack of effective thermoregulation, seems to be an adaptation to quick growth (channel all available resources into rapid growth!) instead of an imperfection.

Development of effective thermoregulation in precocial species also often seems to be ecologically influenced: cold-adapted birds, such as arctic ducks, or in general the young of diving-duck species, can attain effective thermoregulation very soon after hatching, species from temperate climates, or surface feeding ducks in general, achieve it at a later age.

In general, young animals have a much higher metabolic rate than would be expected simply from the Kleiber formula (see above). In fact, even in species who, as adults, do have a low metabolic rate, this value for growing young approaches the boundary curve for endothermy which means they operate at the upper limit of thermal possibilities in terms of metabolic rate. This obviously is an investment by the young, to allow high growth rates. It has been hypothesized that the switch to a high metablolic rate in juveniles, to achieve both growth and effective thermoregulation, is a taking-over of at least part of the investment into further growth from parents to offspring: In altricial young, this take-over is more gradual parents feed and huddle them much longer than in precocial species.

Ontogenetic influences, however can also be on an even longer time scale. A study on Australian *Amphibolurus* dragons revealed a significant correlation between the degree of parental basking behavior and personality (shy-bold syndrome, feeding and exploration) of offspring.

Evolutionary Considerations

This already leads to the question of phylogenetic development of thermoregulation. In order to understand this tradition, it may be helpful to look at some taxa that are somewhere in between ecto- and endothermy. Some insects, for example, large, nocturnal

moths (*Sphingidae*), bees, dragonflies or wasps, are able to regulate thoracic and in some cases also abdominal temperature. However, this endothermy is only achieved when they are active, they perform wing-movements, called shivering, decoupled from flight. Moths at least, due to their hairy scales, have values of thermal conductance similar to birds and mammals, and they can keep large differences between Ta and Tb (some North American moths can fly at a core body temperature of around 30°C at Ta = 0°C). However, these small animals cannot achieve continuous endothermy similar to same-sized vertebrates if they are not active day and night (which insects are not).

Larger species in the continuum between ecto- and endothermy are found among fish. Bluefin tuna (*Thunnus thymnus*) of 200–350 kg can uphold temperature differences of up to 20°C. In these fish, contrary to "cold- bodied" species, we find large amounts of red (=aerobic) skeletal muscles near the body core (along the vertebral column) instead of under the skin. Also a high BMR, and a countercurrent heat-exchanger in the circulatory system are further characteristics of these endothermic fish. Besides red skeletal muscles, endothermic fish also have local heat sources in stomach, gut and liver tissue. Also (again kept up by retia mirabilia = countercurrent heat exchangers) in the eyes and the brain of warm-blooded fish such as Mako sharks (*Isurus oxyrhynchus*) there is a temperature difference to the environment of >5°C. However, there are no heat generating tissues in the sharks, heads, instead warm blood from abdominal red muscles is transported directly to the eye and brain regions. In some bony fish (e.g., Swordfish, *Xiphias gladius*) contrary to sharks, eye muscles are working as local heat sources, the whole complex of heater muscles, brain and eyes is thickly isolated in fat, and temperature differences of up to 14°C can be upheld between brain and surrounding water.

There is also evidence for mechanisms of physiological and behavioral temperature control in these fish. Also some python snakes and Leatherback turtles (*Dermochelys coriacea*) are able to obtain a certain control over their body temperatures.

Thus, the question of when and why endothermy could evolve has to be approached very broadly. The adaptive value of real endothermy and effective thermoregulation could have been to allow a decrease in body size at a constant body temperature. This would not only have allowed an increase in activity, but also an increase in reproduction. However, endothermy also is costly, and thus certain preconditions had to be met before achieving it. On the biochemical level, changes in membrane permeability for ions, are discussed as necessary preconditions for increasing metabolic rates. On the organismic level, it seems plausible at least in the evolution of mammals to assume that the large (up to 250 kg) therosaurus reptiles, the ancestors of mammals, had, due to their large size, achieved a certain degree of thermal independence, and that a whole array of morphological and physiological changes (development of isolating fur, increasing efficiency of ventilation by developing a bony palate and diaphragm, etc.) then allowed the transition from large reptile (with so called inertial homeothermy, which means they simply were too large to lose enough heat for being poikilotherms) to small mammal with an active, regulatory endothermy.

Combining Strategies, Living in Extremes

Finally, some extreme habitats whose inhabitants combine several of the adaptations discussed above shall be briefly mentioned. Marine mammals, particularly those in arctic or deep-sea conditions, such as sperm whales, or elephant seals developed isolatory fat tissues of up to 50 cm in whales, at least 5–10 cm in seals, and a reduction in body surface area by shortening limbs and other appendages. Behaviorally in sperm whales it is obvious that only large, fully adult animals perform real deep dives. Mothers actively discourage their calves from following them, handing them over to a surface near babysitter instead, and in elephant seals the deepest dives are performed by the large males. Development of countercurrent heat exchangers in the fins and flukes of whales allows for a reduction of heat loss into the environment and a very high fat content in the milk (up to 70% in some arctic seals!) allows a very rapid build up of the isolating fat tissues in the young.

Living at high altitudes is another extreme condition with a lot of thermal challenges. Blood flow through the extremities in large species of high alpine (e.g., Andean) animals normally is increased to prevent tissue damage by freezing, skin temperature is higher at low Ta, metabolic rates and O_2 consumption are increased in high altitudes to uphold these regulatory mechanisms. Isolating structures (fur, fat) are well-developed, countercurrent heat exchangers exist in the limbs, and behavioral thermoregulation sets in: In Andean camelids, there are patches almost without any fur in the abdominal and inguinal regions. These areas can either be exposed to wind and air (by standing alone and with limbs stretched) or gradually covered more and more (by standing crouched, lying down with limbs folded under the belly) or finally huddling while lying down in a group. Thus, heat loss by radiance and conductance can be effectively altered according to different ambient temperatures.

Degree of ability to cope with previously unexperienced changes in climatic conditions following global warming may be one of the most important influential factors in adaptation to global warming in many species, not only from polar areas but also alpine and other montane regions.

Biodiversity Indices

Peter Fedor and Martina Zvaríková, Comenius University, Bratislava, Slovakia

Glossary

Climax The final stage of biotic succession attainable by a community in an area under the environmental conditions present at a particular time.

Holistic Emphasizing the importance of the whole and the interdependence of its parts.

Niche A role (position) that a species plays in the environment, the status of an organism within its environment which affects its survival.

Resilience A property of ecosystems to respond to disturbance by resisting damage and recovering quickly.

Resistance A property of ecosystems to remain unchanged.

Introduction

Biological diversity represents the variety of life at all possible interpretation levels, from genes and populations to the most complex ecological systems (biomes), including morphological (genotypes and phenotypes), taxonomic (usually measured as species diversity), and ecological diversity (variety of ecological interactions). Even from a spatial point of view, global variety of life (gamma diversity) is a compound of local units (alpha diversity) to some degree of their mutual similarity (beta diversity) in a general concept:

$$\gamma = \beta \cdot \alpha$$

Biodiversity is not an isolated unit. On the contrary, it forms an open permeable structure in deep conjunction with abiotic conditions (habitat), behaving as a semiautonomous network, known as an ecological system (ecosystem), with all its general features and aspects. According to the Biological Diversity Convention, biodiversity has been officially defined as the variability among living organisms from all sources, including, "inter alia," terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part. This also includes species diversity, however, within the limits between the variety of elementary genetic subsystems on the one hand, and holistic ecological supersystems on the other. Unquestionably, species diversity indices have for a long time often been used as indicators of biodiversity.

This article presents an overview of the most well-known biodiversity indices in a concept of species, as well as ecological diversity from a single species richness to the proportional distribution of species in samples and communities (Fedor and Spellerberg, 2013). Apart from the mathematical expressions which are necessary for understanding specific features, disadvantages, and potential of numerous species diversity indices, with a particular emphasis on the Shannon–Wiener and Simpson index, there is strong postulation on its consequences in applied ecology, bioindication, monitoring of ecological change, and environmental assessment.

Introduction to Biodiversity Indices

When viewing a wide variety of ecological indices, it may seem very difficult and disputable in selecting the best model for measuring biodiversity. Without any doubt, there is absolutely no universal index suitable for all theoretical or real cases in ecological research, although some of them may appear more widely used in literature. Some indices are calculated in a very simple manner (e.g., Berger–Parker index, Margalef index, Menhinick index), while others are based on complex mathematics (e.g., Brillouin index). Before any ecological evaluation, a researcher should know and identify the real performance of biodiversity indices offered within a specific situation, and this predominantly includes:

- response to changes in ecological systems (from the smallest to the most significant);
- emphasis on species richness and evenness in ecological communities;
- dependence on a sample size (especially for rare species);
- discriminability as the ability to detect differences between sites and samples; and
- frequency in ecological research (how widely the index is used in literature, for comparing results more reliably).

In the most simple and elementary method, species diversity can be expressed as a "single species richness," indicating the number of species in a sample. However, for even the most basic ecological research, this value appears quite insufficient and hardly informative, raising more questions than answers. Therefore, ecologists prefer to express species richness in its more sophisticated form as species richness indices (e.g., Margalef index, Menhinick index). For many decades, the most advanced approach, widely used in environmental assessment and monitoring ecological change, has been established on a large cohort of species diversity indices with emphasis on the distribution of species within a sample or community, expressed as relative abundance or dominance. The performance and specific features of a range of the most well-known diversity measures were summarized by Magurran in 1988, and may be adapted as shown in **Table 1**.

Although calculation of some indices may appear more or less complex and difficult in current ecological research, manual calculations have been replaced by automatic and user-friendly processing within plenty of computer statistical applications, such as SPSS, SAS, and R software. Unfortunately, users often do not know any mathematical details of the indices in order to recognize their most elementary advantages and disadvantages.

From Single Species Richness to Its Indices

Species richness represents a measure of the variety of species based simply on a count of the number of species in a particular sample, although it can be expressed more usefully as species richness pre unit area, ranging from alpha (referring to a certain site) to gamma (for an entire study area) level.

The terms "biodiversity," "species diversity," and "species richness" are sometimes used in confusing ways. In some papers, the term "species richness" is used in the title and in the text it is assumed to mean the number of species, but this may not be made clear. By way of contrast, "diversity" is sometimes used in the title, but in the text the data seem to refer to the number of species only. However, in 2003 Spellerberg and Fedor suggested that "species richness" should be used to refer to the number of species (in a given area or in a given sample) and "species diversity" should be retained for use in this context, that is, as an expression of some relation between the number of species and number of individuals. Rather than using the terms "species richness" and "species diversity" interchangeably, it is helpful to distinguish between these two terms.

Apart from a single species richness (number of species), there are various simple species richness indices based on the total number of species and the total number of individuals in a sample or site. In fact, they represent the simple measures of species richness, taking into account only the number of species and the total abundance of all specimens in a sample. One of them was successfully developed by the American ecologist Edward F. Menhinick in 1964:

$$D = \frac{S}{\sqrt{N}}$$

with S being the species richness and N being the total number of all specimens in a sample.

The Margalef index, summarized by the Spanish ecologist Ramon Margalef López in 1958, several years before Menhinick, is calculated as follows:

$$D = \frac{S-1}{lnN}$$

with S being species richness and N being the total number of all specimens in a sample. This can also be a simple measure of mean population size and using the form $(S - 1)$ gives a zero value for just one species present in a sample. The maximum appears for $S = N$.

Ramon Margalef López (1919–2004): Professor of Ecology at the University of Barcelona, Spain, one of the most reputable Spanish ecologists. His scientific work is connected with applied information theory in ecology, including mathematical models in populations, presented particularly in his books *Natural Communities* (1962), *Perspectives In Ecological Theory* (1968), *Ecology* (1974), *The Biosphere* (1980), *Limnology* (1983), and *Theory of Ecological Systems* (1991).

Table 1 Basic biodiversity measures with their specific characteristics for ecological research (particularly based on Magurran, 1988)

Species diversity	*Discriminability*	*Sample size sensitivity*	*Emphasis on*	*Calculation*	*Use in literature*
Species richness	Good	High	Richness	Simple	Very frequent
Margalef index	Good	High	Richness	Simple	Frequent
Shannon index	Moderate	Moderate	Richness	Intermediate	Very frequent
Simpson index	Moderate	Low	Dominance	Intermediate	Very frequent
Brillouin index	Moderate	Moderate	Richness	Complex	Rare
Berger–Parker index	Poor	Low	Dominance	Simple	Frequent
McIntosh U index	Good	Moderate	Richness	Intermediate	Rare

Despite their simplicity, the species richness indices are undisputedly affected by sample size, and thus the sampling effort represents the investment in obtaining study material. The greater the sampling effort, the potentially higher index value; however, the different levels of sampling effort might be difficult and, in fact, incomparable. Furthermore, species richness indices could be misleading when they fail to take abundance patterns into account. As an example, in two theoretical communities A and B, both with the same species richness (S) of only 3 species and with the same total abundance (N) of 12 specimens, there is a significant difference in their proportion, as shown in **Fig. 1**.

Despite a difference in proportion of all three species X, Y, and Z, both species richness indices will be calculated with the same values, as shown in **Table 2**.

Nevertheless, from the species richness point of view, both communities appear perfectly alike; there should definitely be supportive statements coming from calculations of advanced diversity indices.

As a real example of applying species richness indices in environmental monitoring, Olawusi-Peters and Ajibare studied shellfish (Crustacea) communities in Nigeria to evaluate the degree of human-induced impact on marine ecosystems. Although the single species richness values did not appear significant across the four study sites, the Margalef index indicated a significant difference between two of them.

Very similar results were obtained by Jorgensen et al. when, during the analysis of the subtidal communities from the Mondego Estuary (Portuguese), they revealed that the Margalef index correlated significantly with phosphate concentration levels and was capable of detecting significant differences between polluted and unpolluted areas.

Species Diversity Indices

Species diversity indices express diversity in a more sophisticated way, correlating species richness with distribution of all elements in a sample or community within their relative abundance or dominance to avoid the same values for structurally different assemblages (**Fig. 1**). Undisputedly, there are more features describing the diversity of heterospecific groups (such as a community) apart from a single species richness. Except for the most well-known indices (e.g., Shannon and Simpson index) described in more detail in the following articles, the whole cohort of biodiversity measures include some that are less frequently used but should be

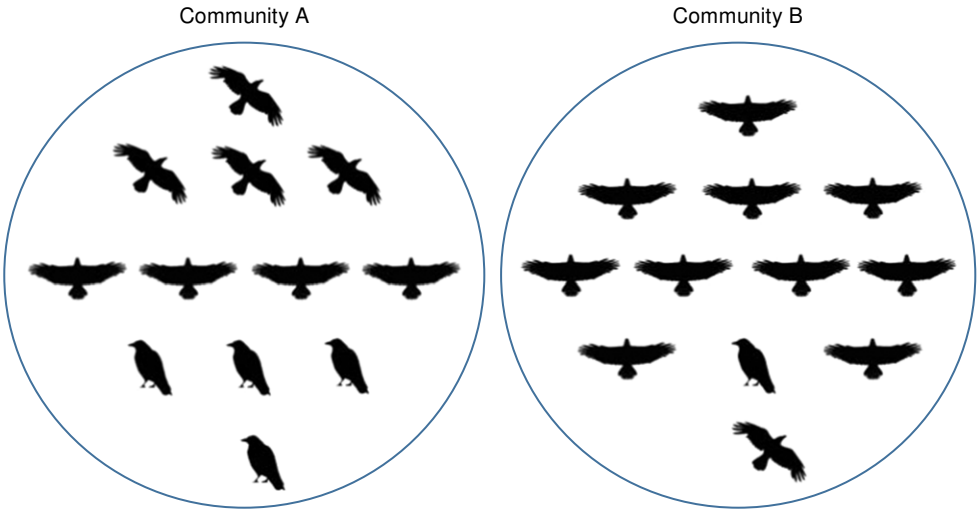

Fig. 1 Two different communities with the same species richness.

at least mentioned in the following survey.

Table 2 Structure of two different communities with the same species richness

	Community A	*Community B*
Species richness (S)	3	3
Total abundance (N)	12	12
Abundance of species X	4	10
Abundance of species Y	4	1
Abundance of species Z	4	1
Margalef's index	**0.80**	**0.80**
Menhinick's index	**0.87**	**0.87**

Fisher Alpha Index

A parametric index of diversity, with good discriminant ability and low sensitivity to the sample, assuming that the abundance of species follows the log series distribution.

$$S = \alpha \cdot ln\left(1 + \frac{N}{\alpha}\right)$$

with α being the index, S being the total number of species in the sample, and N being the total number of individuals.

Berger and Parker Dominance Index

A relatively simple index of species dominance was first introduced by Berger and Parker in their study on planktonic Foraminifera in sea sediments and later modified by Robert May as

$$d = \frac{N_{\max}}{N}$$

with $N_{\max}$ being maximum abundance among the species and N being total abundance in a sample. The lower the values of the index, the more equitable the community is.

Brillouin Index

$$H = \frac{1}{N} log_{10} \frac{N!}{N_1! \cdot N_2! \ldots N_s!}$$

with H being diversity index, N being total abundance, and N_1 being abundance of species 1…

This index has been discussed as inappropriate under certain conditions, for example, when random sampling is not guaranteed.

McIntosh *U* Index

$$D = \frac{N - U}{N - \sqrt{N}}$$

with N being total abundance and U given by the expression

$$U = \sqrt{\sum {n_i}^2}$$

where n_i is abundance of a species i.

This index has not been used in ecological research very frequently. The higher the value, the more homogenous the distribution species is in a sample.

Shannon (Shannon–Wiener) Index of Species Diversity

Claude Shannon was an expert in mathematics and electrical engineering. He undertook a great deal of research on theories of information communication. Following this research, he summarized his ideas in a technical journal. It was in this particular paper that there was a reference to his mathematical theory of communication. The main objective of this theory is to try to measure the amount of "order" (or "disorder") within a particular system. The concepts of order and disorder have long been a topic of discussion in natural history. In the 1950s and 1960s, ideas such as links between "information" and "diversity," were debated by ecologists. A commonly used index in ecology and ecological monitoring is the Shannon index (or Shannon–Wiener index). This has been derived from the Shannon function H and is expressed as follows:

$$H = -\sum_{i=1}^{n} p_i \ ln \ p_i$$

where H is the index of species diversity and p_i is the relative abundance of the ith species (n_i is the number of the ith species). For example, and with reference to **Table 2**, the diversity of the community A and B is calculated as follows:

Community A

$$H_A = -\left(\frac{4}{12} ln \frac{4}{12} + \frac{4}{12} ln \frac{4}{12} + \frac{4}{12} ln \frac{4}{12}\right) = 1.1$$

Community B

$$H_B = -\left(\frac{10}{12}ln\frac{10}{12}+\frac{1}{12}ln\frac{1}{12}+\frac{1}{12}ln\frac{1}{12}\right)=0.57$$

According to various ecological papers, any log-base is acceptable for calculations; however, *ln*-base is the most widely used and original. The Shannon function H has played a central role in information theory as a measure of information, choice, and uncertainty. This in turn led to its useful role as a measure of evenness or equitability.

There is some confusion in the literature in that the Shannon–Wiener index is sometimes mistakenly called the Shannon–Weaver index. This confusion has come about partly because Claude Shannon collaborated with the mathematician Warren Weaver on several occasions to publish papers and books, in particular the book The Mathematical Theory of Communication. Shannon first published an account of the entropy "H" in 1948. Weaver builds on this in 1949 in the second part of the above book. In his paper, Shannon acknowledges the fact that "communication theory is heavily indebted to the mathematician Norbert Wiener for much of its basic philosophy and theory," and cites several of Wiener's publications that refer to basic cybernetics. Shannon also refers to earlier work, including that of Boltzmann. In 2003, Spellerberg and Fedor suggested that the "mislabeling" of the Shannon Index "H" has come about partly because of the joint authorship of Shannon and Weaver's book, which has led to a belief that these two authors can be attributed to the index (the Shannon index is sometimes called the Shannon and Weaver index). However, the index should refer to "H" (the species diversity index) as the "Shannon index" or the "Shannon and Wiener index." Had Weaver's name been anything else and not similar to "Wiener," this confusion might not have arisen.

One of the advantages of the Shannon–Wiener index is that it is not greatly affected by sample size. One early study that examined the effects of sample size was by Wilhm and Dorris. They calculated species diversity indices from values that were pooled from successful samples. They found that sample size had a very small effect on the measures of species diversity.

Another advantage of using diversity indices such as the Shannon–Wiener index is that they capture a lot of information in one expression. This can be helpful when communicating large sets of data to a general audience. On the other hand, such expressions can appear to be very impressive only because they are derived from simple mathematics. It is essential, therefore, that anyone using such an index explains how it is calculated.

From many aspects, the Shannon index appears almost universal for general ecological use, as it behaves moderately in discriminability to detect different sites and samples with rather simple calculations and frequent use in literature. However, the measures of species diversity must be put into context. The context can be considered in two parts. One is the minimum and maximum that are theoretically possible, and the second is the range of values that could be expected in one particular ecological community. It is easy to measure the minimum and maximum for any species diversity index; the Shannon index, for instance, theoretically varies between 0 (at the lowest evenness) and lnS with S as a species richness. Similarly, it is relatively easy to assess the likely limits in any ecological community.

Claude Elwood Shannon (1916–2001): American mathematician and electrical engineer. In 1936, he worked in the Department of Electrical Engineering at the Massachusetts Institute of Technology and later spent a short time in advanced study at Princeton University. In 1941, he commenced work for the Bell Telephone laboratories in New Jersey where he spent 15 years among a well-respected scientific community. Following his research on information communication, he summarized his ideas on mathematical theory of communication in 1948 (*Bell System Technical Journal*) with the first form of the present Shannon expression as

$$H = -K\sum_{i=1}^{n} p_i \log p_i$$

where K is a positive constant. This expression has a central role in the information theory as a measure of information, choice, and uncertainty.

Norbert Wiener (1894–1964): American mathematician and philosopher, Professor of Mathematics at Massachusetts Institute of Technology. He is considered the inventor of cybernetics, inspiring future generations to develop sophisticated computer technologies.

Evenness or Equitability

The Shannon–Wiener index is particularly based on the concept of evenness or equitability. Simply put, the concept of evenness refers to the extent to which each species is represented among the sample. The extremes would range from one species being dominant and all other species being present in very low numbers (the lowest equitability close to 0), to all species being represented by equal numbers (the highest equitability of 1). For instance, in a sample of 10 species with total abundance of 100 specimens, the extreme A would be a sample with one species represented by 91 individuals and the other 9 being represented by 1 individual each. The other extreme (B) would be where each of the 10 species was each represented by 10 individuals. Equitability based on the Shannon index (E_H), assuming a value between 0 and 1, can be then calculated as

$$E_H = \frac{H}{lnS}$$

where H is the Shannon index of species diversity and S is species richness. Equitability is also known as the Pielou evenness index.

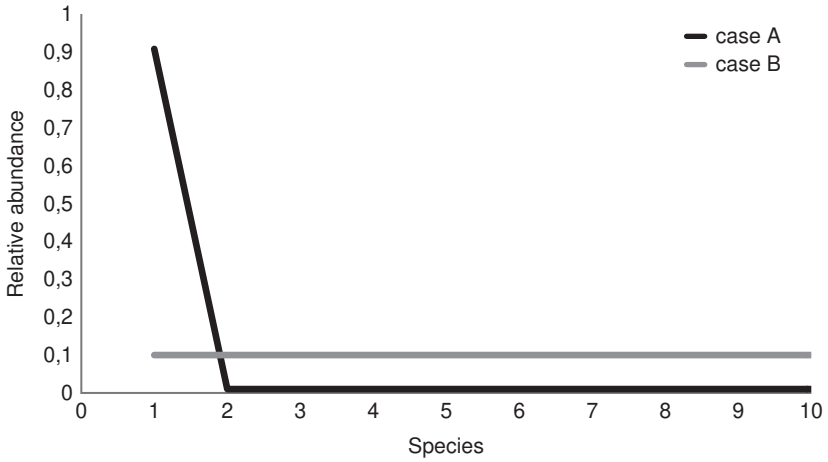

Fig. 2 Rank-abundance curves for two extreme cases A and B.

Equitability plays an important role in any ecological analysis using species diversity indices. For instance, for more equitable communities, the Shannon index becomes more sensitive to species richness.

Except for precise mathematical calculations based on the Shannon index, evenness in a studied assemblage can be expressed optically more suitable in a rank-abundance curve figuring distribution of relative species abundances (Pi) within the full array of Pi values by plotting Pi against rank. The rank-abundance diagram visually depicts species richness, as well as species evenness, with all species organized on the *X*-axis from the most to the least abundant with their relative abundances on the *Y*-axis. Species evenness is reflected within the slope of the final line from higher equitability with a shallow gradient to its lower values indicated by a steep gradient (Fig. 2).

Applied Cases

Species diversity indices are widely used in ecological monitoring and state-of-the-environment reporting. Although species diversity indices do summarize a lot of data, it is recommended that in ecological monitoring, diversity indices are used alongside other measures of the state of the environment. This is simply because different measures of the state of the environment are based on different parameters or variables.

Diversity in ecology has been the subject of much research. There have been debates about links or between diversity and resilience of ecosystems. In 1983, for example, Moore provided a brief summary of several research programs on ecological diversity and stress. In that summary, he referred to several authors including del Moral, who reported some research on subalpine meadows on the slopes of the Olympic Mountains in the western United States. In these grasslands, productivity is related to many biotic and abiotic factors. It was found that diversity (measured by the Shannon–Wiener index) had maximum values where there was moderate stress and where total productivity was suboptimal. Furthermore, it was reported that species transplanted from high-diversity sites to highly productive sites generally survived well if the surrounding plots were cleared of competitors. However, they did not do well if the plots were not cleared.

In another study (summarized by Moore), the researchers Hixon and Brostoff described complex links where predatory damsel fish in Hawaiian coral reefs control populations of herbivorous fish, which in turn influence the algae components of the reef ecosystem. They discovered that the greatest diversity (Shannon–Wiener index) was found inside the damselfish territories and the lowest outside.

In fact, the Shannon–Wiener index has been widely used to study the different effects of stress and disturbance on diversity of animal and plant communities. Because it provides more complex information than simple species richness and is based on the number of species as well as their equitability, the index serves as a valuable tool in monitoring ecological change.

Simpson Index of Species Diversity

The Simpson index was brought in by statistician Edward H. Simpson in 1949, but it had already been partially introduced in 1945 by the economist Albert O. Hirschman. Therefore, the same index is usually used as the Simpson index in ecology (D or λ), and as Herfindahl's index or the Herfindahl–Hirschman index (HHI) in economics.

The Simpson index belongs to dominance diversity indices because it counts more on common or dominant species. Thus, a few rare species that are only represented by a few individuals will not affect diversity markedly. The Simpson index measures the degree of concentration when individuals are classified into types, and takes into account the number of species present, including their relative abundance in a sample. The natural definition of the Simpson index can be interpreted as the probability that any

two individuals from the sample, chosen at random, will be found to belong to the same species (λ or D is always ≤ 1). It is expressed as follows:

$$\lambda = \sum_{i=1}^{s} p_i^2$$

or for diversity statistics it is taken as reciprocal:

$$D = \frac{1}{\sum_{i=1}^{s} p_i^2}$$

where p_i is the relative abundance of the i-th species (absolute abundance of each particular species (n_i) divided by the total number of individuals found (N)) and s is the number of species. The value of the index ranges between 0 and 1. The higher the score, the higher the probability that two individuals belong to the same species, along with a decline in diversity. Therefore, the index is sometimes expressed as

$$\lambda = 1 - \sum_{i=1}^{s} p_i^2$$

to reverse it. For the reciprocal it is $D > 1$, and the higher the score, the more diverse the community is considered to be. With reference to data in **Table 2**, the Simpson index will be calculated as follows:

Community A

$$D_A = \frac{1}{\left(\frac{4}{12}\right)^2 + \left(\frac{4}{12}\right)^2 + \left(\frac{4}{12}\right)^2} = 3$$

Community B

$$D_B = \frac{1}{\left(\frac{10}{12}\right)^2 + \left(\frac{1}{12}\right)^2 + \left(\frac{1}{12}\right)^2} = 1.41$$

Evenness or Equitability

The most stable communities usually have large numbers of species, almost evenly distributed. Seeing that dominance is the complement of evenness, an equitability index takes its largest value when all species have the same abundance. In this context, species diversity is a function of species richness and evenness; thus as species richness and evenness increase, diversity also increases. Analogous to "Shannon equitability," "Simpson equitability" is interpreted as follows:

$$E = \frac{D}{D_{max}}$$

where D stands for the Simpson index of species diversity and D_{max} stands for the maximal value of the index, which is the species richness of the sample (for the reciprocal form). The Simpson index is strongly influenced by the evenness of the species distribution, and it is weakly affected by species richness.

Edward Hugh Simpson (1922): British mathematician and statistician. In World War II, he worked as a cryptanalyst at Bletchley Park. In 1951, he described Simpson's paradox (also known as the Yule-Simpson effect) in which a certain trend appears in various groups of data but disappears or reverses after combination of the groups. He retired in 1982 as a British civil servant and lives in Oxfordshire.

There is a good example in soil-dwelling thrips (Thysanoptera) assemblages from Pannonian oak woods in Slovakia (**Table 3**) studied by Zvaríková and Fedor. Despite an increase in species richness during the vegetation season, the Simpson index remains stable with almost no response (**Fig. 3**). Due to the trend of high correlation between the Simpson index and equitability, there is no reason for a parallel increase of the index in accordance with species richness. The main emphasis refers to distribution of individual species.

Shannon-Wiener versus Simpson Index

Parallel use of species diversity indices in ecological studies is a general practice, and a typical case is the parallel application of the Shannon–Wiener and Simpson index. However, while the Shannon–Wiener index is strongly influenced by species richness and by rare species, the Simpson index gives more weight to evenness and common species. The effect of the sample size is generally negligible for both of them.

The use of both diversity indices improves the output information of the dataset, which is unique for each community or sample analyzed. Looking at the wider content—both emphasizing the richness, and the specimen distribution into the individual species—adds to the more complex information of the diversity in ecosystems.

In this sense, H has an advantage over D because it depends more on species richness and less abundant species, so it is very sensitive to even small diversity changes, and thus is widely used to assess the actual state of environment. On the other hand, D

has the advantage over *H* in counting more on dominant species and is not affected by less abundant elements; therefore, it is used to show the trend of ecosystem diversity heading.

Applied Cases

There are many papers that assess diversity using species diversity indices. Without doubt, the Shannon–Wiener and Simpson indices are most often applied in ecological cases. Despite a recent effort to invent new measures that take species richness, as well as the number of individuals of each species into account, they mostly remain based on Shannon–Wiener and Simpson. For example, Hooker, in 2009, explains the importance of using both indices in the assessment of lake plankton diversity and community structure. The choice of using one index over the other strongly depends on what needs to be emphasized. If one is interested in assessing the recovery of a lake after a catastrophic event, the Shannon–Wiener index might be most useful because of its sensitivity to the return of initially rare species. On the other hand, evaluation of species that are relatively dominant, and therefore more important as a source of food for fish, might be of higher interest, so the Simpson index would be more suitable.

During the assessment of managed boreal forests in Finland, Pitkänen calculated several diversity indices (including Shannon and Simpson). Applying these indices to 166 forest sites, it was revealed that it is possible to classify forests in terms of biodiversity based on habitat characteristics. One could expect that species richness itself would be enough to distinguish between the forest sites, but in fact the mean values for species richness did not differ significantly. The indices had higher variability in their mean values, which may have been caused by the fact that they were influenced to varying extents by the evenness in the species abundances. The results indicate a correlation between stand structure and diversity of the ground vegetation in connection with forest classes, for which diversity measures can be analyzed. The Simpson index significantly correlated with every alpha diversity index and measurement of evenness ($P < 0.001$), but the Shannon diversity index mainly reflected species richness of the stands.

There is a small disadvantage of these indices when they are applied to large-scale monitoring of diversity intactness. Since information on species identity is lost, they cannot be used to monitor species turnover. At any rate, the Shannon–Wiener and Simpson diversity indices remain the most widely used in ecological research.

Bioindication and Biodiversity Indices

Species do not appear to be isolated. They form more or less complex systems (e.g., communities) with specific structural features, such as species richness, evenness or trophic interactions as a reflection of certain ecological conditions they live under and reflect. Many of them have been widely applied in bioindication within environmental assessment of monitoring ecological change. For example, some freshwater invertebrate communities have been the basis of some ecological monitoring programs. The community structure and the species present have also been bases for the classification of rivers and lakes. For instance, a software package aptly called RIVPACS (the river invertebrate prediction and classification system) is based on the assumption that the presence of certain taxonomic groups depends on certain physical and chemical variables. So there are two basic levels of bioindication potential: species dimension (presence, absence, morphological or physiological symptoms) and community dimension with its species diversity indices and ecological indices, expressed as numbers or scores that have been derived or transformed from quantitative data. For example, the Trent biotic index of water quality is derived from a mix of the presence or absence of certain indicator species and the number or diversity of taxa (or groups) or organisms present. One of the most well-researched indices is the Common Bird Index, which was established in the United Kingdom by the British Trust for Ornithology. This index came about because of a desire to monitor the state of bird species and because it was impractical to count every individual bird.

The climax ecosystem, as a final mature natural ecosystem along the complicated ecological succession, possesses the highest degree of stability based on the optimum network architecture of its components (e.g., species) and mutual interactions. All the niches (ecological positions) are unique and complementary. To provide the highest homeostasis according to May's criterion for stability, we use

$$\beta(SC)^{1/2} < 1$$

where β is the average strength of interaction between species, S stands for species richness, and C is the connectance of the web; (SC) should be constant. Thus, the tropical forests with high species richness are accompanied by lower connectance (linear and simple trophic chains); however, the temperate forests in Europe with lower richness work on forked chains. Both of them actually have the same ecological diversity and stability. Undoubtedly, diversity usually correlates with stability. The greater the diversity, most probably, the greater the stability. Therefore, measuring diversity plays a crucial role in the assessment of the ecosystem conditions within bioindication.

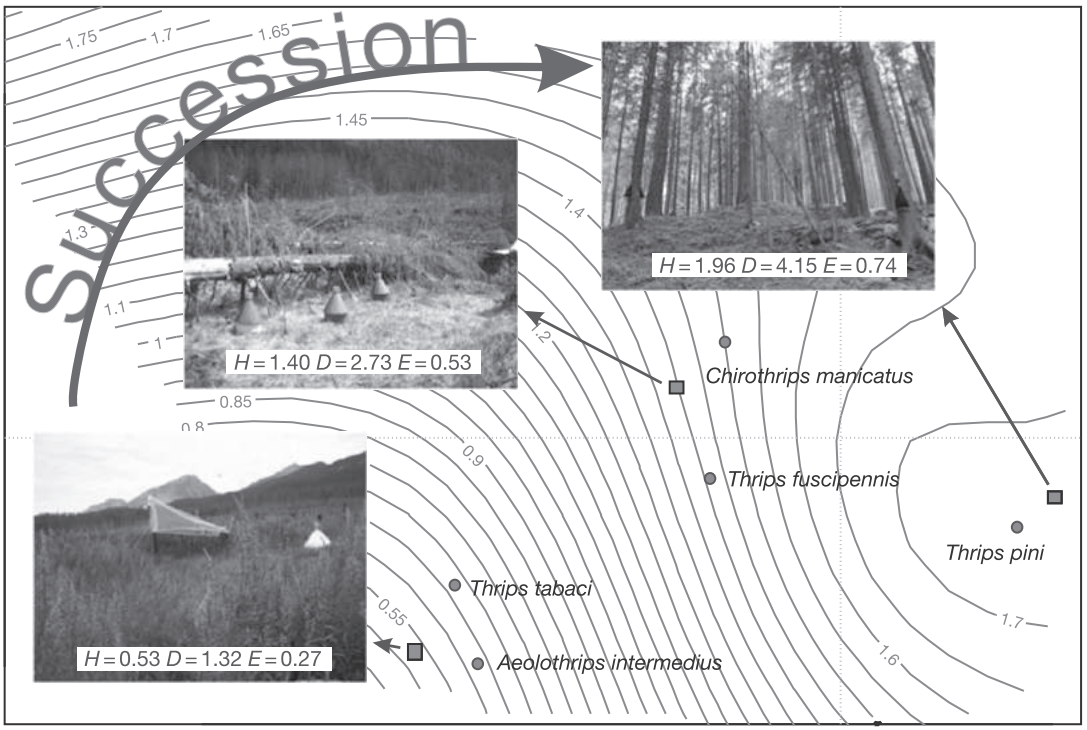

Fig. 4 A model case of complex bioindication.

As an example, in 2004, a massive windstorm devastated 13,000 ha (with 3 million m^3 of wood) of forest in the High Tatras, the oldest national park in Slovakia. The main damage appeared in artificial soft-wooded spruce monocultures with low resilience mechanisms. In climax ecosystems with no artificial bark beetle control, infestations reduce the dominant spruce stands, which are consequentially replaced by stronger tree species (e.g., silver firs), thereby building higher homeostasis. Simply put, the natural ecosystems with high biological diversity, including species richness and ecological interactions, are more resistant to disturbance and stress impacts. Ironically, the windstorm brought about a challenge for intensive ecological research. **Fig. 4**, adapted from NMDS analysis, describes the growth of three diversity measures (the Shannon index, its evenness, and the Simpson index) from the initial succession stage of the forest to 4 years after the windstorm, including massive fire devastation with all the wood destroyed or burnt, through to the stands affected by the windstorm's devastation with wood that remained, to the protected climax forest with the highest degree of ecological stability. Moreover, the figure includes some bioindicator species reflecting mature ecosystems (*Thrips pini*) or, on the other hand, open stands with low stability (*Thrips tabaci*) (**Fig. 4**).

Summary

The only pragmatic strategy to provide and maintain the huge potential of biodiversity in ecosystem services is associated with its sustainable use, meeting progressive human development within carrying capacity of environment and sustaining an essential network of ecological interactions. This approach, however, requires detailed knowledge on quantitative and qualitative parameters and bioindication potential of biodiversity, sophisticatedly expressed by its indices and predominantly represented by species diversity indices. On the other hand, without sufficient ecological knowledge, such analyses may bring more questions than answers.

For many years, the most advanced approach widely used in environmental assessment has been established on a large cohort of species diversity indices with emphasis on species richness, as well as distribution of species within a sample. Besides the most well-known indices (e.g., the Shannon and Simpson indices), the entire set of biodiversity measures includes some that are less frequently used, such as the Berger and Parker dominance index, the Fisher alpha index, and the Brillouin index. However, before any ecological evaluation, researchers should identify the real performance of biodiversity indices within a certain situation, including their specific response to changes in ecological systems, emphasis on species richness and evenness, dependence on a sample size, discriminability, as well as use frequency in literature to compare results more reliably.

Biological Integrity☆

Robert J Miltner, Ohio Environmental Protection Agency, Groveport, OH, United States

Glossary

Appreciative inquiry An approach to problem solving that focuses on the desired state and solutions to reach that state, rather than individual problems inhibiting that state.
Biocondition gradient The response of a biological system or assemblage to a range of disturbance or induced stress.
Biocriteria Standards for biological integrity relative to the biocondition gradient.
Biotic ligand model A water quality model that determines the bioavailability of metals to bind to membrane surfaces.
Cumulative distribution function A function that graphically illustrates the position of a given value in relation to all values in a continuous series.
Serotinous Delayed; in ecological contexts, usually referring to seed dispersal.

Integrity and Biological Systems

Integrity is defined as the state of being whole, undivided or uncorrupted. Applied to biological systems, the concept of integrity is hierarchical and dendritic: hierarchical in that biological systems can be categorized from the level of the biome (e.g., estuaries) to ecosystems (e.g., *Spartina* sp. marsh) to communities (e.g., fish and invertebrates living in the marsh) to an assemblage (e.g., benthic meiofauna), to populations of a given species within an assemblage (e.g., *Nereis diversicolor*). Biological systems are also organized by a trophic hierarchy from primary producers to consumers to predators, but brought full circle by decomposers. The trophic web is obviously one aspect of the dendritic nature of biological systems, but biological systems clearly depend on an interconnection of both biological and physical components. Littoral transport of sand nourishes the coastal barrier islands that protect the *Spartina* marsh from wave erosion. Nutrients delivered by rivers and tides sustain the *Spartina* that, in turn, interacts with the tides to provide a physically complex environment for juvenile fish and shellfish.

Apart from the collection of physical and biological parts that define a given biological system, a biological system cannot be considered whole unless it has the capacity to perpetuate itself, barring some epochal disturbance. So another aspect of biological systems is resilience to disturbance. In fact, many systems are dependent on periodic disturbance, with familiar examples being the boreal pine forest and fire, or rivers and seasonal flooding. For a boreal forest to be resilient to fire, it must contain species that are fire-adapted; hence, the serotinous cones of the jack pine. Although most jack pine cones only open from the heat of fire, some open from the heat of the day, demonstrating a range of traits, and implying a degree of genetic variation. Genetic variation is central to a biological system being able to persist through time. Perhaps nowhere has this been more apparent than with populations of lake trout in the Great Lakes of North America where restoration efforts following the collapse of the fishery due to overfishing and the invasion of the sea lamprey have been largely unsuccessful because, among other reasons, the hatchery reared fish used to supplant the native stocks are not genetically adapted to reproducing in specific open lake environments.

Taken collectively, the biological integrity of a system can be measured by the collection of its biological parts (from assemblages to species to genes) and the physical, chemical and biological processes that link those parts together and sustain the system. Biological integrity can be further measured by the resiliency of the system. The aspect of resilience is particularly important because it begins to frame how biological integrity can be measured against a gradient of human disturbance or corruption. Going back to the lake trout example, stocks of lake trout were resilient to fishing pressure (i.e., a human disturbance) until the introduction of the monofilament gill net, and the systemic corruption induced by invasive species (e.g., sea lamprey, alewives, and smelt) and industrial pollution. Stated another way, the system could be seen as having a high degree of biological integrity when it was capable of producing a desirable renewable resource. And that, in fact, has become the reference condition that animates the restoration efforts of the Great Lakes Fisheries Commission.

It is obvious from this example that measuring biological integrity hinges on a frame of reference, and that frame of reference is dependent on a necessarily subjective construct. Taking the reference condition as the state of the system in the absence or near absence of human disturbance is one way to attempt an objective framework. Similarly, but more realistically for developed landscapes and more commonly in practice, reference conditions are given by the least disturbed examples of a particular system available. More recently, the concept of the reference condition has been decoupled from a natural or least disturbed condition to one that can be identified through human-centered, appreciative inquiry. The lake trout example in the previous paragraph echoes

☆*Change History:* November 2017. RJ Miltner updated the text, replaced figures with three new figures, replaced Table 1 with a new table, and updated further reading of this article.

This is an update of J.R. Karr, Biological Integrity, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 408–412.

the appreciative inquiry approach by essentially asking the question of when was the system performing well, and then identifying that state as the desired condition. Similarly, the biocondition gradient approach to deriving expectations is informed by expert judgment to partition a given resource along a human disturbance gradient. For example, because the environmental tolerances and requirements of trout are generally well-understood, experts can partition the resource into tiers based on which species of trout a particular stream is capable of supporting, and set appropriate expectations for those tiers. Brook trout may only survive in relatively undisturbed headwaters, but brown trout are capable of surviving in modestly disturbed agricultural landscapes. This approach concedes loss (e.g., the erstwhile brook trout stream is now inhabited by brown trout), but recognizes the reality of the modern landscape.

Applying the Concept of Biological Integrity in Practice

The US Clean Water Act of 1972 called for the restoration and maintenance of the biological, physical and chemical integrity of the nation's waters, and more recently the European Union Water Framework Directive (EU WFD) called for surface waters in member states to meet "good ecological status" as a general requirement of ecological protection. These directives have led many countries in the EU and many states in the US to put in place biological monitoring, and develop methods to translate results from biological monitoring into information that can track attainment of water quality goals. Similarly, Australia and New Zealand employ robust biological monitoring programs and biological endpoints to track the condition status of their waters. More broadly, many countries or regional governing bodies have developed biological indicators to measure and track the status of their waters, either as a precursor to, or to help facilitate state adoption of biological requirements.

As is readily apparent, the focus thus far of biological monitoring and attendant condition indicators centers on surface waters, particularly rivers and streams. This is by dint of the fact that rivers have suffered and continue to suffer so heavily from pollution because they were or continue to be treated as simple waste conveyances rather than systems capable of producing multiple goods and services. Thus, measures of biological integrity for rivers and streams are the most widely developed and employed. Other environments where measures of biological integrity have been developed include estuaries, riparian areas, grasslands, coral reefs, lakes, wetlands, and upland forests.

There are two basic approaches widely employed to measure biological integrity: multimetric indexes, and observed-expected (O/E) models. Although the ensuing examples will center around rivers and streams, the concepts are generally applicable across systems. A multimetric index, as the name implies, includes various measures of the system parts previously described to form a single, composite index to gauge biological integrity against a reference condition. Individual candidate metrics are first proposed based on knowledge of the system, and natural attributes of the assemblage of interest. For example, to develop a fish-based index of biological integrity (IBI) for rivers and streams, one could divide the fish community into any number attributes, for example, trophic position, and then propose metrics based on the number or percent composition as herbivore, benthic insectivore, or top carnivore. Knowledge of the system in question is used to exclude inappropriate metrics; one would probably not consider the number of headwater-obligate taxa in a large river index. Other attributes such as tolerance or sensitivity to particular pollutants, temperature, dissolved oxygen, hydrologic stability, etc., can be included as candidate metrics. In practice, metrics used in fish biotic indexes typically fall into several categories: metrics reflecting habitat condition (e.g., species richness metrics), metrics reflecting trophic status (e.g., the percent composition of top carnivores), metrics reflecting pollution stress (e.g., number or percentage of pollution sensitive species), and general condition metrics like relative abundance and total species richness. **Table 1** maps attributes from three different indicator assemblages to a series of generic biotic metrics. Once candidate metrics are selected, samples are collected from reference sites and known stressed sites to ascertain which individual metrics are responsive to the disturbance gradient, and the direction of the response. Finally, of the metrics proving responsive, redundant metrics (i.e., those with very similar responses to disturbance) are identified and dropped from the final summary index. The samples collected from the reference sites are used to set scoring expectations for the individual metrics. Typically, either percentile ranges from the distribution of metric values are used to demarcate scoring bands, or the cumulative distribution function is used for continuous scoring.

O/E models also depend on an identified collection of reference sites to set expectations. Unlike multimetric indexes, however, the expectations in traditional O/E models are not assemblage attributes, rather the expectations are the probability of capture of a given species or taxon for the given environmental setting. The environmental setting is defined by classifying reference

Table 1 Broadly applicable multimetric index components and example metrics for three different indicator groups

Generic metric	*Fish*	*Macroinvertebrates*	*Diatoms*
Trophic guild	% Insectivore	% Scraper	% Eutrophic
Pollution tolerance	Sensitive richness	Presence of *Cricotopus* sp.	Bahls' tolerance
Habitat condition	% Gravel nesters	% Piercers	% Siltation tolerant
Hydrologic disturbance	% Pioneering	% Noninsects	Biovolume
General condition	Native abundance	EPT richness	Diatom richness

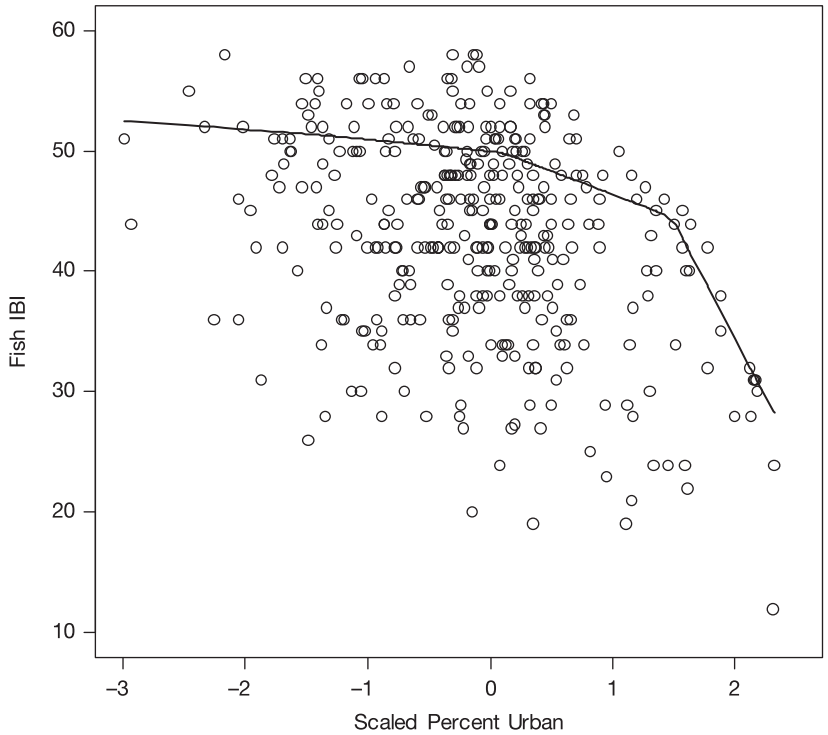

Fig. 1 Fish index of biotic integrity (IBI) scores plotted by scaled (i.e., *z*-scores) percent impervious cover. Zero on the *x*-axis corresponds to ~2% impervious cover; 1 corresponds to ~10%; 2 to ~50%. The line in the plot follows the local 75th percentile ($\lambda = 1$).

sites according to several or more geographic (e.g., latitude and longitude), physical (e.g., stream size, gradient), chemical (e.g., alkalinity, conductivity), physiochemical (e.g., temperature, dissolved oxygen), and hydrologic (e.g., base flow index) properties. For a novel site being sampled, the site is classed into its environmental setting, and the probabilities of capture for each taxon found at that site-type in the reference population is summed to give the expected number of taxa under the reference condition. The actual number of expected taxa found in the observed sample is then compared to the expected number under reference condition, and expressed as the ratio of observed over expected. The up-front effort to develop expectations is not trivial, and may be seen as a disadvantage compared to a multimetric index, but the advantage is that once done, scores from different stream classes can be compared on equal footing.

Although multimetric indexes and O/E models each have advantages and disadvantages, there are also advantages and disadvantages in the choice of assemblage used as a biological indicator. In larger rivers and streams, fish are relative easy to identify, but take great skill to sample effectively. Macroinvertebrates and diatoms are relatively easy to sample, but require great skill to identify. Fish are long lived, and can reflect episodic or intermittent disturbances that shorter lived macroinvertebrates or diatoms might recover from before being sampled. Conversely, macroinvertebrates and diatoms respond rapidly to disturbances.

Properties of a Multimetric Biological Index

Several properties of multimetric biological indexes make them particularly useful for evaluating ecosystem condition:

1. focus on biological endpoints to define condition;
2. use of reference condition (no disturbance or minimal disturbance) as a benchmark;
3. organization of sites into classes (e.g., large streams, small streams, wetlands), each with a select set of environmental characteristics;
4. assessment of change caused by human activities;
5. standardized sampling, laboratory, and analytical methods;
6. numerical scoring of sites to reflect position along a disturbance gradient; and
7. numerical and verbal expressions of biological condition that can be easily understood byscientists, citizens, and policy makers.

Unlike single-attribute chemical measures of water quality, analytical tools such as multimetric indexes or O/E models enhance practitioners' ability to measure condition in a manner that communicates the severity and extent of biological impairment. When combined with surrogate or direct measures of human activities such as water chemistry, pollutant loadings from wastewater sources, or land use, they function as response variables against those measured gradients to assess the severity of degradation. And

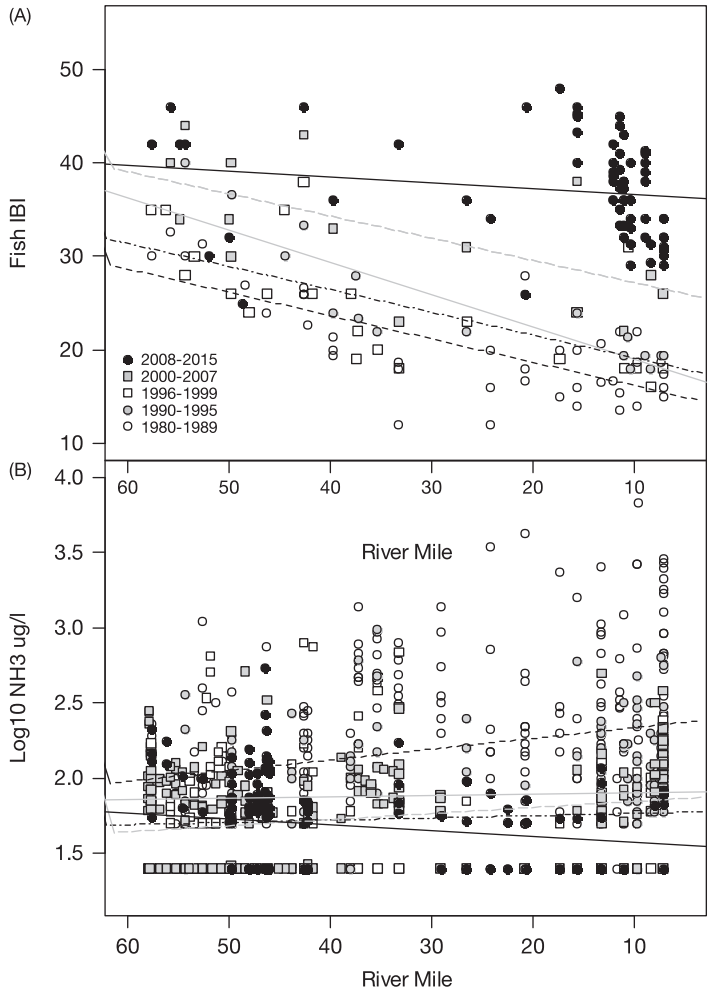

Fig. 2 (A) Fish index of biotic integrity scores obtained from the Cuyahoga River (Ohio, USA) grouped by survey years. (B) Ammonia nitrogen concentrations from the Cuyahoga River similarly grouped by survey year. Lines in the plots are from ordinary least squares regression.

when combined with multivariate ordination techniques like canonical correspondence analysis, help facilitate the identification of stressors when measured environmental variables are associated with diffuse sources of pollution. In addition to being scientifically rigorous, multimetric biological indexes or O/E models are also policy relevant. They are, for example, sensitive enough to provide reliable assessments of both existing and emerging problems and to evaluate the effectiveness of environmental policies and programs. Integrative approaches to biological monitoring directly support efforts to attain the integrity called for in national and international policy initiatives.

Applying Biological Integrity in Resource Management

Site-specific scores generated from either a multimetric index or an O/E model show how closely the biological condition at a given site matches the reference condition. When scores from a collection of sites are mapped along a gradient of disturbance, these scores quickly convey the effect of that disturbance on the biological integrity of the resource (Fig. 1). Impervious surfaces are a convenient measure of disturbance, and serve as a proxy for the combined effects of toxicity and hydrologic alteration associated with urban stormwater. In numerous case examples from disparate urban areas around the globe, biological index scores plotted against percent impervious cover essentially follow the same pattern as in Fig. 1. Because biological index scores were so effective at conveying the effect of stormwater on streams, enough public attention was drawn to the problem that management policies and strategies to address the problem became politically tenable. For example, these results informed modification of the general municipal stormwater permit issued to medium and large urban areas in the US. Additionally, many urbanizing areas have adopted construction performance standards that include setbacks, and provisions to treat runoff and maintain pre-construction hydrology.

Similar to the impervious cover example, biological index scores arrayed along specific stressor gradients have identified weaknesses in chemical water quality criteria. For example, water quality standards for ammonia'nitrogen were determined to be

under-protecting aquatic communities in general, and sensitive components (e.g., unionid mussels) in particular, leading to more stringent criteria. Conversely, water quality standards for some metals were determined to be over-protective, leading to more refined criteria like the biotic ligand model for copper.

A common thread running through these last examples is the benefit of biological monitoring on informing management decisions. In terms of managing pollution in surface waters, this thread can clearly be seen running through various provision of the Clean Water Act (CWA), conceptually if not in practice. Although the CWA calls for restoration and maintenance of biological integrity, few states have adopted numeric standards for biological criteria. In contrast, the EU WFD sets a biological goal, and defines operational methods for assessing that goal. For US states with biological criteria, information from biological monitoring is programmatically more integrated. For example, in Ohio, biological index scores obtained from monitoring near permitted wastewater discharges are consulted prior to making permit modifications. In Maine, biological criteria are a component of a numeric water quality standard for nutrients. In Florida, biological criteria and index scores are used in a stressor identification framework to identify impaired waters and associated causal pollutants, and set appropriate limits for the identified pollutants. Fully integrated, biological information and criteria can inform whether an increase in the discharge of specific pollutant has a reasonable potential to cause harm, even if that increase does not result in concentrations exceeding a numeric chemical criterion. Similarly, biological criteria can be invoked to prevent degradation of existing conditions if an activity, such as construction, threatens the status of a waterbody. Conversely, where degradation is allowed to occur, biological criteria can set mitigation standards.

Arguably the most important aspect of fully integrated biological information is that because biological communities are persistent through time, measures from those communities allow management actions to be translated into tangible and quantifiable results, and tracked through time. The success of the Construction Grants Program to modernize wastewater infrastructure is well-documented in Ohio (Fig. 2; IBI or Invertebrate Community Index [ICI]; ammonia nitrogen [NH_3] through time for Cuyahoga). The Cuyahoga River, once the poster child for the CWA, now meets the basic CWA goal throughout much of its length. Considering the starting point, that is no small accomplishment, and the degree of impairment and ensuing improvement would not be so apparent in the absence of biological index scores. More interestingly, however, is that biological monitoring has also been able to demonstrate the net effectiveness of a suite of agricultural conservation practices applied over a broad geographic region. Specifically, the net effect of conservation practices applied in Ohio's Eastern Corn Belt Plain Ecoregion between 2003 and 2012 was a mean increase of 4 IBI points (about 8% of the possible range) in headwaters.

Biological criteria provide a concrete goal for protection and restoration. However, because scores or expectations are calibrated to a reference population, caution should be applied when interpreting scores from sites that fall on the edge or outside the calibration range, be that geographically or physically (e.g., stream size). Similarly, because a defined percentile (e.g., the 25th) of index scores from the reference population is often used to set the biocriterion for a multimetric index, caution is needed when interpreting scores from sampled sites that fall close to either side of the criterion. This is especially important when examining scores collected from probability or systematic surveys of watersheds, where the distribution of survey scores may match (or even have a higher mean) than the distribution from reference sites (Fig. 3—box and whisker and longitudinal reach). Scores obtained from longitudinal reach surveys conducted around point sources are easier to interpret against the biocriterion because the natural variation within a reach is expected to be low (i.e., scores within a short reach should be autocorrelated).

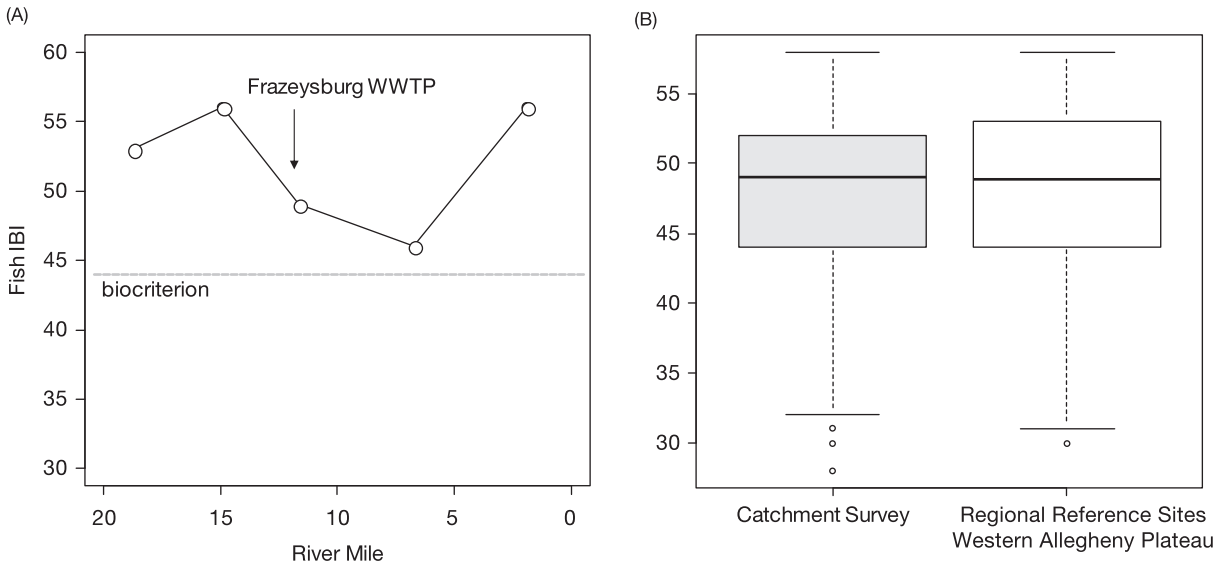

Fig. 3 (A) Fish index of biotic integrity scores from a longitudinal reach survey of a small stream receiving treated wastewater from a wastewater treatment plant (WWTP). The direction of stream flow in orientation to the *x*-axis is from left to right. The numeric biocriterion (IBI = 44) is shown. (B) Distributions of fish IBI scores from a localized catchment survey conducted in the Western Allegheny Plateau Ecoregion of Ohio (gray-shaded box plot), and from regional reference sites throughout the Western Allegheny Plateau of Ohio. The distributions are statistically identical.

Summary

Biological integrity depends on the sum of many parts, and systems with a high degree of biological integrity demonstrate that those parts are largely working and intact. Measures of biological integrity provide a framework for judging where a system is positioned on the human disturbance gradient, how susceptible that system may be to further disturbance, and for highly disturbed systems, determining feasible levels of restoration. Interpreting measures of biological condition and the desired state of that condition depend on reference expectations. The reference condition has traditionally been defined as "natural" or least disturbed, but also can be set to an agreed upon desired state. Integrated into resource monitoring and protection programs, measures of biological integrity can be used to assess and demonstrate the effectiveness of management.

Biomagnification

KG Drouillard, University of Windsor, Windsor, ON, Canada

Introduction

This article provides an overview of biomagnification as it applies to bioaccumulation of hydrophobic organic contaminants in ecosystems. While the term biomagnification has been applied to other pollutant classes including certain metals, the origins of the term, major case studies, and advancements in the mechanistic interpretation of biomagnification have largely been focused on hydrophobic organohalogen compounds. The first section of this article defines the term biomagnification, related terminology, and traces the origins of the term. The second section provides a brief overview of major empirical evidence documenting biomagnification in various food webs, and the last sections provide a summary of alternative mechanisms that have been used to explain the biomagnification phenomena.

Definitions and Terminology Related to Biomagnification

The term biomagnification has classically been defined as the condition where the contaminant concentration in an organism exceeds the contaminant concentration in its diet when the major chemical exposure route to the organism is from food. By extension the term food web biomagnification has been defined as the increase in contaminant concentration with increasing trophic status of organisms sampled from the same food web.

Biomagnification and food web biomagnification were originally coined from observations of chlorinated pesticide bioaccumulation in aquatic food webs. However, the term biomagnification has been applied to other contaminants including mercury, heavy metals, and certain compounds of biogenic origin. The first demonstration of biomagnification was described for dichlorodiphenyldichloroethane (DDD), closely related to the pesticide dichlorodiphenyltrichloroethane (DDT), in Clear Lake California. Rachel Carson subsequently used the term `biological magnifiers' in her book, *Silent Spring*, to describe how earthworms concentrate DDT residues from soil in their bodies and transfer these residues to robins who consume them which in turn achieve even greater concentrations of the pesticides than worms. The term `biological magnification' was later used by Woodwell to describe the `systematic increase in DDT residues with trophic level' in his description of DDT trophodynamics in a salt marsh near Long Island, New York. Biological magnification subsequently became truncated to the commonly used term `biomagnification' in later years.

The mechanism of biomagnification as applied to organic chemicals, particularly compounds demonstrating physical properties of low water solubility and high hydrophobicity, was intensely studied and vigorously debated in the 1980s and 1990s. During this period, biomagnification was conceptually distinguished from the process of bioconcentration which refers to chemical bioaccumulation due to exposure of contaminant across respiratory exchange surfaces (i.e., gills and lungs). Research conducted in the 1960s and 1970s demonstrated how physical–chemical properties controlled environmental partitioning and diffusive flux of hydrophobic substances. Hydrophobic organic contaminants tend to distribute preferentially to organic phases which includes organic carbon of soils and sediments and lipid phases of organisms. Equilibrium partitioning theory was subsequently used to equate bioconcentration in animals to the equilibrium lipid/water distribution coefficient. Although equilibrium partitioning theory described laboratory bioconcentration data well and predicted laboratory bioconcentration factors (BCFs; defined as the lipid-normalized chemical concentration in the animal divided by the chemical concentration in water), it failed to fully account for elevated contaminant concentrations accumulated by upper-trophic-level animals in the field.

The failure to validate equilibrium partitioning as a theory explaining biomagnification prompted redefinition of the term, as applied to hydrophobic organic susbstances, to describe the thermodynamic context of biomagnification. Under this new definition, biomagnification refers to the condition where the chemical potential achieved in an animal's tissues exceeds the chemical potential in its food and its surrounding environment. Similarly, food web biomagnification was redefined as the increase in chemical potential of organisms with increasing organism trophic status. In practice, chemical potentials are not directly measured, but rather are compared relatively across different samples by normalizing the chemical concentration in a sample by the sample partitioning capacity for the chemical/sample matrix of interest. Since hydrophobic organic contaminants distribute primarily to neutral lipids within organisms, expression of lipid-normalized chemical concentrations have been used as surrogate measures of chemical potentials when comparing biomagnification between biological samples. Alternatively, chemical fugacity is used as a proxy for chemical potentials when comparing equilibration of contaminants between interacting abiotic and biotic samples. These data analysis methods apply to hydrophobic organic chemicals but do not necessarily apply to mercury or other contaminant classes which undergo biomagnification by the classic definition, but do not exhibit preferential internal distribution to lipids within animals.

The biomagnification factor (BMF) for organic contaminants is defined as the ratio of the lipid-normalized chemical concentration in the animal to the lipid-normalized chemical concentration in its diet. A BMF value greater than 1 indicates that the animal has achieved a greater chemical potential than its diet. Since organisms may include multiple food items in their diet, the

BMF can also be expressed according to the weighted average lipid-normalized chemical concentrations in its various food items. Similarly, when the BCF value is shown to exceed the *n*-octanol/water partition coefficient (K_{OW}; a standard laboratory-measured partition coefficient used as a surrogate measure of the equilibrium lipid/water partition coefficient) this indicates that the chemical potential achieved in the animal exceeds that of water. Similar expressions can be derived for air-breathing animals by comparing the lipid-normalized concentration in the animal/air concentration ratio with the octanol/air partition coefficient.

Determination of food web biomagnification requires establishment of the trophic level of different organisms included in the sampling program. Traditionally this has been carried out using diet analysis and establishing discrete trophic steps (see **Fig. 1**). More recently, emphasis has been placed on use of stable isotopes of carbon and nitrogen to define continuous trophic positions for different organisms in a sampled food web. The food web magnification factor (FWMF) has been defined as the slope generated from a regression of the logarithm of lipid-normalized chemical concentrations in biota expressed against trophic level on the independent axis.

Empirical Field Data Supporting Biomagnification

Hunt and Bischoff provided the first data demonstrating progressive bioaccumulation and increases in concentrations of the chlorinated insecticide DDD through an aquatic food web. DDD was applied to Clear Lake, California during three administration events in 1949, 1951, and 1957. Administrations were designed to achieve a nominal concentration of DDD in water of 50 mg l^{-1}, although reportedly water residues never achieved such levels. Mortalities of fish-eating birds were observed within months after the second and third applications, with the population of western grebes decreasing from 1000 pairs prior to DDD administration to less than 30 pairs in 1960. Food web sampling and residue analysis indicated phytoplankton achieved concentrations of approximately 5 mg g^{-1}, pelagic fish contained between 50 and 300 mg g^{-1} and a brown bullhead contained 2500 mg g^{-1} of DDD. DDD concentrations in western grebes and California gulls were reported at more than 2000 mg g^{-1}. Soon after, other studies began documenting DDT bioaccumulation in different food webs. Woodwell *et al.* determined DDT concentrations in water, soil, plankton, invertebrates, mussels, fish, and fish-eating birds in a salt marsh south of Long Island, New York. DDT increased from 0.04 mg g^{-1} in plankton to 75 mg g^{-1} in ring-billed gulls. Plankton concentrations were 800-fold higher than residues measured in water. Invertebrates and fish exhibited intermediate concentrations of DDT compared to plankton and birds, consistent with their trophic status. Unfortunately, the above studies did not determine lipid concentrations of samples submitted for insecticide residues. As such, these data could not be used to test the thermodynamic criteria associated with equilibrium partitioning theory and biomagnification.

Advancements in analytical technology in the 1980s, particularly with the development of capillary gas chromatography columns, greatly increased the ability of environmental scientists to examine individual chemical concentrations in more complex field matrices. This led to a plethora of food web data sets documenting biomagnification of other organic contaminants including polychlorinated biphenyls (PCBs). Two major studies documenting food web biomagnification of individual PCB congeners were

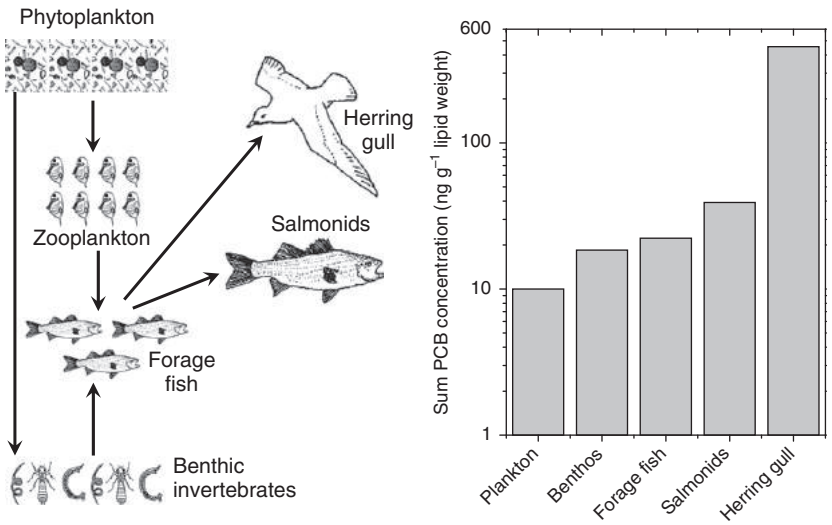

Fig. 1 Food web biomagnification of polychlorinated biphenyls (PCBs) in Lake Ontario. Data for aquatic organisms collected in Lake Ontario during 1984 from Oliver, B.G., Niimi, A.J., 1988. Trophodynamic analysis of polychlorinated biphenyl congeners and other chlorinated hydrocarbons in the Lake Ontario ecosystem. Environmental Science and Technology 22, 388–397. Data on Herring gulls collected in Lake Ontario during 1985 from Braune, B.M., Norstrom, R.J., 1989. Dynamics of organochlorine compounds in herring gulls: III. Tissue distribution and bioaccumulation in Lake Ontario Gulls. Environmental Toxicology and Chemistry 8, 957–968.

published in 1988. Oliver and Niimi measured individual PCB concentrations in water, sediments, amphipods, slimy sculpin, alewife, and lake trout from Lake Ontario. The authors also measured lipid contents in the biological samples allowing them to directly test predictions of the equilibrium partitioning theory. Their data demonstrated increases in lipid-normalized PCB concentrations with increasing trophic status (see Fig. 1). Salmonids were also shown to have fivefold higher lipid-normalized concentrations than predicted from equilibrium partitioning theory based on residues in water. Herring gulls from the same lake collected 1 year later in another study demonstrated lipid-normalized PCB concentrations that were tenfold higher than measured for salmonids by Oliver and Niimi. Conolly and Pederson also demonstrated that the fugacity ratio of rainbow trout/water exceeded a value of 1 for PCBs having a log K_{OW} value of 4 and greater in Lake Ontario. The authors demonstrated that the trout/water fugacity ratio for PCBs increased with increasing chemical K_{OW} up to values from 10 to 100 for PCBs having log K_{OW} values of 6 and higher. The same authors also demonstrated progressive increases in the animal/water fugacity ratio for PCBs with animal trophic status in the Lake Michigan food web. PCB animal/water fugacity ratios ranged from 3 to 5 for white fish and chub occupying a trophic level of 2 and up to a value of 14 for fish occupying a trophic level of 4. Similar case studies of food web biomagnification using lipid-normalized data sets have subsequently been demonstrated in several other aquatic systems including all five Great Lakes, Lake Baikal, and in agricultural and arctic terrestrial ecosystems.

Other data sets have shown the relationship between hydrophobic organic contaminant bioaccumulation and food chain length or number of trophic steps within the system. Using data generated from the Ontario sport fish contaminant surveillance program, Rasmussen *et al*. examined PCB bioaccumulation in lake trout from a large number of lakes in Ontario, Canada. The authors demonstrated that planktivorous lake trout from lakes lacking suitable forage fish exhibited lower PCB bioaccumulation compared to piscivorous lake trout from lakes containing forage fish. Finally, lake trout from lakes containing both forage fish and mysids achieved the highest contaminant residues. Lakes were also categorized and analyzed by location to remove confounding factors associated with different loading sources to individual systems. The authors attributed the lake to lake differences in PCB bioaccumulation by lake trout to reflect differences in food chain length. A more recent study documented enriched toxaphene bioaccumulation in fish from Lake Labarge, Yukon Territory, Canada as contrasted with other subarctic lakes which showed much lower bioaccumulation of the same contaminants in fish. Lake Labarge was isolated from known pollutant sources and thought to receive most of its inputs via atmospheric deposition. Water concentrations of toxaphene were also found to be similar in Lake Labarge relative to the other lakes which showed lower toxaphene bioaccumulation in fish. The major difference noted for Lake Laberge lake trout, burbot, and lake whitefish was that fish from this lake were feeding at higher trophic levels as revealed both by diet analysis and trophic enrichment of stable nitrogen isotopes. This study, similar to that of Rasmussen's work provided the empirical linkage between ecosystem structure, number of trophic links, and magnitude of biomagnification realized in top predator fish.

Mechanism of Biomagnification

Dietary Exposure

A number of mechanisms have been proposed to describe the biomagnification process as it applies to persistent, hydrophobic organic compounds. The first model published to describe biomagnification of the insecticide DDT described the lipid co-assimilation mechanism. In this model, both lipids and contaminants are efficiently assimilated from food; however, a smaller fraction of lipids are retained as a result of metabolism of these nutrients to satisfy energetic requirements. Recalcitrant contaminants are retained in tissues and over time, in conjunction with the number of feeding events, magnify in concentration over that of ingested food. Under this mechanism, the maximum biomagnification potential in nondeterminant growing animals is inversely related to growth-conversion efficiency (i.e., rate of tissue growth relative to food consumption) when contaminant elimination from the animal approaches a value of 0. For determinant growers, biomagnification will continue to increase with age as a function of number of feeding events. In practice, most environmental contaminants do exhibit elimination, which will attenuate biomagnification in proportion to the magnitude of the elimination rate coefficient. In this case, the steady-state biomagnification factor will be positively related to the feeding rate of the animal and chemical assimilation efficiency from the diet and inversely proportional to the elimination rate coefficient and growth rate.

The lipid co-assimilation mechanism was also used to explain food web biomagnification. In this case, biomagnification as achieved in top predator organisms is assumed to correspond to the inverse of ecological efficiency. Thus, the low energy transfer efficiency across trophic levels ($<10\%$) coupled with efficient chemical transfer efficiencies and high chemical retention among different organisms results in progressively increased residues through successive trophic steps. This model indicates that the number of trophic levels and trophic transfer efficiencies across each step specify the maximum contamination achieved for top predators whereas growth and elimination by individual organisms attenuates food web biomagnification.

Although lipid co-assimilation as a mechanism of biomagnification is consistent with concepts of bioenergetics and trophodynamics, environmental chemists were quick to point out that such a mechanism is not consistent with chemical bioaccumulation through passive partitioning mechanisms as is thought to occur for hydrophobic organic chemicals. Lipids, fat-soluble vitamins, and hydrophobic organic contaminants cross biological membranes by passive diffusion. In the case of the proposed lipid co-assimilation model of biomagnification, net chemical diffusive flux would have to proceed in a direction of low concentration (ingested food and digesta of the gastrointestinal (GI) tract) to high concentration (animal tissues). The GI

magnification model was subsequently developed as a competing model with lipid co-assimilation. This model is able to account for biomagnification while preserving chemical diffusion as the major mechanism of chemical flux between the organism and its gut contents.

Gastrointestinal magnification was first described in 1988. The model considers the GI tract and its contents as a separate compartment from animal tissues. The premise of the GI magnification model is that nutrient and lipid absorption occur independent of contaminants in the GI tract. The absorption of nutrients from digesta decreases both the volume and partitioning capacity of gut contents as digestion proceeds along the length of the intestines. The failure of mass balance within the GI tract compartment and loss of partitioning capacity raises the chemical potential of digesta in the GI tract above that of ingested food, providing the necessary gradient on which net diffusion can proceed from GI tract to animal even if the animal has a higher chemical potential than the food it has ingested. The animal thus equilibrates with the elevated chemical potential of its GI contents rather than its food.

Under the GI magnification model, the change in chemical partitioning capacity of feces relative to food and the volume reduction of feces produced relative to food consumed (i.e., diet absorption efficiency) provides the upper limit for the maximum biomagnification potential that can be achieved in an animal. These limits may vary according to the diet absorption efficiency for a given diet type and/or differences in digestive physiology between different species feeding on similar diets. The GI magnification model has been subject to experimental and field validation through studies that demonstrated increases in chemical potential of animal GI contents above that of ingested food. Careful laboratory measurements indicate maximum biomagnification potentials on the order of 3–12 in fish which appear to be consistent with field biomagnification factors experienced by fish. The GI magnification model has subsequently been adopted in numerous food web bioaccumulation models applied to hydrophobic organic contaminants. Food web bioaccumulation models allow consideration of relative exposures and biomagnification potentials in animals exposed to multiple diet items as defined by the diet matrix established for each species being modeled.

Recent studies have suggested amendments to the GI magnification model to account for additional physiological factors which may increase the biomagnification potential of an animal beyond diet assimilation and partitioning changes of feces relative to food. One of the simplifying assumptions applied in the original GI model solution was that the mass transport parameter describing chemical flux from gut contents to animal is equal to the mass transport parameter describing flux from animal to its gut contents. This asserts that uptake and elimination flux is diffusion-controlled and coupled throughout the length of the GI tract. However, evidence on hexachlorobenzene bioaccumulation in rats suggested that uptake occurs primarily in the upper GI tract whereas fecal elimination occurs predominately in the colon. Experimental studies on ring doves showed that PCB dietary assimilation efficiencies in ring doves during the uptake phase were higher than feces/animal exchange efficiency measured during the depuration phase. Similar observations were documented in humans.

The fat-flush model and micelle-mediated diffusion model have been suggested as potential submodels for use to augment the GI magnification model. Both the above models are used to explain the phenomena of decoupling of the site and timing of uptake and elimination processes in the GI tract. According to the fat-flush model, fatty acids assimilated by enterocytes of the intestinal mucosa of the small intestine become resynthesized into triglycerides and incorporated into growing chylomicron vesicles. This growth in lipid content of enterocytes increases the partitioning capacity of these cells and temporarily dilutes their chemical potential relative to blood and other body compartments. The lower chemical potential of enterocytes then favors chemical assimilation by diffusion. This process maximizes chemical absorption and minimizes losses of chemical from small intestine cells back to the lumen of the GI tract. When chylomicrons reach a critical size, they are released by active transport from the enterocyte into the circulatory system which again causes a temporary dilution of the blood compartment relative to other body tissues. Following the absorption of dietary lipids (and assimilated contaminant) from blood by other tissues, the chemical potential of blood once again re-equilibrates with other body compartments and becomes maximized. During the fasting state, when chemical potential in blood is highest, fecal elimination becomes more pronounced. At this time, the gut contents are found primarily in the large intestine where fecal elimination has been shown to take place. The fat-flush model therefore describes decoupling in both the site and timing of contaminant assimilation compared to fecal elimination.

The micelle-mediated diffusion model focuses on the physiological role of mixed micelles as vectors for lipid, hydrophobic vitamin and contaminant uptake in the GI tract. Mixed micelles are produced in the intestine as a result of the interaction of bile salts and fatty acids. These amphiphilic vesicles diffuse through the unstirred water layer (UWL) between the gut lumen and intestinal mucosa. Mixed micelles are capable of dissolving long-chain fatty acids, fat-soluble vitamins, as well as other hydrophobic compounds including contaminants in their interiors and transporting these compounds across the UWL. Recent physiological evidence indicates that mixed micelles are unidirectional in their movements between the lumen to enterocyte. A pH microgradient stimulates the breakup of mixed micelles at the interface of the intestinal mucosa of the small intestine. Thus, mixed micelles appear to be involved in the efficient assimilation of hydrophobic contaminants in the upper part of the digestive tract but do not facilitate elimination of chemical from enterocytes back to the lumen of the gut compartment.

Both the mixed-micelle and fat-flush models reflect extensions of the GI magnification model that bring about physiological realism to the digestive process. Current calibration of these models in birds and humans suggests that maximum biomagnification factors may be higher by a factor of 2–4 (i.e., total biomagnification factors ranging from 15 to 20 or higher) than predicted by the original GI magnification model. Calibration of the fat-flush model or mixed-micelle models in fish is yet to be completed. Further research to calibrate maximum bioaccumulation potentials in a wider variety of animal species as well as calibrated animal to gut and gut to animal transfer efficiency terms are required to substantiate these new model predictions and adopt them into food web bioaccumulation models as has been performed with the GI-magnification model.

Nondietary Mechanisms Explaining Biomagnification

The earliest critics of biomagnification identified equilibrium partitioning as the main mechanism of bioaccumulation and suggested that the phenomena of food web biomagnification could be explained primarily by differences in whole-body lipid content, and hence chemical partition capacities, of upper-trophic-level animals relative to lower-trophic-level organisms. As described above, food web bioaccumulation data sets generated in the late 1980s and 1990s provided lipid-normalized chemical concentration data and these studies were consistent with the thermodynamic definition of biomagnification. However, other alternative mechanisms of biomagnification, which do not involve special properties associated with dietary exposures, have been proposed.

Differences in spatially integrated exposures of sampled animals arising due to habitat size and/or differences in migration movements of organisms could potentially result in similar observations as biomagnification particularly in environments where the contaminant distribution in sediments and water is heterogeneous or subject to point sources. Smaller animals are likely to exhibit small spatial movements and be more reflective of contamination conditions at the local site of capture. Larger animals such as piscivorous fish may exhibit larger spatial movements and consequently integrate chemical exposures over broader spatial scales. Birds may carry residues over very long distances across their migration routes. Indeed the phenomena of biological vectors of pollution related to major spawning migrations of fish and seabirds flying to breeding sites have been recently described. Food web sampling programs for contaminants rarely consider the spatial scale of sample collections as it relates to the potential movements of organisms included within their collections. Spatial movements can confound interpretation of biomagnification factors when all animals are collected from the same location. If animals are collected at a highly contaminated site, food web biomagnification may appear attenuated as a result of high locally accumulated residues in benthic invertebrates and zooplanktons. Similarly, biomagnification trends may appear exaggerated when animals are sampled at relatively clean locations but are situated near enough hot spots that some of the larger animals are affected by the more distant contaminated areas.

Similar to the spatial scale described above, temporally explicit exposures may also confound biomagnification observations. Chemical elimination rate coefficients for negligibly biotransformed contaminants are inversely related to body size. Under conditions of pulses in environmental loadings, smaller, lower-trophic-level organisms are more likely to reflect equilibrium with water whereas larger organisms may exhibit lags in their ability to equilibrate with water during or after a pulse. For example, following reductions in water contamination after a seasonal pulse in inputs, as may be experienced during spring melt, phytoplankton and zooplankton may be capable of depurating their residues at a sufficient rate to maintain equilibration with the drop in water concentrations. However, larger fish will take longer to depurate their residues to water and will exhibit both higher concentrations and higher chemical potentials than their zooplankton/plankton counterparts. If the frequency of environmental pulse inputs is faster than the steady-state time of larger fish then this disequilibrium condition may be maintained. For some contaminants which do not achieve steady state in organisms, different animal ages also need to be considered when comparing residues among populations or between populations of species having different age structures.

Another confounding factor arises due to rapid changes in animal lipid contents, either through growth or weight loss. When an animal loses weight and lipids at a faster rate than it can lose contaminant, it concentrates its tissue residues and raises its chemical potential above its previous state even though net chemical flux proceeds in the direction of elimination. Rapid lipid depletion, and subsequent tissue concentration of contaminants, is likely to be common in animals that undergo seasonal cycles of weight gain and lipid loss or in animals that exhibit bioenergetic bottlenecks at critical times in their life history. Such observations were reported in depuration experiments involving birds and fish. In the case of birds, contaminant residues were found to become concentrated in blood following weight losses experienced by the animals during spring warming. The opposite was noted for warm-water fish, the yellow perch, where winter weight losses due to prolonged fasting caused an increase in chemical potential in animal tissues despite the fact that the study was measuring chemical elimination. Other examples documenting rapid weight and lipid loss during specific life-history points and subsequent tissue magnification of PCBs include metamorphosis in amphibians and pipping (hatching) of chicks.

The opposite condition of solvent depletion occurs during rapid growth. Extremely rapid turnover times demonstrated by algae during peaks in primary production result in growth rates that are faster than chemical-uptake coefficients. This causes phytoplankton to exhibit chemical potentials that are lower, and less than equilibrium, compared to water. Rapid growth dilution as experienced in juvenile animals will also reduce biomagnification factors due to high growth-conversion efficiencies experienced during these life stages.

Summary

Biomagnification is a well-documented phenomenon where persistent hydrophobic organic contaminant concentrations in an animal become elevated over and above its food. This increase in contaminant concentration propagates through successive trophic steps in a food web. Later definitions of biomagnification and food web biomagnification have imposed thermodynamic criteria specifying that biomagnification reflects a nonequilibrium process in which the chemical potential in an animal is elevated above that of its diet and environment. The GI magnification model and the new amendments to this framework explain how exposures through the diet can raise the chemical potential of the animal above that of its food and environment. The above mechanisms apply specifically to hydrophobic organic contaminants. However, other contaminants such as mercury are assimilated and distributed through tissues by different processes. Thus, while mercury conforms to the classic definition of

biomagnification and food web biomagnification it is difficult to evaluate the behavior of this compound in the context of the thermodynamic definition of biomagnification. Further understanding of uptake, assimilation, and elimination mechanisms and the free energy relationships associated with these processes are needed to provide a unifying theory of biomagnification across other contaminant types.

Biotopes☆

Panayiotis G Dimitrakopoulos and Andreas Y Troumbis, University of the Aegean, Mytilene, Greece

Glossary

Community structure The range of species along with their relative abundances in a biological community.

Complementary resource use Resource partitioning in space and time among cooccurring species at a given community.

Conservation planning The identification of priority areas for conserving natural values.

Diversity-ecosystem function relationship The relationship between plant or animal diversity and ecosystem processes such as primary productivity, nutrient cycling, and decomposition.

Ecosystem functioning Energy flow and nutrient cycling through abiotic and biotic compartments of an ecosystem.

Habitat The living area of a species (plant, animal or microorganism).

Introduction

Biotope is a synthetic Greek work combining "bios" (meaning life) and "topos" (meaning place). The German scientist Friedrich Dahl introduced the term biotope in 1908 as the habitat in which a particular group of animal and plant species live. This term was a complement of the term biocoenosis (attributed to Karl Möbius in 1877) meaning the group of animals and plants living together in a specific habitat. In this sense, biotope is considered to be the physical (abiotic) conditions in which a biocoenosis exists. In 1935, biotope and biocoenosis were incorporated into the term of ecosystem coined by Arthur Tansley.

The term biotope is being used interchangeably with habitat, the latter more in the Aglo-Saxon ecological literature and the former more in other European one. The term habitat has a number of different uses, but is generally considered to represent the physical conditions that surround a species, a species population and an assemblage of species or community. However, biotope has to be assigned to the community concept and habitat to the species concept. In addition, the term biotope is not limited to encompassing only physical conditions that surround a community of organisms but it also includes the relative biota. Therefore, biotope is a division of the landscape (a topographic unit) characterized by similar environmental (physical) conditions and a specific assemblage of plant and animal species, that is, a set of adjacent places in a given geographic region having more or less similar biotic and abiotic features. Thus, a species has a certain habitat, but the group of species that share an ecosystem with that species in a geographic region, share a biotope.

As a structural component of the ecosystem, the spatial and temporal definition of a biotope comes up against the same methodological difficulties as its higher level organizational capstone concept, i.e., ecosystem. The definable boundaries of a biotope are more dependent on the aim of the study and on the criteria posed by the researcher than geographical, and, thus, are somewhat arbitrary. Biotopes are often described based on dominant species or suites of conspicuous species present in areas sharing similar physical conditions. When geographically defined discontinuities occur such as small islands, mountain peaks, caves, thermal vents, hot springs, vernal pools, nutritionally imbalanced substrates (e.g., serpentine, limestone) and isolated vegetation fragments in the landscape, distinct biotopes can be easily identified. Differentially, biotope identification, as well as ecosystem identification, is far more problematic because the natural environment can not be easily divided into a series of discrete and discontinuous units as it represents different parts of a high variable continuum.

The earliest static perceptions of biotope tended to link it to the location, extent and substratum of a given biocoenosis. As a "container" system, the biotope was viewed as qualitatively uniform, where ecological factors are invariable in space. The cognitive evolution towards the concept of ecosystem allowed a functionalist and dynamic approach since it has introduced the processes of transformation, circulation and accumulation of energy and matter between and within the components of the system. Within this ecosystemic framework and its primacy in modern ecological thinking, the biotope is connected directly and/or indirectly to values, functions, goods and services of natural systems and biodiversity in the perspective of global change. Biodiversity is being eroded across all levels of biological organization due to the changing pattern of land use and climate change. These changes are expected to have major impacts upon processes that maintain ecosystem functioning (e.g., productivity, decomposition, nutrient cycling and resistance to weed invasion) by altering species richness and composition, as well as the evenness of plant communities.

☆*Change History*: October 2017. Panayiotis G Dimitrakopoulos and Andreas Y Troumbis made changes in sections "Biotope, niche and ecosystem functioning," "Community succession and biotope changes" and "Biotope and nature conservation," added new references in "Further Reading" section and a list of "Relevant Websites," and added Table 1.

This is an update of P.G. Dimitrakopoulos and A.Y. Troumbis, Biotopes, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 471–475.

Thus, the concept of biotope appears instrumental in the investigation of theoretical issues such as the ecological niche, the functional relationship between biodiversity and ecosystem processes such as production and the applied problems of nature conservation such as designing nature reserve systems or networks.

Biotope, Niche and Ecosystem Processes

Assuming that the boundaries of a biotope are described in an adequate manner in terms of scale, structure or composition, or a specific combination of environmental factors, the explanation of the presence of a small or large number of species (the alpha diversity) is an open question that is intimately connected with the perception of the biotope. Among the major theories explaining variations of species diversity across environmental gradients, the so-called dynamic or energy theory well matches the view of a biotope as an entity of available resources such as water, nutrients and energy. These resources determine the total biomass and the population size of the biota, and then short-term ecological processes determine the species number while long-term evolutionary processes determine structural properties such as niche widths and species packing.

Biotope Space, Species Richness and Ecosystem Functioning

When diversity (species richness, taxonomic composition and abundance distribution) is considered as an 'ecosystem property' driven by the variation in the biotope's variables (abiotic and biotic)—such as productivity or soil nutrient content—then a unimodal or hump-back relationship between them is considered as widely valid at plot scale. The relationship between ecosystem productivity and diversity, produced from field survey data, varies among taxa, between spatial scales and within as against between biotopes. Recent studies conducted in grassland ecosystems found that productivity explains a small part of the variation in species richness, and that large-scale processes (e.g., the size of the local species pool) seem to govern local plant species richness.

Effects of plant species diversity on plant productivity can be analyzed in comparative studies in which a set of natural communities is selected to represent different levels of diversity, being as similar as possible in other characteristics except productivity, or in experiments where plant communities of different diversities were constructed. These experiments treat diversity as the independent variable driving variation in ecosystem processes, considered as the dependent or response variables. Field experiments (e.g., cross-European BIODEPTH experiment, Jena experiment or biodiversity experiments at Cedar Creek, Minnesota), as well as of theoretical models, suggest that the processes maintaining ecosystem functioning could be adversely affected by the loss of diversity. The increasing probability in presence of one or a few dominant species (selection effect), and more complete exploitation of available resources (complementarity effect, including facilitative interactions between species) in species-rich communities than less diverse ones have been proposed as underlying mechanisms to explain positive diversity effects on ecosystem functioning. In the long term, complementarity effects may become increasingly important in relation to selection effects.

In 1957, George Hutchinson discriminated niches as properties of species and biotope as the physical space in which all, part, or none of a species' niche may occur: "… niche may be regarded as a set of points in an abstract *n*-dimensional N space. If the ordinary physical space B of a given biotope be considered, it will be apparent that any point $p(N)$ in N can correspond to a number of points $p_i(B)$ in B, at each one of which the conditions specified by $p(N)$ are realized in B" (Fig. 1). Hutchinson presents a simple lake system as an example of a biotope that is a "segment of the biosphere with convenient upper and lower boundaries, which is horizontally homogeneously diverse."

Hutchinson's niche definition includes the combination of an organism's environmental tolerances and habitat requirements in determining the conditions and resources needed for its survival and reproduction. For example, species performance is limited by soil moisture but different species demonstrate different tolerances at a different range of values of this variable. This range determines one dimension of the species' niche. Various conditions (e.g., pH, temperature, salinity) or resource states (e.g., food size, water, nutrient or light levels) could serve as other dimensions of a species' niche. The combination of range of values of n dimensions fixes a subset of space—an abstract *n*-dimensional hypervolume—inside which the organism can perform its biological activities. The niche can become easily perceptible as the diversity and range of values of the biotope's resources that are exploited by a species (called niche width).

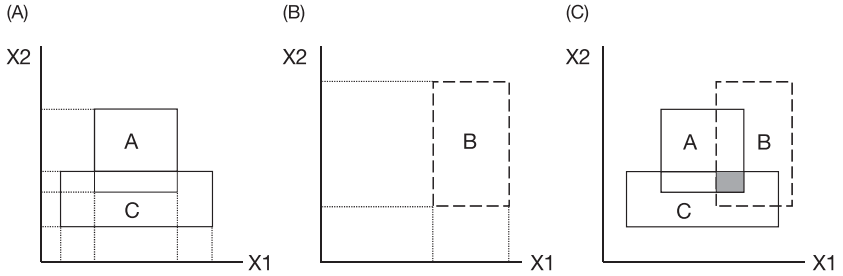

Fig. 1 The biotope and the niche. (A) A pair of variables (X1, X2) define two-dimensional areas that represent the niche of species A [N_A ($X1_A$, $X2_A$)] and of species C [N_C($X1_C$, $X2_C$)] respectively. (B) The ordinary physical space B(X1, X2) of a given biotope. (C) Part of species niches (N_A and N_C) represented within this biotope. Overlap of species niches in the biotope shows the amount of interspecific competition (*gray box*).

Consequently, niche overlap—the amount of competition—depends on the extent (or the degree) to which two or more species are able to utilize the same range of values of a resource (Fig. 1). According to niche theory, species can coexist in the same particular biotope as long as their niches do not fully overlap within this biotope. If species differ in their niches (i.e., more complete utilization of available resources) and the niches are considerably smaller than the entire biotope space (i.e., niche axes length) then communities richer in species may have higher productivity and other process intensities than species-poor mixtures or monocultures because of complementarity. These diverse communities would not become, as strongly dominated by individual species as expected under the selection effect. Fig. 2 illustrates mechanisms driving different biodiversity—ecosystem functioning relationships.

Does Reducing Biotope Space Weaken the Strength of the Diversity—Ecosystem Functioning Relationship?

In the example of soil volume, several species with different rooting architecture and depths may be combined, provided the biotope is sufficiently large and deep to fully accommodate these species niches. Therefore, complementarity and beneficial biodiversity effects should increase with biotope space. Experimental approaches, using constructed plant communities of various diversities growing on a gradient of increasing soil depths and volumes that offer increased rooting space to species and related to the niche dimension of nutrient acquisition by the roots of plants, showed that biodiversity effects due to species complementarity increased linearly with biotope space. Scaled up to agricultural systems, this means that benefits of intercropping may be greater in deep soils and that soil erosion may reduce intercropping benefits.

In the case of resource availability, biotope space can be defined in relation to a chemical, spatial or temporal aspect. For example, organic matter decomposition processes, derived by decomposer microorganisms and detritivores, regulate availability of different forms of nutrients (e.g., nitrogen, phosphorus) on a spatial and temporal scale, and, through enlarging biotope space for plant roots (e.g., utilization of deeper soil strata), increase the degree of complementarity among plant species. Along with resource availability, resource complexity has recently come into use in the definition of biotope space. Increasing resource complexity or heterogeneity in resource environments (i.e., large biotope space), can permit an increased number of species with complementary niches within communities, leading to positive diversity effects on community performance. In a smaller biotope

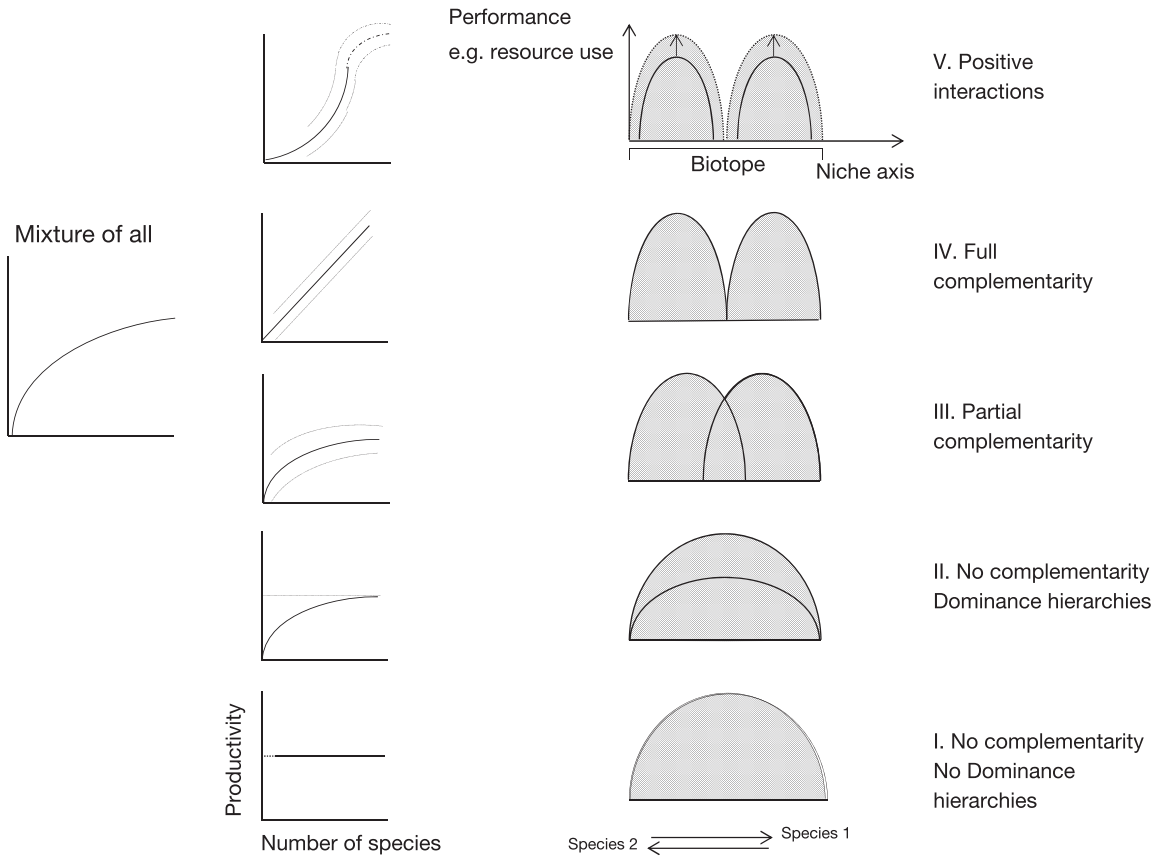

Fig. 2 Mechanisms explaining various responses of ecosystem processes in changing diversity. Two plant species performance curves along a niche axis represented in a particular biotope were used to depict potential niche separation and overlap. Species performances are hypothesized to be directly correlated with competitive ability. Each case (I–V) represents a different rule based on which species were assembled, shaping a different biodiversity—ecosystem functioning relationship. When a mixture of mechanisms operates together, the expected relationship is shown. From Kinzig, A.P., Pacala, S.W., Tilman, D. (Eds.), 2002. Functional consequences of biodiversity: Empirical progress and theoretical extensions. Princeton: Princeton University Press.

space (i.e., more homogeneous resource environments), competition will be more intense (i.e., species niches will overlap to a larger degree), reducing positive diversity effects or making them negative.

Comparatively, the strength of the positive relationship between species richness and productivity appeared to decrease in disturbed biotopes, as in grassland ecosystems where horse trampling and drought stresses were induced, indicating that reductions in biotope space through environmental stresses decrease the potential for positive effects of niche separation among species.

Community Succession and Biotope Changes

Biotopes are not constant in time; as they are intimately linked with a biocoenosis, they undergo gradual changes in a series of ecological factors generated by the biotic components of the community. In turn, these changes influence the nature of the biocoenosis modifying its species composition and therefore the structure of the entire ecosystem, and so on. In a given area these interactions determine a sequence of successive biocoenoses until equilibrium is reached. Various explanations of the causes of succession have been proposed, emphasizing key environmental (biotope) factors as determinants of the theoretical "end" stage of the succession. However, they converge in the hypothesis that when a biotope is physically modified at the limits of the capacities of the organisms composing the community, then compositional stability is reached.

There is a long tradition in ecology of studying the composition of plant communities. At the beginning of the 20th century, two contrasting views concerning plant community assembly were introduced by Fredrick Clements and Henry Gleason. Clements considered communities as well-organized associations of coevolved species, whereas Gleason viewed communities as more or less random aggregations of species in time and space. When species distributions are plotted along a biotope gradient, communities appear to have sharp boundaries based on Clements' model, while the Gleason model predicts that species are arranged independently of one another thus no distinct communities exist (Fig. 3). Compared with real communities, the two models can be considered as the extremes of a continuum. The Gleason vision seems to fit better communities of early secondary succession. These communities often show geometric dominance–diversity curves, indicating that the dominant species takes a certain proportion of the total resources offered by the biotope, the second most dominant species the same proportion of the remainder and so on. In contrast, dominance hierarchies are less strongly developed in late-successional communities, indicating less niche overlap and more niche separation, presumably due to there being more time for coevolutionary processes in shaping species interactions. The Clements model seems to better fit these late-successional communities. The species diversity and composition of a community is, in both models, treated as a function of succession.

Niche concept has been used in explaining species distribution patterns as well as in the understanding of community features (e.g., species richness) and of dynamic process patterns such as successional changes. For example, a community could support a greater number of species relative to another because biotope provides more available resources (longer length of the niche axes) and thus, more species niches can be accommodated. For a given range of resources, species richness can be increased because either mean species niche width within the community is smaller (i.e., species are more specialized in resource exploitation) or average overlap between adjacent species niches within the community is larger. In the end, when the available range of resources is not fully exploited, communities will contain a more limited richness of species than they potentially could.

Biotope and Nature Conservation

Given the alarming rates of biodiversity loss, conservation policies are being developed at various scales and within a range of institutional and legal frameworks. Conservation aims at maintaining biodiversity that contributes to the provision of key ecosystem services, i.e., the useful output for humans resulting from ecosystem functions. According to the Millennium Ecosystem Assessment classification, they are divided into four categories: (a) provisioning services—the variety of goods obtained from ecosystems, (b) regulating services—the benefits obtained from the regulation of ecosystem processes, (c) cultural services—

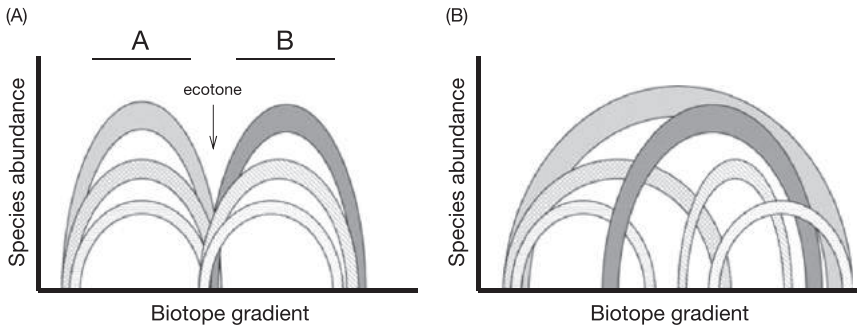

Fig. 3 Species distributions along a biotope gradient. (A) Communities (A, B) appear to have clear boundaries and are separated by intermediate zones (ecotones), (B) Species are arranged independently of one another, resulting in no distinct communities.

Table 1 Levels of hierarchical classification of the European marine habitats

No.	*Level*	*Description*	*Example*
1	Environment	Used to distinguish main types e.g., marine, terrestrial or freshwater	Marine
2	Broad habitats	Extremely broad habitat categorization	Littoral sediment
3	Main habitats	Very broad habitat divisions that mirror differentiation in their biological aspect	Littoral sand and muddy sand
4	Biotope complexes	Groups of biotopes that feature similar physical and biological attributes	Barren or Amphipod-dominated mobile sand shores
5	Biotopes	These are described based on dominant species or assemblages of conspicuous species present	Amphipods and *Scolelepis* spp.
6	Subbiotopes	These are characterized using less conspicuous species or on the basis of subtle physical habitat differences	*Eurydice* subbiotope

recreation and other nonmaterial benefits and (d) supporting services—the essential services for the production of all other ecosystem services. Ecosystem values measure the significance of ecosystem services to improve human welfare; they are dictated by cultural attitudes and society determines their relative benefits.

Evidently, conservation of biodiversity cannot be separated from maintenance of biotopes. From that perspective, a series of terms that correspond to conservation objects and refer to the biotope context have been developed and are mostly used in conservation planning strategies and language. Terms such as site, conservation area, ecotope, ecoregion and so on, often serve the conceptual needs of approaches to conservation strategies.

Selection and prioritization of areas i.e., biotopes is the most important stage for conservation planning, on a regional (or higher) scale. Conservation strategies can be species or ecosystem oriented. Species oriented strategies lay the emphasis on the analysis of population size and geographic distribution of individual species or the protection of biotopes important to particular taxonomic groups such as biotopes that are characterized by high levels of species richness or high concentrations of endemic, restricted-range or red-listed species. However, long-term maintenance of biodiversity within conservation areas can be achieved conserving both the biodiversity patterns and the natural processes that sustain those patterns. Ecosystem oriented strategies aim at protecting the range of ecological conditions found in a region of concern, using criteria such as species richness, endemism and uniqueness as well as elements of the abiotic environment, ecosystem processes, disturbance regimes and succession stages that assist in the definition of the ecosystems. Ecosystem approaches emphasize on protecting most species within conservation areas that are representative of natural or seminatural biotopes of a geographic region.

Conservation planning should define a hierarchy in conservation objectives that generates nested protection levels, necessary for the maintenance of the stability of the ecological landscape as a functional entity. The biotope or habitat-type approach that focuses on selection of conservation areas using criteria such as representativeness of vegetation types and high plant and animal species richness, is supposed to optimize ecological functions. The landscape-approach, where the landscape is understood to be a product of the combination of biotope attributes and human activities in a historical time frame, takes into consideration not only ecological but also socio–economic and aesthetic functions. Ideally, the integration of these approaches should incorporate dynamic aspects such as fluxes of organisms, energy and nutrients. Such a holistic conservation planning strategy will inevitably focus on the maintenance of the functional relation between sites through a spatial system of functionally interconnected elements, i.e., an ecological network. Certainly more difficult to design and achieve, it will probably require a creative integration of different policies (agricultural and agro-environmental policies, housing and tourism etc.), but will permit the collection of key areas for biodiversity conservation to become an ecological network.

Biotope Classification Schemes for Nature Conservation Purposes

The selection of sites to be included in an ecological network for conservation necessitates, apart from specific techniques, the clarification and classification of the correspondence between the conservation-driven terms (e.g., site, area, ecotope) and the meaning of fundamental concepts such as biotope, habitat, landscape, community etc. For example, sites are "geographically defined areas, whose extent is clearly delineated," within which conservation targets can persist. Based on this definition, sites are synonymous to landscape units or include a combination of both broad habitat divisions and landscape units. In the European Union, the CORINE-biotopes scheme uses the term site in order to avoid various etymological problems presented with the use of the term biotope in the various languages of the EU. The equivalence between the scientific term biotope and the practically used term site is provided by the definition of site as "…an area of land or a body of water which forms an ecological unit of Community significance for nature conservation, regardless of whether this area is formally protected by legislation." On a continental scale, ecoregions, considered as large-scale biodiversity units, are defined as "a relatively large area of land or water containing a characteristic set of natural communities that share a large majority of their species, ecological dynamics and environmental conditions." Recently, ecoregions representing the distribution of a wide range of flora and fauna species are

classified within major habitat types of the world (biogeographic biomes and realms). Comparisons between the biodiversity attributes of ecoregions (such as species richness, endemic species, unusual higher taxa, unusual ecological or evolutionary phenomena and the global rarity of habitats) in order to estimate their distinctiveness, have identified 238 important areas for global conservation goals—known as the Global 200. Biodiversity hotspots analysis, identifying the 36 most threatened terrestrial areas of the Earth richest in endemics, coincide, to a large extent, with the Global 200.

As to the classification problem of biotopes for conservation, various schemes have been proposed. In an analogy to species classification, which is based upon well-established rules of systematics and it structured in a hierarchy from genera to phyla, habitat classification schemes are designed for various ecosystem types. Habitats include assemblages of species coming from different taxonomic hierarchy that consistently occur together at a given spatial scale. Habitat classification can be arranged in a hierarchy from biotopes to broad habitats. For example, the marine habitat classification system of Britain and Ireland, very close to the corresponding European one, includes six levels of hierarchy (**Table 1**). In this hierarchy, broad habitat divisions (levels 2 and 3) are described based mainly on differences in their physical attributes reflecting differences in their relevant biota. At the lower end of the classification, biological features (e.g., characteristic species, species abundances, community structure) are combined with physical factors to define biotope types (levels 5 and 6), that can be grouped into higher levels with similar characteristics (level 4). Landscape units are comprised of sets of habitats consistently occurring together, coming from different levels of habitat classification hierarchy.

Criteria for the Identification of Important Biotopes for Biodiversity Conservation

Specific criteria or rules are used, tested or implemented at an international level. For instance, in the Ramsar Convention (or "Convention of Wetlands"), the criteria for the identification of internationally importance wetlands (Ramsar Sites) are organized into two groups based upon: (a) representativeness/uniqueness of wetland types included and (b) biodiversity supported (species and communities with specifications for water birds and fishes for which wetlands are important biotopes). A wetland classification system has been developed for the identification of the wetland habitat type within each Ramsar Site. 42 wetland types have been included and categorized into three broad groups: (a) coastal/marine, (b) inland, and (c) human-made. The European Union's CORINE-biotopes scheme selects priority sites based on species conservation attributes (e.g., degree of threat, richness for a taxonomic group of species) and on habitat characteristics (e.g., habitat sensitivity, richness of habitat type). A site should satisfy at least one from the following criteria in order to be evaluated as of community interest: (a) the site is one of 100 or fewer (or the 100 most important) in the Community or one of five or fewer (or the five most important) sites in a region for a threatened species or for a sensitive habitat and (b) the site supports at least 1% of the population of a threatened species at the Community level. This scheme proved an exceptionally useful tool in the creation of the Natura 2000 network of Special Areas of Conservation, known internationally as the "Habitat Directive," which is based on the idea of preservation of listed (i.e., endangered or sensitive) species and habitat types qualified as being of community interest. Sites are selected for inclusion into the network mostly on the basis of representativeness, quality of the habitat, surface area occupied, size and density of listed species and the degree of their isolation.

Such classification schemes are considered to support typical biotope/habitat-type strategies for nature conservation, since the sites are, in theory, selected on the criteria of the representativeness of phytosociological units and of the presence of threatened species. However, one can formulate the rather robust prediction that while conservation efforts focus on key areas for rare and endangered species and habitats, the remaining areas, large in scale, are exposed to an ever increasing intensification or to changes in management practices that devalue their long-term ecological and economic value which, consequently, can affect the environmental conditions within the protected biotopes.

Connectivity and Ecological Networks

Robert HG Jongman, Wageningen University and Research, Wageningen, The Netherlands

Ecological Connectivity

Introduction

Isolation and connectivity are natural characteristics of ecosystems. Mountain tops and islands are typically isolated ecosystems while in an undisturbed situation natural forests and tundra's are extensive and connected systems. Connectivity is a key concept of landscape ecology as it relates to flows and movements of organisms trough landscapes (Burel and Baudry, 2005). Movement is a key process for survival of plants and animals. Faunal species move daily in search for food and to avoid predators.

Moving from one habitat to another can be done by passive transport (floating by wind, water or moving on or in other species) as well as actively by swimming, flying or walking. Passive transport is important for plant species. The easterly wind direction at the southern hemisphere and not the geographical position determines the flora relationships between the islands around Antarctica.

Migration is a prerequisite for many species from northern parts of the globe to survive the winter period. It is risky but essential for wetland birds (Boere and Stroud, 2006). Amphibians migrate from and to spawning habitats and to wintering habitats. For them distances are short and barriers hard to take. Migrating fish such as the Atlantic salmon (*Salmo salar*) migrate between spawning rivers and the northern Atlantic Ocean. The tropical fish species Pacu (*Piaractus mesopotamicus*) migrates from small rivers in the Brazilian savanna (cerrado) to the wetlands of the Pantanal and the Amazon. It feeds on plants, fruits and seeds and in this way it plays a role in the plant species migration.

Migration as a species or population's periodic movement is typically a long distance movement from one habitat area to another to avoid unfavorable seasons or conditions (Stenseth and Lidicker, 1992). The European stork (*Ciconia ciconia*), for instance, has adapted to the cultural landscapes of Europe, because they provide food and are accessible. Its wintering habitat is in Africa, 10,000 km away. Changes in area and habitat quality in both non-breeding and breeding sites have effect on species survival and the size of the populations. The biggest dangers that can affect populations of migrating species are the barriers and events during migration.

Corridors for dispersal and migration are species dependent and can vary from single wooded banks for voles, bats and badgers to small-scale landscapes for forest birds and from river shores for otters to whole rivers and coastlines for migratory fish species. Corridors may be continuous as linear connections or interrupted as stepping stones.

Ecological connectivity is, however, not a self-evident issue. The world has been shaped by humans nowadays and all species have to adapt or get extinct. Protecting the migration and dispersal process is one of the most difficult conservation challenges that we are facing as there is a growing conflict between nature and other land use. Habitat protection and international cooperation are essential to achieve this goal. This requires insight in the processes of species exchange through landscapes and designing and adapting the way we deal with land use with regard to the needs of other species.

Islands: Isolation and Metapopulations

The occurrence of wildlife species within a habitat is determined by its (1) habitat conditions, such as the availability of water, nutrients, energy, (2) habitat size, (3) connection to other habitat sites, and (4) by human disturbance. A habitat in a network depends on the landscape fluxes, such as air movements, water flows and species migration. Islands are in this respect special habitats. They are isolated from the mainland, are relatively small and mostly the variability in habitat conditions is restricted. They are on the one hand protected from outside influences, but on the other also restricted in species exchange. This isolation makes them also special as here new species or subspecies can develop such as on the Galapagos Islands, Madeira and Madagascar. Islands therefore have always attracted scientists to explore their wealth and specialized species, such as Linnaeus and Darwin.

In the second half of the 20th century Island biogeography was elaborated by several, mainly American biogeographers, among which May, Diamond, Ehrlich, McArthur and Wilson. They studied and discussed the role of islands, their isolation and habitat characteristics. In 1967 MacArthur and Wilson published the theory on island biogeography, bringing isolation, distance and habitat characteristics into a coherent mathematical model. The primary question to be answered was the explanation of the dissimilar number of species on different islands. They used as variables the relation between area and diversity, with isolation, extinction and colonization as key factors for establishing populations. Biodiversity of an island is by them expressed by the formula:

$$S = I + s - E$$

In which S is the number of species on the island, I is immigration, E is extinction and s is speciation (evolution). The number of species is determined by immigration of species from a continent or other islands and by extinction of species (**Fig. 1**). The variable s depicts evolution of new species, but this is a long term (evolutionary) factor.

 doi:10.1016/B978-0-12-409548-9.10619-0

Fig. 1 Human land use, urbanization in Shanghai, China, and large scale agriculture in Alentejo, Portugal.

In a set of islands with a more or less uniform climate and tiopography the number of individuals of a taxon on an island is according to MacArthur and Wilson (1967) linearly related with the area of the island:

$$J = \rho A$$

In which J is the number of individuals, A is the areas of the island and ρ the density of the individual organisms.

The relationship between the number of species and the area of an island can then be expressed as:

$$S = CA^z$$

In which S is the number of species, A the area, C is a constant, that varies among taxa and z is also a constant between 0.20 and 0.35 and consistent with lognormally distributed frequency curves of species.

Levins presented the mathematical basis of metapopulation theory in the 1979 in a lecture at the congress of the American Mathematical Society. This paper is not easily available. It describes the principle of a "population of populations," as a model for the basic properties of fragmented populations. Later Hanski and Gilpin (1991) defined metapopulations as ensembles of interacting individuals of which each ensemble has a finite lifetime. The metapopulation model focuses on the processes of population turnover by extinction and establishment of new populations, defining for each species the conditions under which these two processes are in balance. The assumption is that a population goes extinct when the area and quality of the required habitat goes below a critical level. *Re*-establishment of a population can take place through colonization by individuals from another population. The different populations form subpopulations within a metapopulation. Hanski (2001) formulated this in his spatially realistic metapopulation theory in which he provided a framework for integrating island theory and metapopulation theory.

The metapopulation concept laid a basis for understanding the dynamics of species populations not only in naturally fragmented situations, such as on islands or mountain tops, but also in fragmented landscapes as caused by human land use.

Changing Landscape: Homogenization, Fragmentation and Climate Change

To connect these ecological models with real life requires knowledge of landscape change processes. The dominant processes worldwide can be described as homogenization and fragmentation (Jongman, 2002). Homogenization means that landscapes are becoming more or less the same everywhere, without much variation. Some parts of the land are accessible for wildlife, but most is not. Fragmentation means that on the other hand that the land is dissected by barriers and increasingly difficult to go through. In the last 50 years new landscape types became dominant such as (sub) urban landscapes, motorway landscapes, recreation landscapes and industrial landscapes (**Fig. 1**). They replace forest landscapes, small scale agricultural landscapes with hedgerows, natural rivers and wetlands. Homogenization and fragmentation of the landscape contributes significantly to the decline and loss of wildlife populations and to the increasing endangerment of species.

In the entire world landscape fragmentation is increasing especially through the development of transport infrastructure, by building dams in rivers and by making agricultural land inaccessible by fencing and intensive land use. Landscape fragmentation caused by transportation infrastructure and built-up areas has four important ecological effects: direct habitat loss, traffic mortality, barrier for migration and dispersal and cutting populations into subpopulations (**Fig. 2**).

For Europe this process has been analyzed and made visible by the Swiss Environmental Agency together with the European Environmental Agency (FOEN-EEA, 2011). In general, landscapes are getting more connected for human use, but are at the same time ecologically disintegrating and fragmenting. (Sub-) urbanization is the driving force for ecological fragmentation. In Europe there are additional trends. National borders are getting less important and international issues are becoming more important, international transport and exchange is increasing (Jongman, 2002). The motorways and river regulation that are needed for it are the main ecological barriers in the landscape (**Fig. 3**).

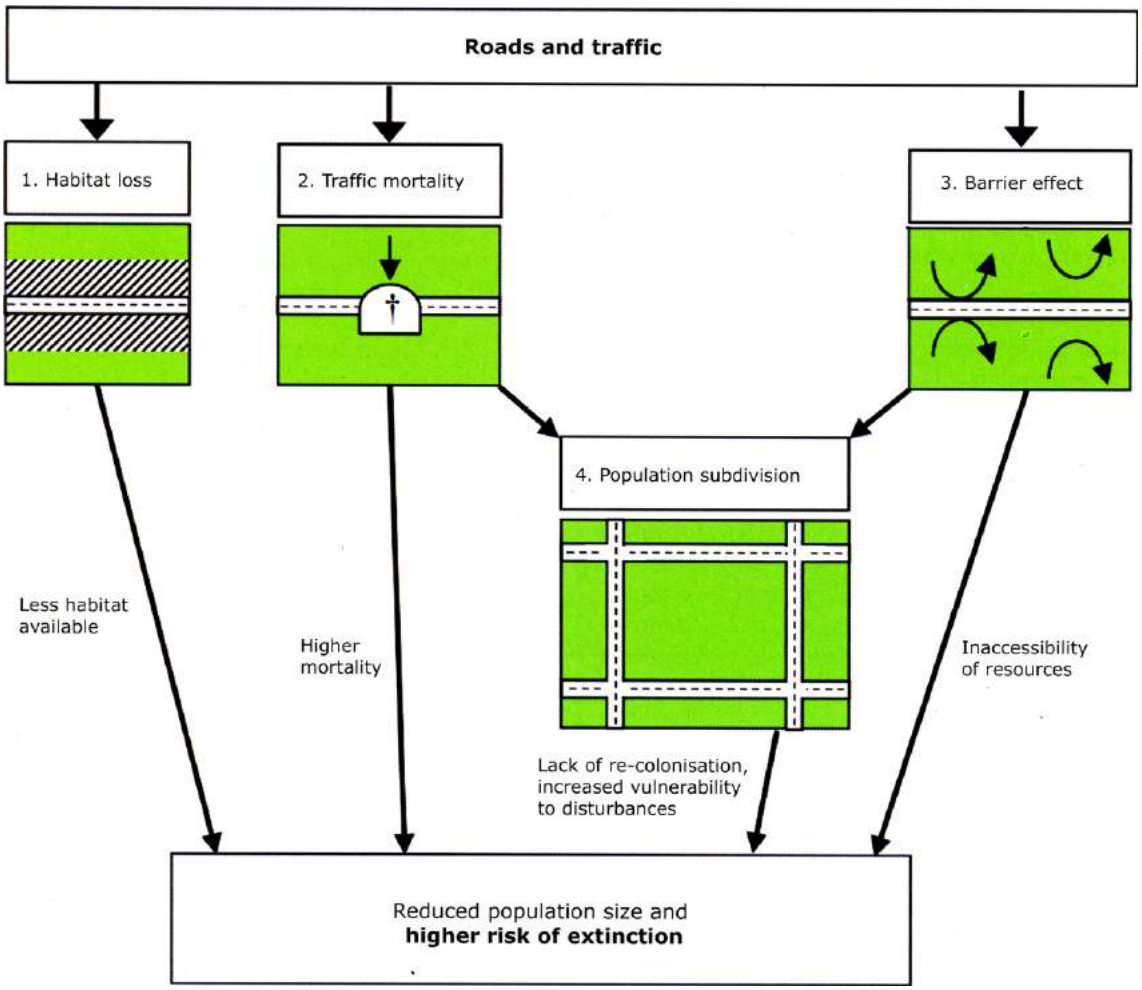

Fig. 2 Effects of transportation infrastructure on wildlife populations (Jaeger *et al.*, 2005).

Fig. 3 Human infrastructure as barriers: a motorway (A50, The Netherlands) and a river dam (Fukutomi dam, Honshu Island, Japan).

Climate change is complicating this development. Biodiversity depends on the protection and management of designated sites in an increasingly fragmented landscape. But habitats and species also have to adapt to a changing environment as a result of climate change. Over time, the conditions at habitats may change so much that species are moving to other sites. However, this is getting increasingly difficult because of homogenization and fragmentation of the landscape. Small, natural landscape elements within the agricultural landscape such as tree lines, hedgerows, road/waterway verges, ponds, and small woods can provide

suitable areas for dispersal and migration of species. However, often these natural landscape "routes" are too scattered and of poor quality from a biodiversity perspective. For improving connectivity between protected areas landscape and river management in a broader context is important.

Ecological Networks to Foster Ecological Connectivity

Introduction

From the beginning of the 19th century on, individuals as well as national and international conservation movements have elaborated strategies for species preservation and nature conservation through establishment of nature reserves and national parks. In the past these were sufficient to mitigate the human impacts on nature caused by animal use, urbanization and agricultural development. The restructuring of the landscape for urbanization and industrialized agriculture and the building of transport networks have isolated these protected areas, deteriorated ecosystems and made species extinct. Species survival is dependent on habitat quality, such as food availability, habitat size and for most species the ability to move through the landscape. This movement is needed for daily activities such as foraging, dispersal and reproduction migration and for avoiding unfavorable environments or seasons (Opdam, 1991).

Ecological networks can be defined as systems of sites of high biodiversity value and their interconnections that make a fragmented natural system coherent to support more biological diversity than in non-connected form. The definition of ecological network by Bennett (2004) is in line with this paradigm: "A coherent system of natural and/or semi-natural landscape elements that is configured and managed with the objective of maintaining or restoring ecological functions as a means to conserve biodiversity while also providing appropriate opportunities for the sustainable use of natural resources."

An ecological network is composed of core areas, usually protected by buffer zones and connected through ecological corridors (Jongman and Pungetti, 2004). The nature reserves and national parks, established in the past by traditional nature conservation policies form the majority of the core areas. The insight gained from island theory, metapopulation theory and landscape dynamics teaches us that these traditional conservation sites should be linked with each other through ecological corridors that have often multiple functions. Ecological corridors are the new elements in nature conservation policy and planning. However, they are also highly disputed because they are landscape elements where many functions coincide and that might lead to conflicts and discussion on, for instance, their use by migrating geese, wolves and invasive species.

At the heart of the ecological network approach is the awareness that without the full engagement of various sectors of economy and society in the management of ecosystems, there can be no effective biodiversity conservation. This "Ecosystem Approach" incorporates interaction of organisms, ecosystems, and the human component and it is the framework for holistic decision-making and action (Bennet, 2004). It is changing paradigms in protected area management moving from strictly nature oriented to a nature and society oriented approach. The goal of the network strategy is to conserve and restore ecological corridors and "stepping stones" (habitat islands), which function as habitat structures between core nature areas and facilitate ecological connectivity in the landscape. This cannot be done without finding compromises with other land use. It is however, the only strategy to cope with ecosystem fragmentation in the human dominated landscape and also with the changes to be expected through climate change. Changing climate will mean that land use will change, but also habitat quality and the suitability of the existing habitat islands; consequently there will also be a change in the role of connectivity. This means species will search for new, better adapted habitats and we have to facilitate this (European Commission, 2013a).

Ecological Corridors

Ecological links between habitats have always existed also in natural landscapes. Most obvious are migration routes for birds, ant-routes, badger routes and river corridors for fish migration like for the eel and the salmon. The term "corridor" has appeared very early in the literature to refer to long range dispersal. The current use of the term ecological corridor stems from the 1960s when it was used in spatial population dynamics for enhancing the chance of survival of smaller populations through exchange between patches. Metapopulation dynamics presupposes that some degree of connectivity exists between subpopulations within the fragmented landscape. Ecological corridors are based on either commuting, migration or dispersal movement functions. It can be defined as: A functional linkage between resource habitat of a species or a group of species, consisting of landscape structures that are different from the surrounding landscape resulting in a favorable effect on the genetic and species exchange (individuals, seeds, genes) as well as on species migration (Foppen *et al.*, 2000).

Ecological corridors therefore link isolated nature areas into one large "living" network (**Fig. 4**). An ecological corridor allows dispersal of plants and animals, and is often smaller and more linear than the natural areas it connects. These connections must, of course, be suitable for the species concerned, that is, they must contain the right habitat and be located in the right position in the landscape.

Due to differences in needs migration and dispersal routes can be manifold, from single wooded banks to small-scale landscapes and from river shores to whole rivers and coastlines. For fish it means that rivers do not only have a good water quality, but are also not blocked by dams. Most of the ecological corridors are primarily a mitigation of human disturbance regimes. Ecological corridors are therefore various landscape structures, varying in size and shape from wide to narrow and from

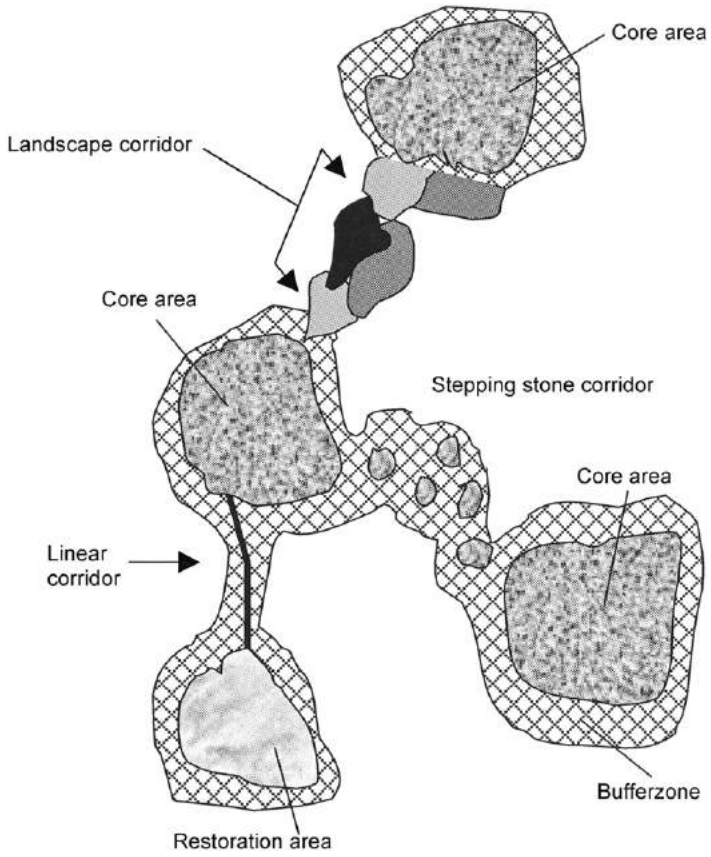

Fig. 4 Schematic example of an ecological network (Bouwma *et al.* 2002).

meandering to straight, providing ways to permeate the landscape, maintaining or re-establishing natural connectivity. Their density and spatial arrangement change according to the human land use. Nature needs different types of ecological corridors that have a complementary role to play in an interconnected habitat island system.

For mammals and amphibians it means that routes are available and that man-made barriers can be crossed. The need for these species to disperse can be between over distances from several meters to hundreds of kilometers. For small mammals ecological corridors can be hedgerows, brooks and all kind of other natural features that offer shelter. Migration is important for grazing animals like red deer (*Cervus elaphus*) and roe deer (*Capreolus capreolus*), but also for predators like the golden eagle (*Aquila chrysaetos*), the lynx (*Lynx lynx*), and the wolf (*Canis lupus*).

The nature of ecological corridors and their efficiency in interconnecting remnants and in permeating the landscape depend on their origin and the land use mosaic within which they are embedded and of which they consist. Forman (1995) makes a distinction in four main types of corridors:

1. line corridors, which are narrow strips of edge habitat, such as paths, hedgerows and roadsides,
2. strip corridors, with a width sufficient for the ready movement of species characteristic of path interiors (e.g., a wide power line corridor permitting movement of open country species through a forest),
3. stream corridors, which may function as one of the previous two, but which additionally control stream bank erosion, siltation and stream nutrient levels, and
4. network corridors, which are formed by the intersected corridors, usually resulting in the presence of loops, as well as subdividing the landscape matrix into many patches.

The Policy Context of Ecological Networks

Landscape changes are the reason that managing ecological connectivity is important and that nature conservation should take care of connectivity between reserves. Natural habitats in many parts of the world are now isolated islands. The smaller and more isolated these "habitat islands" are as a consequence of intensifying land use and road networks, the more likely it is that species decline. In many places in the world movements have been built to mitigate this development. In the 1970s already in several east European countries plans for nature networks have been developed, in the Netherlands in the 1980s the national Nature plan was designed (Jongman *et al.*, 2004), In Canada and the United States the Wildlands project and the Yellowstone-Yukon Conservation

initiative (https://y2y.net/) have been started also in the early 1990s. In 2010 connectivity has also been expressed in the 11th Aichi target of the Convention of Biological Diversity, to be reached by 2020.

Aichi target 11: By 2020, at least 17% of terrestrial and inland water, and 10% of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well connected systems of protected areas and other effective area-based conservation measures, and integrated into the wider landscapes and seascapes (https://www.cbd.int/sp/targets/).

This target means that ecological corridors should link natural areas and especially protected areas into a coherent system: an ecological network. Accordingly, already years before the COP in 2010 in Nagoya various conservationists and conservation authorities have been changing their strategy from only of conservation of the existing, more and more isolated natural "islands" to the conservation and restoration of interconnected natural areas (Jongman and Pungetti, 2004).

Already in the end of the 19th century Parkways have been designed in both Europe and the United States but then mainly for other (recreational, hydrological) purposes. The most famous is the still existing park system of Frederick Law Olmstead in Boston, the Emerald Necklace as a connected systems of parks and greenways. This greenway approach (https://www.greenway.org/), is integrating local interests in hiking and biking with biodiversity conservation and building on the tradition of Parkway Planning (Jongman and Pungetti, 2004). Greenway systems have been created in many states such as in Florida (Florida Greenway Commission, 1994).

National authorities as well as non-governmental organizations around the world establish now ecological networks at different scales. If one looks at Europe, at present the Bern Convention and several EU directives support each other to realize the Pan European Ecological Network, the Natura 2000 network as spatial result of the Habitats- and Birds Directives and the Emerald Network (Bonnin *et al.*, 2007, Jongman *et al.* 2011).

Ecological networks and other habitat networks require planning also across borders. If decisions are not coordinated across borders then misunderstanding can lead to ineffective planning and waste of government budget. Bouwma *et al.* (in: Jongman and Pungetti, 2004) reviewed conventions and EU-legislation in order to assess, which European endangered vertebrates are considered to benefit from corridors with a European dimension. In total 420 vertebrate species were reviewed. It is estimated that of these species 104 species could benefit from European corridors. Of these 69 are bird species, 23 are mammals (mostly large herbivores and carnivores) and 12 are fish species. The highest number of potential species is in the Mediterranean and Continental biogeographic region. Realizing this means international cooperation in conservation policies.

The "Waterbirds around the world" conference in 2004 reviewed waterbird migration at many levels of detail, from the long distance migration routes to the relative short distance movements. In almost all cases the word "flyway" has been used to indicate the geographical region of migration. A general definition of a flyway is: "A flyway is the entire range of a migratory bird species or groups of related species or distinct populations of a single species, through which it moves on an annual basis from the breeding grounds to non-breeding areas, including intermediate resting and feeding places as well as the area within which the birds migrate" (Boere and Stroud, 2006). Flyways can be single species flyways or multi-species flyways. From knowledge of the various single migration systems it is possible to group the migration routes especially used by waterbirds into multi species flyways. This allows grouping the global migrations of waders into eight flyways: the East Atlantic Flyway, the Mediterranean/Black Sea Flyway, the West Asia/Africa flyway, the Central Asia/Indian sub-continent Flyway, the East Asia/Australasia Flyway, and three flyways in the Americas and the Neotropics.

Fish can migrate through oceans as well as rivers. Some species such as eel (*Anguilla anguilla*), Atlantic salmon (*Salmo salar)* and sturgeon (*Acipenser sturio*) combine both. Fish require river corridors like large rivers up to its headwaters dams and good water quality (Lafaille *et al.*, 2005). Fish species in larger wetlands or river complexes also migrate upstream for spawning as is the case in the Pantanal and the Mekong. Because of the great variety of feeding and reproductive niches for fish, these river wetlands harbor a high species diversity and abundance. Fish are an important resource, both ecologically, economically and socially. However, many of these river systems have been made inaccessible in the past due to damming and river regulation. Fish therefore often require adaptation by building fish ladders and removal of dams.

Green Infrastructure

The concept of ecological networks is developing further and is being accepted more widely by urban planners and river managers as principles for restoring nature and including it in their management plans. The name is changing towards "Green Infrastructure (GI)." Edward T. McMahon (The US Conservation Fund) says that Green infrastructure is "… an interconnected network of protected land and water that supports native species, maintains natural ecological processes, sustains air and water resources, and contributes to the health and quality of life for people." The European Commission (http://ec.europa.eu/environment/nature/ecosystems/) writes on its website that it: … is addressing the spatial structure of natural and semi-natural areas but also other environmental features which enable citizens to benefit from its multiple services.

Green infrastructure or blue-green infrastructure is a network providing the "ingredients" for solving rural, urban and climatic challenges by building with nature. Comparable approaches are being developed in the USA and in the EU. Habitat restoration and green infrastructure are key topics at present for the US Environmental Protection Agency (EPA, https://www.epa.gov/green-

infrastructure). This policy can be used to translate landscape ecological principles into practice concerning mitigating ecological homogenization and fragmentation.

Regional Implementation and Technical Solutions

The aim of establishing ecological networks is improved protection of nature and biodiversity. Its development is stimulated by science and nature management practice. The initiative taken in 1994 by the Council of Europe to formulate the Pan European Biological and Landscape Diversity Strategy (PEBLDS) and its action point on the Pan European Ecological Network (PEEN) was one of the drivers of a real European and global approach and recognition of corridors as inevitable part of nature conservation in a fragmenting world. The Pan-European Ecological Network (PEEN, Jongman *et al.*, 2011) aims to ensure that:

- A full range of good quality ecosystems, habitats, species and landscapes of European importance are conserved;
- Habitats are large enough to guarantee a favorable conservation status for key species;
- There are sufficient opportunities for dispersal and migration of species;
- Damaged parts of key environmental systems are being restored;
- The key environmental systems are buffered from threats.

In the meantime many countries have developed their own regional or national ecological networks (Jongman *et al.*, 2004) and have started to implement them in their own way (**Fig. 5**). In the meeting of the Standing Committee of the Bern Convention in December 2015 it was reported that at present ecological networks or conservation corridors do exist in 35 countries that signed the Bern Convention. Their status varies from pilots to implementation. The EU Green Infrastructure initiative is an important stimulus in this now.

Ecological networks are a way to make the landscape aesthetic again and to give a landscape back its regional characteristics. It should not only fulfill a role as linking element in the landscape but it should be possible to be used for education and recreation and fulfill ecosystem services such as flood surge and water storage.

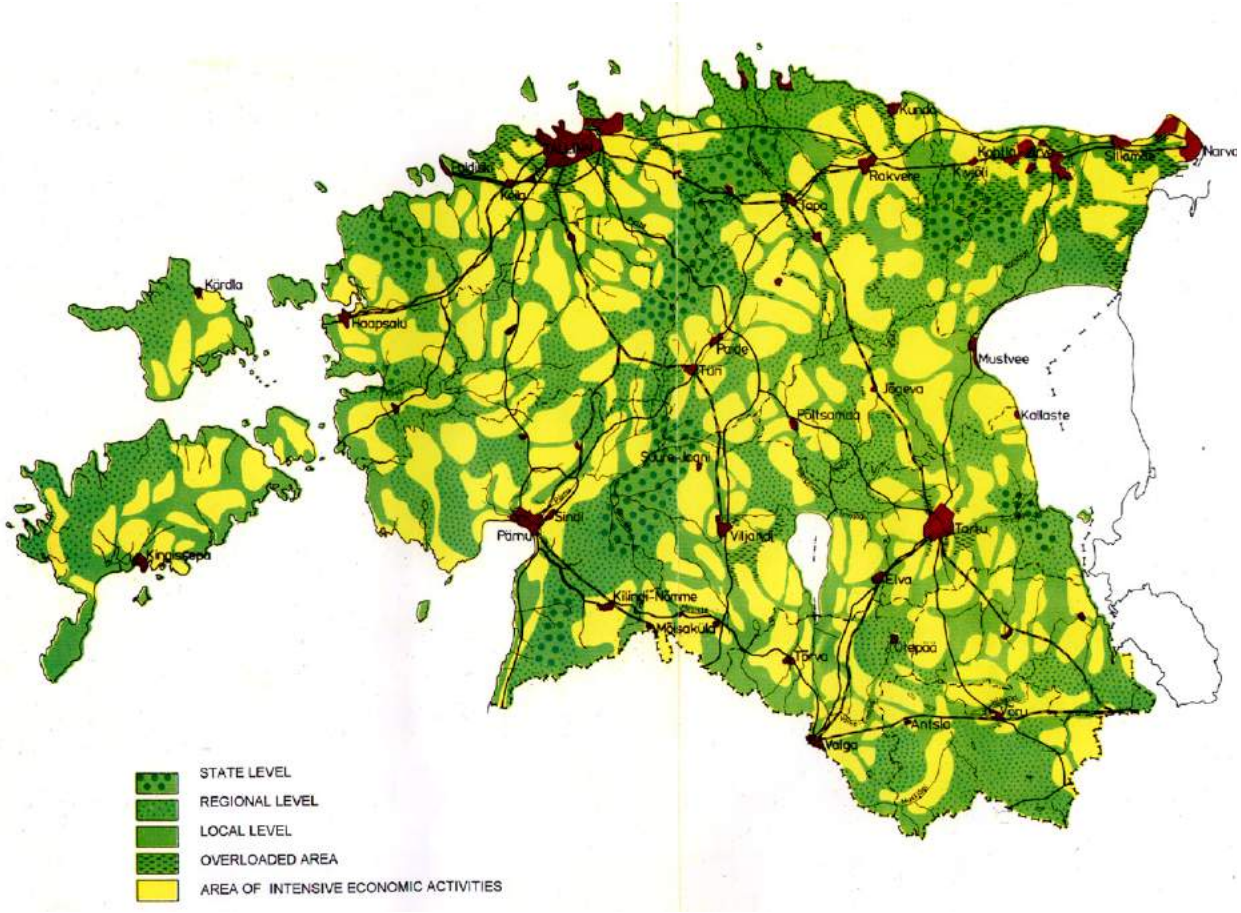

Fig. 5 Different approaches for development of ecological network or greenway system: in Estonia (Sepp *et al.*, 2013) and Florida (Florida Greenway Commission, 1994).

Motorway crossings for species are essential in a human dominated landscape. It has become an important issue in all countries in the world. In Europe about 50% of the country reports to the Bern Convention and to the CBD describe initiatives or the need to develop this kind of initiatives (http://www.coe.int/en/web/bern-convention/-/35th-standing-committee-meeting). The EU Directorate General for Environment was important in providing incentives for developing Green Infrastructure (GI) and large-scale infrastructure crossings for fauna. Such initiatives act as flagship actions and serve as examples at national, regional and local levels to boost the further implementation of trans-European GI in policy, planning and financing decisions. Member States and regions have in this way been stimulated to develop GI in a cross-border/transnational context (European Commission, 2013b).

Conflicts with human infrastructure can be overcome by spatial and technical solutions. The consequence is also, that the development of ecological networks and green infrastructure takes time for planning, finding funding and implementation. As it is a societal process, all stakeholders should be involved but they do not necessarily have to agree on all issues. Preparation takes time, the design has to be agreed based on landscape ecological knowledge, societal needs and spatial context. With a good landscape design, finances have to be found and afterwards maintenance and monitoring is needed as well. Technical solutions can be ecoducts for larger fauna (**Fig. 6**), culverts under roads for smaller fauna (**Fig. 7**) and fish ladders for fish (**Fig. 9**).

Fig. 8 Adapted culvert as wildlife underpass for small mammals (photo Rob Jongman).

Fig. 9 Fish ladder in one of the headwaters of the Tweed (Scotland) for migration of Salmon (*Salmo salar*) to its spawning waters. (photo Rob Jongman).

Implementation of fauna bridges and tunnels depend on willingness of sectoral (transport) policy makers and planners at national and regional level to consider biodiversity as an issue of the same importance and value as other societal interests. In some countries this change in perception and willingness to invest has been reached and solutions are being elaborated jointly by road planners, spatial planners and conservation planners. The Karpaten-Alpen corridor between Austria and Slovakia (www.alpenkarpatenkorridor.at/) has been elaborated and realized as an important European wildlife corridor system. It ensures the migration and genetic exchange between wild animal populations between Alps and the Carpathians by securing an ecological corridor through an urbanized area and to strengthen awareness of the importance of green connected areas and eco-friendly land use. In Croatia the highway from Zagreb to Rijeka stretches 68.5 km through a wildlife core area in Gorski Kotar. It has now a 100 m wide wildlife bridge at Dedin. Here on average 15.8 wildlife crossings (among others brown bears) per day have been counted (Kusak *et al.*, 2009). In The Dutch national Ministry for traffic and water management has set up a multi-annual defragmentation program in which 215 obstacles have been identified in national roads, rail and water infrastructure. Efforts to eliminate them involve measures like wildlife bridges (**Fig. 6**), wildlife underpasses (**Fig. 7**), and eco-culverts (**Fig. 8**). For supporting the design of fauna crossings and to integrate them in road construction there is a special guidance document (Kruidering *et al.*, 2005). The target of the program is to eliminate these obstacles by 2018 at the latest. At present it is expected that by then 94% is realized.

Defragmentation of rivers is an important target for the conservation of aquatic species, in particular fish. The US Forest Service is actually removing non-functional dams in rivers. In 1996, Benelux countries announced their intention of achieving free fish migration in all water catchments by 2010. In Belgium and the Netherlands this has not yet been realized, while Luxemburg does mention that in the 1990s multiple projects have been carried out leading to a more continuous water system. The Czech Republic mentions the existence of 6000 transverse barriers across rivers in the country. Hungary reports the disappearance of six fish species in its rivers due to damming of the Danube. Moldova announces agreements with Romania and Ukraine for the restoration of

common river systems. Also in the UK river connectivity is being restored by projects such as the revitalization of the Tweed catchment for the salmon by the Tweed water authorities and the Tweed Foundation boosting its Salmon population as well as regional tourism for salmon fishing (**Fig. 9**) and other projects by the Wildlife Trusts (http://www.wildlifetrusts.org/restoringrivers).

International corridors, such as in large rivers are difficult to manage as they require international agreements. The International Commission for the Protection of the Rhine (ICPR) has started in 1999 to restore the ecological river corridor of the Rhine and it has taken the salmon as its symbol and target species to be back as a healthy population in 2020 (Schulte-Wülwer Leidig, 2004). This project for accessibility of the river Rhine requires both national actions in seven countries and international political agreements on making the river accessible through among others fish ladders and other passages, long term projects for adaptation of locks and weirs including as final step the improvement of exchange between river system and the North Sea. This project is, of course, not only important for the salmon, but also for other migratory fish such as eel, sturgeon and shad.

Conservation Biological Control and Biopesticides in Agricultural[☆]

ED Fountain and SD Wratten, Lincoln University, Canterbury, New Zealand

Prior to 1995, almost no research was conducted on biopesticides but recently a high number of new biopesticides are being researched, tested and introduced to the market. At the end of 2008, there were approximately 245 registered biopesticides in the USA. The Environmental Protection Agency (EPA) recognizes three major classes of biopesticides: microbial, biochemical, and plant-incorporated-protectants (PIPs). Although the use of biopesticides has increased, there is still resistance to their use. One of the major contributors to the negative perception of biopesticides is that growers do not know about biopesticides and the cost/efficacy. In an industry survey conducted in the USA, growers indicated that biopesticide companies need to place heavy emphasis education about the products and how to use them. Another barrier to biopesticide use is the highly competitive, capital intensive marketplace which is often dominated by multibillion-dollar agrichemical companies. However, these companies more recently have begun to recognize the benefit of biopesticides and have begun to produce new products. In 2008, Dow AgroSciences LLC, a major agrichemical company, won the Designing Greener Chemicals Award from the EPA for their product, Spinetoram.

Conservation biological control is the modification of the environment or of agronomic practices to protect and enhance the efficacy of natural enemies of pest organisms. Biopesticides are natural enemies of pest organisms released *en masse* to control the pest, where the agent does not usually persist in high numbers in the crop environment. These two methods are the two most recent forms of biological control and are relatively early in their developmental stages. However, these techniques are proving to have potential as effective tools in pest management and do not carry the sometimes high risks of classical biological control. This article will not concentrate on conservation biological control or biopesticides in particular crops, pest species, or diseases. Rather, it will assess the theories involved, progress to date, and prospects for further adoption of these practices and products.

Modern Agriculture

During the last 50–60 years, worldwide agricultural practices have been characterized by high inputs, high yields, unsustainable practices, and ecosystem damage. This production method, often termed 'substitution agriculture', relies on inputs of fertilizers and agrochemicals to maintain and enhance soil fertility and manage weeds, pests, and diseases. These chemicals damage the environment, reduce biodiversity and ecosystem function, and are increasingly becoming ineffective due to pest resistance and other factors mentioned above. Subsequently this form of agriculture has become dependent on these chemical inputs to maintain production. Public concerns about the unsustainability of these practices are being raised, along with concerns of the impacts of these practices on environmental and human health. Ecosystem services (ES) to humanity have been valued in excess of US$ 33×10^{12} pa worldwide. They include food production and quality, climate, soil and hydrological regulation, nutrient cycling, maintenance of genetic diversity/resources, and recreation. Recognition of the value of these services and a change in agricultural practices to restore ecosystem function are necessary to create sustainable growth, especially as the world population is expected to increase 50% in the next 50 years to 9 billion. In response to these social, economic, and marketing pressures, agriculture is being forced to discontinue the use of some agrochemicals (e.g., organochlorine insecticides) or they are to be phased out over time (e.g., methyl bromide). This has raised attention in the research community to find sustainable alternatives to 'substitution agriculture'. One area of focus has been biological control, especially conservation biological control and biopesticides, both as part of an agro-ecological approach. The early stages of these disciplines were rudimentary but current research is now showing great potential to play an important part in sustainable pest management in sustainable agriculture. However, there are several restrictions that impede a faster expansion of the discipline and its transfer to the agricultural community. These include the availability of selective biodegradable chemical pesticides, the lack of a strong information-transfer infrastructure, highly regulated restrictions on the

 http://dx.doi.org/10.1016/B978-0-12-409548-9.00539-X

introduction and deployment of exotic agents, and poor grower perception and knowledge of biological control and how to use and enhance it. Also, there are not enough market-based incentives (or instruments) to deploy biological control technologies. This is in spite of the fact that ample evidence exists that the (ecosystem) service-providing unit (SPU) is well established and that the economic value of such provision/avoided costs, maintenance of, and increases in markets has been well demonstrated.

Conservation Biological Control

Insects

Conservation biological control has been the least-studied area of all biological control techniques and has been dominated by arthropod pest systems. This technique usually adds plant biodiversity to agricultural systems through the provision of shelter and nonprey food, especially in high-value crops such as wine grapes. One of the most successful conservation biological control techniques has been 'beetle banks' which were developed by the Game and Wildlife Trust and the University of Southampton in the United Kingdom. They comprise overwintering refugia for predatory arthropods in arable land and have the added benefit of providing nesting sites for rare farmland birds and mammals. Although floral resources for pests' natural enemies were planted in the 1980s and 1990s, their selection and deployment were not obviously informed by ecological science. There later developed a growing awareness of the possible impact of the plants on the pest itself and on any parasitoids of natural enemy species. Bioassays to measure the effects of flowers on fecundity and longevity in these trophic levels have recently been carried out so that the deployment of selective floral diversity in agricultural systems is now possible. Recently, floral nectar has been analyzed for its sugar ratio, then the same plants were assessed with pests' natural enemies. Flower structure and size also have an impact on the system. Long, narrow flowers may provide nectar only to larger insects with long mouthparts, whereas large, shallow flowers provide nectar to all species. Further knowledge of such aspects of floral resources will allow plant selection to benefit the third trophic level more than the second and the fourth, which will allow agriculturalists to maximize the effects of the technology.

An area of recent development in conservation biological control is the awareness of herbivore-induced plant volatiles (HIPVs). These (mainly terpenoids and indoles) are systemically released by the plant during insect herbivore feeding and attract predatory and parasitic insects to the plant. In tomato, this response led to twice as many parasitoid larvae (*Hyposoter exiguae*) developing on tomato fruitworm (*Spodoptera exigua*) than in the control. There is a large range of volatiles released by different plant species; some attract a narrow range of natural enemies, others a broad range. If natural enemies can be attracted into a crop in this way ('attract') and their 'fitness' enhanced by the provision of appropriate selective nectar resources ('reward'), then the prospects for an 'attract and reward' pest management program will have been developed.

Attention is now greatly focused on not only the importance of the floral resource and the species on which it impacts, but also the importance of each species with regard to ecosystem function. Ecologists generally agree that higher biodiversity *per se* does not necessarily increase ecological function, so the role of particular species or groups of species is being investigated. This will further refine research efforts to effectively maximize ecosystem services, including biological control. Also, adding resources to enhance a particular ES is likely to enhance others, too.

Plant Pathogens

Conservation biological control of plant pathogens is in the early stages of development but the technology shows great potential. The most recent work has been done on the grapevine/*Botrytis cinerea* system where the pathogen's life cycle was disturbed and levels of primary inoculum were reduced through the use of organic mulches or of cover crops, mulched *in situ*. Levels of primary inoculum from vine debris were reduced under mulch, through an increase in the activity of soil biota, both through competition with the pathogen for resources and through increasing rates of vine debris degradation. The changes in soil biota were linked to soil moisture and possibly soil nutrient levels. The vines under the organic mulches used in this work sustained half the rates of botrytis bunch rot at harvest, compared with nonmulch controls, averaged over 2 years (**Figure 1**), and brought the disease below the economic threshold of the region. Progressive grape growers are now using organic mulches for this purpose in their vineyards. This adoption sets a precedent for other growers and large-scale adoption of the technique is possible. Other advantages of the mulches that may help adoption are that they are easy to apply/manage and the materials they use are either cheap or waste-stream products from the vineyard itself. This biological system is potentially applicable to other plant pathogen systems (e.g., downy mildew (*Plasmopara viticola*)) which overwinter on plant debris. The technology could also be integrated into other understorey manipulation techniques, such as the provision of flowering plants (discussed above), where plants could be mulched after flowering.

Biopesticides

Insects and Pathogens

The technique does not include toxins or secondary metabolites that are produced from living organisms as these are nonliving. In 2000, biopesticides sales worldwide had a value of US $160 million of which about 90% contained *Bacillus thuringiensis* (Bt), a Gram-positive bacterium found in soil or on plant surfaces. The sales of biopesticides have been increasing rapidly since the 1980s.

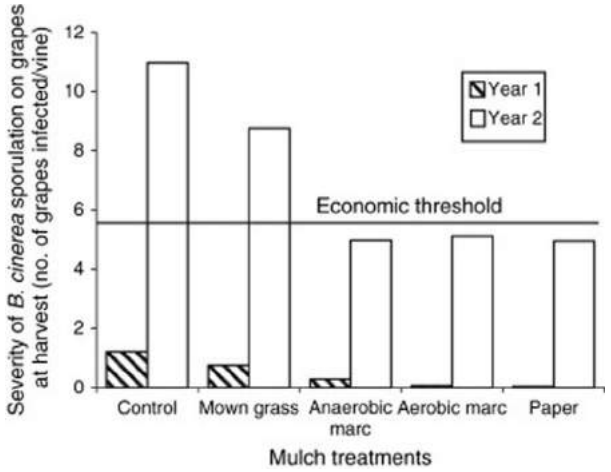

Figure 1 Severity of botrytis bunch rot in grape vines at harvest, under different mulch treatments over two consecutive seasons in Seresin Estate Vineyard, Marlborough, New Zealand. Three of the mulch treatments bring botrytis bunch rot below the economic threshold in the second year.

This market is mainly driven by consumer requirements for environmental and human health and the increasing problem of pest resistance. Currently, key markets for these products are organic and integrated pest management (IPM) systems and those with high pest resistance and high-value speciality crops.

The first example of a commercially available biopesticide was in the 1920s, where *Encarsia formosa* was sold to control greenhouse whitefly. This biopesticide is currently widely available commercially and has been sold in increasing amounts since initiation. This is one of the several examples where an invertebrate species has been used as a biopesticide agent and is largely successful because of the controlled environment of a greenhouse. Generally, invertebrates are not considered to be appropriate for the technique as they are too difficult to apply and are generally too mobile for field conditions. The first biopesticide containing a microorganism as the biologically active ingredient was Bt and was used in France in the 1930s; it is a product which has dominated the biopesticide market ever since. From this time, development in the area has been focused on creating a product that is easy to culture, store, and apply, has a fast impact, and is environmentally robust. Initially potential agents were usually tested and found to be effective under the ideal environmental conditions of the laboratory, then applied under field conditions where they often failed. Failures were commonly a result of poor spray coverage, low spore viability, or unfavorable environmental conditions. The importance of the environment for agent virility was then fully acknowledged and agents were then screened and tested for effectiveness under different climatic conditions. This approach not only assessed compatibility between the agent and the host, but also propagule hardiness and viability under adverse conditions. Efforts were also spent on formulating a nutrient-rich, stable medium in which the propagule could be stored and applied, in an attempt to maximize the agent's efficacy.

Currently, research in the area comprises many disciplines including pathology, physiology, genetics, mass culturing, formulation technology, and propagule stabilization and application; yet there is little collaboration between the disciplines and this hinders the rate of development of the technology. Interest in biopesticide products from agriculture is also generally low due to the fragmented nature of the industry, the lack of interest from agrochemical industries, the availably of 'soft' orthodox pesticides, low grower awareness, and their education about and perception of biopesticides. For the technology to develop further, these things need to change and growers need to change their view of biopesticides from purely a substitute for agrochemicals to a valuable biological organism with environmental requirements.

Biopesticides – Areas of Use

Biopesticides are currently used to manage invertebrate pests, plant pathogens, and weeds. The microorganisms used include bacteria, yeasts, fungi, and viruses. Most research has been conducted on fungal species; as many are easily cultured, their spores are environmentally stable and can be easily managed, amended, and manipulated – they can hence be applied with convention spray systems. To date, much more research effort has been spent on the development, registration, and commercialization of products for plant pathogens and pest species than of weed species, so only the former two will be covered here.

Plant Pathogens

Biofungicides attack plant pathogens through several mechanisms, including antibiosis, hyperparasitism, and competition, with the latter usually being the predominant and most important mechanism. There are many products available for a wide range of crop/pathogen systems which are effective on both foliar and root diseases. Many agents are highly competitive for space and nutrients but usually have a low capability of displacing developed microorganisms. These characteristics make biofungicides preventative treatments but some have limited curative potential. Biofungicides share the characteristics of the best biological

control agents of being highly reproductive, environmentally hardy, and highly antagonistic. Many of the current products contain a series of species from the same genus that operate through different mechanisms to obtain higher levels of control. To date, most products for foliar and soil plant pathogens are *Trichoderma* species and can help to manage economically important plant pathogens such as botrytis rot, powdery mildew, and *Sclerotinia* species. Products have also been developed as seed dressings from the genus *Bacillus* and *Pseudomonas* to control several soil-borne plant diseases. Species have also been investigated as potential biofungicides when they are suspected to have a role in suppressive soils, a concept where plants grown in soils high in particular soil flora are more resistant to disease. Fluorescent pseudomonades are one of these species and can inhibit germination of fungi through competition for ferrous minerals.

Microorganism biopesticides for the management of invertebrate pests

More than 1500 species of known fungi, viruses, bacteria, and protozoa can infect arthropod species. The first attempt to use them as bioinsecticides was in 1884 when a Russian scientist, Elie Metchnikoff, used *Metarhizium anisopliae* to infect two invertebrate pests, the cereal cockchafer, *Anisoplia austriaca*, and the sugar-beet weevil, *Bothynoderes punctiventris*. The first commercially available bioinsecticide, Bt, was produced in the 1930s and many bioinsecticides have been produced since, the majority of which are entomopathogenic hyphomycete fungi. Bioinsecticides have not always provided consistent control of insect pests, as the relationship between the agent, the pest, the timing, and the environment is inherently complex. Of these variables, the environment is the most important and the one most likely to lead to a breakdown in the system. Consequently, bioinsecticides have been most successful in the warm, humid conditions of the tropics. When environmental conditions change, both the pest and the biological control agent are affected. Both species have an optimum range of temperatures and humidities. In temperate climates, the agents' optimum temperature and humidity conditions are usually higher than those of the pest species, so the agents' performance can decline and the pests' fitness can increase with a decline in these environmental variables. Pest health also has impacts on resistance to fungal attack, especially pest nutrition, age, genetics, and physical damage through mechanical, chemical, or biological means. Agriculturalists can influence pest health and, as a consequence, increase pest susceptibility to bioinsecticides, by using resistant crop cultivars or manipulating the habitat to alter pest nutrition. Other variables that influence the success of the technique are the virulence and hardiness of the agent, its compatibility with the host, and the viability of the propagule after storage. To increase the effectiveness of the products, agriculturalists are urged to monitor environmental conditions to assist in deciding when bioinsecticides should be applied and when to apply them to optimize environmental conditions. Spray machinery should also be calibrated to ensure good spray coverage at the correct rate, as this will increase the likelihood of exceeding the pest propagule threshold and lead to effective management of the pest as a consequence.

Conclusion

Conservation biological control and biopesticides have great potential in organic agriculture or in IPM programs. These systems are complementary and elements of them can be integrated into conventional pest management systems. The two techniques do have their limitations, however, and most agriculturalists need to adjust their perception of the technologies, especially biopesticides. Currently, the latter are viewed as substitutes for agrochemicals, and the products are expected to operate at the same speed and under the same wide range of environmental conditions as conventional products. Agriculturalists require education about the biology of the biopesticide and the target pest. They need to set up pest monitoring systems, develop a network of contacts to assist in decisions concerning when and how to apply biopesticides, and realize the limitations of the technology. Limitations include being effective only pre-infection, of needing different biopesticides for particular pests, of environmental conditions, etc.; these are important influences on the efficacy of control. Acceptance of the limitations and the gaining of appropriate knowledge should allow biopesticides and conservation biological control techniques to be integrated into agroecosystems to produce a more sustainably produced, higher-value product. This approach can enhance the contribution of ecosystem services to pest, weed, and disease control, satisfying increasing environmental, energy, human health, and marketing demands. However, as long as conventional pesticides remain relatively inexpensive, because the economics of their negative external costs (human health and environment) are no included in the price, biopesticides may continue to have a small market share. Nonetheless, the factors mentioned under 'Modern Agriculture' are likely to change this system.

Conservation Genetics

Richard Frankham, Macquarie University, Sydney, NSW, Australia and Australian Museum, Sydney, NSW, Australia

Glossary

Effective population size (N_e) The number of individuals that would result in the same loss of genetic diversity, inbreeding, genetic drift, or coalescence if they behaved in the manner of an idealized population.

Evolutionary potential The ability of a population to evolve, especially to cope with environmental changes. Often equated with genetic diversity, especially for quantitative characters such as fitness.

Genetic diversity The extent of genetic variation in a population, or species, or across a group of species e.g., heterozygosity, or allelic diversity, or heritability.

Genetic drift Changes in the genetic composition of a population due to random sampling in finite populations. Also referred to as random genetic drift.

Genetic load The load of harmful alleles in a population, some due to mutation-selection balance (mutation load), and others to heterozygote advantage and other forms of balancing selection.

Genetic rescue Improvement in reproductive fitness and increase in genetic diversity due to crossing to another distinct population, of a population previously suffering from inbreeding and low genetic diversity.

Inbreeding depression Reduction in mean for a quantitative trait due to inbreeding, especially manifest in reproductive fitness traits.

Kinship The probability that two alleles, one from each of two individuals, are identical by descent (also termed coancestry). The inbreeding coefficient of any real or imagined progeny of the two individuals.

Mutation-selection balance Equilibrium between the occurrence of harmful mutations and natural selection removing them, resulting in low frequencies (typically $<1\%$) of harmful alleles at individual loci in populations. This occurs at loci throughout the genome.

Outbreeding depression A reduction in reproductive fitness compared to either parent observed in the progeny of F_1, F_2 or later generation crosses between two genetically divergent populations (or sub-species, or species) caused, for instance by some combination of fixed chromosomal differences and/or disruption of local adaptation and long isolation.

What Is Conservation Genetics?

Conservation genetics is the application of genetics to understand and reduce the risk of population and species extinctions. It deals with genetic factors causing rarity, endangerment and extinction (inbreeding and loss of genetic diversity), genetic management to minimize these impacts, and the use of genetic markers to aid in resolving taxonomic uncertainties in threatened species, to understand their biology, and in wildlife forensics. It is an applied discipline drawing on evolutionary and molecular genetics and genomics.

The need to conserve species arises because the biological diversity of the planet is rapidly being depleted as a direct or indirect consequence of human actions. An unknown but large number of species are already extinct, while many others have reduced population sizes that put them at risk. Many species now require human intervention to ensure their survival. The scale of the problem is enormous; 26% of mammals, 13% of birds, 42% of amphibians and 40% of gymnosperms are categorized as threatened by the International Union for the Conservation of Nature (IUCN), with similar problems in other groups, but insufficient species evaluated to provide reliable statistics for them.

Four justifications for maintaining biodiversity have been advanced; the economic value of bioresources, ecosystem services, aesthetics, and rights of living organisms to exist. IUCN recognizes the need to conserve biodiversity at three levels; genetic diversity, species diversity, and ecosystem diversity. Genetics is involved in all three of these. In what follows, the emphasis is on the first two.

When Did Conservation Genetics Begin and How Has It Developed?

Sir Otto Frankel, an Austrian born Australian, was largely responsible for the recognition of genetic factors in conservation biology, beginning only in the early 1970s. Frankel collaborated with, and strongly influenced Michael Soulé of the United States, the founding father of modern conservation biology, and they wrote the first book on conservation biology that considered genetic factor (published in 1981). There was initially controversy regarding whether inbreeding had harmful effects on reproductive fitness (reproduction and survival) in wild species. In captivity, a series of pioneering studies by Katherine Ralls, Jonathan Ballou and collaborators in the late 1970s and early 1980s showed that inbreeding had harmful effects on juvenile survival: they found that inbred offspring had lower juvenile survival than outbred offspring in 41 of 44 mammal populations. The issue then turned to

 doi:10.1016/B978-0-12-409548-9.10559-7

the relationship between inbreeding and extinction in wild species in natural habitats, and whether nongenetic factors typically drive species to extinction before genetic factors could impact them. Empirical evidence refuted this hypothesis for most species: it showed that inbreeding caused harmful fitness effects, including elevated extinction risk, and the impacts were more severe than in captivity. The first textbook in the field was only published in 2002. More recently, there has been growing emphasis on the genetic impact of population fragmentation.

How Does Conservation Genetics Advance?

Conceptual advances in conservation genetics originate from mathematical modeling, computer simulations, laboratory experiments, field experiments, meta-analyses, and the feedback between them. Given that conservation genetics is a complex system with many variables, especially in the wild, single experiments and approaches rarely resolve issues relating to wild populations. Consequently, several independent approaches are often required to resolve issues, as was the case for the role of genetic factors in extinction (where theory, computer simulations, lab experiments, field experiments and meta-analyses all contributed).

Such approaches are complemented by technical advances, as with the improvements in statistical power and precision obtained with the progression from morphological and fitness traits, to protein electrophoresis, to DNA markers, and to genomics.

Why Is Conservation Genetics Important?

Conservation genetics is important because it deals with significant factors contributing to species and population extinctions (inbreeding, loss of genetic diversity and mutational accumulation), and by providing convenient techniques to obtain important information on species biology that contributes to their conservation, as discussed below.

Inbreeding

Inbreeding is the production of offspring from individuals that are related by (recent) descent from a common ancestor of their parents. It is measured using Wright's inbreeding coefficient (F), the probability that two alleles at a locus in an individual are identical by descent. This coefficient ranges from 0 to 1, and is 0.5 for the progeny of self-fertilization, 0.25 for the progeny of brother-sister mating, and less for progeny of matings between cousins. It is an unavoidable occurrence in small closed population (ones with no gene flow), accumulating slowly over generations in random mating populations: in hermaphrodites, F increases by the proportion $1/(2N_e)$ per generation, where N_e is the genetically effective population size.

Effective Population Size

All of the genetic impacts of small population size (inbreeding, loss of genetic diversity and genetic diversification among replicate populations) depend upon the genetically effective population size (N_e), rather than the census size (N). The genetically effective size is the number of individuals that would result in the same loss of genetic diversity, inbreeding, genetic drift, etc., if they behaved in the manner of an idealized population. An idealized population consists of hermaphrodites with equal number in each generation, random union of gametes, Poisson variation in family sizes, nonoverlapping generations, and no migration, mutation or selection.

How Are Effective and Census Sizes Related?

As real populations violate the assumptions of the idealized population in having fluctuations in population sizes over generations, greater than Poisson variation in family sizes, unequal sex-ratios, and overlapping generations, effective population sizes are generally much less than census sizes. Since we rarely have N_e values for threatened species, we often wish to infer it from census sizes and N_e/N ratios from related species where the ratio is known. On average the N_e/N ratios are ~ 0.13 based on three meta-analyses, but the ratio varies with life-history attributes, especially age at maturity and adult lifespan. In particular, species with high fecundity have lower ratios on the order of 10^{-3}–10^{-6}, based on data from fish, oysters, shrimp and seaweed. Low ratios mean that harmful genetic effects occur sooner and at a greater rate than assumed from census sizes.

Inbreeding Depression

Inbreeding results in reductions in fitness (inbreeding depression) in all naturally outbreeding species, and to a lesser extent in species with inbreeding mating systems. It has been known since as early as Darwin's work in the 1870s, but its full impact has only recently begun to be documented. All fitness traits are susceptible to inbreeding depression, but traits peripheral to fitness exhibit little or no inbreeding depression. For example, inbreeding depression is observed for fecundity and survival in *Drosophila* fruit flies, but not for number of bristles on abdominal segments.

How Does Inbreeding Depression Arise?

Inbreeding depression occurs because species contain a load of rare harmful partially recessive alleles due to mutation-selection balance, and because some loci exhibit heterozygote advantage. Inbreeding increases homozygosity at these loci exposing harmful recessive alleles in homozygotes. There must be directional dominance (beneficial alleles dominant, and harmful ones partially recessive) across loci for there to be inbreeding depression. Such directional dominance is found for fitness traits as they are typically subject to directional selection, whilst traits peripheral to fitness typically experience stabilizing selection (favoring phenotypic intermediates), or selection that varies over space and time. Inbreeding depression is found for all fitness components, including mating and fertilization ability, sperm production and quality in males, fecundity, survival, disease resistance, predator avoidance, mothering ability, etc., in animals, and equivalent traits in plants. Inbreeding of mothers and of zygotes both result in harmful effects on offspring fitness.

Inbreeding depression is found in all animal and plant species that are diploid or have higher ploidies. Haploids do not exhibit inbreeding depression, while haplodiploid species (e.g., Hymenoptera) may experience it in diploid females, but not in haploid males.

How Large Are the Effects of Inbreeding Depression?

Offspring resulting from brother–sister matings for mammals in captivity have on average 33% lower juvenile survival than noninbred offspring, with there being no clear differences among mammalian orders. However, the effects are greater in the wild than in captivity. Further, the effects accumulate across the life cycle and are devastating for total fitness in the wild (**Table 1**). For example, offspring of a full brother–sister mating in the New Zealand takahe bird experience a total reduction in fitness of 88%. Inbreeding depression is proportional to the amount of inbreeding, and is greater in more stressful environments, for outbreeding than inbreeding species, and for populations that have not previously been inbred versus ones subject to prior inbreeding.

Mutational Accumulation and Meltdown

Mutational meltdown describes the accumulation of new harmful mutations in small populations and their subsequent adverse effects on fitness and population persistence. It is a phenomenon closely related to inbreeding depression in that both involve exposing harmful recessive alleles. They differ in that inbreeding depression predominantly increases homozygosity for preexisting harmful mutations, while mutational meltdown focusses on accumulation and homozygosity of new harmful mutations.

While harmful alleles are kept at low frequencies in large populations due to the balance between mutation and natural selection, in small populations genetic drift becomes the primary determinant of whether alleles become more (or less) common each generation. Thus, mildly harmful alleles behave as if they are subject only to genetic drift (become effectively neutral), and some increase in frequency and reduce reproductive fitness. Over many generations, sufficient harmful alleles may accumulate to cause negative population growth and a decline to extinction. The contribution of mutational accumulation to extinction risk in small populations of outbreeding sexually reproducing species is controversial, but it appears to be minor compared to other genetic threats. However, it is expected to be somewhat more important in asexual and selfing species.

Loss of Genetic Diversity

Genetic diversity ultimately arises by mutation and is lost by selection favoring particular alleles over others, and by chance sampling effects (genetic drift). Genetics diversity is lost in small closed populations at rates per generation that are inversely

Table 1 Inbreeding depression (ID) for total fitness in wild species of animals and plants due to a brother–sister mating expressed as percentage reduction in mean of inbred progeny compared to outbred progeny in the same wild environment (Frankham *et al.*, 2017)

proportional to the genetically effective size of populations (N_e), and diversity progressively erodes across generations (t), as described by the following equation for loci not subject to selection:

$$H_t/H_0 = (1-1/[2N_e])^t$$

where H_t is the heterozygosity at generation t and H_0 that initially. For example, a population with an N_e of 25 is expected to lose 40% of its heterozygosity over 25 generations. Loss of genetic diversity for microsatellite DNA markers (variable number short tandem repeats of bases, that and are subject to little or no selection) in experimental populations occurs at a rate that is close to the predictions of this equation. Genetic diversity for loci subject to selection is also lost in small closed population. From theory we expect that genetic diversity in closed population will be related to population size, and this is observed within and across species. Further, as threatened species have, by definition smaller and/or declining population sizes than nonthreatened species, they typically have lower genetic diversity than taxonomically related nonthreatened ones.

Reduced Evolutionary Potential

Populations and species experience environmental change and in the face of persistent directional environmental change must evolve or they will go extinct. The ability to evolve depends on genetic diversity for fitness, selective forces, and genetically effective population size of populations. Consequently, threatened species are expected to have poorer ability to evolve than taxonomically related nonthreatened ones.

Do Genetic Factors Increase Extinction Risk?

Since inbreeding and loss of genetic diversity reduce reproduction and survival and the ability to evolve, they might be expected to increase extinction risk. However, it was hypothesized by Russell Lande in the late 1980s that demographic factors (human factors, plus demographic and environmental stochasticity and catastrophes) would often drive species to extinction before genetic factors could impact them, and this view was widely promoted. However, empirical evidence refuted this hypothesis for most populations. Further, genetic factors have been shown in increase extinction risk in wild habitats for outbreeding diploid species, based on direct observations and computer simulations parameterized with data from real threatened populations. For example, inbreeding explained 26% of the variation in extinction risk in wild populations of the Glanville fritillary butterfly in Finland. Further, populations of deerhorn clarkia plant (*Clarkia pulchella*) with an inbreeding coefficient of 4% had a 25% extinction rate, while those with an 8% inbreeding coefficient had a 69% extinction rate over 3 years in the wild i.e., a small increase in inbreeding resulted in a large increase in extinction rate. Computer simulations indicate that inbreeding increases extinction risk over a wide range of scenarios in outbreeding species. For example, across 30 vertebrate species, inclusion versus exclusion of inbreeding depression at realistic levels resulted in a 37% reduction in median times to extinction in wild populations over a range of population carrying capacities. Loss of genetic diversity has also been shown to increase extinction risk under environmental change.

It is important to recognize that human impacts, genetic impacts, catastrophes and demographic and environmental stochasticity (natural fluctuations) all contribute to extinction risk, and that they typically interact in a downward feedback loop termed the extinction vortex.

Extinction Vortex

Inbreeding and loss of genetic diversity typically exert their impacts on population persistence in concert with other catastrophic, demographic and environmental and human factors in a downward spiral towards extinction (termed the extinction vortex). Typically human impacts reduce population size, increasing susceptibility to demographic, environmental and genetic threats which further reduce the population size, and so on in a downward spiral towards extinction. Such extinction vortices have been observed in a number of populations. Various software packages exist to simulate such interactions of genetic and nongenetic factors, especially VORTEX (Lacy and Pollak 2014).

An important implication of this is that if genetic factors are ignored, conservation programs for threatened species may fail, even if the original cause of decline was nongenetic. This happened in the case of the greater prairie chicken population in Illinois. Restoration of habitat failed to alleviate the bird's decline, and it only recovered after its genetic deterioration was reversed by gene flow from isolated populations in other states.

Genetic Management of Captive Populations

Many species are incapable of persisting in the harsh conditions in the wild, often as a results of persistent human impacts, and so must be captive bred to save them from extinction. The three major genetic issues in management of captive populations of threatened species are inbreeding depression, loss of genetic diversity, and genetic adaptations to captivity that are harmful when species are returned to the wild. The first two issues were addressed by seminal work from Jonathan Ballou and Robert Lacy

published in 1995: they proposed that management by mean kinship was the optimal means for managing pedigreed populations. The kinship of two individuals is the inbreeding coefficient of their potential offspring. This procedure has been validated in a *Drosophila* fruit fly experiment, and applied widely in captive management of threatened species.

The success of reintroductions of threatened species into the wild depends on their fitness in their natural environment. Unfortunately, adaptations to captive environments are overwhelmingly harmful when populations are returned to the wild. For example, salmonid fish lose approximately 37.5% of their wild fitness for each generation of captive breeding. Similar processes occur in other species, but the rates of decline in wild fitness per captive bred generation are expected to vary widely according to the life-history of the particular species. Genetic adaptation to captivity can be reduced by minimizing selection, extending the generation interval, and especially by deliberate use of population fragmentation, but there has been little deliberate captive management to address this issue.

Genetic Management of Wild Populations

Despite the need to conserve genetic diversity being specified in the United Nations Convention on Biodiversity and legislation and regulations in many countries, genetic management of wild population has been slow to take off. For example, only ~50% of recovery plans (66% in United States, 55% in Australia and 33% in Europe) mention genetics, only 7% mentioned inbreeding, and even fewer inbreeding depression, and fitness-related parameters were generally overlooked in all plans (Pierson *et al.* 2016).

Much of the concern with genetic management of wild populations centers on genetic management of fragmented animal and plant populations, an issue considered as one of the most important, largely unaddressed issues in conservation biology. Most species have fragmented distributions, often with genetically isolated fragments. Adverse genetic impacts in these occur at a rate that is much more rapid than in the species as a whole, as inbreeding and loss of genetic diversity occur at rates dependent on the effective population size of the fragment, rather than that of the species. Consequently, these small isolated fragments have much elevated extinction risk due to genetic and combined genetic, demographic, environmental and human-associated factors. Further, population extinction is a step on the path to species extinction. Many of these small isolated population fragments could be rescued by gene flow from other population segments (genetic rescue). However, there are only ~30 cases worldwide where genetic rescue has been attempted for conservation purposes, yet there are ~1.4 million population fragments of threatened species that would benefit from it (Frankham *et al.* 2017).

Frankham *et al.* (2017) proposed a paradigm shift whereby evidence of inbreeding and loss of genetic diversity in isolated population fragments is followed not by inaction or separate management, but by asking:

- Does the population fragment needs genetic rescue?
- If so, is there any other population of the same species that can rescue it?
- If so, will augmentation of gene flow be beneficial or harmful?
- If beneficial, will the predicted benefits justify the cost and effort?

In this way they hope to stem the erosion in number of population fragments of species, and total species' population sizes.

Why Is Genetic Rescue Attempted So Infrequently?

There are nine main reasons why genetic rescues have probably been attempted so rarely:

- outbreeding depression/diluting local adaptation
- lack of quantitative data on its effectiveness
- causal relationship between genetic divergence among populations and genetic diversity within them
- overly stringent guidelines
- cost
- risks of disease, pest and parasite spread
- disrupting social systems in some animals
- moving biological material across political jurisdictions
- regulatory barriers

The first four are primarily genetic issues, and are discussed below. The remaining issues require consideration, but are rarely insuperable barriers to gene flow.

Crossing of populations can yield either beneficial or harmful effects. Harmful effects are sometimes found in the F_1, F_2, F_3 or later generation progeny of population crosses (outbreeding depression), and this is widely considered to be an impediment to genetic rescue attempts. However, such harmful effects are predictable, as they are dependent mainly on fixed chromosomal differences (ploidy, translocations, centric fusions and inversions) between the parental populations, or to the parental populations being adapted to different environments. A method for predicting the risk of outbreeding has been devised and shown to have a high degree of accuracy.

A second impediment to genetic rescue attempts has been a lack of quantitative date on the frequency and magnitude of beneficial effects of genetic rescue. In a recent meta-analysis, I found that gene flow into small inbred populations was beneficial in 93% of cases with a low risk of outbreeding depression. The median benefit on composite fitness (fecundity plus survival) in the wild was 148%, and was similar in vertebrates, invertebrates and plants. Benefits were larger in outbreeding than inbreeding species, in wild/stressful than captive/benign environments, for outbred than inbred immigrants, and increased with the magnitude of reduction in maternal and zygotic inbreeding coefficients as a result of crossing. Further, the fitness benefits persisted across generations: they were at least as large in the F_2 and F_3 (and later) generations as in the F_1.

A third impediment is that there is a causal links between genetic differentiation among populations and low genetic diversity within them, a fact that is underappreciated in the field. Thus, the most diverged small populations are likely to be assessed as different (even distinct taxa) and needing separate management, but these are the very ones with the lowest genetic diversity, and in most in need of augmented gene flow.

A fourth impediment to genetic rescue attempts has been overly stringent guidelines that do not adequately account for the urgency of action, or the recent evidence on the magnitude of genetic rescue effects on fitness, or of the ability to predict the risk of outbreeding depression. Frankham *et al.* (2017) contains guidelines that address these shortcomings.

Genetic Management for Global Climate Change

The impact of global climate change on species persistence has recently come to prominence as an issue, and increases the need for genetic management. Average global temperatures are increasing, their variability is growing, and oceans are acidifying as a result of anthropogenic carbon pollution of the atmosphere. Many species are expected to be unable to either evolve to keep up with environmental change, or to move to new locations, or both. Augmentation of gene flow into populations with limited genetic diversity may genetically rescue some of them so that they can evolve fast enough to keep up with climate change.

Genetic augmentation in the face of the predicted rapid environmental change may require sourcing new genetic diversity from other subspecies, or even closely related species. Use of genetic engineering to transfer specific adaptive genetic diversity has much to offer, and is less problematical than crossing genetically diverged species. Insertion of a wheat allele into the American chestnut confers resistance to a fungal disease that almost exterminated the tree species. Further, if species cannot evolve fast enough to keep up with climate change, genetic rescue may assist them to cope with new locations, whether they are translocated to within their historical range, or outside it (assisted colonization).

Aiding in Taxonomic Delineation

A crucial first step in conservation management is to decide which populations require separate, versus combined management. Taxa of conservation concern should be delineated such that species persistence is maximized. If populations and species are not appropriately delineated, genetically differentiated populations (including distinct species) may be inappropriately crossed leading to outbreeding depression. Alternatively, populations that are inbred and depleted of genetic diversity may be inappropriately classified as distinct taxa, causing genetic rescue of small populations to be blocked by regulatory and legal hurdles. Unfortunately, species delineations suffer from a multitude of problems, including:

- no standardized sampling regimes, list of characters to use, or analyses to perform
- many disparate definition of species that often lead to different delineations
- widespread use of diverse methods
- instability of delineations to technological change, especially with some species concepts
- poor repeatability of delineations, especially those done using different approaches
- over-lumping is common (especially in older delineations)
- over-splitting is common currently, and worsening

Frankham *et al.* (2017) have suggested means to overcome these and other problems. For example, they have shown that use of species concepts based on partial reproductive isolation between species, but not within species (such as the biological and the differential fitness species concepts) minimize each of the above problems. Conversely, the use of phylogenetic or general lineage species concepts is not recommended in conservation contexts, as they exacerbate several of the problems.

The most fundamental evidence required for species delineations for conservation purposes comes from crosses between populations carried out in the wild and taken to the F_3 generation. Populations with sympatric (overlapping) or parapatric (abutting) distributions carry out such experiments naturally. However, such evidence is rarely available or feasible to obtain for allopatric (geographically isolated) populations. When crossing data cannot be obtained for populations with allopatric distributions, they recommend the use of integrative taxonomy, the use of multiple lines of evidence in species delineations, especially evidence that predicts reproductive isolation (adaptive differentiation and fixed chromosomal differences). It does not make sense to ignore relevant information when it exists or is practical to obtain. The multiple lines of evidence they envisage being used in integrative taxonomy include:

- genotypes for multiple independent genetic loci
- morphological measurements for multiple characters
- chromosomal assays (essential), preferentially banded karyotypes to detect all relevant types of chromosomal change
- life history and behavioral information
- ecological (habitat) characteristics

The genetic loci used should include both near neutral and adaptive ones. Sole reliance on mitochondrial DNA (mtDNA) data is unacceptable.

Use of Molecular Genetics in Wildlife Forensics

Many species are threatened by poaching, including bears, large cats, elephants, parrots, whales and some plants. Molecular genetic approaches are now used to detect poaching and trade in threatened species and their parts, and to supply evidence for use in court cases against the perpetrators. Species can be identified from DNA in hair, horns, ivory, meat, eggs, turtle shells and plant material. As of 2016, there were 52 laboratories around the world that are members of the Society for Wildlife Forensic Science, including the US Fish and Wildlife Service forensics laboratory in Oregon, United States and the Australian Museum one in Sydney, Australia. Wildlife forensics came to prominence following an evaluation of the source of whale meat on sale in Japan and Korea. Studies using mtDNA revealed that some of the meat was not from minke whales for which Japan undertakes "scientific" whaling, but from protected blue, humpback, fin and Bryde's whales. Further, some "whale meat" was from dolphin, porpoise, sheep and horse. Not only was illegal whaling suspected, but consumers were being deceived. Forensic DNA analyses have also identified poaching in a variety of species including Eurasian badgers, Arabian oryx, and sika deer. Most species level identification in animals is based on mtDNA sequences for cytochrome B (*cyt b*) and cytochrome oxidase 1 (*COI*), while that for plants uses two chloroplast DNA loci, especially the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (*rbcL*) and maturase K (*matK*) (Johnson *et al.* 2014). However, only limited molecular forensic work has been carried out on plants for conservation purposes.

Use of Molecular Genetics to Aid in Understanding Species Biology

For many threatened species, important aspects of their life-histories are unknown and difficult, time consuming and expensive to determine. Molecular genetic tools and chromosomal assays can aid conservation in a wide array of species. The molecular methods of choice have progressed from allozyme electrophoresis that detects heritable differences in proteins beginning in the later 1960s, to DNA methods such as microsatellites in the 1990s, and single nucleotide polymorphisms (SNPs) that rose to prominence post-2000. Extremely powerful genomic methods are now rising to prominence and can involve hundreds of thousands of SNP loci. Activities include the following:

- estimating population sizes using noninvasive sampling
- estimating effective population sizes
- determining demographic history
- detecting and dating population size bottlenecks
- measuring migration and gene flow
- delineating population structure
- identifying source populations to recover endangered species
- detecting introgression and genetic swamping
- detecting secondary contact
- identifying sites for reintroduction
- identifying populations for reintroduction
- determining mating systems
- determining mode of inheritance
- revealing paternity
- identifying founder relationships
- identifying sources of new founders for endangered populations
- sexing of animals
- detecting disease
- analyzing diet

These are detailed by Frankham *et al.* (2010) and Freeland *et al.* (2011), so only a selection of these are addressed below.

Censusing Populations

Many species are difficult and expensive to census, especially nocturnal, fossorial ones. Increasingly they are being censused using molecular methods. For example, critically endangered northern hairy-nosed wombats live in burrows in Epping Forest National

Park in inland central Queensland, Australia. They are nocturnal and difficult to census by trapping (which stresses the animals). Using DNA from hair collected on adhesive tape attached to frames at the opening of their burrows, individuals can be identified from their microsatellite genotypes, sexed using X and Y chromosome markers, and the population size estimated (~196 individuals in the National Park in 2013). Further, microsatellite analyses of museum skins revealed that animals from an extinct population at Deniliquin about 2000 km to the south belonged to the same species, thereby identifying a potential reintroduction site.

Migration and Gene Flow

Migration can be detected following multilocus genotyping (for example with microsatellites) and clustering to identify differentiated populations. Immigrants are individuals that belong to a genetic cluster other than the one they are found in. However, immigrants do not necessarily breed and result in gene flow. Consequently, more advanced analyses on similar data are used to measure gene flow. F_1 and F_2 individuals of crosses between populations will have constitutions lying approximately mid-way between their two parental populations, etc.

Detecting Introgression and Genetic Swamping

Introgression refers to gene flow from another taxon. While low levels of gene flow between species are not uncommon, it is a serious issue when an introduced invasive species hybridizes with a native species and overwhelms its genetic constitution (genetic swamping). This is a major threat in canids, ducks, fish and plants. For example, exotic rainbow trout introduced into the habitats of native cutthroat trout in the Western United States led to hybrid swarms that eventually overwhelmed the local species. Introgression is readily detected by molecular genetic and genomic methods.

Mating Systems

It is important to determine mating systems, as species with different systems have altered characteristics that often require modified conservation management. Mating system refers to the proportion of mating events resulting from self-fertilization e.g., selfing, mixed mating, outcrossing, and self-incompatible. These can be distinguished by genotyping mothers and offspring for genetic markers, such as microsatellites. In selfing species offspring will carry only alleles present in the mother, while outcrossing results in offspring with alleles not present in the mother.

Mode of Inheritance

This refers to deviations from transmission of haploid gametes from parents, such as polyploidy (greater than two sets of each chromosome), haploidy, haplodiploidy (typically diploid females and haploid males, as in Hymenoptera), and asexual reproduction. These are important to distinguish, as they result in different evolutionary genetic characteristics, and may require modified conservation management. For example, haploid species do not exhibit inbreeding depression, while haplodiploid species experience it in females and not males, and the extent is less than in diploids. Many plant species are polyploids, and they are less susceptible to loss of genetic diversity and (probably) inbreeding depression than similar size diploid populations.

If a species is exhibiting asexual reproduction, genotypes for genetic markers (such as microsatellites) in the mother and offspring will be identical, apart from rare mutations. Ploidy differences can be determined by chromosomes counts in dividing cells, or comparing DNA content per cell. For example, the endangered button wrinklewort daisy in Australia has forms that are diploid (22 chromosomes), tetraploid (44), and hexaploid (66).

Paternity

Paternity has been determined in a wide array of species, mainly by comparing microsatellite genotypes of offspring and potential fathers. This has overturned a number of presumptions about mating habits. For examples, most bird species were presumed to be monogamous. However, genotyping of attending "parents" and offspring has revealed that nearly 90% of socially monogamous passerine species have at least occasional extra-pair paternities.

Ecological Health Indicators☆

Paul L Angermeier[1], U.S. Geological Survey, Virginia Cooperative Fish and Wildlife Research Unit, Virginia Tech, Blacksburg, VA, United States
James R Karr, University of Washington, Seattle, WA, United States

Glossary

Adaptive management An iterative approach to managing ecosystems and what humans do to alter ecosystems, whereby management actions are conducted like scientific experiments, and the outcomes are monitored to facilitate learning and improve management.
Biological integrity Wholeness of a living system, including the capacity to sustain the full range of organisms and processes having evolved in a region.
Biota All living organisms, including microbes, fungi, plants, and animals.
Biotic impoverishment Systematic reduction in Earth's capacity to support life.
Ecological health Condition of an ecosystem that is sustainable, that conserves all life-forms, and that society deems acceptable and beneficial.
Ecosystem A community of living things and the biophysical environment in which they interact, including genetic, physiological, morphological, population, energy-flow, and nutrient-cycling characteristics of living things.
Ecosystem service An ecosystem product, process, or condition that benefits or is valued by people.
Environment Surroundings; the complex of physical, chemical, and biotic factors acting upon a living system and influencing its form, function, and survival; the biophysical realities that govern everything on Earth.
Human well-being The state of wellness, happiness, security, and prosperity of a person or community; comprises personal health and safety, access to healthy living conditions, social relations, and personal freedoms.
Multimetric index A numeric measure reflecting combined scores (e.g., the sum) of selected metrics; such indexes are often used to represent ecological, economic, human health, and social well-being.

Introduction

Human societies have a vested interest in tracking the status and trends of their environment. Every human environment comprises physical, chemical, and biological elements, as well as social, cultural, and political elements. A healthy environment—one that nurtures and is sustainable—promotes a healthy society—one that can prosper, is equitable, and conserves other forms of life. Moreover, recognizing and monitoring instructive indicators of a healthy environment enable society to manage itself and its environment in beneficial ways. In this essay, we focus on physical, chemical, and biological environments. We examine key concepts related to indicators of ecological health and why those indicators are important to society. Simply stated, ecological health indicators are signs and symptoms reflecting the health of ecosystems in which human societies live and on which they depend. We contend that thoughtful measurement and analysis of these indicators can inform air, land, and water management in ways that decrease the impoverishment of Earth's living systems and increase human well-being.

What Are Ecological Health Indicators?

Defining Health

People have an intuitive understanding of what it means to be healthy (or unhealthy) and why being healthy is desirable. That said, our understanding of a "healthy" condition is strongly shaped by cultural context and values. For example, a person's body weight may be deemed healthy in one culture but unhealthy in another. A person's physical condition may range from the extreme fitness of an Olympic athlete to near death due to illness. Medical practitioners use established protocols and standards, based on indicators such as cholesterol level and blood pressure, to assess where each person lies along the healthy-to-unhealthy continuum. Other indicators—of diet and lifestyle, for example—may be used to assess a person's likelihood of becoming unhealthy. Further, appropriate standards vary

☆*Change History*: October 2017. Paul L. Angermeier and James R. Karr updated the entire chapter, including Abstract, Keywords, and Glossary; updated the sections "Introduction," "What Are Ecological Health Indicators?" "What Are We Trying to Indicate?" "What Makes a Good Ecological Indicator?" "How Are Ecological Health Indicators Used?" "Conclusions," and "Bibliography"; updated Tables and Figures; and added "Relevant Websites."

This is an update of J.R. Karr, Ecological Health Indicators, In Encyclopedia of Ecology, edited by Sven Erik Jørgensen and Brian D. Fath, Academic Press, Oxford, 2008, pp. 1037–1041.

[1]The Virginia Cooperative Fish and Wildlife Research Unit is jointly sponsored by the U.S. Geological Survey, Virginia Tech, Virginia Department of Game and Inland Fisheries, and Wildlife Management Institute.

with a person's age or home region. For instance, residents of the high Andes of South America have naturally higher tolerance of low atmospheric oxygen than residents of coastal Florida in the United States.

The health concept is often applied to systems other than individual people. For example, we may characterize the health of an ecosystem, an economy, a farm community, or an international collaboration. In each case, what is viewed as "healthy" reflects the values of those involved, benefits stakeholders, and implies the system is viable and beneficial over the long term. As with human health, assessing the health of such systems requires development of appropriate protocols, indicators, and standards. Below, we adapt this generic concept of health to assessing the condition of ecosystems and their many dimensions. We use "ecosystem" in the conventional sense, referring to a community of living things (including people) and the physicochemical environment in which they interact.

The notion that an ecosystem can range from being healthy to unhealthy is intuitively appealing, although its application has presented challenges because people often disagree on what makes up a "healthy" ecosystem. Experts concerned about undesirable trends in environmental quality have developed well-reasoned rationales for distinguishing healthy versus unhealthy ecosystems. These rationales are founded on the relative importance of the various values—such as intrinsic or utilitarian—through which we judge our relationships with other people and other life-forms. The health of both human and nonhuman life is typically central to how we view ecosystem health. Given some consensus on what constitutes a healthy ecosystem, ecologists can help identify and calibrate useful indicators.

A well-established frame of reference for the condition of an ecosystem is its natural state, which is shaped by natural evolutionary processes that align the adaptations of a biota with prevailing environmental conditions. Many people view natural ecosystems as inherently healthy, realizing, for example, that the flora and fauna of a remote desert are healthy, as well as distinct from those of a healthy rainforest. If people converted a rainforest to a desert (or vice-versa), however, the result typically would be judged ecologically unhealthy.

To evaluate a place's ecological condition, we must first identify and define natural attributes useful as measures of system condition. Physicochemical and biological attributes are chosen to collectively represent that place's ecological integrity (i.e., state of being whole or unimpaired)—a benchmark for measuring condition and judging health. The word *integrity* refers to the complex systems that evolved at a place, with proven capacity to persist in the associated physical, chemical, and biological environment. The evolutionary ties between natural assemblages and their home places validate integrity as a benchmark for assessing the ecological condition of places altered by human activities.

Naturalness also underpins biological integrity, a concept that is widely used to assess ecological condition. If a place has biological integrity, a multiscale, integrated, adaptive biological system is present, including the full range of evolved parts (e.g., genes, species, and assemblages) and processes (e.g., dispersal, biotic interactions, and energy flow) expected in the absence of substantial recent human influence. This definition recognizes several key complexities. First, ecosystems encompass spatio-temporal scales from individuals to landscapes, any of which can inform an assessment of ecological condition. Second, living systems include items we can count (the parts) plus the processes that generate and maintain them; any of these can be useful indicators. Third, living systems are embedded in dynamic evolutionary and biogeographic contexts that influence and are influenced by their physical, chemical, and biological environments. An important upshot of this definition is that the natural conditions embodied in integrity vary through time and space within some normal range. Understanding this range is essential to accurately assessing ecological condition.

Maintaining *ecological health* is the goal for sites managed intensively for human benefit—as for crop cultivation, tree harvest, urbanization, recreation, and the like (Karr, 1996). Protection of integrity in an evolutionary sense is unrealistic as a goal for such places; instead three criteria for their management are important: Ecological damage from intensive use should not threaten the long-term beneficial use of the area. Intensively managed areas should not degrade or damage other areas beyond their boundaries, such as downstream or downwind. Finally, what is viewed as "healthy" for a given site should reflect the values of those involved—the stakeholders at relevant spatial and temporal scales.

Identifying Indicators

Ecological indicators can be calibrated to measure deviations from integrity, including deviations that are acceptable (healthy) or unacceptable (unhealthy). The acceptability of any given deviation is negotiated and determined by society via its environmental policies and regulations. Compared with conditions embodied in integrity, conditions deemed unacceptable are more fluid, reflecting prevailing value systems. Further, what is unacceptable in one place may be acceptable in another, depending on societal goals. For example, the health of a wilderness forest and an industrial timberland might be assessed via different ecological criteria or indicators, even though they are both assemblages of trees with shared natural conditions. Even for intensively used ecosystems, however, we can set limits for the acceptability of ecological deviations. Consider a farm. If practices there damage the land for future farming or harm nearby waterways or people downstream, those practices and the resulting ecological conditions may be considered unhealthy. Regardless of which conditions are societally acceptable, ecological indicators can be calibrated objectively to distinguish the healthy from the unhealthy.

Numerous ecological indicators are in use, typically chosen to match the specific ecosystem and issue of interest (Feld *et al.*, 2010; O'Brien *et al.*, 2016; Yu *et al.*, 2017). Some indicators reflect conditions at a given point in time (e.g., pH, number of species), while others reflect processes over a given time frame (e.g., annual soil erosion, population growth rate). Although many potential physical, chemical, and biological indicators can be measured, the biological assemblages that persist in a place provide the most integrative and

instructive indicators of prevailing ecological conditions. Monitoring such assemblages is crucial to understanding the full array of ecological consequences produced by human actions or natural events. Without regular biological report cards, humanity is ill-equipped to protect ecologically intact places, restore degraded places, or make informed decisions about how to manage natural resources. Thus, development of reliable, instructive ecological indicators is vital to society.

Accurately assessing ecological condition requires attention to the key factors and processes that drive ecosystem dynamics. This knowledge may be synthesized into a conceptual model of how factors and processes produce ecological outcomes (Lindenmayer and Likens, 2010), including biological responses such as changes in the behavior of an organism, changes in the abundance of a population, or shifts in the interactions among species. Such responses are important links to how people value ecosystems and view ecological health. Knowledge of species' life histories and habitat use is crucial to such models. Because ecosystems are dynamic, ecological assessments involve teasing the signals of interest from background environmental noise. Accurately interpreting such signals requires care in designing a monitoring protocol and selecting indicators to monitor. Translating monitoring results into management action further requires setting up thresholds for action that relate selected indicators to societal goals. For example, suppose monitoring shows that the ecological condition of a stream is unhealthy because of excessive sediment and bacteria attributed to livestock; that is, the stream's condition is unacceptable to local or downstream users who would otherwise benefit from the stream's flow. Managers might implement practices meant to improve the stream's condition and restore beneficial uses to stakeholders, such as restricting livestock access and planting riparian vegetation.

What Are We Trying to Indicate?

The short answer to this question focuses on ecological conditions of interest to people. Fully answering the question, however, is complicated by the fact that indicators can serve many purposes, which differ from case to case. In each case, the purpose of monitoring ecological indicators reflects a subset of their many links to human well-being, plus the kinds of knowledge needed to make wise decisions about human actions with environmental consequences.

Ecological Indicators Have Long Been (and Still Are) Relevant

Living organisms, including people, experience and assess their environment through a cacophony of sensory information. Only some of that information is useful to stimulate physiological and behavioral responses that may enhance one's livelihood. For example, accurately characterizing important threats (e.g., predators) and opportunities (e.g., food) is crucial. Organisms selectively use available information as indicators of the condition of their world. If they respond appropriately to relevant indicators, ecological and evolutionary success typically follows.

The indicators deemed important to people have changed dramatically over history. Early humans, knowingly dependent on nature for their well-being, no doubt tracked indicators such as weather, plant fruiting, and animal migration. Technological advances—such as using tools, controlling fire, and tending crops—gave humans more control of their environment. Increased proficiency in procuring food facilitated rapid growth in human populations and technology. Communication technologies such as written language (and, eventually, electronic media) greatly expanded the scope of people's sensory capability, as well as the kinds of knowledge that were valued. Although some 21st-century human communities still depend directly on natural systems, most people are far less aware of any such dependence, now focusing on other kinds of indicators (e.g., economic) to assess and plan for their well-being. In addition, when environmental problems arise, we are more inclined to try to redesign an ecosystem (via engineering) than to adapt to prevailing ecological conditions.

Because modern people are far less connected to nature than their hunter-gatherer ancestors, some believe that tracking the status and trends of ecological indicators is far less important to their well-being than tracking economic indicators. Others, however, believe that such a view is shortsighted and risky, because ecosystems—even unnatural ones—are still the foundation of life support on Earth and contribute greatly to human quality of life. Only by carefully monitoring the condition of nonhuman living systems can we assemble the knowledge needed to manage the collective consequences of our actions for the continued benefit of people and Earth's biota. This management challenge is far more complicated than our ancestors' challenge to find food and mates and to escape predators.

Since the mid-20th century, concern about environmental trends—particularly, widespread chemical pollution—sparked the development of a variety of indicators to assess how environmental regulations were being enforced. Initially, such indicators described regulatory activity and pollution loading rather than the broader condition of ecosystems, thereby reflecting the dominance of toxicological approaches to solving environmental problems (e.g., see Karr, 1991). These indicators fall into five classes:

- Administrative indicators, such as numbers of pollution-discharge permits and enforcement actions.
- Technological indicators, such as numbers of implemented "best management practices" (e.g., storm-water detention ponds, conservation tillage).
- Stressor indicators, such as measurements of pollutant loads.
- Exposure indicators, such as measured or modeled concentrations of pollutants in water, soil, or air.
- Response indicators, such as measures of biological condition, including taxa richness, population abundance, production, and multimetric indexes that integrate multiple biological attributes.

Exposure indicators and response indicators gained use as scientists, environmental managers, and regulators recognized that the other indicators neither assessed ecological conditions nor ensured that legally mandated goals (e.g., protecting the integrity of living systems) were attained. Only exposure and response indicators merit use as ecological indicators.

Causes and Consequences of Ecological Change

Ecological change is continual, but much of it goes largely unnoticed by people. Of course we notice infrequent but dramatic changes, such as those caused by volcanoes, tornadoes, epidemics, or wars, but we may pay little attention to gradual changes, such as the daily shifts accompanying transitions between seasons. We can observe change at many spatial scales (e.g., local, regional, global) and temporal scales (e.g., daily, annual, millennial). Change at any of these scales can be induced by natural forces, human actions, or some combination. Regardless of cause, it seems prudent to keep track of ecological changes that may influence human well-being and to measure indicators that enable us to manage the outcomes. Over the long term, documenting conditions before important ecological changes occur can reveal factors that make ecosystems more or less sensitive to change. History repeatedly confirms the tragic consequences of ecological ignorance: over the past 4500 years, dramatic societal collapses have occurred in Mesoamerica, Mesopotamia, and South Asia when ecological indicators were ignored (Diamond, 2005).

Human action is now the principal driver of environmental change on Earth, rivaling astronomical forces in its impact and prompting many environmental experts to call the present epoch the Anthropocene (Waters *et al.*, 2016; Johnson *et al.*, 2017). People profoundly shape ecosystems—at all spatial and temporal scales—and ecosystems' capacity to support life. Whether a change is purposeful and obvious (e.g., a prairie converted to a cornfield or a wetland drained to build houses) or nearly invisible (e.g., altered biotic communities after a dam is built), when such changes happen widely across regions, the consequences add up. The upshot is that human uses of Earth's resources are causing worldwide changes in living systems, creating an unprecedented level of biotic impoverishment (Woodwell, 1990). These changes are manifest from genetic to ecosystem levels because of diverse human actions that degrade or destroy habitat; spread diseases, invasive species, or pollutants; and alter climate (**Table 1**; Scheffers *et al.*, 2016; Chu and Karr, 2017).

Loss of biodiversity is a common consequence—as well as indicator—of rapid or extensive ecological change. Although extinctions of species are inevitable, even under natural conditions, current human-induced extinction rates of mammals, birds, and fishes are at least 100 to 200 times greater than in prehistoric times (Burkhead, 2012; Johnson *et al.*, 2017). Anthropogenic changes to ecosystems may also depress the production of species with commercial or recreational value, as often happens in overharvested forests and fisheries. Moreover, all forms of biodiversity loss represent significant costs to society (Cardinale *et al.*, 2012). Monitoring trends in biodiversity can help minimize such societal costs.

Some consequences of ecological change are more apparent as shifts in ecosystem processes than as shifts in particular species. Myriad organisms—from megafauna to microbes—form the building blocks of ecosystems. Their interactions, which play out at multiple spatial and temporal scales, control the dynamic mixes and flows of air, water, nutrients, and energy that are essential to life on Earth. Although we may not readily observe such processes, we do see some of the outcomes that are enormously beneficial to human society. For example, biota play crucial roles in purifying air and water, forming soils, pollinating crops, and regulating local climate and floods. Collectively, these processes make civilization possible. Conversely, widespread human actions that alter ecological conditions have the potential to disrupt our life-support systems. Keeping track of well-chosen ecological indicators can help ensure that we recognize a dangerous aberration before an ecosystem is irreparably damaged.

Links between Ecological Health and Human Well-Being

In addition to revealing the condition of ecosystems, ecological health indicators also reveal information pertinent to human health and well-being (Chivian and Bernstein, 2008; Gottdenker *et al.*, 2014). Human well-being—physical and mental—is closely tied to ecological conditions, often in subtle or complex ways. Biotic impoverishment often precedes or accompanies diminished human health. Perhaps best known are the thousands of harmful chemical by-products of various technologies, including heavy metals, pesticides, and endocrine disruptors. Most of these find their way into our air, water, or food, with both predictable and unpredictable consequences for personal health. The plants and animals that live in the same ecosystems we do are often sensitive to the same contaminants and pathogens we are, which makes them ready-made indicators of conditions that pose risks to human health. Moreover, research increasingly shows how much the naturalness of our daily environment—such as visible water, trees, and sky—enhances our mental health and capacity to handle stress (Sandifer *et al.*, 2015). Medical and ecological experts alike conclude that healthy ecosystems promote healthy people.

Beyond the effects of pollutants on personal health, human-induced biotic impoverishment may also threaten human well-being more generally. For example, deforestation can accelerate soil erosion and undermine the capacity of an ecosystem to produce crops (Breure *et al.*, 2005); overharvesting fish and wildlife populations can destabilize biotic communities and deplete food resources for people; and introducing new weeds and pests can reorganize ecosystems and impair production of farmed or wild foods. Although the long-term outcomes of such changes for specific people are difficult to predict, it is certain that shifts in ecosystem conditions broadly affect the well-being of many.

Countering industrial societies' overemphasis on economic indicators, many current conceptions of sustainability recognize that human well-being and progress depend on three cooperative systems: ecological, social, and economic (Kates *et al.*, 2005; Wu,

Table 1 The many faces of biotic impoverishment

Indirect depletion of living systems through alterations in physical and chemical environments

1. Degradation of water (redirected flows, depletion of surface and groundwater, wetland drainage, organic enrichment, destruction and alteration of aquatic biota)
2. Soil depletion (destruction of soil structure, erosion, salinization, desertification, acidification, nutrient leaching, destruction and alteration of soil biota)
3. Chemical contamination (land, air, and water pollution from pesticides, herbicides, heavy metals, and toxic synthetic chemicals; atmospheric ozone depletion; ocean acidification; fish kills; extinctions; biotic homogenization and biodiversity loss; bioaccumulation; hormone disruption; immunological deficiencies; reproductive and developmental anomalies; respiratory diseases; intergenerational effects)
4. Altered biogeochemical cycles (alteration of the water cycle; nutrient enrichment; acid rain; fossil fuel combustion; particulate pollution; degradation of land and water biota; outbreaks of pests, pathogens, and red tides)
5. Global climate change (rising greenhouse gas concentrations, altered precipitation and airflow patterns, rising temperatures, effects on individual and community health, shifts among and within global ecosystems)

Direct depletion of nonhuman life

1. Overharvest of renewable resources such as fish and timber (depleted populations, extinctions, altered food webs)
2. Habitat fragmentation and destruction (extinctions, biotic homogenization, emerging and reemerging pests and pathogens, loss of landscape mosaics and connectivity)
3. Biotic homogenization (extinctions and invasions, lost biodiversity among food crops and livestock)
4. Genetic engineering (homogenization of crops, antibiotic resistance, potential extinctions and invasions if genes escape, other unknown ecological effects)

Direct degradation of human life

1. Emerging and reemerging diseases (occupational hazards, asthma and other respiratory ills, pandemics, Ebola, AIDS, hantavirus, tuberculosis, Lyme disease, West Nile fever, chikungunya, Zika virus disease, antibiotic resistance, diseases of overconsumption and stress, altered human microbiomes)
2. Loss of cultural diversity (religious wars and genocide, loss of cultural and linguistic diversity, loss of knowledge)
3. Reduced quality of life (malnutrition and starvation, failure to thrive, poverty)
4. Environmental injustice (environmental discrimination and racism; economic exploitation; growing gaps between rich and poor individuals, segments of society, and nations; environmental refugees; gender inequities; trampling of the environmental and economic rights of future generations)
5. Political instability (civil violence, especially under intransigent regimes; resource wars; international terrorism; increased number of refugees)
6. Cumulative effects (environmental surprises, increased frequency of catastrophic natural events, boom-and-bust cycles, interactions between disease and biodiversity, collapse of civilizations because of environmental degradation)

Modified from Karr, J.R., Chu, E.W., 1995. Ecological integrity: Reclaiming lost connections. In: Westra, L., Lemons, J. (Eds.), Perspectives in Ecological Integrity, pp. 34–48. Dordrecht: Kluwer Academic.

2013). This thinking presumes that human well-being is best served by promoting a "triple bottom line," which can be tracked by monitoring indicators of ecological, social, and economic well-being. Clean water and green space are common landscape features that contribute to a person's ecological well-being. As is the case for ecological health, human well-being can be measured at a range of spatial scales, such as a community or a nation.

Scientific understanding of nature's contributions to human well-being has expanded rapidly over the past three decades, with contributions commonly grouped into four classes of "ecosystem services": provisioning, regulating, cultural, and supporting. Provisioning services—the most readily recognized—include tangible goods such as water, food, and lumber. In contrast, regulating services derive from ecological processes that are often less apparent, including the purification of air and water and the regulation of climate and floods. Cultural services, which include aesthetic, recreational, educational, scientific, and spiritual benefits, are also largely intangible. Finally, supporting services include ecological processes such as primary production and soil formation, not all of which benefit people directly but which do underpin the maintenance of tangible ecological goods and other services. Many ecological health indicators inform us about whether ecological changes are likely to affect the capacity of ecosystems to deliver valued services.

Perhaps the most comprehensive assessment of ecosystem services—the Millennium Ecosystem Assessment—was completed in 2005 (**Fig. 1**). It synthesized input from hundreds of scientists and catalyzed discussion among policymakers regarding how to manage ecosystems sustainably. A key strength of this approach is that it provides an integrative framework to account for the many benefits provided by healthy ecosystems, well beyond those considered in conventional economic analyses.

In economic terms, human well-being can be viewed as forms of wealth stemming from various forms of capital—including but not limited to financial capital (Hancock, 1997). How we value different sources of wealth strongly influences how we value healthy ecosystems and their indicators. For example, ecological economists presume the human economy is a subsystem of the global ecosystem and that much of our wealth ultimately depends on the persistence of the natural capital that underpins healthy ecosystems. In contrast, neoclassical economists (who prevail in most policy arenas) presume that ecosystems are subsets of the

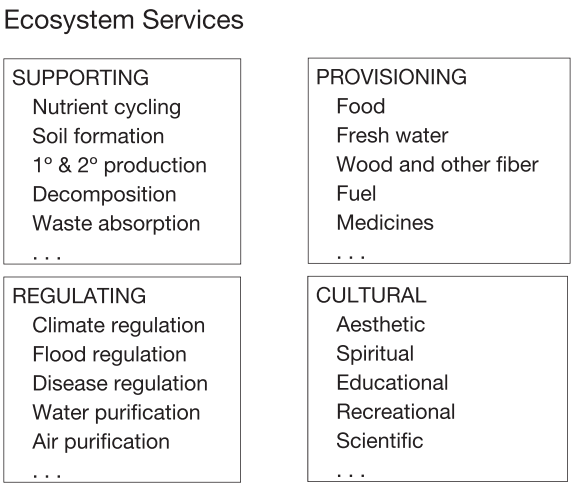

Fig. 1 Four major categories of ecosystem services with examples from each category. Modified from Millennium Ecosystem Assessment (2005). Ecosystems and Human Well-Being: Biodiversity Synthesis. Washington, DC: World Resources Institute, with permission from United Nations Environment Programme.

human economy and that natural capital can be traded indefinitely for other forms of capital, such as financial capital, without dire long-term consequences. Subscribing to one of these disparate worldviews can profoundly affect how an economist sees the relevance of ecological health indicators to socioeconomic policy. Because no one can be certain of the current or future value of natural capital, directly monitoring ecological indicators linked to human well-being helps ensure that ecosystems continue to provide crucial goods and services for people.

What Makes a Good Ecological Indicator?

The many efforts to develop and apply ecological health indicators over the past 40 years have taught us much about which indicators are or are not useful (Table 2). Most important, the knowledge gained from monitoring ecological indicators adds to understanding ecosystems and guides management actions. For example, data on a suite of indicators can help a manager interpret where an ecosystem lies along a gradient of biological condition; the manager can then choose specific actions, such as protection or restoration, aligning with societal goals. Overall, ecological indicators are simplified lenses through which we can better understand complex ecosystems and use that understanding to improve our management of people to protect those ecosystems. Although the most useful indicators tend to be case specific, several features apply generally.

Ecological indicators are most useful when they are readily measurable, integrative, ecologically and societally relevant, interpretable, cost-effective, anticipatory, measured at appropriate spatial and temporal scales, and able to detect status or trends. Further, indicators are most informative when they provide data that are quantitative, statistically robust, reliable, and comparable and when they can be used to diagnose problems. Data collection for ecological monitoring is typically designed to do no long-term harm or substantially alter the ecosystem being assessed. Ideally, indicators are sensitive to a broad range of known stressors and likely to be sensitive to unknown or as yet unidentified stressors. Most of these features require that indicators make sense in the context of empirical and conceptual ecological frameworks reflecting present scientific understanding of real ecosystems. Combining indicators that represent individual, population, assemblage, and landscape levels of ecological organization enriches our ability to understand the many dimensions of ecosystems. Depending on the ecological impact(s) of particular concern, indicators of genetic, physiological, morphological, population, community, energy-flow, nutrient dynamics, and landscape conditions may be especially informative. Multiple complementary indicators are often combined into composite ecological indexes, analogous to the widely familiar economic indexes based on multiple economic indicators (such as the consumer price index).

How Are Ecological Health Indicators Used?

Protocols for Measuring Ecological Health

The utility of the integrity concept is reflected in its widespread appearance in policy and planning documents. The phrase "biological integrity" was first used in 1972 to establish the goal of the US Clean Water Act for the nation's waters. Thanks to the conceptual and management success of Clean Water Act programs, maintaining biological or ecological integrity became a primary goal in other environmental policies, including the Canada National Parks Act, the US National Wildlife Refuge System

Table 2 Sample indicators for assessing ecological health. Indicators may target specific media (such as air, land, or water); habitat types (such as forests, grasslands, or streams); or taxa (such as plants, fishes, or insects). Indicators can be used individually and to construct multimetric indexes. Although not comprehensive, this table illustrates the breadth of ecological indicators in use or potentially usable

Indicators for nonhuman biological systems
Individual and population levels: body burden of toxic contaminants; condition index (ratio of a fish's weight to its length); population size and density, especially for threatened and endangered species; population sex and age structure; recruitment and population growth rate; shifts in phenology; migration rate; harvest rate by sport, commercial, and subsistence interests; rates of fish stocking, including supplementation; genetic diversity within a population; rates of spread by nonnative species; primary and secondary production; standing stock biomass; presence and condition of iconic species, such as bald eagles or giant pandas
Community level: species or higher-level taxonomic richness; proportional abundance of functional groups, such as predators, grazers, or carrion feeders; shifts in community composition and proportional abundances (biotic homogenization, tropicalization, desertification); biomass, primary production, and secondary production; standing stock of timber; forest regrowth rates; total basal area of a timber stand; persistence of coevolved species groups, such as plants and their pollinators and seed dispersers; persistence of predator-prey relationships; rates of pest and disease outbreaks; shifts in presence or abundance of tolerant or intolerant species; toxin levels in plant and animal tissues across taxa
Ecosystem level: altered rates of biogeochemical processes; altered rates of nutrient cycling; altered rates or pathways of energy flow; embodied energy (i.e., energy), solar energy required to produce goods and services; concentrations of key chemicals in ecological interactions; trophic state of lakes; chlorophyll concentrations; shifts in social or economic outcomes stemming from ecological relationships
Landscape level: rates of habitat fragmentation and destruction; patch size and patch distribution; width of riparian vegetation along streams or lake margins; measures of fragmentation, aggregation, and connectivity; shifts in extent, structure, or stability of habitat mosaics; abundance and type of soil organic matter; extent and stability of major communities, such as coral reefs, forests, or wetlands
Indicators of human well-being
Production systems (e.g., agriculture, forestry, marine and freshwater fisheries and aquaculture): proportions of organic versus conventional agriculture; proportions of grass-fed versus grain-fed livestock; spatial extent of bottom-trawling versus nontrawling fisheries; extent and intensity of aquaculture and its human health consequences; ratio of harvest of fish or other resources to annual production; production of genetically modified organisms and associated risks; social and economic stability of production
Human health: human body burdens of toxins; rates and extent of disease transmission in people (and wildlife); rates of malnutrition, overnutrition, and related diseases; rates of disease stemming from polluted air, land, or water; rates of mental illness; rates and extent of spread by pathogens resistant to antibiotics and other drugs; rates of emergence and reemergence by diseases associated with habitat alteration
Cultural ecology: rates of cultural diversity loss; rates of loss of specific cultures or traditional ecological knowledge, including languages; degree of social or economic isolation; extent and rates of environmental injustice, including toxic exposures and access to potable water; measures of ecosystems' ability to supply recreational opportunities outdoors; availability or consumption of wild foods
Abiotic indicators of ecological condition
Chemical: concentrations of contaminants or toxins in air, water, and soil; nitrogen and phosphorus concentrations in water bodies; rates of soil salinization from irrigation; rates of greenhouse gas emissions; application rates of fertilizers or pesticides in urban and agricultural areas
Physical: physical structure of an environment as determined by substrate type and topography, geology, hydrology, or biota (e.g., coral reefs, marine and terrestrial forests, grasslands, or deserts); rates of stream or river flow; frequency, duration, and magnitude of floods; measures of stream-channel morphology or substrate composition; degree of seasonal variation in surface and subsurface water flows; temporal shifts in stream channel morphology; rates of sediment loading into water bodies; soil mineral and organic content, structure, and tilth; soil generation and erosion rates; atmospheric structure and stability; frequency, duration, and magnitude of severe storms; diurnal and seasonal variation in water temperature; changes in sea levels; glacial melt rates; permafrost extent

Improvement Act, the Canada–US Great Lakes Water Quality Agreement, the European Union's Water Framework Directive, and the Earth Charter.

The integrity concept has catalyzed development of many programs that use ecological indicators to monitor and assess the condition of living systems. These programs recognize that wild living things are ideal indicators of ecological health and sensitive sentinels for human health. For example, healthy fish and insect assemblages are good indicators of healthy water bodies, which pose fewer health risks to people than do degraded water bodies. This relationship underpins the programs that use biotic assemblages to monitor the quality of waters in the United States and around the world. Similarly, the US Forest Service uses the ecological integrity concept to guide land-use planning and conservation in national forests, and the US National Park Service incorporates the concept into inventory and assessment programs (Wurtzebach and Schultz, 2016).

Ecological indicators are widely used to summarize technical information about the condition of ecosystems in a form nonexperts can readily understand. For example, the Heinz Center has reported (in 2002 and 2008) on the status of and trends in ecosystems of the United States. The center synthesized input from more than 300 scientists, who compiled data on 108 indicators for six ecosystem types (coasts and oceans, forests, farmlands, fresh waters, grasslands and shrublands, and urban and suburban areas) at local, regional, and national scales. The Heinz indicators are organized into four groups—system dimensions, chemical and physical condition, status of biological components, and ecosystem services (**Fig. 2**). Each group comprises more than 20 indicators. The resulting assessments are widely used by policymakers to understand the condition and use of ecosystems.

Composite ecosystem "report cards" are commonly used to broadly summarize ecological conditions for cities, states, estuaries, river basins, and islands (Harwell *et al.*, 1999; see also http://ian.umces.edu/ecocheck/report-cards/). Report cards simplify the complex relations among environmental goals, ecosystem stressors, and ecological endpoints. Report cards provide timely assessments based on selected indicators, usually presented as maps and tables derived from scientific studies. Such assessments are accompanied by numeric or letter grades, allowing for quick and straightforward understanding by nonexperts.

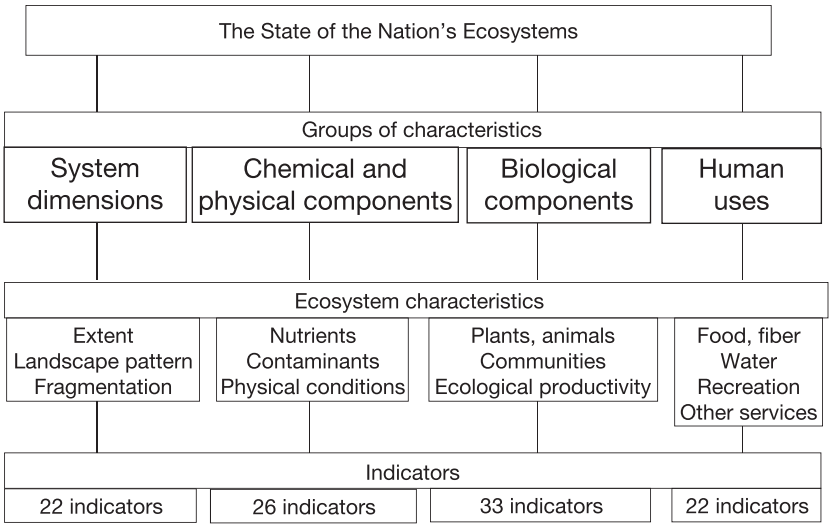

Fig. 2 Organization and examples of ecosystem characteristics, with number of indicators examined, in the *State of the Nation's Ecosystems* report. Modified from Heinz Center (The H. John Heinz III Center for Science, Economics and the Environment) (2002 and 2008). The State of the Nation's Ecosystems: Measuring the Lands, Waters, and Living Resources of the United States. New York: Cambridge University Press. Reprinted from Heinz Center 2002.

Ecosystem scientists and managers need standardized methods for sampling biota, analyzing data, and assessing ecological conditions. Further, integrative information from individual, population, assemblage, and landscape levels is needed to provide an accurate assessment of how far a system's condition diverges from integrity. A multimetric measurement approach—the index of biological integrity (IBI; Karr, 1991, 2006)—has been widely used since the 1980s to facilitate such assessments. IBIs have been applied in contexts such as resource management, engineering, and public policy, in the United States and at least 85 other countries (J.R. Karr, unpublished). Initially, IBIs were developed to assess streams and rivers, but the conceptual framework has since been applied to other environments (wetlands, lakes, reservoirs, coral reefs, estuaries, riparian corridors, forests, grasslands, sagebrush steppes, and caves) and to diverse taxa (vascular plants, algae, diatoms, bacteria, benthic invertebrates, fishes, zooplankton, crayfishes, freshwater molluscs, amphibians, coastal amphipods, nematodes, and birds; J.R. Karr, unpublished). Many states incorporate IBI values, based on fish or macroinvertebrate communities, into water quality standards (O'Brien *et al.*, 2016). Such applications are key components of implementing the US Clean Water Act and the European Union's Water Framework Directive.

IBI metrics are carefully chosen to collectively characterize human impacts on ecosystems. Each metric represents a verifiable biotic response, analogous to an organism's response to varying dosages of a toxin. Because their values reflect cumulative impacts of all human activities in an ecosystem, IBIs represent ecological dose-response relations (**Fig. 3**). Before inclusion in an IBI, individual metrics are validated empirically to ensure they (1) are ecologically meaningful, (2) increase or decrease as human influence increases, (3) are sensitive to a range of stresses, (4) distinguish stress-induced variation from natural and sampling variation, (5) are relevant to societal concerns, and (6) are scientifically robust, yet easy to measure and interpret. The ecological breadth and depth of metrics make the resulting IBIs more informative about ecosystem condition than are simpler chemical measures.

Specific IBIs vary in the number of metrics included and how numeric scores are assigned, but all IBIs share certain features. Scores for metrics are summed to yield a single index value. Metric and index scores enable comparisons between a locale's present condition and what integrity would look like there. Low scores indicate altered conditions, whereas high scores indicate natural conditions. The original IBI (based on stream fishes) comprises 12 metrics, each of which is assigned a score of 5, 3, or 1. Thus, this index ranges from 60 to 12. Similarly, the benthic invertebrate IBI (B-IBI) for streams comprises 10 metrics, so this index ranges from 50 to 10. In Washington State, monitoring results based on B-IBI are instrumental in enforcing the US Clean Water Act and in managing Pacific salmon (**Table 3**). Here, a stream is considered impaired when its B-IBI falls below 35, indicating it cannot support a salmon population.

Using Health Indicators in Ecosystem Management

Using health indicators to inform management of ecosystems has parallels in how people manage personal health. The ecological analog of a human patient might be a wild population, a local assemblage of many species, or the global biosphere. Indicators could be developed to assess ecological health at any of these scales. The ecological analog of a medical practitioner is a natural resource manager, such as someone working at a regional, state, or federal agency or nongovernmental organization. Another parallel is that regular "wellness exams" on the condition of an ecosystem can alert us to emerging problems and help us choose

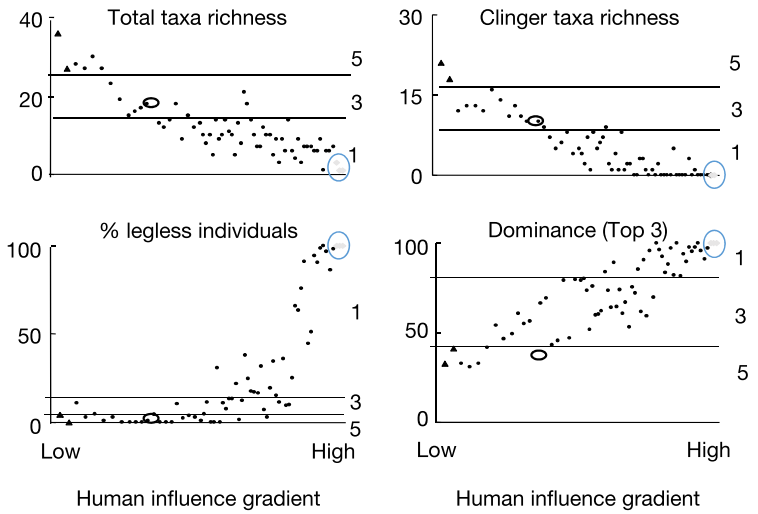

Fig. 3 Examples of dose-response relations for a hypothetical four-metric IBI based on data from Japanese streams. The four metrics are benthic invertebrate taxa richness (top left); taxa richness of clinger taxa (top right); percentage of individuals in sample that are legless, such as snails and worms (bottom left); and dominance, measured using the three most abundant taxa (bottom right). Black triangles represent values from reference streams considered to be minimally influenced by humans. Gray triangles (enclosed in blue ovals) represent values from highly disturbed streams. Black ovals represent a sampling site that has an IBI value of 16 (3 + 3 + 5 + 5) out of a possible 20. In each graph, high-quality sites appear on the left side and low-quality sites appear on the right. Modified from Karr J.R. and Chu E.W. (1999). Restoring life in running waters: Better biological monitoring. Washington, DC: Island Press. Reproduced by permission.

Table 3 Benthic invertebrate index of biological integrity (B-IBI) as applied in US Pacific Northwest streams. Index scores, which can range from 50 to 10, are partitioned into five levels designed to associate regulatory language with specific biological conditions. (Developed in consultation with Ed Chadd, Streamkeepers of Clallam County, Washington, USA.)

Score	*Regulatory language*	*Biological condition*
50–46	Healthy	Ecologically intact, supporting the most sensitive life-forms
44–36	Compromised	Showing signs of degradation: impacts expected to one or more salmon life stages; loss of some intolerant, long-lived, or other taxa (e.g., stoneflies)
34–28	Impaired	Ecosystem parts and processes demonstrably impaired; cannot support self-sustaining salmon populations
26–18	Highly impaired	Highly inhospitable to many native fishes and invertebrates
16–10	Critically impaired	Cannot support a large proportion of native life-forms; only the most tolerant taxa present

corrective actions. Effective treatment of any health problem requires basic understanding of relations between causes and symptoms (i.e., indicators). Two other lessons are important: (1) Preventively treating the causes of poor ecological health is more cost-effective than reactively treating the symptoms, and (2) evaluating the effectiveness of treatments to promote health goals is crucial to avoid repeating the same mistakes in the future.

Choosing how to manage the effects of human actions on ecological conditions requires analyzing trade-offs between benefits and costs and how these are distributed among stakeholders. Some trade-offs involve local stakeholders in the near term, whereas others involve stakeholders living in other regions or who will live in the future. For example, converting a forest to a cornfield diminishes the capacity of the converted land to purify water, regulate floods, and maintain biodiversity but enhances its capacity to produce food. The costs of increased water pollution and flooding are mostly borne by people living literally downstream, whereas the benefits of increased food production are enjoyed by local farmers, as well as distant consumers. Trade-offs can be difficult to sort out—and agree upon—if all ecosystem services and stakeholders are to be considered equitably. Additionally, management choices vary among places and times. In national parks, for example, we choose to emphasize aesthetic and spiritual benefits along with widespread ecological services, while in commercial forests we choose to emphasize timber production. As societal values shift, choices that once made sense may be altered to align with current notions of human needs or well-being. In any case, analyses of changes in ecological condition (divergence from integrity) and the delivery of ecosystem services—both informed by appropriate ecological indicators—can summarize trade-offs and inform management choices.

Successfully managing ecosystems is complicated by the fact that we often know little about how ecosystems work, and the problems we try to solve may be too "wicked" to have straightforward solutions (DeFries and Nagendra, 2017). Managers can

become more effective by embracing structured, adaptive approaches, which use the knowledge gained from monitoring to guide future management actions (Conroy and Peterson, 2013). Adaptive management emphasizes "learning by doing," where learning is not achieved by simple trial and error but instead by careful, hypothesis-driven monitoring and by treating management actions as experiments (Murphy and Weiland, 2014). Properly chosen ecological indicators are crucial to adaptive management's four phases: plan, do, check, and adapt. Further, an adaptive approach allows an indicator to be chosen on the basis of current knowledge, then revisited as more is learned. Sometimes adaptive management is combined with a process called "ecosystem-based management," in which nonscientist stakeholders help develop indicators. Although this approach commonly promotes ecological understanding among stakeholders, outcomes for improving ecological health have been mixed (Layzer, 2008). Unfortunately, although monitoring is essential to adaptive management, insufficient monitoring—especially of biological indicators—too often limits the ability of managers to improve ecological health.

Conclusions

Whether the issue is endangered species, threatened water supplies, or emerging human diseases, understanding patterns, trends, and causes of biotic impoverishment in Earth's dynamic ecosystems is essential to informed, effective policy. Monitoring indicators of ecological health helps improve our understanding of ecosystems and diagnose the causes of ecological degradation. Ecological indicators inform scientists, the public, and policymakers about the environmental, social, human-health, and economic consequences of ever-changing ecological conditions. Sound environmental monitoring based on scientifically well-chosen ecological indicators is the best means of supplying concrete evidence for the importance of ecological health—no matter who may try to deny or discount it. When put to use, knowledge of ecological health has enormous potential to enhance human well-being.

Some of the most serious and complicated challenges now confronting humanity come from the impoverishment and declining condition of Earth's living systems. No single set of indicators—economic or ecological—will be enough to resolve the resulting debates and social dislocations. Ecological indicators can and must play an irreplaceable role in informing those debates and turning decisions toward protecting Earth's ecosystems and the human society that depends on them. Achieving a more sustainable human society requires greater ecological awareness and stewardship, as well as greater commitment to conserving all of Earth's biota well beyond the 21st century. We need ecological health indicators—widely measured, analyzed, and discussed—to reach these goals.

Ecological Risk Assessment☆

Glenn W Suter II and Susan B Norton, National Center for Environmental Assessment, US Environmental Protection Agency, Washington, DC, United States

Glossary

Assessment endpoint An explicit expression of the environmental value to be protected. An assessment endpoint must include an entity and specific attribute of that entity.

Ecological risk assessment A process that evaluates the likelihood that adverse ecological effects may occur or are occurring as a result of exposure to one or more agents.

Effects characterization A phase in an ecological risk assessment in which the relationship between exposure to contaminants and effects on endpoint entities and properties and associated uncertainties are estimated.

Exposure characterization A phase in an ecological risk assessment in which the spatial and temporal distribution of the intensity of the contact of endpoint entities with contaminants and associated uncertainties are estimated.

Exposure–response The functional relationship between the degree of exposure to an agent and the nature or magnitude of response of organisms, populations, or ecosystems.

Measure of effect A measurable or estimable ecological characteristic that is related to the valued characteristic chosen as the assessment endpoint (equivalent to the earlier term "measurement endpoint").

Measure of exposure A measurable or estimable characteristic of a contaminant or other agent that is used to quantify exposure.

Problem formulation The phase in an ecological risk assessment in which the goals of the assessment are defined and the methods for achieving those goals are specified.

Risk characterization A phase of ecological risk assessment that integrates the exposure and the exposure–response profiles to evaluate the likelihood of adverse ecological effects associated with exposure to the contaminants.

Risk management The processes of deciding whether to accept a risk or to take actions to reduce the risk, justifying the decision, and implementing the decision.

Uncertainty Lack of knowledge concerning an event, state, or relationship. It may include bias or imprecision in an estimate due to the estimation process, natural variability, or a fundamental lack of knowledge.

Introduction

Managers and decision makers are challenged to solve complex environmental problems associated with the increasing pressures placed on vital natural resources by human activities. These challenges are made difficult by the sheer number and diversity of human disturbances and exacerbated by the complexity of imperfectly understood natural ecological systems. The process of ecological risk assessment (ERA) addresses ecological complexity and incorporates uncertainty in characterizing the impacts of natural and man-made disturbances on ecological resources (Fig. 1).

ERA integrates ecology, environmental chemistry, environmental toxicology, geochemistry, hydrology, and other fundamental sciences in estimating the probabilities of undesired ecological effects. In practice, ERAs derive from specific needs to assess human-induced effects on the environment. Many ERAs conducted in the United States are motivated by legislation, including the National Environmental Policy Act (NEPA), the Toxic Substances Control Act (TSCA), and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA or Superfund). ERAs are also undertaken by private industry to determine future risks and liabilities associated with the development, use, and disposal (i.e., life cycle) of new or existing products (e.g., herbicides, pesticides, and industrial chemicals).

Several different approaches for performing an ERA have been developed internationally. However, the approach developed by the United States Environmental Protection Agency (US EPA) guides many ERAs performed in the United States and has served as a model for ERAs in other nations. It consists of three basic steps: problem formulation, analysis and characterization. The following discussion emphasizes this methodology.

☆*Change History*: March 2018. Glenn Suter and Susan Norton edited the original entry authored by Steve Bartell. They added information on the problem formulation phase, exposure–response modeling for ecological communities, and the use of weight of evidence. They also updated the Further Reading list and added a figure, a glossary of ecological risk assessment terms and a list of selected relevant websites.

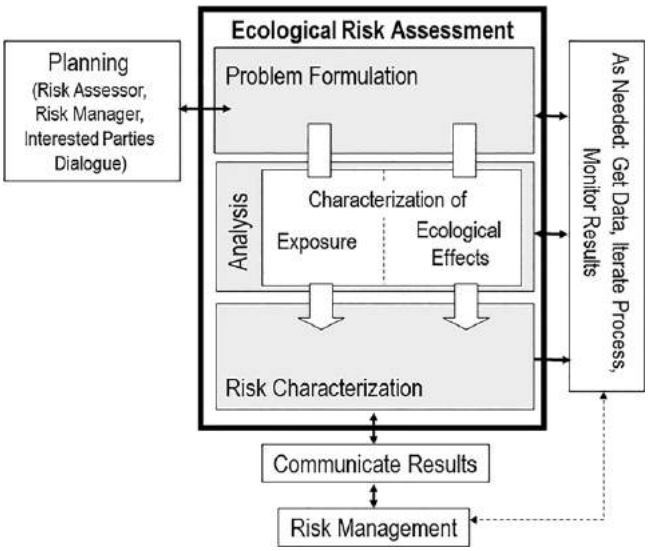

Fig. 1 US EPA's ecological risk assessment process Modified from US Environmental Protection Agency (1998). Guidelines for ecological risk assessment, EPA/630/002F, Washington, DC.

Definition of Ecological Risk

Risk is defined as the probability that an undesired event will occur. Correspondingly, ecological risk refers to the probability of the occurrence of an undesired ecological event. Alternative definitions of risk include an evaluation of the consequences of the undesired event along with estimation of its occurrence. For the most part, risk pertains to the probability of occurrence and this definition will serve this presentation.

ERA originally focused on the undesired ecological effects of toxic chemicals. As ERA evolved, the set of stressors has expanded to include physical, geological, hydrological, and biological stressors. Examples of these kinds of stressors include physical habitat degradation, erosion of soils or sediments, drought, floods, and introductions of exotic species.

Problem Formulation

This initial and perhaps most important part of the assessment defines the nature and scope of the ERA. It determines and describes the stressors that pose the risk and their sources, the processes by which the stressors may induce effects, and the undesired ecological effects (i.e., endpoints). This information is summarized in a conceptual model of the system to be assessed. This model should be viewed as dynamic and subject to change throughout the ERA in relation to modifications to the objectives and the development of new data and information.

Performing the problem formulation requires collaboration among risk managers and risk assessors to define the assessment objectives and scope and develop the corresponding conceptual model. The interactions might also involve other organizations and concerned members of the public (stakeholders). Initial discussions can help ensure that all important aspects of the assessment are identified, included as part of the problem formulation, and represented in the conceptual model. Such interactions can also ensure that the kinds of results produced by the ERA can be used effectively in the processes of decision making and risk management.

Following construction of the conceptual model, problem formulation continues by developing a plan to estimate the risks from each stressor to each endpoint. The resulting analysis plan characterizes the stressors, identifies specific ecological effects of concern, and identifies applicable data, as well as measures or models that can be used to quantitatively relate the stressors to the expected ecological effects.

Upon completion of risk estimation, risk managers, risk assessors, and stakeholders may reconvene to discuss the nature and interpretation (e.g., conclusions, assumptions, caveats) of the results in the context of the overall assessment objectives. Possible outcomes of these interactions include revisions to the conceptual model, collection of new data, and subsequent iterations of risk estimation. Once the requirements of risk managers and decision makers are fulfilled and documented, the process ends.

Following the problem formulation, the ERA continues with analyses that characterize exposure to the stressor(s) and the ecological effects of concern. The subsequent derivation of functional relationships between exposure and effects sets the stage for risk estimation.

Analysis: Exposure Characterization

Exposure is characterized by identifying the processes and mechanisms that bring organisms into contact with the stressor(s) of concern and quantifying the frequency, magnitude, and duration of such contact. The nature of the stressor(s) and the kinds of ecological effects of concern will strongly influence the exposure analysis. Each identified stressor will suggest a relevant spatial and temporal scale for analysis. The scales might be local and relatively short term, as for accidental spills of toxic, yet readily degraded or volatilized chemicals that result, for example, from hazardous waste management. Conversely, some stressors (e.g., fire, climate change) can exert ecological impacts over large expanses and for durations that greatly exceed the generation time of most organisms. Stressors are also evident at intermediate scales, for example, major oil spills and certain exotic species (e.g., in North America: gypsy moth, zebra mussel, Asian long-horned beetle).

The nature of specific stressor(s) can provide information concerning the processes or mechanisms of exposure that should be evaluated in an ERA. Chemical contaminants introduced into the environment are naturally transported by the movements of wind and water. Certain chemicals can accumulate in organisms and be transmitted throughout food webs. Some organic chemicals are comparatively insoluble in water and are rapidly adsorbed to soils and sediments, while other chemicals remain in solution and are transported by water. In contrast, movements of biological stressors such as invasive species might be augmented by private and commercial transportation. Corresponding characterization of exposure might emphasize delineation of transportation networks in place of physical–chemical processes.

The kinds of ecological effects included in the conceptual model can also provide insights into exposure analysis. Organisms occupy certain dimensions in space and time. Habitats have measurable spatial extent; ecological processes exhibit characteristic rates. Such observations can guide the analysis of exposure. For example, knowledge of the timing and duration of a sensitive life stage (e.g., eggs, larvae) can focus the corresponding measurement of stressors of concern and provide more meaningful quantification of exposure than longer-term averages or monitoring that might completely miss the critical time period for exposure. Similarly, seasonal changes in light, temperature, precipitation, and other physical factors can result in spatial–temporal variability in exposure. The important point is that variability in both the processes that influence the stressor and the characteristics of the ecological entities of concern should be addressed in performing a meaningful analysis of exposure.

Alternative approaches can be used to assess exposure. Worse-case scenarios can be developed that assume maximum values of the stressor. For example, end-of-pipe concentrations of toxic chemicals can be used without accounting for physical dilution, chemical alterations, or biological degradation that would otherwise reduce the concentrations experienced by the organisms of concern. This approach is biased toward overestimating exposure and risk, but it ensures that hazardous agents are not overlooked. If acceptable risks result from these extreme exposures, the assessment process might reasonably stop. As an alternative to worse-case scenarios, exposures might be measured. Actual measures of exposure are undoubtedly the most easily defended scientifically (presuming competent sampling and analysis) and the most realistic inputs to an ERA. Finally, exposures might be estimated using physical (e.g., microcosms, mesocosms) or mathematical models.

Exposure characterization generates an exposure profile. For chemicals, the profile includes the nature of the source; pathways of exposure; identification of environmental media of concern (e.g., soils, water, sediments, contaminated biota); estimates or measures of exposure concentrations (magnitude, timing, duration, recurrence); and uncertainties associated with these concentrations. Analogous exposure profiles are developed for nonchemical stressors addressed by an ERA.

Analysis: Effects Characterization

The large number and different kinds of ecological effects that are of potential concern distinguish, in part, ERA from more traditional human health risk assessment. The diversity of effects reflects the comprehensive nature of ecology and the environmental sciences. Ecologists have recognized several levels of organization as being useful in describing the natural world including organisms, populations, communities, ecosystems and landscapes. ERAs commonly identify more than one kind of ecological effect of concern in problem formulation. The ecological effects of concern identified during problem formulation should be ecologically important, sensitive to the stressor(s), and relevant to risk management.

Endpoints in ERA can include several effects at different levels of organization. An ERA might address alterations in basic physiological processes (e.g., photosynthesis, respiration) as long as they had implications for relevant endpoints the organism level (e.g., reduced survival or growth). In rare instances, effects to individual organisms might be selected as endpoints. In these cases, the individuals are likely to represent small populations of endangered species. Such instances would be equivalent to assessing risks to a maximally exposed human.

ERAs routinely assess effects on populations, expressed in terms of changes in survival, growth or reproduction in assessment populations. However, in cases in which the production or abundance of a particular population is important, assessments may be based on population dynamics. It is not uncommon for species officially designated as threatened or endangered or for a commercially or recreationally important species to be the focal points for ERA. Population models are well developed and these models are being used increasingly to estimate ecological risks.

Ecologists recognize that individual populations do not persist in an ecological vacuum. The number of species, their absolute and relative abundances, and their correlation of occurrence in space and time define community structure. The most common expression of effects on communities is the proportion of species affected. The most common exposure–response model is a

species sensitivity distribution, which is usually derived using toxicity test data for individual species but may also be derived from field data. Field tests such as mesocosm and field observational studies may also be used to derive exposure–response models for other community endpoints. These may include reductions in species diversity, indices of biotic integrity and measures of community similarity.

Ecosystem ecology addresses important feedback mechanisms between biotic and abiotic processes that determine ecosystem structure and function. The effects of stressors on fundamental ecosystem processes (e.g., primary production, system respiration, decomposition, nutrient cycling) can be important endpoints in ERA. The ecosystem concept also emphasizes the scale dependence and asymmetry of ecological interactions. Even in highly complex systems, not all components and processes are of equal importance. Delineation of critical scales and feedbacks can help define the relevant spatial–temporal scales in designing ERAs.

Assessments of stressors that operate at larger scales (e.g., acid precipitation, climate change) has led to the consideration of landscape-level effects in ERA. The most common landscape endpoints in risk assessment are alterations in the spatial distribution and extent of different habitat types within landscapes. Changes in the size, shape, and proximity of similar habitat areas (patches) can be measured or modeled.

Exposure–Response Relationships

The core of ERA is a causal relationship between exposure to the stressor and effects on the ecological endpoint, expressed as an exposure–response functions. For a given stressor, these functions estimate the severity of the expected ecological response in relation to the magnitude, frequency, and duration of the exposure. The derivation of exposure–response functions depends on the quantity and quality of available data.

Sources of data that might be used in the construction of exposure–response functions include: the results of toxicity tests performed under controlled laboratory conditions, direct measures of exposure and response in controlled field experiments, or uncontrolled field observations. Field observations are the most realistic and complete, but laboratory toxicity tests are less variable and less confounded by extraneous variables. In the absence of directly relevant data, the development of exposure–response functions may require extrapolations among similar stressors or ecological effects for which data are available. For example, effects might have to be extrapolated from an available test species to an untested species of concern. Similarly, toxicity data might be available only for a chemical similar to the specific chemical stressor of concern. An extrapolation from the known chemical to the unknown would be required to perform the assessment.

The most generally useful exposure–response relationships are statistical functions fit to paired exposure and effects levels. They generally increase monotonically and are nonlinear. Exposure levels corresponding to particular centiles of effects—may be used as benchmark values. The most common such value is the concentration (or dose) that produces effects in half of the organisms or 50% of the maximum response. For example, the concentration that results in 50% mortality during a prescribed period of exposure (e.g., 48, 96 h) defines the LC_{50} (lethal concentration that produces 50% mortality). An EC_{50} defines an exposure that results in a 50% decrease in an endpoint other than mortality, for example, growth. Dichotomous functions based on statistical significance such as the lowest observed effects concentration or LOEC have been used, but should be avoided. Significance tests do not measure the size of an effect and they do not correspond to biologically meaningful thresholds.

Risk Characterization

Risk characterization combines the exposure profiles with the exposure–response relationships to estimate ecological risks in ERA. A variety of methods and tools are available for risk estimation. For assessing risks posed by toxic chemicals, one simple method simply divides the exposure concentrations by a relevant toxicity benchmark value. A test endpoint such as an A LC_{50} or EC_{50} or a modeled threshold value such as a 10% loss of biodiversity may be used as a benchmark. Quotients equal to or greater than 1.0 are typically interpreted as implying risk; quotients less than 1.0 suggest minimal or no risk. Such quotients can prove useful in initial screening-level assessments to reduce the number of stressors that should be analyzed in greater detail. The screening assessments may be particularly effective if exposure estimates used in risk characterization are biased toward overestimating risk. However, 50% mortality or 50% reduction in growth or fecundity clearly are not thresholds for effects. Therefore, benchmark values, particularly when used for screening assessments often require safety factors.

More information is obtained by using the entire exposure–response relationship to characterize risk. That is, the model is solved for an estimated level of exposure that generates a predicted level of effect.

Depending on the availability of data, distributions of exposure and toxicity can be constructed and compared. Risk can be estimated by statistically comparing the degree of overlap between these distributions: the greater the overlap, the higher the risk. Using comparisons of distributions in assessments incorporates much more information than the quotient approach, including uncertainty, in the risk estimate. However, it must be remembered that they still are subject to the inherent uncertainties of using laboratory tests, standard species, and chemical transport and fate models.

Mathematical and computer simulation models can be used to estimate ecological risks. Following decades of model construction in support of basic ecological research and development, it stands to reason that some of these models might prove useful in estimating ecological risks posed by various stressors on organisms, populations, communities, and ecosystems. To be

useful in characterizing risk, the selected ecological model must include some representation of one or more of the assessment endpoints as a dependent variable. The model must also represent the stressor as an independent variable. The remaining critical aspect in selecting or adapting models for assessing risk is the ability to derive exposure–response relationships for the stressor(s) and ecological effects of interest.

Commonly in ERA, risks may be estimated by more than one method. Exposure–response relationships may be based on laboratory tests, microcosms, mesocosms, field tests, and field observations. Exposure may be estimated by modeling or field measurements. Weight-of-evidence methods can be used to evaluate those alternative types of evidence and to either combine them or to choose be one that gives the best estimate.

Uncertainty

Risk implies uncertainty. ERA was designed expressly to include uncertainty as an integral component of the assessment process. Sources of uncertainty, as used here, include natural variability in ecological and environmental phenomena, as well as lack of knowledge or bias and imprecision in estimates of exposure or exposure–response functions. This latter source of uncertainty can be exacerbated if extrapolations were involved in the derivation of the functions (e.g., laboratory to field, species to species). Incomplete and imperfect understanding of baseline ecological phenomena also adds uncertainty to ERA.

Uncertainties inherent to the risk assessment process can be quantitatively described using, for example, statistical distributions, fuzzy numbers, or intervals. Corresponding methods for propagating these kinds of uncertainties through the process of risk estimation include Monte Carlo simulation, fuzzy arithmetic, and interval analysis. Computationally intensive methods (e.g., the bootstrap) that work directly from the data to characterize and propagate uncertainties can also be applied in ERA. Implementation of these methods for incorporating uncertainty can lead to risk estimates that are consistent with a probabilistic definition of risk.

Methods of numerical sensitivity and uncertainty analysis can be used to examine uncertainty and identify the key sources of bias and imprecision in quantitative estimates of risk. Once identified, limited resources (e.g., time, funding) can be efficiently allocated to obtain new information and data for those major sources of uncertainty and reduce uncertainty. These analyses can be repeated until uncertainties associated with the risk estimates are of an acceptable degree or until uncertainties cannot be further reduced. Importantly, application of these methods for analyzing uncertainty will identify whether unacceptably high estimates of risk derive from the inherent severity of the stressor or from high uncertainty.

Ecosystem Health Indicators☆

Marion Kruse, Kiel University, Kiel, Germany

Authors of first version on which this updated is based on: B. Burkhard, Leibniz Universitat Hannover, Hannover, Germany; F. Müller and A. Lill, Kiel University, Kiel, Germany.

Introduction

The fundamentals of the ecosystem health concept have been already set in the 18th century with the ideas of the Scottish geologist James Hutton, who started to describe the Earth as an integrated system. Later, the writings about land sickness of the pioneering ecologist Aldo Leopold in 1941 created the first roots of the ecosystem health concept. Since then, the definition of ecosystem health has been constantly evolving toward an integration of more and more human and societal contexts, in order to understand what is considered a healthy ecosystem. Ecosystem health can be understood as a management concept that contributes to solve environmental problems. In the United States and Canada the concept of ecosystem health has been adopted in legislation and it is part of international political programs, for example the so-called Rio Convention on sustainable development. Therefore, the assessment of ecosystem health does not only take into account ecological components but also requires a comprehension of social, economic, and cultural dimensions. Hence, its definition is more comprehensive than the definition of human health.

☆*Change History:* April 2018. M. Kruse extended the abstract, introduction, and conclusion and introduced small edits to the other parts of this article. The further reading list was updated.

These facts have to be reflected while defining appropriate sets of indicators that can be applied within respective assessments of ecosystem health. Indicators must fulfill diverse scientific and practical requirements (e.g., a distinct relationship between the indicator and the subject to be indicated (indicandum), measurability and data availability). The selection and application of indicators determine the results of the quantification of the ecosystem health and have a major impact on the management targets and their success.

Suitable indicator sets have to consider both the structure and the function of ecosystems in different spatial and temporal scales. As pointed out in various studies, ecosystems on our planet already are, and will continue to be, degraded under the pressure of increasing human activities. Anthropogenic impacts, such as intensive and unsustainable land use causing erosion and eutrophication, pollution, urbanization and loss of biodiversity have become more and more evident during the last decades. There are no more ecosystems on Earth which are not impacted by any human activity. Hence, preventative and restorative strategies are needed in order to achieve the health of regional and global ecosystems on a long-term perspective. Due to the complexity of ecosystems and their interactions in human–environmental systems, there is a demand for holistic management concepts that can tackle these problems. With regard to different well-known and established indicators, for example species diversity or water quality, many of the ecosystems on our planet can be considered unhealthy. Several of their functions, especially those needed to sustain life of the human community, have become impaired. Consequently, ecosystem health has been changed significantly, that is, because it refers to systems that are manipulated to satisfy human needs. This makes the difference to other related concepts, for example, some notions of ecological integrity, which refers to the functioning of ecosystems based on nature-near, self-organized processes.

Generally speaking, an ecosystem is often called healthy if it is stable (respectively resilient) and sustainable in the provision of goods and services used by human societies (ecosystem services). This implies that the ecosystem has the ability to maintain its structure (organization) and function (vigor) over time under external stress (resilience). Further ecological principles and theories like homeostasis, diversity, complexity, emergent properties, or hierarchy principles are closely related or included in the concept of ecosystem health as it refers to complex adaptive systems. These systems are characterized by certain dynamics including sudden reconfigurations from one state of organization to another. Some changes can be inherently unpredictable. Both positive and negative feedback processes and cause and effect chains, operating over a range of spatial and temporal scales, predominate these dynamics.

Besides these theoretical considerations on ecosystem health, a list of further aspects, which are also, included in currently available definitions have been compiled in de Kruijf and van Vuuren:

- Healthy ecosystems are free from ecosystem distress syndrome, a set of signs present in most heavily damaged ecosystems;
- Healthy ecosystems are resilient—they recover from natural perturbations and disturbances;
- Healthy ecosystems are self-sustaining and can be perpetuated without subsidies or drawing down natural capital;
- Healthy ecosystems do not impair adjacent ecosystems—that is, healthy ecosystems do not result in stress in neighboring systems;
- Healthy ecosystems are free from risk factors;
- Healthy ecosystems are economically viable;
- Healthy ecosystems sustain healthy human communities.

Hence, ecosystem health represents the sustainability of an ecosystem as a whole that needs a minimal external support by management measures. It comprises biophysical, socioeconomic, cultural, and human dimensions of the environment. This notion of ecosystem health is closely interrelated to the ability of ecosystems to provide and sustain ecosystem services.

In the beginning of the article, a short review of the historic development of ecosystem health assessment and indicators is given. Afterwards, different categories and examples of corresponding ecosystem health indicators are presented. This part is supplemented by several examples of commonly applied ecosystem health indicators from aquatic as well as from terrestrial ecosystems. At the end, some examples of applied methods of ecosystem health assessment are given to show the diversity of ecosystem health indicators and application contexts.

Ecosystem Health Assessment and Indicators

The idea of ecosystem health assessment (EHA) has started in the late 1980s with an increasing amount of publications on this topic. Since then, there have been wide discussions about adequate concepts and methodologies. As the individual ecosystems are never identical with reference to basic features (e.g., forest ecosystem and a wetland ecosystem), it is challenging to find general and reproducible approaches instead of case specific techniques. Furthermore, appropriate assessments have to bridge the gaps between natural, socioeconomical, and health sciences, and must integrate human norms and values with the aim to support sustainable management of natural resources. Defining management goals and their indicators is a further challenge in the ecosystem health assessment.

As ecosystem health cannot be measured or observed directly, surrogate measures (indicators) have to be applied to assess it. These indicators should be backed by ecological principles and systems theory. They should be suitable for applications on varying temporal and spatial scales. Parameters needed for their quantification have to be obtainable and reproducible within ecological assessments. Moreover, indicators have to give adequate information about ecosystem quality trends, useful for managers and

scientists that take into account the complex cause and effect chains in human–environmental systems. Different values and processes have to be integrated in order to assess the health of an ecosystem in relation to economic and social aspects, regional and global environmental changes, and alterations in the provision of ecosystem services and their consequences for human well-being.

Categories of Ecosystem Health Indicators

As ecosystems are extremely complex, any single indicator cannot be completely representative with reference to all possible demands, features, and conditions. Nevertheless, there is a wide spectrum of indicators that can be used for the assessment of ecosystem health. They can be classified into different categories that include varying levels of integration, ranging from rather reductionistic to holistic indicators, integrating a broad range of environmental information:

- Indicators based on the abundance of selected species;
- Indicators based on the concentration of selected elements;
- Indicators based on ratios between different classes of organisms of elements;
- Indicators based on ecological strategies or processes;
- Indicators based on ecosystem composition and structure;
- Systems theoretical holistic indicators.

The identification of appropriate indicator-indicandum (the phenomenon that has to be assessed) relations has to be carried out thoroughly, especially while dealing with holistic and highly aggregated indicators.

Commonly Applied Ecosystem Health Indicators

In the following, some examples out of the huge amounts of specific indicators and sets of indicators are given.

Indicators Based on the Abundance of Selected Species

These biological indicators cover the presence or absence of selected species. Indicator species have to be selected in order to be representative for a certain phenomenon or to be sensitive to distinct changes. Hence, their appearance and dominance is associated with a certain environmental situation, the usage of this kind of indices implies on the one hand a certain level of uncertainty, on the other, the results can directly be linked to biological phenomena which is useful for proper management of resources. In the following, some examples will be outlined.

Saprobic classification

The saprobe system is a collection of organisms that give information about the degree of water pollution. The different pollution intensities (saprogenic stages) are related to certain indicator organisms (e.g., bacteria, fungi, algae, amoeba, mussels, worms, insect larvae, and fishes) and ranges from polysaprobic (very highly polluted), α-mesosaprobic (highly polluted), β-mesosaprobic (medium polluted) to oligosaprobic (rather clean and clear water).

Bellan's pollution index

Bellan considers aquatic species like *Platynereis dumerilii, Theosthema oerstedi, Cirratulus cirratus,* and *Dodecaria concharum* as water pollution indicators. Clear water is indicated by species like *Syllis gracilis* or *Typosyllis prolifera*. The equation of the Bellan's pollution index can be formulated as follows:

$$\mathrm{IP} = \Sigma\ \text{dominance of pollution indicator species} / \text{dominance of pollution (clear) water indicators}$$

If the index value is bigger than 1, a pollution disturbance in the community is indicated.

AZTI marine biotic index

For this indicator the soft bottom macrofauna is distinguished into five groups in accordance to their sensitivity to increasing stress:

I. species that are very sensitive to organic enrichment and eutrophication and that are only present under unpolluted conditions;
II. species that are indifferent to organic enrichment, occur always in low densities and show no significant variations over time;
III. species tolerant to excess organic matter enrichment (these species can also be found under normal conditions but usually their populations are supported by organic enrichment);
IV. second-order opportunist species, very often small polychaetes; and
V. first-order opportunist species (deposit feeders).

$$\text{AMBI (bioticcoefficient)} = \{(0\ \text{x\%I}) + (1.5\ \text{x\%II}) + (3\ \text{x\%III}) + (4.5\ \text{x\%IV}) + (6\ \text{x\%V})\}/100$$

The AZTI marine biotic index (AMBI) results can be classified as: normal (AMBI coefficient between 0.0 and 1.2), slightly polluted (1.2 and 3.2), moderately polluted (3.2 and 5.0), highly polluted (5.0 and 6.0), or very highly polluted (6.0 and 7.0). The AMBI has been considered useful in terms of the application of the European Water Framework Directive to coastal ecosystems and estuaries.

Bentix

The Bentix is based on the AMBI but has only three groups in order to avoid errors in the grouping of species and to make the calculation of the index easier:

- *Group I*: Species generally sensitive to disturbances.
- *Group II*: Species that are tolerant to stress or disturbance. Populations may respond to organic enrichment or other source of pollution.
- *Group III*: First-order opportunistic species (pioneer, colonizers or species which are tolerant to hypoxia).

$$\text{Bentix} = \{(6 \times \%\text{I}) + 2(\%\text{II} + \%\text{III})\}/100$$

The Bentix results can be classified as: normal (4.5–6.0), slightly polluted (3.5–4.5), moderately polluted (2.5–3.5), highly polluted (2.0–2.5), or very highly polluted (Bentix = 0).

Macrofauna monitoring index

This index comprises 12 indicator species. Each of them is assigned a score, based primarily on the ratio of its abundance in control versus impacted samples. The index value is the average score of those indicator species which are present in the sample.

Benthic response index

The Benthic response index (BRI) is calculated as abundance weighted average pollution tolerance of species that occur in a sample. This is similar to the weighted average approach used in gradient analysis.

Indicators Based on Concentration of Selected Elements

Many assessments are based on measurements or monitoring of concentrations or densities of selected elements that can be linked with altering system states. In the context of environmental management, a link to anthropogenic activities is convenient: for example, the estimation of the level of eutrophication on the basis of total phosphorus concentrations. Another typical measurement is the pH value, referring to the activity of hydrogen ions, which, for instance, can be linked to effects of air pollution (acid rain).

Indicators Based on Rations Between Different Classes of Organisms or Elements

Increase or decrease of one species in relation to another can give useful information about changes in systems. Depending on the problem and the system that has to be investigated, different indices are applicable.

Nygaard's algal index

This index is used to evaluate the nutritional status of lake ecosystems and their fertility. The index can be calculated as a compound quotient out of:

$$\text{Myxophycean} + \text{Chlorococcales} + \text{Centric} + \text{Euglenophyceae}/\text{desmids}$$

Oligotrophic systems have a quotient between 0.01 and 1.0, eutrophic systems between 1.2 and 2.5. Further Nygaard's indices are based on ratios between Myxophyceae and desmids, chlorococcales and desmids; centric and pinnate diatoms or Euglenophyta and Myxophyceae + chlorococcales.

Diatoms/non diatoms ratio

In the context of altering nutrient charges in aquatic systems, the ratio of the major phytoplankton groups, diatoms versus flagellates (diatoms–non diatoms ratio), can be used as an indicator. Regarding for example eutrophication, nutrient reductions can be seen in a decrease in flagellate abundance.

Indicators Based on Ecological Strategies or Processes

Regarding ecosystems as entities of complex processes and interactions, varying strategies and processes are related to altering system's conditions caused by human activities or different stages of natural development.

Process and rate indicators

One functional way to assess the health of ecosystems is to measure or model indicators that represent important processes in the ecosystem from which conclusions for the whole system can be drawn. Primary production or growth rates are among the most commonly used indicators. The cycling of matter, water, or energy between the different components of a system, and the transformation of matter, water, or energy into different forms, are main processes in natural systems. Examples include cycling of nitrogen or phosphorus, the fixation of energy by plant photosynthesis, or the water cycle based on precipitation, runoff, and evapotranspiration.

Indicators based on ecological strategies

Further indices consider the distinct behavior of different taxonomic groups under environmental stress situations, for example, the nematodes/copepods index. Some authors have criticized these indices because of their dependence on parameters such as water depth and sediment particle size, and also because of their unpredictable pattern of variation depending on the type of pollution. More recently, indices, for example, the polychaetes/amphipods ratio or the index of r/K strategists, which consider all the benthic taxa, were developed.

Index of r/K strategists

In a rather stable system with infrequent disturbances, the competitive dominants in most communities are k-selected, or conservative, species with the attributes of large body size and long life span. They are usually dominant in terms of total biomass, but not dominant in number. R-selected, or opportunistic, species with shorter life spans are usually numerically dominant but do not represent a large proportion of the total biomass of the community. After a more significant disturbance, conservative species are usually less favored, and the opportunistic species can become dominant as well in biomass as in number. Thus, the analysis of r- and K-strategists' distributions can be used for the indication of ecosystem health.

Often, different feeding strategies of organisms are used to describe ecosystem conditions and developments.

Infaunal index

For the assessment of the trophic infaunal index, the macrobenthos species are divided into four groups:

1. suspension feeders,
2. interface feeders,
3. surface deposit feeders, and
4. subsurface deposit feeders.

The infaunal index is calculated with the following equation:

$$\mathrm{ITI} = 100 - (100/3) \times (0n1 + 1n2 + 2n3 + 3n4)/(n1 + n2 + n3 + n4)$$

$n1$, $n2$, $n3$, and $n4$ are the number of individuals that are sampled in each of the four species groups. If the ITI value approaches 100, suspension feeders are dominant which indicates an environmental disturbance.

Indicators Based on Ecosystem Composition and Structure

Ecosystems are dynamic systems that show varying compositions and structures during their different stages of development or due to perturbations. Different indicators to describe systems' composition and structure exist.

Shannon–Wiener index

Indices based on the diversity values are very common. One of the most often used is the Shannon–Wiener index, developed by C.E. Shannon and W. Wiener. This index originates in information theory and assumes that individuals are sampled at random out of a community which is indefinitely large, and that all the species are represented in the sample.

The Shannon–Wiener index is calculated by the following equation:

$$\mathrm{H}' = -\Sigma p_i \log_2 p_i$$

In this equation, p_i is the proportion of individuals found in species i. The values of this index can vary between 0 and 5. H' reaches a maximum value if the individuals of all species occur with the same density. Other indices based on the diversity value are, for example, the Pielou evenness index, the Brillouin index, the Margalef index, the Berger–Parker index, the Simpson index, and K-dominance curves.

Food webs

Food webs describe the connections of plants and animals which depend upon each other referring to the flow of energy. Organisms are assigned to different trophic levels that classify their position in the food chain which is determined by the number of energy transfer steps to that level. In general, food webs become more complex during the development of a system. Hence, their structure

and composition can be used to assess the condition and stage of development of a system. Network theory plays an important role for the interpretation of food web structures.

Ascendency

Ascendency and related indices are abstract concepts for the quantification of the size and organization of flows in systems using information-theoretic terms. Ascendency values indicate the overall status of dynamic systems in a quantitative fashion and show the limits of system growth and development. The response of a system to perturbations can be measured which is useful in the context of ecosystem health.

Systems Theoretical Holistic Indicators

Indicators based on systems theory have high potentials to represent complex issues in a holistic manner, but they tend to be rather abstract and difficult to communicate.

Vigor, organization, and resilience (V–O–R model)

Measures of vigor, organization (or performance), and resilience are often used to assess ecosystem health. However, they are more easily described in theory than quantified in practice. Vigor is usually represented by activity, metabolism, or primary productivity. A study of the Great Lakes Basin (North America) showed the decline in the abundance of fish and infertility of agricultural soils within the basin as an example of reduced vigor. Organization represents the diversity and number of interactions between system components. An example also from the Great Lakes, is the reduced morphological and functional diversity of fish associations that occur under multiple stresses. Resilience is normally understood as a system's capacity to maintain structure and function in the presence of (external) stress. When resilience is exceeded, the system can shift to an alternate state. A prime example is the shift from benthic to pelagic dominated fish associations in the Laurentian Lower Great Lakes Basin. In this approach ecosystem health is closely related to the concepts of stress ecology, where vigor, systems organization, resilience and the absence of signs of ecosystem distress are the main factors for the health of a system.

Exergy indices

Further holistic indicators are the exergy index and the specific exergy index. Exergy is derived from thermodynamics and measures the energy fraction that can be transformed into mechanical work. In ecosystems, the captured exergy is used to build up biomass and structures during succession. Hence, exergy can be used as a measure of biomass, structure, energy, and information stored in the biomass. Therefore, more complex organisms and systems also have more built in exergy that simpler ones. Specific exergy is defines as exergy per biomass. Both exergy and specific exergy can be used as indicators for ecosystem health. Relations between the exergy values and other ecosystem health characteristics like diversity, structure, or resilience can be found. For example, specific exergy expresses the dominance of the higher organisms as they per unit of biomass carry more information (they have higher β-values). A very eutrophic ecosystem has a very high exergy due to the high concentration of biomass, but the specific exergy is low as the biomass is dominated by algae with low β-values. The combination of exergy index and the specific exergy index usually gives a more satisfactory description of ecosystem health than the exergy index alone, because it considers the diversity and the life conditions for higher organisms.

The Holistic Ecosystem Health Indicator

The holistic ecosystem health indicator (HEHI) was developed in 1999 in Costa Rica as an integrative indicator which might be an appropriate tool for assessing and evaluating health of managed ecosystems. The HEHI follows a hierarchical structure starting with three main branches: ecological, social, and interactive. Measures about the condition and trend of the ecosystems are organized within the ecological branch. Socioeconomic measures concerning the community dependent on the ecosystem or affected by management decisions are organized within the social branch. The interactive branch includes measures relating to land-use and management decisions that characterize the interactions between the human communities and the ecosystem. Furthermore, each branch is subdivided into categories or criteria.

The indicators belonging to the categories serve as measures for the performance of each category. If we, for example, take soil quality, this is a category within the ecological branch and it can be measured using indicators such as microbial biomass, water infiltration, compaction, etc. Each category is given a target or a benchmark, which is based on references available in scientific literature, policies, etc. For example, a water-quality indicator can have a target defined by legal limits specified by the administrative authority in charge, while a target for a productivity indicator may be defined by a combination of the capacity of the system and objectives set by stakeholders.

NRCS indicator selection model

The National Resource Conservation Service (NRCS) of the US Department of Agriculture assigned an NRCS indicators action team in 1994, which developed an indicator selection model for the use of indicators in evaluations of ecosystem conditions.

The team identified framing questions for four different ecosystem aspects, namely: ecosystem processes, recovery processes, landscape and community structure, and abiotic features. The framing questions represent a minimum set of diagnostic questions,

which need to be answered when doing comprehensive evaluations of ecosystem conditions or health. The questions are asked at all scales of ecosystem evaluation:

System Processes: The questions asked at "system processes" are as follows:

1. Are precipitation and groundwater resources captured, stored, used, and released in a safe and stable manner?
2. Are kinds and flows of chemicals (minerals, nutrients, other) and energy in balance and optimized for plant and animal communities and biomass production requirements?
3. Are annual cash flows, technical assistance, and conservation incentives timely and adequate for desired community and land user income?

Recovery Processes: The questions asked at "recovery processes" are as follows:

1. Are soil, water, air, plant, and animal resources and biophysical processes in place and in a condition to allow timely and full recovery from stresses and disturbances and to meet management objectives?
2. Are social and economic systems available to allow land users and communities and the resources they manage to recover from environmental and socioeconomic stresses?
3. Are there human and animal resource health concerns associated with the management of present or planned enterprises?

Landscape and community structure: The questions asked at "Landscape and community structure" are as follows:

1. Do landscape features and patterns facilitate use, protection and optimization of ecosystem processes?
2. Do commodity markets, investment capital and public programs encourage land uses, enterprises and resource management that are compatible with ecosystem processes?
3. Are decision-making processes available to communities and individuals to resolve conflicts regarding current and desired uses, management and protection of natural resources?
4. Does the social infrastructure (healthcare, education, multicultural recognition, etc.) support and promote the desired quality of life for the communities and individuals?

Abiotic features: The question asked at this scale is: Are current and planned land uses and desired future conditions suited to the abiotic conditions (e.g., stream temperature, flow velocities, riffle/pool ratios, riparian shading, climate, topography, soils, and geology)?

Within the next step, for all ecosystem components (environmental, ecological, socioeconomic, cultural, or political factors), which are considered to be necessary elements of the respective system, appropriate indicators are listed. These indicators are the quantitative or qualitative tools in this model to assess the status, condition, or trend of a given ecosystem attribute or component. The underlying assumption for the use of such indicators is that relationships can be inferred between a relatively easily measured ecosystem attribute (i.e., litter distribution and amount) and the more difficult to measure ecosystem components or processes (i.e., energy flow and nutrient cycling).

Applied Methods of Ecosystem Health Assessment

The concept of ecosystem health has been criticized for being too fuzzy and not concrete enough for practical application. Nevertheless, it found entry in different management strategies and definitions of political targets. For example, in principle 7 of the Rio Declaration of 1992, it has been claimed that "States shall cooperate in a spirit of global partnership to conserve, protect, and restore the health and integrity of the Earth's ecosystem." More recently, the consideration of ecosystem health was integrated into the ecosystem approach of the Convention on Biological Diversity (CBD) and in connection to the precautionary principle which is part of the environmental and nature conservation strategies in different countries. Furthermore, the ecosystem health concept was implemented in the strategies of the OSPAR (Convention for the Protection of the Marine Environment of the North-East Atlantic) and the HELCOM (Baltic Marine Environment Protection Commission—Helsinki Commission) commissions for the protection of marine environments or in the European Union Water Framework Directive. The development of appropriate monitoring and indicator systems and methods to assess ecosystem health in practice are main targets of these initiatives.

Three examples for methods for possible ways of ecosystem health assessment applications are given in the following. The first one, the ecosystem health index method (EHIM) is based on a combination of different sub indicators which are synthesized into index values using individual weighting factors. Whereas in the ecological model method (EMM), modeling procedures are used to quantify indicator values, the direct measurement method (DMM) is based on values that are measured directly or calculated indirectly for the assessment of ecosystem health.

Ecosystem Health Index Method

For this method, a synthetic ecosystem health index (EHI) in a scale of 0–100 has been developed in order to quantitatively assess the state of ecosystem health. The worst health state exists when EHI is zero. To make description easier, the EHI was divided into

five categories: 0%–20% (worst health state), 20%–40% (bad health state), 40%–60% (middle health state), 60%–80% (good health state), and 80%–100% (best health state). Five steps are necessary to calculate the EHI:

1. selection of basic and additional ecosystem indicators;
2. calculation of sub-EHIs for all selected indicators;
3. determination of weighting factors for all selected indicators;
4. calculation of synthetic EHI using sub-EHIs and weighting factors for all selected indicators; and
5. assessment of ecosystem health based on synthetic EHI values.

Ecological Model Method

Five steps are applied when using the ecological model method (EMM):

1. determination of the model structure and complexity according to ecosystem structure;
2. establishment of an ecological model by creating a conceptual diagram, developing model equations as well as estimating model parameters;
3. calibration of the model in order to assess its suitability in application to ecosystem health assessment process;
4. calculation of the ecosystem health indicators; and
5. assessment of the ecosystem health using the values of the indicators.

Direct Measurement Method

The direct measurement method (DMM) is used by applying the following three steps:

1. identification of relevant indicators which are needed for the assessment process;
2. direct measurement or indirect calculation of the selected indicators; and
3. assessment of ecosystem health based on the resulting indicator values.

Conclusion

Ecosystem health is not simply defined because it is a holistic management concept that must deal with the complexity of human–environmental systems and today's diverse environmental problems, which are jeopardizing the supply of ecosystem services and human wellbeing. There are several definitions presented in the literature and the term "health" with its easily transferable metaphoric character can act on the one hand as a positive connotation in some regions, where it was on the other hand not successfully integrated in management and decision-making in other areas.

There is a broad range of ecosystem health indicators available to cope with this spectrum of ecosystems and human pressure, to which they are exposed. Depending on the questions or environmental problem to investigate, such indicator sets can be combined and used to supplement each other in order to carry out holistic ecosystem health assessments since environmental problems are often diversified. Therefore, indicators applicable for all different kinds of research and management questions have not been developed so far. The presented indicators are examples of the wide range of possible approaches developed so far, which also reflects the versatile definitions and viewpoints of ecosystem health. Another critical point is the availability of data for the quantification of respective indicators on suitable spatial and temporal scales. If ecosystem health indicators are linked to existing monitoring networks or easily transferable methods (e.g., by means of remote sensing data or report cards), appropriate data sets can be on-hand. Further data can be derived by new modeling techniques. Especially the linkage with social, economic, and land-use data can give valuable information with regard to the effects of human action on the state of ecosystems. This has been presented and discussed in several published case study applications in different socioecological context and regions.

Glossary

Adverse outcome pathway (AOP) AOP is structured representation of biological events leading to adverse effects and is considered relevant to risk assessment.

Dynamic energy budget (DEB) DEB offers a systematic way to relate processes at different organizational levels: molecules, cells, organisms, populations and ecosystems, and which focuses on metabolic processes that are common to large groups of organisms.

Ecological risk assessment (ERA) ERA is the process for evaluating how likely it is that the environment may be impacted as a result of exposure to one or more environmental stressors such as chemicals, land change, disease, invasive species and climate change.

Lowest observed effect concentration (LOEC) LOEC is the lowest concentration or amount of a substance found by experiment or observation that causes an adverse alteration of morphology, function, capacity, growth, development, or lifespan of a target organism distinguished from normal organisms of the same species under defined conditions of exposure.

Mass-balance ecosystem model (MBEM) MBEM is a series of linear equations to describe biomass interactions between trophic levels, and gives a static, mass-balanced representation of food web structure.

No observed adverse effect level (NOAEL) NOAEL is the highest tested dose of a medicine at which there is no increase in the frequency of any adverse effects (biological or statistically significant) when compared to its control.

No observed effect concentration (NOEC) NOEC is the highest experimental point that is without adverse effect, denotes the level of exposure of an organism, found by experiment or observation, at which there is no biologically or statistically significant (e.g., alteration of morphology, functional capacity, growth, development or life span) increase in the frequency or severity of any adverse effects in the exposed population when compared to its appropriate control.

Omics Omics informally refers to a field of study in biology ending in -omics, such as genomics, transcriptomics, proteomics or metabolomics. Omics aims at the collective characterization and quantification of pools of biological molecules that translate into the structure, function, and dynamics of an organism or organisms.

Persistent organic pollutants (POPs) POPs are compounds that resist photolytic, chemical, and biological degradation. They are low water solubility and high lipid solubility, resulting in bioaccumulation in fatty tissues of living organisms.

Introduction

Ecotoxicology is the study of the effects of toxic chemicals on different scales, ranging from the biomolecule, cell, organ, system, whole organism, population, community, ecosystem, and biosphere levels. Ecotoxicology examines the movements of harmful chemical pollutants in the environment, including migration, transformation and degradation. Ecotoxicology is a multidisciplinary field, which integrates toxicology and ecology. Furthermore, Ecotoxicology is the science of contaminants in the biosphere and their effects on constituents of the biosphere, including humans.

[☆]*Change History*: March 2018. We have updated the abstract, keywords, glossary, the text, current trends in ecotoxicology. Additionally, we extended introduction, the further readings to this entire article, and deleted the old Fig. 3 and added new Fig. 3. Regarding the text, we added the latest theory and approaches in this field, such as Adverse Outcome Pathway, Reverse transcription real-time quantitative PCR, Effect-Directed Analysis, Omics technologies, Dynamic Energy Budget (DEB) model, Mass-Balance Ecosystem Model, Ecopath with Ecosim (EwE) approach, etc. In a word, these updates and extension can help us better understand and the knowledge and methods, also contribute to chase the latest trends in the field of ecotoxicology.

In 1962, the publication of Rachel Carson's seminal volume, *Silent Spring* catalyzed the separation of environmental toxicology from classical toxicology. This separation continued into ecotoxicology, the direct descendant of environmental toxicology. The revolutionary element in Carson's work was her extrapolation from single-organism effects to effects at the whole ecosystem and the "balance of nature." Ecotoxicology is a relatively young field that was first defined by Rene' Truhaut in 1969 as "the branch of toxicology concerned with the study of toxic effects, caused by natural or synthetic pollutants, to the constituents of ecosystems, animal (including human), vegetable and microbial, in an integral context (Bard, 2008)." Ecotoxicology includes environmental science, environmental chemistry, biology, molecular biology, physiology, environmental law and so on. It has been regarded as a critical and cutting edge field. From the standpoint of environmental compartments, ecotoxicology can be divided into aquatic ecotoxicology, terrestrial ecotoxicology, soil ecotoxicology, and sediment ecotoxicology mainly.

The impetus for this new science was the need to understand and make decisions about environmental contaminants. Between World War II and the 1960s, several pollution events occurred with consequences universally acknowledged to be unacceptable. These watershed events included population crashes of raptor and piscivorous bird species due to DDT's effects on reproduction, widespread water pollution, and high-profile incidents of heavy metal poisoning like the Minamata disaster. Expertise for dealing with such issues became critical to society and several practical sciences coalesced into the nascent science of ecotoxicology.

Furthermore, ecotoxicology can be applied to access the enrichment capacity of lipophilic persistent organic pollutants through the food chain. Nowadays, the given reference limits RfD of majority of environmental compounds are determined by the no observed adverse effect level (NOAEL) or LOAEL identified by toxicity study of animal experiments. This is unreliable calculating the health risks combined with uncertainty factors. Due to the differences between human and animals, it may be unsuitable for researchers to use animal models to study human diseases. Pharmacokinetic studies at present are difficult to simulate the background exposure and chronic low-dose exposure. Epidemiologic studies, as a new type of toxicology, playing a very important role in the search of sensitive biomarkers for health risk assessment. The exposure assessment can estimate the degree of people exposure on a kind of chemical pollutants.

Ecotoxicology is a comprehensive science that combines causal explanations and information from many sciences, particularly molecular biology, Oimcs, biogeochemistry, ecology, and mammalian, aquatic, and wildlife toxicology. The integration of paradigms and data from these disciplines is presently incomplete. Chief among remaining challenges is establishment of congruency among theories and data emerging from different levels of biological organization. Because ecotoxicology is an applied science, ecotoxicologists take on different roles that are also not fully integrated. Some ecotoxicologists are concerned chiefly with scientific goals, that is, organizing facts around explanatory principles. Others focus on the technical goals, that is, developing and applying tools to generate high-quality information about ecotoxicological phenomena. Still others focus closely on resolving specific, practical problems such as assessing ecological risk due to a chemical exposure or the effectiveness of a proposed remediation action. Associated activities overlap but are presently integrated inconsistently in many instances. For example, the ecotoxicity tests applied today focus on effects at molecular, cell, organ, system and individual organism's levels, but predictions of consequences to populations and communities are a very high priority for ecotoxicologists. A major theme in ecotoxicology today is finding the best way of achieving scientific, technical, and practical goals while organizing a congruent body of knowledge around rigorously tested explanations.

Some general trends exist in ecotoxicology relative to different levels of the biological hierarchy (Fig. 1). Causes of lower-level phenomena such as biomolecular effects tend to be easiest to identify and relate to immediately adjacent levels such as to cells or tissues. Techniques for study of lower-level effects often have the advantage of documenting quicker responses than those occurring at higher levels. Unfortunately, the ecological relevance of change at the lowest levels is more ambiguous than that for higher-level changes. This creates a dilemma for ecotoxicologists attempting to develop better technologies, such as Omics. The ecotoxicologist tries to avoid measuring precisely the wrong effect or imprecisely the right effect. Another trend is that lower-level effects tend to be used proactively and those at higher levels are applied reactively by ecotoxicologists trying to solve specific problems. Lower-level effects tend to be more tractable than those at the higher levels.

Ecotoxicologists rely on conventional methods although these conventions vary among scientists focused at different levels of organization. Controlled experiments tend to be practiced more during studies of lower-level effects such as biochemical shifts; whereas, while higher-level effect studies rely more on observation and natural experiments such as accidental toxic releases. Regardless of the manner in which insight is obtained, the scientific intent is to organize facts around rigorously tested paradigms. Some ecotoxicologists work to produce more precise or detailed information around existing paradigms while others work to rigorously test existing paradigms or to propose novel ones. Both of these activities are essential to the growth of ecotoxicology as a science.

Activities to develop new or enhance existing technologies produce tools with which to understand the effects and fates of contaminants in the biosphere. Ecotoxicological technologists develop analytical instruments, procedures for studying regional impact, and specific tools for documenting exposure or effects. As examples, biomarkers are continually developed and improved for documenting effects from the molecular to individual level. Biomarkers consist of measurable molecular, cellular, tissue, body fluid, physiological, or biochemical changes in individuals. These biomarkers can quantify the effect of exposure even in the absence of any discernible adverse effect. At higher levels of organization, biomonitors, changes in organisms or groups of organisms, can be used to infer adverse impact of contaminant exposure. Qualities valued in ecotoxicological technologies are biomarker or biomonitor effectiveness (including low cost and ease of application), precision, accuracy, appropriate sensitivity, consistency, and capacity to generate clear results.

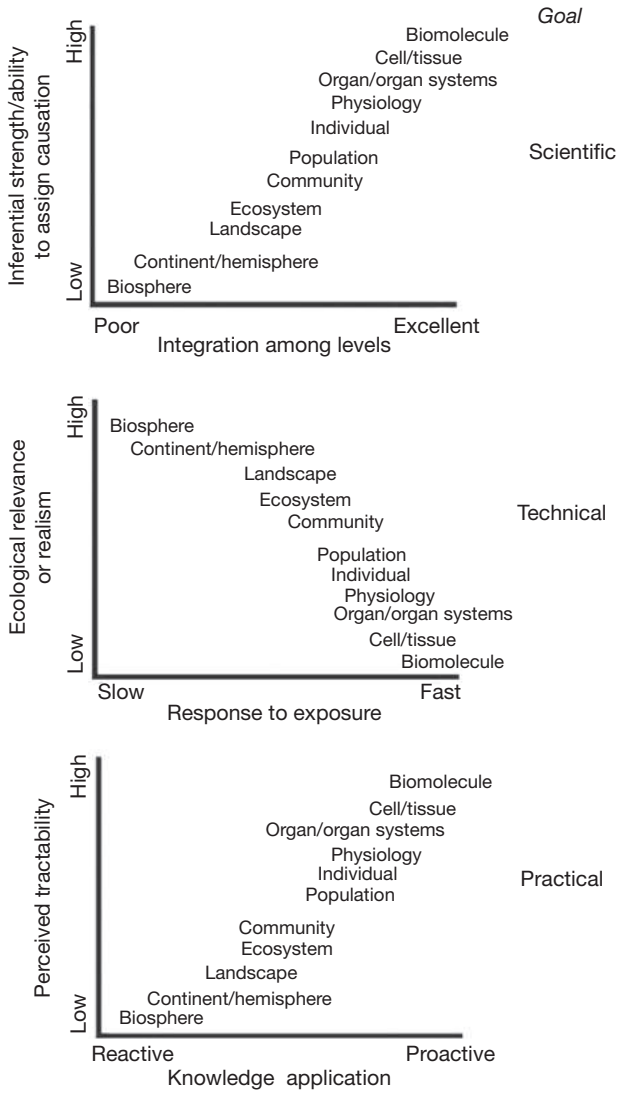

Fig. 1 Qualities of ecotoxicological knowledge based on the three goals to which it is applied and the biological levels for which it is generated.

The ultimate goal of ecotoxicology is to reveal and predict the effects of pollution within the context of all other environmental factors. Based on this knowledge, the most efficient and effective action to prevent or remediate any detrimental effect can be identified. In those ecosystems that are already impacted by pollution ecotoxicological studies can inform as to the best course of action to restore ecosystem services and functions effectively. Much of practical ecotoxicology is currently done within the Ecological Risk Assessment (ERA) framework (Fig. 2). ERAs can be retroactive, predictive, or comparative. A retroactive ERA estimates the risk from an existing situation such as a contaminated site, whereas a predictive ERA predicts the same for a future situation such as the proposed licensing of a new agrochemical. A comparative risk assessment might be done if the risks of two or more alternative actions are contrasted during environmental decision-making. Regardless of the type of ERA, the best available science is applied to formulate the plausible consequences of future action. The best available science and technologies are applied next for ecological effects and exposure characterizations.

Due to limited methods of toxicology experiments, the common application usually only focusses on the toxic effect in a particular field or a few molecular indicators. These limitations leave the methods open to questioning and challenging.

One method used in ecotoxicology is the adverse outcome pathway (AOP) (Fig. 3). Ankley et al. proposed the concept of the adverse outcome pathway framework and first and applied it to ecotoxicological research and chemical risk assessment. The AOP linearly links existing knowledge along a series of causally connected key events (KE). The AOP framework starts with a molecular initiating event (MIE) and leads to an adverse outcome (AO) that occur at a level of biological organization relevant to risk assessment. AOP related the structure of chemical pollutants, toxic effects, and the harmful outcomes of biological toxicity. This framework provided a new model to decipher the effects of chemical pollutants on populations of different species in the environment. AOPs offer a powerful approach to collect, organize and generalize toxicity-related information, allowing new

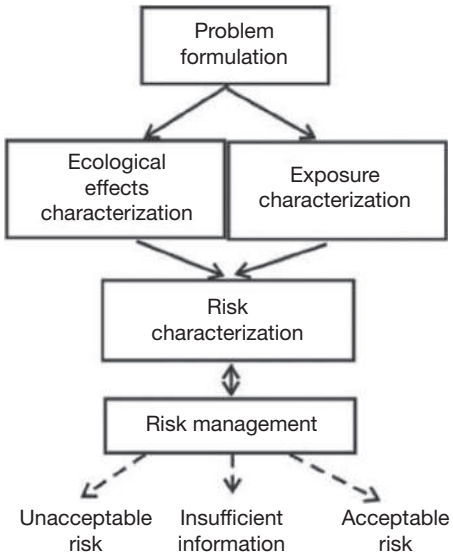

Fig. 2 The ecological risk assessment paradigm including problem formulation, exposure characterization, ecological effects characterization, and risk characterization. This paradigm was derived from that developed by the National Academy of Science.

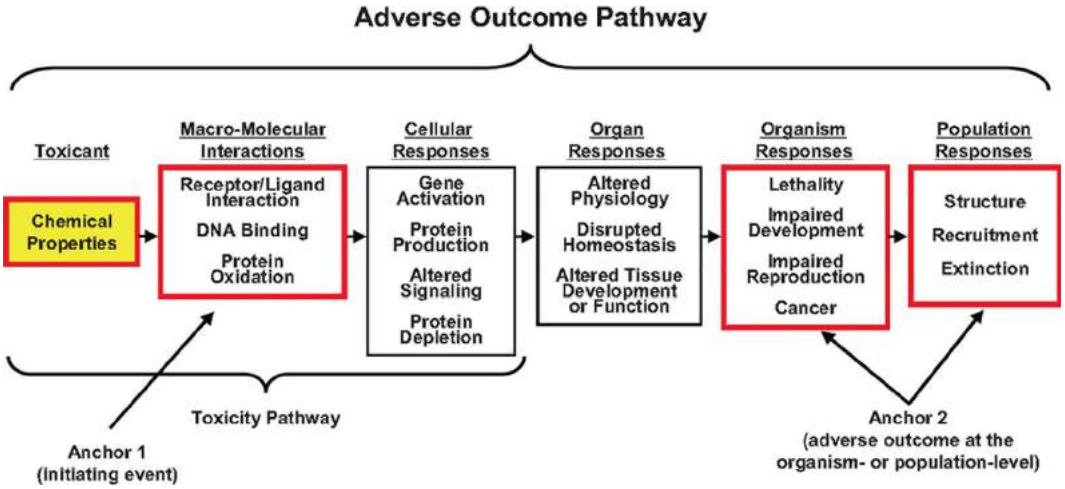

Fig. 3 Conceptual diagram of key features of an adverse outcome pathway (AOP). Each AOP begins with a molecular initiating event in which a chemical interacts with a biological target (anchor 1) leading to a sequential series of higher order effects to produce an adverse outcome with direct relevance to a given risk assessment context (e.g., survival, development, reproduction; anchor 2). The first three boxes are the parameters that define a toxicity pathway, as described by the National Research Council (cited from Ankley et al., 2010).

insights, guiding further research and targeted application of computational models, facilitating the development of alternative tests useful for practical risk assessment purposes and aiding prioritization of environmental exposures that warrant further toxicological assessment.

Additional methods of studying ecotoxicology, effect-directed analysis (EDA) and molecular toxicity identification evaluation (mTIE) are common in toxicology research. Chemical methods were first used to concentrate the pollutants in water. After this, indoor experiments are needed for biological research a concrete process consisting of four parts: Fractionation of toxicity test, Screening for toxic substances, Identification of induced toxic substances, and Confirmation of toxicity. The term mTIE refers to use acute exposure experiments to monitor and evaluate the toxic effects exposed directly on combined-pollution at gene levels. Recently, Altenburger et al. proposed a conceptual framework for combined toxicity studies making use of Omics approaches to support AOP development.

A computer model might predict movement of the contamination or the contaminant concentration might be measured in the relevant media. The best information is gathered to relate the contaminant concentrations to possible effects to valued ecological entities. All of this information is combined in the last stage of ERA to produce a risk statement. This information is shared with risk

managers who decide on the most appropriate action. This decision could mandate remediation, which would draw on ecotoxicological science and technologies.

Scales of Study

Ecotoxicological subject matter spans a wide range of biological levels. Levels from the molecular to the individual draw heavily on classical toxicology. Some population issues addressed by ecotoxicologists also benefit from the work of epidemiologists. Ecological issues at these levels of organization could be described as autecotoxicology, just as similar subjects in ecology are classified as autecology. Issues at higher levels would then be within the realm of synecotoxicology. Considerable biogeochemical and ecological knowledge are applied in synecotoxicological studies. A brief sampling of major autecotoxicological and synecotoxicological research approaches as follows.

Biomolecule

Information from the molecular level of organization is key to elucidating molecular mechanism of toxicity, differences in sensitivity among individuals, and adaptation of populations to contamination. Understanding the molecular mechanism of toxic action also helps to predict how contaminants might affect exposed individual. From a technological vantage, biochemical shifts are frequently used as evidence of toxic exposure or effect. Perhaps the best illustration would be the biomolecular shifts involved in phase I and II reactions of organic contaminants. The levels of associated biomolecules can quickly increase during exposure. Type I reactions are mediated by enzymes that catalyze contaminant hydrolysis, reduction, or oxidation, producing more reactive metabolites. The metabolites might be more readily eliminated from the cell or participate in phase II detoxification reactions. The best-studied phase I system is cytochrome P-450 monooxygenase which transforms contaminants such as polycyclic aromatic hydrocarbons (PAHs), chlorinated hydrocarbons, polychlorinated biphenyls (PCBs), hydrocarbons, dioxins, and dibenzofurans. Although phase I transformations are intended to facilitate detoxification, some transformed contaminants are more toxic than the parent compounds or might even be carcinogenetic. Phase II enzymes facilitate conjugation, that is, the addition of endogenous groups to contaminants or phase I metabolites which make the compounds more water soluble and readily eliminated. Other biomolecules provide mechanistic insight and a foundation for biomarker technologies. Elevated concentrations of metallothioneins, cysteine-rich proteins that bind and sequester metals, are often employed as evidence of heavy metal exposure. Also, commonly used as biomarkers are stress proteins, proteins induced by chemical stressors that function to reduce protein damage.

In the past, antoxidase enzyme activities are applied to ecotoxicology at the level of the cellular, and DNA damage is also applied at molecular level frequently. Biomarkers are biological macromolecules in organisms, whose changes can indicate a response to exogenous substances. For example, the Comet Assay can detect DNA strand breaks and, with the evaluation of other biomarkers, it can determine the effects of contaminants in exposed organisms. There were some positive correlations between the results given by the Comet Assay and other biomarkers such as enzyme activities. Gene expression analysis is another powerful tool to investigate the underlying mechanisms of toxicant exposure in nontarget organisms. Reverse transcription real-time quantitative PCR (RT-qPCR) has been established as a method of choice for the quantification of mRNA transcripts of a selected gene of interest (GOI) in biological samples. Although the defense mechanism of organisms respond to exogenous pollutants can be received, the big challenge is toxic effects of low dose relationship are hard to get.

The recent surge in genetic and Omics technologies provide another suite of biomarkers. Changes in DNA, RNA, protein products, and cellular metabolites are used separately or together to reveal mechanism of response or damage, and to document effects at the molecular level. Researchers increasingly apply omics technologies to carry out ecotoxicology studies to solve this boundedness, including the integrated study of transcriptomics, proteomics, metabolomics and other biological-omics subdisciplines. The major advantage of using omics methods in a systems approach is that one can assess hundreds to thousands of molecular responses simultaneously within an organism, facilitating a more holistic understanding of the organism's physiological status. Transcriptome research mainly probes the gene expression and the associated changes in biochemical pathway in the biological process, capturing the physiological response at the molecular level. This potentially reveals the mechanism of biological toxicity and population damage caused by environmental pollutants. Proteomics can reflect the function of the expressed genes effectively, including the interaction of protein to peptide and protein to protein. Proteomics integrated with bioinformatics can evaluate the response of the biochemical reactions of organisms exposed on environmental pollutants. Metabolites of abiological systems (e.g., cell, tissue or organism) exposure on environmental disturbance can be used to analyze the overall toxicity effect. Metabonomics can be applied to find a biomarker exposure on pollutants and analyze the metabolic pathways. Notably, High-throughput screening platforms have been demonstrated as a useful alternative to traditional in vivo experiments for drug development and agrochemistry.

Additionally, Molecular and ionic qualities of contaminants also influence the nature of exposure. At the same time, an organism's exposure to the same amount of a contaminant under different conditions can result in different realized doses and consequences. For example, the free ion form of a dissolved metal is considered the most bioactive. Metals dissolved in water form complexes with ligands such as dissolved inorganic anions and natural organic compounds. Depending on the ionic composition of the water, the same amount of dissolved metal will result in different concentrations of free ion and, consequently, concentrations of bioactive metal. Similarly, some organic contaminants are weak acids. If ingested with food, the capacity of such

contaminants to pass through the gut wall and cause harm is dependent on the amount of unionized compound present. Unionized compounds are generally more amenable to passage across the gut wall than ionized compounds. Under different pH conditions, different amounts of such a weak acid would be unionized as can be easily estimated with the Henderson–Hasselbalch relationship.

Cells and Tissues

Toxin-induced changes in cells and tissues are useful biomarkers. For practical and technical reasons, blood is the most common choice. However, tissues and cells like gills, sperm cells, early larval stages, coelomocytes, liver, and kidney have been also used for biomarker work. Due to the reduced use of experimental animals, low cost and rapid performance, the hemocyte of mollusks has become one of the most-used cell for biomarker work. Some changes used for biomakers reflect a cell's failure to remain viable in the presence of toxicants and others reflect partially successful attempts to maintain homeostasis. For example, histological examination of the liver from an exposed organism might reveal many necrotic cells. In the same tissues, inflammation might occur in an attempt to isolate, remove, and replace damaged cells. Both necrosis and inflammation are common biomarkers. Other changes such as the cellular accumulation of damaged biomolecules or cells modified to cope with toxicant damage are also useful histological biomarkers. Cancer is a cellular response to carcinogen exposure that is carefully studied by ecotoxicologists. Several ecological studies have demonstrated the role of environmental contaminants on cancer etiology. For example, Puget Sound English sole (*Parophrys vetulus*) taken from sites with elevated sediment contamination showed high prevalence of liver cancers. Another case of elevated cancer prevalence (i.e., 27% of dead adults) involved beluga whales (*Delpinapterus leucas*) inhabiting a contaminated region of the St. Lawrence estuary. Exposure studies at this level focus on the routes of contaminant movement into and out of cells, and differences in accumulation in various tissues. Generally, contaminant movement into and out of cells involves (1) simple diffusion across the membrane lipid bilayer or through an ion channel, (2) facilitated diffusion involving a carrier protein, (3) active transport, or (4) endocytosis. Some of these routes are designed for other purposes such as ATPase active transport of cations but also reveal the movement of contaminants such as cadmium. Other mechanisms are more specific. For example, the multixenobiotic resistance (MXR) mechanism specifically removes moderately hydrophobic, planar contaminants from the cell.

Organ and Organ Systems
